Fracture Resistance Testing of Plastics

Kevin M. Kit and Paul J. Phillips, University of Tennessee, Knoxville

Introduction

POLYMERIC MATERIALS are many and varied, ranging from pure glasses to blends to semicrystalline solids. Their mechanical properties range from pure elasticity with very high strains to fracture (rubbers or elastomers) to almost pure Hookian elasticity with low strains to fracture (glasses); the majority of polymers have properties somewhere between these two extremes. Virtually all polymeric materials show some form of inelastic behavior (Ref 1, 2). The elastomers show hysteresis, and the glasses show some form of yielding. The inelastic behavior is not restricted to the tip of a crack, but is present in some form or another throughout the material. The inelasticity is a direct result of the time dependence of the motions of the polymer chains. With the exceptions of certain untoughened epoxy resins and related thermosets, inelasticity is the norm. Hence, the expectation of many theories of fracture mechanics that Hookian behavior can be assumed is not to be realized. Even theories that assume elastic-plastic criteria are inadequate because they assume plastic behavior at the crack tip and elastic behavior throughout the remainder of the specimen, whereas in the real materials, there is viscoelastic deformation of some form or other occurring in the bulk of the specimen.

The presence of inelasticity in the entire specimen, as well as at the crack tip, results in additional energy being required for crack propagation. Hence, in any mechanical test the energy measured to propagate a crack consists of the surface energy of the crack, energy of plastic deformation at the crack tip, and energy of inelastic deformation of the entire specimen (Ref 3). Because the latter two forms of energy absorption are a direct result of the time-dependent behavior of the polymer chains, the energy absorbed displays a strong dependence on the rate at which stress is applied. The crack opening displacements in polymeric materials can be quite large and, hence, the microstrain at a crack tip will be similarly large. In polymeric materials displaying minimal levels of plasticity and/or inelasticity, such as untoughened epoxies, the crack opening displacement is quite small. At the other extreme is the elastomer, or rubber, where the crack opening displacement is so large that the process is usually referred to as tearing. The crack opening displacement can reflect two extremes in deformation behavior: shear yielding or crazing (Ref 3). Both reflect large amounts of plastic deformation at the crack tip. In the case of some polymers, for example, polycarbonate, a large yield zone is observed. In others, the phenomenon is referred to as crazing, where the apparent crack is really a zone of fibrous material produced by the stress field ahead of the crack. This phenomenon can be present in glassy materials as well as semicrystalline materials, and it corresponds to microyielding to levels of several hundred percent strain. A similar phenomenon can also be observed in unnotched specimens where regions in the bulk of the specimen display what is usually described as stress whitening.

In addition to the behavior described above, polymers are also sensitive to the environment, both gaseous and liquid (Ref 3). An example of the effects of gaseous environments is the effect of atmospheric ozone on crack propagation rates in natural rubber (Ref 4). In the case of a liquid the behavior can be caused by several different effects (Ref 5, 6). First, there is always the possibility that the liquid may be a solvent and be absorbed by the polymer; the absorption process may occur more rapidly at the tip of a crack. In this case the liquid will

plasticize the polymer, lowering its glass transition temperature and thereby altering all of its fundamental properties. Second, the liquid may react chemically with the polymer, changing its fundamental structure and properties on a microscopic or macroscopic scale. Third, the liquid may simply wet the polymer, lowering the surface energy and making crack or craze propagation much easier. A well-known example of such behavior is the effect of carbon tetrachloride on polycarbonate.

Fracture Resistance Testing of Plastics

Kevin M. Kit and Paul J. Phillips, University of Tennessee, Knoxville

Historical Development

Fracture in polymers was first studied intensively for rubber, and tests were developed logistically in the early 1900s (Ref 7, 8). Standard test methods included tensile testing with “dog-bone” specimens where the breaking strength was obtained. By the 1920s, standard tests for tear strength, using “trouser-type” specimens, were in use. Such methods are still in common use, the tensile test to failure using a dog-bone specimen being one of the most popular for the characterization of all kinds of polymers (Ref 8). As new polymers are developed and testing is needed, tensile testing on sheets or thin films as a method of characterization still tends to be preferred over the standardized ASTM tests for fracture strength. This may occur sometimes due to the amount of specimen available and at other times due to the simplicity of specimen preparation and characterization.

Fracture testing using standardized linear fracture mechanics approaches, such as K_{Ic}/G_{Ic} methods, has been used for decades as a means of carrying out fracture testing (Ref 3, 9). However, because of the previously mentioned inelasticity problems, polymers have stress distributions at the tip of a crack that cannot be calculated or described adequately by the assumptions of classical elasticity theory. Such approaches clearly cannot describe adequately the behavior of even the most well-behaved systems. Early attempts at describing the fracture phenomenon in a more realistic manner recognized that the most important parameter describing the phenomenon was the energy absorbed by the fracture process (Ref 10). The energy balance approach was suggested very early by Griffith (Ref 11) but was used for rubber by Rivlin and Thomas (Ref 12) who used a \mathcal{G} to describe the total work needed to create a unit area of surface (or the tearing energy in the case of rubber). Attempts at applying this approach were made successfully by Andrews and coworkers (Ref 3), Kambour (Ref 13), and Berry (Ref 14). The beginning of a generalized theory of fracture mechanics, not requiring linear fracture assumptions, was developed by Andrews (Ref 15). Study of fracture then concentrated for several years on the development and understanding of the mechanisms of craze formation because, clearly, the formation of crazes ahead of the crack is the major contributor to the energy absorbed in fracture in most

polymers (Ref 15). Indeed, because crazing is the precursor to fracture itself, it justifies attention on that ground alone.

A concurrent development, which now is used in the testing of polymers, is the J -integral method; it is essentially the equivalent of G_I for a nonlinear system. Discovered by Rice (Ref 16, 17), and developed independently by Begley and Landes (Ref 18, 19), the J -integral method has been applied successfully to polymers by the Williams group and others (Ref 20, 21, and 22). The disadvantage of the method is that it requires multiple specimens in its strict form, discouraging widespread use. A single specimen method was developed and used successfully on polypropylene by Ouederni and Phillips (Ref 23), but it has not yet been converted into a standard ASTM method.

Fracture Test Methods for Polymers

Several methods have been developed specifically for determining the fracture toughness of polymeric materials. ASTM D 5045 (Ref 24) describes a method for determining the linear elastic fracture toughness (K_{Ic} and G_{Ic}) of polymers. This methodology is appropriate for highly crosslinked thermosets (e.g., epoxy) or glassy thermoplastics incapable of significant plastic deformation (e.g., polystyrene). ASTM D 6068 (Ref 25) describes a method for measuring J - R curves (a measure of elastic-plastic fracture toughness) for polymer specimens that are not large enough to experience conditions of plane strain during loading. However, methods originally developed to characterize the elastic-plastic fracture of ductile metallic materials are most commonly used (with slight modifications) to characterize ductile polymers. These methods are based on the concept of the J -integral to determine plane strain fracture toughness values. To date, the most commonly used method is that of ASTM E 813 (Ref 26). This method was discontinued in 1989 and replaced by ASTM E 1737 (Ref 27). The differences between the two are minor, but the methods for data analysis and reporting described in ASTM E 1737 should now be followed.

J-Integral Testing

ASTM E 1737 is more general than ASTM E 813 and describes the method for determining either J_{Ic} or J_c under plane stress conditions. J_{Ic} is the critical value of the J -integral at which onset of stable crack growth occurs. If stable crack growth is not observed, then J_c is defined as the value of the J -integral at which unstable crack growth (i.e., failure) occurs. The J -integral is a measure of the amount of energy absorbed (due to both elastic and plastic responses) during the growth of a crack through the material of interest.

Experimentally, J is determined as a function of crack extension, Δa , in a notched specimen loaded in tension. J is calculated according to (Ref 28):

$$J = \frac{2U}{bB} \quad (\text{Eq 1})$$

where U is the area under the load-displacement curve and B and b are the dimensions of the specimen in the plane of the crack. Testing is most commonly performed on single-edge notched bend or on compact tension specimens containing machined notches (see Fig. 2 in the article “Fracture Toughness Testing” in this Volume). ASTM E 1737 specifies that the specimen be fatigued so that a sharp “precrack” is formed at the base of the notch. However, this is not a viable technique for most thermoplastic polymers. The accepted method for creating a precrack in polymer samples is to tap a fresh, unused razor blade into the notch immediately preceding the test, as specified in ASTM D 6068 and D 5045.

To ensure the existence of plane strain conditions at the crack tip, specimen thickness, B , and the original uncracked ligament, b_o (i.e., the distance the crack would have to extend to separate the specimen into two pieces), must be greater than $25J_{Ic}/\sigma_y$ where J_{Ic} is the elastic-plastic fracture toughness and σ_y is the yield strength. Because J_{Ic} is generally not known a priori, specimen dimensions must be based on an estimated value of J_{Ic} and then verified after testing. It has been shown (Ref 29) that the specimen size requirements specified by ASTM E 1737 can be relaxed for some polymers, such as low-density polyethylene and a polypropylene copolymer, to $B, b_o > 17 J_{Ic}/\sigma_y$.

In order to arrive at a value of J_{Ic} , J -integral values are plotted as a function of crack extension, Δa , to form a so-called R -curve. This data may be collected using single specimen or multiple specimen techniques. The multiple specimen technique is widely accepted as a valid measure of the elastic-plastic fracture toughness of polymers and is commonly employed. However, results from the much simpler single specimen technique have also been shown to be valid, and the implementation of this technique is increasing. These techniques differ only in the determination of the R -curve; specimen requirements and data analysis to determine J_{Ic} are identical. Both are summarized in the following sections.

Multiple Specimen Technique. In both techniques, it is desirable to determine J at a minimum of ten equally spaced Δa points. In the multiple specimen technique, each J - Δa point on the R -curve is generated with a different specimen. Each specimen is loaded to a level judged to produce a desired, stable crack growth extension, Δa , and is then unloaded. Polymer specimens are then removed from the test frame and fractured in liquid nitrogen. (This last step deviates from ASTM E 1737, which specifies that the specimens be fatigued first.) The precrack, stable crack growth and freeze-fracture regions of the fracture surface are usually easily identifiable (Ref 25), and an optical microscope is used to measure Δa (the length of the stable crack growth region) at nine points equally spaced across the thickness of the specimen. These nine values are averaged as described by ASTM E 1737. J is then calculated according to:

$$J = J_{el} + J_{pl} \quad (\text{Eq 2})$$

where J_{el} and J_{pl} are the elastic and plastic components of J , calculated as:

$$J_{el} = \frac{K^2 (1 - \nu^2)}{E} \quad (\text{Eq 3})$$

$$J_{pl} = \frac{\eta A_{pl}}{B_N b_o} \quad (\text{Eq 4})$$

K is a function of maximum load and specimen geometry, ν is Poisson's ratio, E is Young's modulus, A_{pl} is the area under the load-displacement curve for the entire loading-unloading cycle, and B_N is specimen thickness. For single-edge notch and compact tension specimens, $\eta = 2$, while for the disk-shape compact tension specimen, η is a function of geometry. Equations for K for each specimen type are given in Annex 4 of ASTM E 1737.

Single Specimen Technique. The single specimen technique relies on the ability to determine the extent of crack growth, Δa , while the specimen is loaded in the test frame. If this can be done, then many J - Δa data pairs can be collected from one specimen. Crack growth is usually determined by an elastic compliance method or by an electrical resistance method. In the elastic compliance method, the specimen is unloaded periodically during the test. At each unloading point, Δa is calculated as a function of the slope of the unload line, Young's modulus, and specimen geometry. However, due to the viscoelastic behavior of polymers, accurate determination of crack lengths by this method is suspect (Ref 30, 31).

Another method determines the crack length by measuring the voltage drop across the uncracked ligament through which a constant direct current is passed. This method is also not generally applicable to polymers because most are poor conductors. However, Ouederni and Phillips (Ref 23) have developed a method that involves measuring crack extension directly with a video camera. A thin copper grid deposited on the surface of the specimen serves as a scale reference. Another J -integral technique that has been successfully applied to polymers is the normalization method (Ref 31). This method does not require specimen unloading or in situ measurements of crack growth. The crack length is calculated by separating total displacement into elastic and plastic components, each of which is a function of crack length. After a fitting procedure is used to establish a relationship between plastic displacement and crack length, the actual crack length can be calculated at any point on the load-displacement curve. Zhou et al. (Ref 31) used this technique to determine J_{Ic} for two rubber-toughened nylons and found their results very close to values obtained by the standard multiple specimen method.

Determination of J_{Ic} . Before the data can be analyzed, it must be checked to verify that it spans a sufficiently large range of Δa . This procedure to determine qualifying data is detailed in ASTM E 1737. Qualifying J data must also be less than the smaller of $b_o \sigma_y / 20$ and $B \sigma_y / 20$ to ensure that all data points are measured under plane strain conditions. Qualified data are fit by the method of least squares to the curve described by:

$$\ln J = \ln C_1 + C_2 \ln \left(\frac{\Delta a}{k} \right) \quad (\text{Eq 5})$$

where C_1 and C_2 are fitting parameters and $k = 1 \text{ mm}$ (0.04 in.). A linear blunting line must also be constructed along the line defined by:

$$J = 2\sigma_y \Delta a \quad (\text{Eq 6})$$

where σ_y is the average of the 0.2% offset yield strength and the ultimate tensile strength. The blunting line accounts for deflection that occurs due to plastic deformation near the crack tip prior to the onset of stable crack

growth. ASTM E 1737 specifies that the J value at the intersection of the fit data and a line offset 0.2 mm (0.008 in.) from the blunting line defines an interim value, J_0 , which is used to verify the existence of plane strain conditions. If both B and b_0 are indeed greater than $25J_{Ic}/\sigma_y$, and some additional data qualifications are met, then the value of J_0 is taken to be equal to J_{Ic} . Experimental and fit R -curves for an acrylonitrile-butadiene-styrene (ABS) copolymer are shown in Fig. 1 along with the blunting and 0.2 mm offset lines. The intersection of the fit R -curve and the 0.2 mm offset line indicates a J_{Ic} of 5.31 kJ/m^2 .

Fig. 1 Experimental R -curve for an ABS copolymer showing power-law fit, blunting line, and 0.2 mm offset line. Source: Ref 32

Modifications for Polymeric Materials. Due to the unique properties of polymers, several modifications to the J -integral method have been proposed and used. Some of these modifications that affect the collection of J - Δa data have already been mentioned, and these are quite widely accepted as standard.

In some cases, crack tip blunting may not occur before or during stable crack growth in polymers. Crack tip blunting can be verified by direct microscopic observation or if J data follows the blunting line ($J = 2\sigma_y\Delta a$) for small amounts of crack growth. Some of the data in Fig. 1 lie on the blunting line, indicating that blunting does occur (Ref 32). If blunting is not known to occur, J_{Ic} should be determined by extrapolating a linear fit to the J - Δa data to zero crack growth ($\Delta a = 0$). It has been argued in Ref 33 that J - Δa data should, under conditions of plane strain, follow:

$$J = J_{Ic} + \frac{dJ}{d\Delta a} \Delta a \quad (\text{Eq 7})$$

For small crack growth, J should vary linearly with Δa , and the value of J_{Ic} should be determined as previously explained. Optical microscopy (Ref 34, 35) has shown that crack blunting does not occur in certain grades of high-density polyethylene, toughened nylon 6/6, ABS, and toughened polycarbonate. As further evidence, the J data collected from the high-density polyethylene (Ref 35) does not follow the blunting line for small Δa , as shown in Fig. 2.

Fig. 2 Experimental R -curve for a high-density polyethylene showing the dashed blunting line and the absence of blunting behavior. Source: Ref 35

If crack tip blunting does occur, the procedure described will yield conservative values of J_{Ic} . If blunting is known to occur, then J_{Ic} should be determined by the methods of ASTM E 1737 or ASTM E 813. The determination of J_{Ic} by ASTM E 813 differs in that J_{Ic} is taken at the intersection of a *linearly* fit R -curve and the blunting line. This construction is shown in Fig. 3 for the same data used in Fig. 1. The intersection of the linear R fit and the blunting line indicates a J_{Ic} of 3.95 kJ/m² (compare to the ASTM E 1737 value of 5.31 kJ/m²). The method in ASTM E 813 usually gives more conservative values than that in ASTM E 1737. Chang et al. (Ref 29, 31, 35, and 36) have analyzed J data of high-impact polystyrene (HIPS), ABS, a polycarbonate (PC)/ABS blend, and a polycarbonate/polybutylene terephthalate (PBT) blend by three methods (ASTM E 1737, ASTM E 813, and the no-blunting method described previously). As can be seen in Table 1, the no-blunting method is the most conservative, while ASTM E 1737 is the least conservative. If no direct evidence of crack tip blunting exists, the most conservative method for calculating J_{Ic} should be used.

Table 1 Comparison of J_{Ic} data for several polymers determined by different methods

Method	J_{Ic} , kJ/m ²			
	HIPS	ABS	PC/ABS	PC/PBT
No blunting	3.24	3.57	3.00	5.47
ASTM E 813	3.60	3.95	3.55	7.17
ASTM E 1737	4.30	5.31	7.85	13.41

Fig. 3 Experimental R-curve for an ABS copolymer showing linear fit and blunting line. Source: Ref 32

Several workers have shown that the plane strain thickness requirements specified by ASTM E 813 and ASTM E 1737 are too conservative in certain cases, while not conservative enough in others. Rimnac et al. (Ref 38) and Huang (Ref 39) have shown that the requirement is too conservative for tough thermoplastics, ultrahigh-molecular-weight polyethylene ($J_{Ic} = 95 \text{ kJ/m}^2$), and rubber-toughened nylon 6/6 ($J_{Ic} = 30 \text{ kJ/m}^2$). Both studies found that size-independent values of J_{Ic} were obtained for specimen thicknesses greater than $6J_{Ic}/\sigma_y$, which is approximately 25% of the recommended minimum thickness. Conversely, Lu et al. (Ref 40) found that size-independent values of J_{Ic} for a relatively brittle PC/ABS blend ($J_{Ic} = 4 \text{ kJ/m}^2$) were not obtained until the thickness was greater than $64J_{Ic}/\sigma_y$, which is more than twice the recommended minimum thickness. In light of these results, it is recommended that J_{Ic} be determined for various thicknesses to ensure that the true plane strain value is obtained.

Linear Elastic Fracture Toughness

Other methods also exist to determine the plane strain fracture toughness of polymers. ASTM D 5045 specifies a procedure for determining the critical strain energy release rate, G_{Ic} , of polymers. This parameter is equivalent to J_{Ic} for materials that exhibit linear (or nearly linear) elastic behavior (Ref 41). ASTM D 5045 specifies the use of single-edge notch bend or compact tension specimens. Precracks are created by tapping a fresh, unused razor blade into the machined notch immediately preceding the test. The samples are then loaded to a level that causes a 2.5% apparent crack extension. However, significant deviation from linear elastic behavior must not occur at this load level. The procedure for testing this requirement is detailed in ASTM D 5045. An interim value of the critical strain energy release rate, G_Q is determined by:

$$G_Q = \frac{U}{Bb\phi} \quad (\text{Eq 8})$$

where ϕ is a function of b and the original crack length, a . This interim value can be qualified as the plane strain critical strain energy release rate if plane strain conditions are verified. The standard specifies that B , b , and a must be greater than $2.5 (K_{Ic}/\sigma_y)^2$ where K_{Ic} is the plane strain fracture toughness and is related to G_{Ic} by:

$$K_{Ic} = \frac{E}{1 - \nu^2} G_{Ic} \quad (\text{Eq 9})$$

Using this relation, the size requirement for plane strain conditions can be written as:

$$B, b, a > \frac{2.5E}{\sigma_y(1 - \nu^2)} \frac{G_{Ic}}{\sigma_y} \quad (\text{Eq 10})$$

Using typical values for E (1 GPa, or 145 ksi), σ_y (60 MPa, or 8.7 ksi), and ν (0.4), the size requirement is $B, a > 50G_{Ic}/\sigma_y$, which is twice the size requirement for determining plane strain J_{Ic} .

Due to the viscoelastic properties of polymers, test temperature and strain rate should be well controlled and reported. The standard recommends 23 °C (73 °F) and a crosshead speed of 10 mm/min (0.4 in./min). The orientation of the specimen with respect to processing direction (e.g., extrusion direction and mold flow direction) should also be reported because of the strong dependence of mechanical properties on molecular orientation that often develops during processing.

Testing of Thin Sheets and Films

In order to ensure the existence of plane strain state, the dimensions of the sample normal to the applied stress are usually required to be greater than $25J_{Ic}/\sigma_y$, where J_{Ic} is the elastic-plastic fracture toughness and σ_y is the yield strength. Both J_{Ic} and σ_y are generally considerably lower than the corresponding values for metallic materials, but the ratio J_{Ic}/σ_y is usually much larger for polymeric materials. Therefore, the plane strain size requirements for polymeric fracture specimens are often unrealistic (on the order of 5 cm or 2 in.). In many applications, the properties of polymeric materials are strongly dependent on the level of molecular orientation and crystallinity. These levels, in turn, are strongly dependent on the thermal and mechanical histories experienced during processing. Specimens that are produced to fulfill the plane strain condition are likely to have quite different thermal and mechanical histories than polymer materials processed into sheet or film. Therefore, the thicker test specimens do not reflect the actual properties of the polymer for the intended application. For these reasons, ASTM D 6068 is often a more desirable method than the plane strain method of ASTM E 813 or E 1737. This method was developed specifically for the determination of R -curves from thin sheets or films. However, this is not a valid method for determining J_{Ic} , and results should not be reported as such. When using this method, specimen size and the values of C_1 and C_2 (which characterize the power-law fit of the R -curve) should be reported.

Other Methods

Alternative methods for determining the fracture toughness of polymer materials have recently been proposed. Most notable are the normalization and hysteresis methods, which are both single specimen techniques. The normalization method does not require unloading cycles or online crack measurement and has been used successfully for metallic materials (Ref 31). The method is based on the assumption that the load, P , on the specimen can be represented by:

$$P = G(a)H(v_{pl}) \quad (\text{Eq 11})$$

where $G(a)$ is a known function of crack length and specimen geometry, and $H(v_{pl})$ is a function of plastic displacement, v_{pl} . After the form of $H(v_{pl})$ is fit to experimental data, values of a (and hence J) can be determined at any point on the load-displacement curve. J_{Ic} can then be determined from the R -curve using the methods described above. Zhou et al. (Ref 31) found that the results of this method are slightly less conservative than those determined by ASTM E 813 and more conservative than ASTM E 1737 for two rubber-toughened nylons (nylon 6/6 and an amorphous nylon).

The hysteresis method requires the application of multiple load-unload cycles to successively larger displacements (Ref 30, 32, and 37), as shown in Fig. 4. The area between the loading and unloading lines on the load-displacement curve is defined as the hysteresis energy, and this is plotted against maximum displacement for each loading cycle, as shown in Fig. 5. For small displacements, crack growth does not occur, and the hysteresis energy varies linearly with displacement. This data is fit with a linear blunting line. After crack growth commences, the hysteresis energy varies nonlinearly with displacement and can be fit with a power law. The displacement at which the linear blunting line intersects with the power-law curve is taken as the critical displacement to initiate crack growth, and the value of J at this displacement is taken as J_{Ic} . It has been found that the results of this method are slightly less conservative than those determined by ASTM E 813 and more conservative than ASTM E 1737 for several polymers (ABS, PC/ABS, HIPS, and PC/PBT) (Ref 32, 36, 37, and 42).

Fig. 4 Hysteresis loops for several loading-unloading cycles for a PC/PBT blend. D, specimen displacement; HR, ratio of hysteresis energy to total strain energy. Source: Ref 37

Fig. 5 J -integral and hysteresis energy vs. displacement for a PC/PBT blend. Test rate, 2 mm/min (0.08 in./min). J_{IC-HE} and D_{C-HE} are critical values of J and D for initiation of crack propagation. Source: Ref 37

Fracture Toughness of Ceramics and Ceramic Matrix Composites

J.H. Miller, Oak Ridge National Laboratory P.K. Liaw, The University of Tennessee, Knoxville

Introduction

CERAMICS are lightweight structural materials with much higher resistance to high temperatures and aggressive environments than other conventional engineering materials. These characteristics of ceramics hold promise in various applications for gas turbines, heat exchangers, combustors and boiler components in the power generation systems, first-wall and high-heat-flux surfaces in fusion reactors, and structural components in the aerospace industry (Ref 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, and 25). However, most of these engineering applications require high reliability and the improvement of ceramic fracture toughness.

Monolithic ceramics are inherently brittle, making them highly sensitive to process- and service-related flaws. Due to their low toughness, monolithic ceramics are prone to catastrophic failure and, thus, may be unsuitable for engineering applications that require high reliability. Ceramic matrix composites (CMCs), however, can provide significant improvement in fracture toughness and the avoidance of catastrophic failure (Ref 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, and 41). The fracture mechanisms in CMCs are identical to those found in monolithic

ceramics (brittle), but “plastic-like” behavior occurs in CMCs because of the toughening mechanisms of crack bridging, branching, and deflection. The reinforcing particles, whiskers, or fibers that are present in the ceramic matrix allow the bulk composite material to avoid unstable crack growth and the resulting catastrophic failure. The toughness of CMCs comes from the fact that the reinforcement can provide crack bridges and cause cracks to branch, deflect, or arrest. These issues are quite complicated, and they demonstrate the critical need for the understanding of the fracture properties of ceramics and CMCs.

Much work has been done to develop methods for evaluating the fracture toughness of ceramic materials (Ref 42, 43, 44, 45, 46, 47, 48, 49, and 50). The concepts of both linear-elastic fracture mechanics (LEFM) and elastic-plastic fracture mechanics (EPFM) are both of interest in regard to ceramic materials. Monolithic ceramics, due to their brittle nature, behave in a linear-elastic manner. This fact has led to the successful use of LEFM methods for monolithic ceramics. Many CMCs, on the other hand, have an elastic-plastic fracture behavior. This fact has led researchers to attempt to use EPFM methods to evaluate the fracture toughness of CMCs.

This article briefly introduces LEFM and EPFM concepts and methods that have been developed or adapted for the evaluation of the fracture behavior of monolithic ceramics and CMCs. The general concepts of LEFM and EPFM are briefly reviewed, and test methods are described for fracture toughness testing of monolithic ceramics and CMCs. More detailed information on the fracture resistance testing of monolithic ceramics is also contained in the article “Fracture Resistance Testing of Brittle Solids” in this Volume, while this article places emphasis on the fracture toughness testing of cmcs. Measuring the fracture toughness of CMCs is not as developed as toughness testing of monolithic ceramics. The toughening mechanisms of microcracking, crack bridging, and crack branching cause CMCs to behave in an elastic-plastic-like manner, which makes EPFM methods attractive. LEFM and EPFM methods have both been used to evaluate the toughness of CMCs, but because the level of understanding of the complex fracture mechanisms present in CMCs is not well developed, no connection has been made between the macroscopic toughness, either elastic or elastic-plastic, and the fracture mechanisms. As a result, evaluation of the fracture toughness of CMCs has been limited. However, as the cracking mechanisms become better understood, LEFM and EPFM methods will become better adapted for use in the evaluation of CMC fracture toughness behavior.

An Overview of Fracture Mechanics

Fracture mechanics involves the stress analysis of cracking in structures or bodies with cracks or flaws. Most of the work in this field has concentrated on the cracking behavior of metals, so this brief overview introduces the concepts and ideas of LEFM and EPFM for metals (Ref 51, 52, and 53). This is followed by a description of the use of LEFM and EPFM methods in the evaluation of monolithic ceramic and CMCs, respectively.

Linear-Elastic Fracture Mechanics

The use of LEFM is applicable under two conditions:

- The applied load deforms a cracked body in a linear-elastic manner.
- The flaw or crack is assumed to be a sharp crack with a tip radius near zero.

The stresses required for cracking under these two conditions can be analyzed according to LEFM by two parameters: the energy release rate and the stress intensity factor.

The energy release rate, G , is the amount of stored energy that is available for an increment of crack extension:

$$G = \frac{d\Pi}{dA} \quad (\text{Eq 1})$$

where Π is the stored potential energy and A is the crack surface area that is created as the crack grows. In other words, G is the amount of stored elastic energy that is converted to surface energy as the crack grows. Because the body behaves in an elastic manner, all of the energy available is used to create the crack surfaces (Ref 51, 52, and 53).

Expressions for the energy release rate can be derived based on the geometry of the crack and the loading conditions. Two basic types of configurations are shown in Fig. 1 and 2 for an edge crack and a central through-thickness crack, respectively, for Mode I (tensile opening) loads. In this case, crack length is defined by typical convention as a for an edge crack (Fig. 1) and as a $2a$ for a central through-thickness crack (Fig. 2). With this convention, then the value of G for a wide plate (plate width $\gg a$) in plane stress is as follows (Ref 51, 52, and 53):

$$G = \frac{\pi\sigma^2 a}{E} \quad (\text{Eq 2})$$

where σ is the applied stress, E is Young's modulus, and a is either the total length of an edge crack (Fig. 1) or half the length of center crack ($2a$ in Fig. 2). Equation 2 thus applies to both of these basic configurations in Fig. 1 and 2 with the appropriate definition for a as shown.

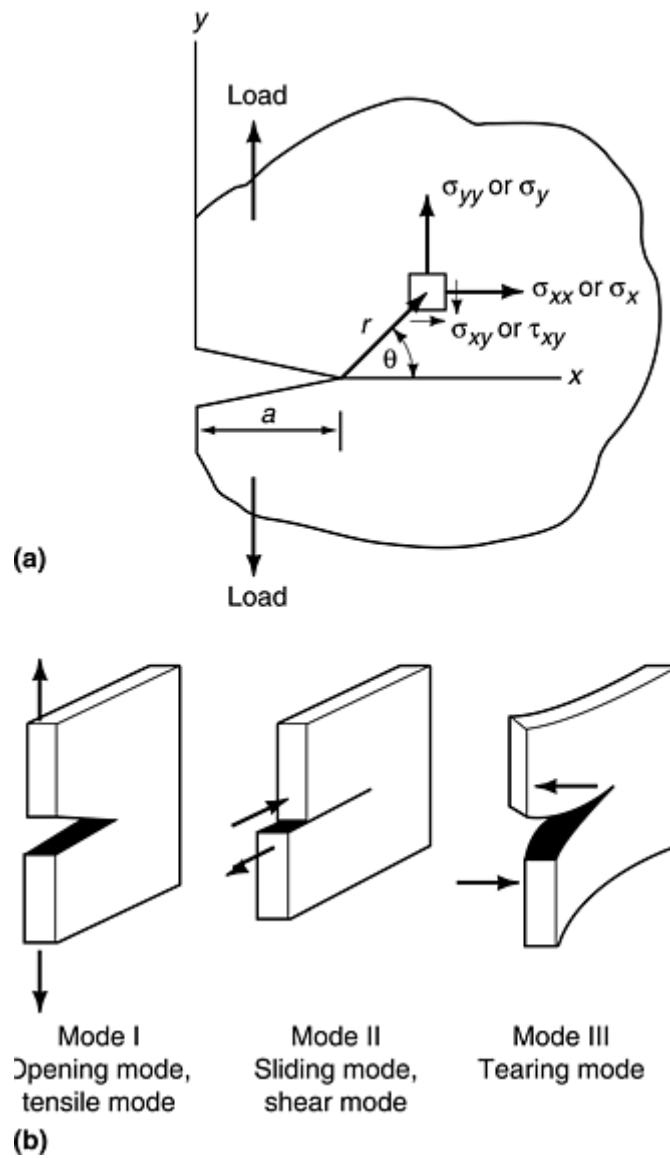

Fig. 1 Schematic illustration of an edge-notched specimen. (a) Crack length, a , and general coordinate system for crack tip stresses in Mode I loading.

Fig. 2 Schematic illustration stress distributions near the tip of a through-thickness crack an infinitely wide plate (plate width \gg than the crack length, $2a$)

The stress intensity factor, K , is a measure of stress intensity in the entire elastic stress field around the crack tip. It is derived based on the analysis of the stress field near the tip of a sharp crack, rather than an energy consideration, as in the case of the energy release rate. The stress intensity factor can be related to the local stress at the crack tip as:

$$\sigma_{YY} = \frac{K_I}{\sqrt{2\pi r}} \quad (\text{Eq 3})$$

where σ_{YY} is the local stress near the tip of the crack, K_I is the stress intensity factor with a Mode I (tensile opening) load, and r is the distance in front of the crack tip (with $\theta = 0$) (Fig. 1). The stress intensity factor in Mode I loading can also be related to the applied or nominal stress as (Ref 51, 52, 53):

$$K_I = \sigma_{\text{nom}} Y \sqrt{\pi a} \quad (\text{Eq 4})$$

where σ_{nom} is the nominal or applied stress and Y is a geometrical factor that is specific to a particular loading condition and crack configuration. As in the case of Eq 2, the crack length, a , in Eq 4 is defined either as the length of an edge crack (a in Fig. 1) or as one-half the length of a through-thickness crack ($2a$ in Fig. 2). With these definitions for a , Eq 4 applies for both an edge crack and a center crack configuration.

Figure 3 shows a schematic plot of the stress normal to the crack plane as a function of the distance, r , from the crack tip for both σ_{YY} and σ_{nom} (Ref 51, 52, and 53). According to Eq 3 and Fig. 3, there is a singularity in the stress field at the tip of the crack. This fact is the reason why elastic action is an important assumption in LEFM. If significant plasticity occurred, the crack would be blunted by the plastic flow, and the stress intensity solution would no longer be valid.

Fig. 3 Schematic plot of the stress field around a crack. Source: Ref 52

With Eq 4, it is possible to relate the magnitude of the single parameter, K , to the applied stress and crack size. This is the basis for most common applications of LEFM. Through the use of published expressions for the geometry factor, Y , many common loading conditions and structures can be analyzed. The published expressions for K_I that include the proper Y for specific loading and cracking conditions are commonly called K -calibrations. The calculated stress intensity factor from the K -calibration and the loading level can be compared to a critical stress intensity value to determine the safety of the structure (Ref 51, 52, and 53). The energy release rate is related to the stress intensity factor by the equation:

$$G = \frac{K_I^2}{E'} \quad (\text{Eq 5})$$

where $E' = E$ (Young's modulus) for plane stress conditions, or where:

$$E' = \frac{E}{1 - \nu^2} \quad (\text{Eq 6})$$

where ν is Poisson's ratio for plane strain conditions.

Critical Crack Growth. Crack extension can either be stable or unstable depending on material properties and specimen geometry. Therefore, an important issue in LEFM is the definition of critical conditions that lead to unstable crack growth. Critical conditions for unstable crack growth can be expressed as either a critical energy release rate or a critical stress intensity factor. The critical value is the value of G or K at the instant when unstable crack extension occurs, that is, when the crack propagates through the specimen and thus causes the specimen to break in two. The critical energy release rate, G_c , or the critical stress intensity factor, K_c , are thus defined as the values of G and K at the instant of unstable crack extension that leads to fracture. Under these conditions, either parameter can be defined as the fracture toughness of the material. Usually K_c is the chosen parameter to express the fracture toughness. If the fracture toughness is not a function of specimen size or geometry then this fracture toughness value can be considered a material property. Otherwise, the fracture toughness result is only valid under the conditions it was measured (Ref 51, 52, 53, and 54).

Crack Growth Resistance and R -Curves. If stable crack growth occurs, a single value for fracture toughness is difficult to define. In the case of stable crack growth, a plot of the experimentally measured fracture parameter, in terms of either G or K , versus crack length is developed. This plot can be generated from the load and crack length data taken from a material test. The stress intensity or the energy release rate is calculated from the measured load and crack length data using expressions similar to those shown in Eq 2 and 4 (the correct expression must be used for the conditions of the test). Fracture parameters calculated in this way are defined as the resistance to crack growth parameters because they are calculated from a crack growing in a stable manner. The resistance to crack growth, expressed in terms of the energy release rate, is given the symbol R , and the resistance to crack growth, expressed in terms of the stress intensity factor, is given the symbol K_R . The plot of resistance to crack growth, either R or K_R , versus crack length is called a crack growth resistance curve, or R -

curve, and the entire curve becomes the measure of fracture toughness. Schematic examples of R -curves plotted in terms of G and K are shown in Fig. 4 and 5, respectively (Ref 51, 52, and 53).

Fig. 4 Schematic crack growth resistance curves and crack driving force curves, in terms of the energy release rate, G . (a) Single-valued fracture toughness. (b) Rising R -curve behavior. Adapted from Ref 52

Fig. 5 Schematic crack growth resistance curve and crack driving force curve in terms of the stress intensity factor, K . Adapted from Ref 52

Figure 5(a) shows a flat R -curve, which is the result of unstable crack growth. The flat R -curve presents the ease of defining fracture toughness as a critical value for unstable crack growth, in this case G_c . Figure 5(b) is an example of an R -curve that demonstrates stable crack growth prior to instability. Stable crack growth occurs because the crack growth resistance increases with increasing crack length. This trend is called the rising R -curve behavior. An R -curve plotted in terms of K rather than G is shown in Fig. 5 (Ref 51, 52, and 53).

The R -curve can be used to predict the conditions that will cause crack extension. To do this, it is necessary to plot the crack driving force on the same axes as the crack growth resistance curve. The curve for crack driving force is calculated using the same expressions of K and G that relate the geometry and loading conditions to fracture. However, instead of using the data from a crack propagation test, the procedure is to calculate crack driving force curves by holding the stress, or load, constant and increasing the crack length incrementally. The point where the crack driving force curve crosses the resistance curve represents the condition under which critical crack growth occurs (Ref 51, 52, and 53). The expected in-service stress levels of a cracked body can be evaluated from this.

In summary, crack growth can either be stable or unstable. If the driving force curve crosses the resistance curve at the tangency point, the crack growth will be unstable. If it crosses below this point, the crack growth will be stable. To determine the point where the unstable crack growth occurs it is necessary to establish an iterative scheme of generating driving force curves for different stress levels until tangency is achieved. Schematic examples of driving force curves plotted with resistance to crack growth curves are also shown in Fig. 4 and 5. Also evident in the figures are definitions of the critical energy release rate, G_c Fig. (4) and critical stress intensity factor K_c (Fig. 5). These critical values are defined at the point of instability (Ref 51, 52, and 53).

Elastic-Plastic Fracture Mechanics

EPFM does not have the requirement that the material behave in a linear-elastic manner. Instead, nonlinear or plastic deformation is allowed in EPFM methods to a much greater extent than in LEFM methods. The primary fracture parameter for EPFM is the J -integral. The J -integral, or more simply J , can be defined in two ways (Ref 56, 57). The first is defined by a path-independent line integral around the crack tip. The second is an energy definition similar to G , except that linear behavior is not required.

The energy definition of J states that J is a more general form of the energy release rate, G , where:

$$J = - \frac{d\Pi}{dA} \quad (\text{Eq 7})$$

When permanent deformation occurs (as in the case of plastic deformation of metals), some of the stored potential energy, Π , is dissipated and is therefore unavailable for crack extension. In this context, J can be thought of as the potential energy absorbed by a cracked body prior to crack growth. In other words, J is a measure of the intensity of the entire elastic-plastic stress-strain field around the crack tip, and J reaches a critical value just prior to crack extension.

A special case of the energy definition of J is the value for G (when the energy is released as a crack grows in a linear-elastic material). For the special case of linear-elastic behavior, there is little or no energy absorbed by permanent deformation, and the only energy dissipation is due to the crack surface creation. Hence, under linear-elastic conditions $J = G$:

$$J = G = \frac{K^2}{E'} \quad (\text{Eq 8})$$

where E' is equal to E or is related to the elastic modulus per Eq 6.

Under nonlinear conditions beyond the elastic regime, calculating J can be much more difficult. Unlike the K solutions or K -calibrations (which exist for many different crack and load configurations with K values for many situations), expressions that relate J values to the applied load and crack configuration are very few. For the simple situation of an edge-cracked specimen under elastic-plastic loading conditions, the energy definition of J is as follows:

$$J = - \frac{1}{B} \left(\frac{\partial U}{\partial a} \right)_{\Delta} \quad (\text{Eq 9})$$

where B is the specimen thickness, Δ is the load-line displacement, and U is the area under the P - Δ curve up to the initiation of crack growth (Ref 51, 52, and 53) where P is the applied load. Because a certain amount of the deformation must always be elastic, the expression for J in Eq 9 can be separated into elastic and plastic components and be rewritten as follows:

$$J = \frac{K_I^2}{E'} + \frac{\eta_{PL} U_{PL}}{Bb} \quad (\text{Eq 10})$$

where η_{PL} is a dimensionless constant that depends on the specimen and loading configuration, U_{PL} is the plastic area under the P - Δ curve, and b is the remaining ligament ($W-a$, where W is the specimen width). Equation 11 is used in experimentally measuring J (Ref 51, 52, 53, and 57).

In the elastic-plastic regime, there is typically some amount of stable crack growth prior to an unstable crack extension. The stable crack growth occurs because of energy dissipation and the crack blunting induced by plastic deformation. As a result, when J is experimentally measured, an R -curve based on the J parameter is generated. This J -based R -curve is a plot of the resistance to crack growth, J_R , as a function of crack length or extension (Fig. 4). The critical J , J_{Ic} in the opening mode, is then taken from the J_R curve at a point near the initiation of crack growth (Ref 51, 52, 53, 54, 55, 56, and 57).

The basic procedure for experimentally measuring J involves testing a bend specimen or a compact tension specimen with a deep crack and using the load, displacement, and crack length data to calculate J with Eq 11. J is calculated for several different crack lengths, and the J_R curve is generated. From the J_R curve, the J_{Ic} is taken at the point where initial crack extension occurred, as shown in Fig. 6. The test can be done with one of two goals. If the point of the test is to determine J_{Ic} , J is calculated with less attention to the fact that some crack extension occurred during the test. Ignoring the crack extension does not present much error because the crack growth initiation is the important feature in the test. If the development of the full J_R curve is the goal of the test, more care is taken in the data analysis to take into account the growing crack (Ref 51, 52, 53, 54, and 57).

Fracture Toughness of Ceramics and Ceramic Matrix Composites

J.H. Miller, Oak Ridge National Laboratory P.K. Liaw, The University of Tennessee, Knoxville

Fracture Mechanics of Ceramics and CMCs

The concepts of both LEFM and EPFM methods, as previously described in the context of metallic materials, provides a general basis for the fracture mechanics of monolithic ceramics and ceramic matrix composites. Generally LEFM methods are applicable for monolithic ceramics while EPFM methods may be suitable for CMCs.

Monolithic ceramics are inherently brittle due to their strong bonding and more complicated (less symmetric) crystal structures. Compared to metallic materials, the mixed ionic and covalent atomic bonding and low-symmetry crystal structure of ceramics severely limit the opportunity for plastic deformation mechanisms from dislocation formation, movement, and slip. Monolithic ceramics thus have high strength and stiffness with much less plastic deformation than metals. As a result, their behavior is primarily linear-elastic, which is one of the required conditions for LEFM methods.

The other condition for LEFM analysis is the presence of a sharp crack or flaw with a crack tip radius approaching zero. Monolithic ceramics meet this condition as well, and LEFM has been used successfully to evaluate monolithic ceramic fracture behavior. Some additional work was necessary to augment LEFM techniques to handle the difficulties of obtaining sharp starter cracks and maintaining stable crack growth that occur in brittle ceramics. Nonetheless, the result of the application of LEFM to monolithic ceramics is a relatively mature state of the art. Techniques exist to determine the single-valued critical fracture toughness and to measure crack growth resistance behavior of monolithic ceramic materials. Current research is centered on the further refinement of these techniques (see also the article "Fracture Resistance Testing of Brittle Solids" in this Volume).

Ceramic matrix composites are being developed in an attempt to increase the toughness and damage tolerance of ceramic materials. The toughness of CMCs is greater than the monolithic ceramics due to the toughening (energy-absorbing) mechanisms of microcracking, crack bridging, and crack branching. These toughening mechanisms enable the CMC to behave in a manner that closely resembles the elastic-plastic behavior of metals. Although this fact may suggest EPFM as appropriate for the study of CMCs, there are differences in the deformation mechanism of ductile metals and CMCs that can bring into question the appropriateness of metal-based EPFM methods for use with CMCs.

Metals dissipate crack-tip energy by the plastic deformation mechanisms of slip, dislocation generation, and dislocation movement. CMCs, on the other hand, dissipate crack tip energy through crack branching, fiber bridging, and microcracking. In both cases, energy is dissipated by nonlinear deformation of the body prior to crack extension. Fortunately, EPFM theory does not depend on the mechanism through which the energy is dissipated during nonlinear deformation, only on the fact that it does occur. As a result, even though the deformation mechanisms are very different, EPFM theory is valid for both metals and CMCs. Unfortunately, the complex nature of the processes that cause the nonlinear fracture behavior in CMCs complicates the

experimental application of EPFM methods to CMCs. The following section describes toughness tests that are used on monolithic ceramics and CMCs.

Fracture Toughness of Ceramics and Ceramic Matrix Composites

Fracture Toughness Evaluation

This section describes some fracture toughness measurement techniques that are being used on ceramics and CMCs. The descriptions are organized by specimen type, and they include advantages and disadvantages of each specimen type as well as experimental control schemes that have been employed on each specimen type. More detailed information on the fracture toughness testing of monolithic ceramics is also provide in the article "Fracture Resistance Testing of Brittle Solids" in this Volume.

Single Edge Notch Bending (SENB). The SENB specimen, shown in Fig. 7(a) has a rectangular cross section with a straight-through saw notch. It is loaded in either three- or four-point bending. The advantages of the SENB include ease of machining due to simple geometry and ease of use due to simple three- or four-point bend loading, which uses a fixture loaded in simple compression. The SENB, while easy to machine and test, is not very stiff. This leads to problems in starting a sharp crack at the end of the saw notch and in achieving stable crack extension (Ref 58).

Fig. 7 Fracture toughness specimens. (a) Single edge notch bending (SENB). (b) Compact tension (CT) or wedge open loaded (WOL). (c) Double cantilever beam (DCB) tensile loading. (d) DCB constant bending moment loading. (e) DCB wedge loading. (f) Tapered DCB. (g) Chevron notch short rod. (h) Chevron notch short bar. (i) Chevron notch bending. (j) Double torsion (DT). (k) Three-point bending with controlled surface flaw (CSF). P , load. Adapted from Ref 58

One method of producing a sharp starter crack in a SENB specimen involves using a hardness indenter to introduce a surface flaw and forcing the surface flaw to propagate to the outer edges and become a sharp edge crack. This can be done by loading the indented specimen in compression between two rigid plates. One of the plates has a single groove, and the indentation crack is positioned over the groove. During the compressive loading, the surface flaw is subjected to tensile opening stresses due to the groove, while the bulk of the material is in compression. This tension allows the crack to grow to become an edge crack, while the compression prevents the crack from propagating in an unstable manner through the specimen (Ref 59).

SENB specimens have been used to measure the fracture toughness of a yttria-partially stabilized zirconia (Y-PSZ) ceramic at ambient and elevated temperatures (Ref 59). The point of this work was to demonstrate the use of a new technique of controlling the fracture test in such a way as to promote stable crack growth so that the R -curve behavior of the ceramic could be measured. Crack mouth opening displacement (CMOD) was monitored using a laser extensometer, and the CMOD signal was used in the control of the servohydraulic testing machine in real time. The results of this type of control were positive, and stable crack growth was achieved (Ref 59).

The SENB method has also been improved by a scheme that employs both a method to provide for stable crack growth and better real-time computer-aided data acquisition (Ref 60). The crack growth stability was augmented by adjusting the stiffness of the test frame in such a way as to promote stable crack growth. The test machine stiffness, or compliance, was adjusted by placing a “parallel elastic element” (PEL) supporting structure between the crosshead and the top of the three-point bend loading fixture (Fig. 8). The optimum compliance for stable crack growth was determined by theoretical analysis and experimentation. During testing, the compliance of the specimen and the test frame were continuously monitored in real time through the use of a computer. The real-time load and displacement data from various points in the test system, as presented in Fig. 8. After the optimum PEL compliance was determined, and stable crack growth was achieved, the R -curves of the test materials were measured. The real-time load and displacement (and, therefore, compliance) monitoring, along with compliance versus crack length calibrations and the stress intensity calibrations, allowed the crack length, crack velocity, and stress intensity level to be calculated in real time during the test (Ref 60).

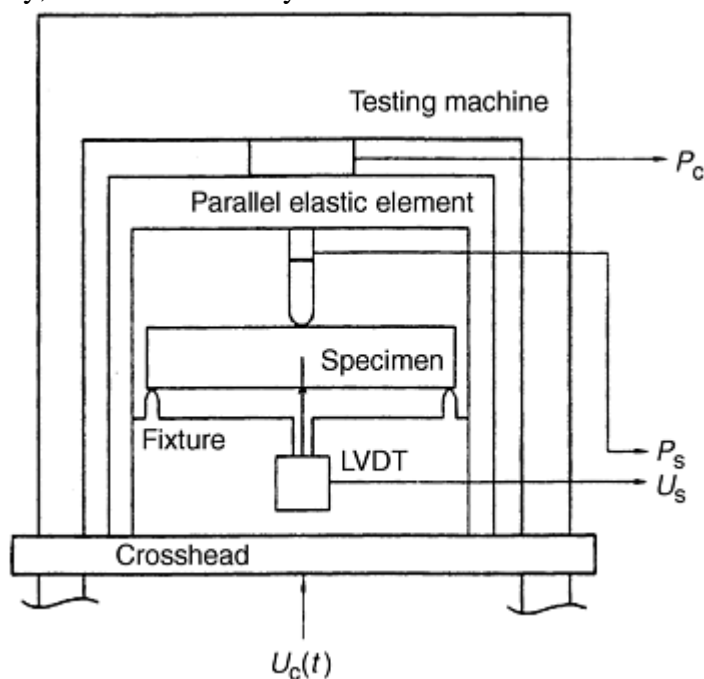

Fig. 8 Schematic of the compliance-controlled three-point bending test with a parallel elastic element (PEL). Adapted from Ref 60

Compact Tension (CT). The CT sample is a common specimen in fracture mechanics tests. It is loaded in tension, but the primary stress is due to bending because the load line is offset from the crack front (Fig. 7b). Relatively stable crack propagation is possible with the CT specimen if a stiff testing machine is used. Also, a variant of the CT can be used in a wedge-opening mode to increase the stable crack growth capability (Ref 49). The stable crack growth capability allows for the generation of R -curves using the CT specimen (Ref 61). The CT specimen is complicated to machine in ceramic materials, and precracking the can be difficult (Ref 58). In addition to R -curve measurements of monolithic ceramics (Ref 61), R -curves have been measured in CMCs using the CT specimen. CT specimens have been employed to generate R -curves for CMCs in an attempt to analyze the crack-face fiber-bridging stress field (the stress field in the wake of the crack that is due to fiber bridging). The crack-face fiber-bridging stress is evaluated by comparing the experimentally measured compliance versus crack length, which includes the contribution of the fiber bridging, to the compliance versus crack length data calculated from the elastic properties of the CMC, assuming no fiber bridges are present (Ref 62).

The J -parameter toughness has also been measured using a CT specimen (Ref 63). A J -based testing technique has been developed for CMCs using the CT specimen geometry. The concept of the J -parameter is used to determine the contribution of the process zone (the contribution of, for instance, fiber bridging and crack branching, analogous to the plastic zone in metals) to the toughness of the CMC. The J -parameter contribution of the process zone is determined using Eq 12 (Ref 63):

$$J_{\infty} + J_b + J_{\text{tip}} = 0 \quad (\text{Eq 11})$$

where J_{∞} is the far field J , J_b is the process zone J (analogous to J_{plastic}), and J_{tip} is the crack tip J . Also, it is assumed that elastic action takes place at the crack tip, so J_{tip} can be calculated from K_{tip} using Eq 9. The value of J_{∞} was experimentally calculated from measurements using CT specimens with two different crack lengths, a_1 and a_2 . The value J_{∞} is the far-field J , as the crack grows from a_1 to a_2 . Therefore, J_b was calculated from Eq 12 (Ref 63).

The J -parameter toughness has also been measured with CT specimens in a study conducted to compare the toughness values of woven fabric-reinforced CMCs with different interphases (Ref 64). The value of J , calculated from the experimental load-displacement curves at the point of maximum load, corresponds to macrocrack initiation in the process zone (Ref 64).

Double Cantilever Beam (DCB) Testing. The DCB specimen looks like a long CT specimen. It can be loaded in three different configurations: direct tension, constant bending moment, and wedge opening. The tensile-loaded DCB is very similar to the CT in all respects (Fig. 7c), but the DCB geometry is better than the CT for growing stable cracks. The tapered DCB, shown in Fig. 7(f), provides a constant K_I level with crack growth. Another DCB variant that provides a constant K_I level with crack growth is the moment-loaded DCB (Fig. 7d). Unfortunately, the fixturing that applies the moment to the arms of the DCB can be difficult to deal with. The final DCB variant is the wedge-loaded DCB (Fig. 7e). The wedge loading allows the specimen to be tested in simple compression. The wedge-loaded DCB specimen was first used in ASTM method E 561. All the DCB variants may need side grooves to keep the crack moving down the center of the specimen. The grooves complicate the K -calibration, and machining damage in the groove can affect the crack extension (Ref 58).

Specimens very similar to the constant bending moment DCB, called the Browne/Chandler test specimen, have been employed in the determination of R -curves for monolithic ceramics (Ref 65). The Browne/Chandler specimen geometry, shown in Fig. 9, applies loads to the outside corners of a specimen, supported by a stiff solid base, that has a rectangular cross section and a vertical edge crack. This loading induces a bending moment around the center of the specimen, which causes the crack to open and extend. If the applied load were held constant, the stress intensity at the crack tip would decrease as the crack grew. Therefore, the load must increase in order for crack growth to continue, which prevents unstable fracture. Also, crack-guiding side grooves are not necessary because the compressive stress parallel to the crack keeps the crack growing down the center of the specimen. Unfortunately, the Browne/Chandler test geometry does not lend itself to an analytical solution of K -calibrations for all crack lengths. As a result, stress intensities have to be estimated using numerical methods at both very short and very long crack lengths (Ref 65).

Fig. 9 Schematic sketch of the Browne/Chandler test geometry. Adapted from Ref 65

Chevron Notch Methods (CHV). The chevron notch is used in three specimens (Ref 58, 66). There is a short rod CHV (Fig. 7g), a short rectangular bar CHV (Fig. 7h), and a bend bar with a rectangular cross section and a chevron notch (Fig. 7i). The chevron notch geometry, due to the increase in the width of the crack surface during crack extension, forces rising *R*-curve behavior in ideally brittle materials. This means that after crack initiation, the crack front is stable and is always ideally sharp. Stable crack growth is not always found in practice due to the fact that excess stored energy in the specimen can overcome the geometrical tendency to force rising *R*-curve behavior. In these cases, the excess stored energy can cause catastrophic failure in the specimen. As a result, a stiff specimen geometry and test machine are important (Ref 58, 66).

One of the main advantages of the chevron notch geometry is the fact that it is possible to calculate the fracture toughness based on the maximum load and the specimen dimensions alone for ideally brittle materials. Due to the shape of the growing crack, the geometry factor, *Y*, goes through a minimum as crack growth occurs. The minimum in the geometry factor corresponds to the maximum load in the test. This unique fact allows the fracture toughness to be calculated without knowledge of the crack length (Ref 58). However, calculation of fracture toughness from the maximum load and specimen dimensions does not work for materials that exhibit natural rising *R*-curve behavior. In these cases, the minimum in the geometry factor versus crack length does not correspond with the maximum load, and the crack length must be known to calculate the fracture toughness (Ref 58).

The chevron notch specimen has become almost a standard for measuring fracture toughness in ceramic materials (Ref 58, 67, 68, and 69). In fact, the only ASTM standard test method for determining the fracture toughness of ceramics, B 771-87, uses the short rod and short bar chevron notch specimen (Ref 69). In addition, chevron notch samples are used in ASTM PS70, "Provisional Test Method For Determining The Fracture Toughness of Advanced Ceramics at Ambient Temperatures" (Ref 66). Also, researchers with new fracture tests use chevron notch results to benchmark the results of the new tests (Ref 61, 70, and 71).

Double Torsion (DT). The DT specimen, shown in Fig. 7(j), is a flat plate with a longitudinal through crack that is loaded in torsion. The torsional loading applies a bending moment that opens the crack on the tensile surface and closes the crack on the compressive surface. The applied moment causes the K_I level to be constant over a wide range of crack length. It also causes the crack front to be significantly curved between the top and bottom surfaces. This curvature of the crack front opposes the straight-through crack assumptions used in the stress intensity calculation, and causes errors in the toughness calculation (Ref 58).

Indentation Techniques. Indentation fracture toughness techniques utilize a sharp crack introduced in the material by a Knoop or a Vickers indenter. The Knoop indenter causes a single crack, which makes it attractive for use in fracture mechanics methods involving a surface flaw. The Vickers indenter creates two cracks that

are mutually perpendicular to each other. Both indentation methods can produce reproducible surface cracks, but the residual stress field from the indentation is complicated and must be removed or accounted for in the analysis (Ref 58, 72, 73, and 74)

Indentation creates subsurface cracks, due to tensile stress formation, just below the contact point of the indenter. These subsurface cracks are called median cracks. As the indenter is removed, the median cracks become unstable and grow to the indented surface. The resulting crack is called a radial crack. In some high-toughness brittle systems, small radial surface cracks can form prior to subsurface median crack formation. These shallow surface cracks are called Palmqvist cracks. Schematic drawings of median, radial, and Palmqvist cracks are shown in Fig. 10 (Ref 58, 72, 73, 74).

Fig. 10 Schematic diagram illustrating types of crack systems formed around an indentation. Adapted from Ref 42, 71

There are three indentation-induced crack techniques for measuring fracture toughness in ceramics: the controlled surface flaw (CSF) technique, the indentation microfracture (IM) technique, and the indentation strength in bending (ISB) technique. The CSF method can provide a quantitative measure of the fracture toughness because the stress intensity around the surface flaw is well known, but the IM and ISB provide only estimates based on empirical expressions (Ref 58, 72, 73, and 74).

The CSF method involves testing a bending specimen with an elliptical surface crack induced by a Knoop indenter (see Fig. 7k). The Knoop indenter is used to create a subsurface median crack. Then, the surface is carefully polished to remove the indent and the associated residual stresses. The polishing also reveals the median crack to the surface, and an elliptical surface flaw with no residual stress is the result. When the specimen is tested, the surface flaw causes the initiation of fracture, and K_{Ic} can be calculated based on the applied loads and the crack size (Ref 58, 73).

The ISB is similar to the CSF technique (Ref 73). The ISB approach uses the Vickers indenter to induce median-radial cracks on the tensile surface of a bending specimen. Through manipulation of the K -calibrations for the crack system, which account for both the applied and residual stresses, it is possible to develop an expression that relates the fracture stress in bending and the indentation load to the fracture toughness. Therefore, the ISB method involves calculating the fracture toughness based on the indentation load and the experimental fracture stress from a bending test. This method has the advantage of being relatively simple to conduct, and there is no need to measure crack size. The disadvantage comes from the use of empirical factors in the manipulation of the K -calibrations that are used to develop the expression relating the indentation load and fracture stress to the fracture toughness. This causes the fracture toughness measured by this method to be only an estimate (Ref 58, 73).

Another fracture toughness specimen that uses a Vickers hardness indenter to introduce sharp cracks into a ceramic material is the miniature disk bend test (MDBT) specimen (Ref 70, 75). These specimens are 3 mm (0.1 in.) in diameter and range in thickness from 200 to 700 μm . Vickers indentation cracks are introduced into the center of the tensile side of the specimen. The disk specimen is loaded in a ring-on-ring bending mode, schematically shown in Fig. 11. The MDBT is similar to the ISB test. In both experiments, the fracture stress

and indentation load are related to the fracture toughness. Therefore, the fracture toughness is calculated from the indentation load and the fracture stress from the MDBT. The advantages of the MDBT are the small amount of material that is needed to conduct the test and the fact that the crack length need not be measured (Ref 70, 75).

Fig. 11 Schematic sketch of the miniature disk bend test (MDBT) geometry. Adapted from Ref 70

The indentation microfracture (IM) method introduces cracks into the surface of a sample with a Vickers indenter and uses the length of those cracks to estimate the fracture toughness (Ref 58, 72). This method is very attractive because it is so easy to conduct the test. As a result, many good empirical toughness relations have been generated for specific crack geometries. It is important in this method to ensure that median-radial cracks are analyzed rather than Palmqvist cracks. The shallow Palmqvist cracks are hard to measure, and, consequently, significant error and scatter are introduced in the data (Ref 58, 71).

Typical Fracture Toughness Properties of Ceramics and CMCs. The critical fracture toughness, K_{Ic} , of monolithic ceramics is low, on the order of 1 to 4 $\text{MPa}\sqrt{m}$ (0.9 to 3.5 $\text{ksi}\sqrt{\text{in.}}$), while CMCs can have toughness values near 20 $\text{MPa}\sqrt{m}$ (18 $\text{ksi}\sqrt{\text{in.}}$). The K_{Ic} values for several ceramics and a few CMCs are shown in Table 1. Where possible, the values of K_{Ic} measured by different methods on the same material are included for comparison. From the table, it is evident that the many methods agree well.

Table 1 Typical ceramic and CMC properties

Material	K_{Ic} ($\text{MPa}\sqrt{m}$)	Method	Reference
Glass ceramic pyroceram (Corning)	2.7	CSF	72
	2.5	DCB	72
	2.9	ISB	73

Ceramics can exhibit either flat or rising *R*-curve behavior, depending on processing-derived microstructure (Ref 67). Figure 12 shows *R*-curves for three different silicon nitride (Si₃N₄) materials, A, B, and C. The *R*-curves were measured using short bar chevron notch methods. Material A is a hot pressed commercial Si₃N₄ (SN-84H by NGK Technical Ceramics) with low fracture toughness; it results in flat *R*-curve behavior. Materials B and C, which have relatively higher fracture toughness, are monolithic Si₃N₄ (AS700 by Allied Signal Inc.) prepared by gas pressure sintering green billets, which were formed by cold isostatic pressing. These two Si₃N₄ materials exhibit rising *R*-curve behavior (Ref 67).

Fig. 12 *R*-curves of three Si_3N_4 ceramic materials measured by the short rod chevron notch technique. Adapted from Ref 67

An *R*-curve from short bar chevron notch tests on a SiC-whisker-reinforced alumina matrix composite is presented in Fig. 13 (Ref 67). The whisker-reinforced alumina composite also exhibits rising *R*-curve behavior.

Fig. 13 Rising *R*-curve of a SiC whisker reinforced alumina ceramic matrix composite (CMC), measured by the double cantilever beam technique. Adapted from Ref 67

The rising R -curve behavior of an isostatically pressed and sintered ceria-partially stabilized zirconia (Ce-PSZ) ceramic is given in Fig. 14 (Ref 61). This R -curve was measured using a crack line wedge-loaded (CLWL) technique, which is a wedge-loaded variant of the compact tension specimen.

Fig. 14 Rising R -curve of a Ce-PSZ ceramic measured by the crack line wedge loaded technique. a and w refer to dimensions defined in Fig. 7(c). Adapted from Ref 61

Table 2 presents critical toughness expressed in terms of the J -integral, J_c , for short Nicalon fiber-reinforced foam glass matrix composites (Ref 63). Values for J_c range from 3.5 to 241.8 N/m, depending on fiber length and fiber volume fraction. The interface condition also strongly affects the value of J_c (Ref 64). Table 3 shows a wide range of J_c values for continuous woven Nicalon fiber fabric-reinforced SiC matrix composites produced by chemical vapor infiltration. In Table 3, the interface condition is given an arbitrary designation of numbers from one to ten. The interfaces of these composites were modified by applying various multilayered carbon and SiC fiber coatings, the details of which are can be found in Ref 64. Table 3 clearly shows that the interface condition causes the value of J_c to vary over a wide range from 11800 to 28520 N/m. Also notice that the values of J_c for the materials of Tables 2 and 3 are quite different. This fact indicates that composite constituent materials, volume fractions, and interfacial properties all have a very pronounced effect on the toughness of CMCs.

Table 2 J_c values for short Nicalon fiber reinforced foam glass matrix composites

Fiber length, mm	Fiber volume fraction, %	J_c , N/m
3	1.0	61.6
6	1.0	147.5
13	0.1	3.5
13	0.2	14.8
13	0.8	210.0
13	1.0	241.8

Fracture Toughness of Ceramics and Ceramic Matrix Composites

J.H. Miller, Oak Ridge National Laboratory P.K. Liaw, The University of Tennessee, Knoxville

Summary

As described in this article (and the article “Fracture Resistance Testing of Brittle Solids” in this Volume), several test methods are used for the determination of the fracture behavior of ceramics. Many of these methods include several variations of their own, suggesting the need for more standardization of test methods.

From the preceding discussions, fracture toughness determination of monolithic ceramics appears to be mature. The fact that most monolithic ceramics behave in a linear-elastic manner has allowed the direct transition of theory from LEFM developed for metals to use on ceramics. Current fracture toughness research on monolithic ceramics is centered on refining test methods, data acquisition techniques, and theoretical and numerical analyses (Ref 48, 60, 67, and 70). Methods have been developed to overcome the difficulties in initiating sharp starter cracks (Ref 58, 59), providing stable crack growth (Ref 61, 65, and 67), and minimizing the amount of expensive test materials required for fracture testing (Ref 59, 70).

Fracture toughness evaluation for CMCs is much less developed than for monolithic ceramics. The elastic-plastic-like failure behavior of CMCs makes EPFM look like an attractive method for evaluating their fracture behavior. Some, but not much, research based on EPFM methods has been used in attempts to quantify the contribution of plastic-like mechanisms in CMCs (Ref 63, 64). Unfortunately, the low level of understanding of the very complicated toughening mechanisms of microcracking, fiber bridging, and crack branching precludes a direct transition of the EPFM theory that exists for metals to CMCs.

The permanent or plastic deformation that EPFM was developed to handle in metals is due to the dislocation creation, movement, and slip. These metallic plasticity concepts were well understood prior to the development of EPFM, and were, therefore, available to influence the development of EPFM. In contrast, the plastic-like mechanisms in CMCs are microcracking, crack bridging, and crack branching. A significant amount of work still needs to be done before these complicated mechanisms are well understood. As a result, the development of EPFM methods for CMCs is, and will continue to be, slow.

The bulk of the current research on CMC behavior centers on increasing the understanding of the CMC toughening mechanisms. Researchers continue to work on understanding the fracture mechanisms in CMCs at many levels (Ref 71, 76, 77, 78, and 79). Much research is still being done to evaluate the forces and stresses involved in the fiber bridging that occurs in the wake of cracks (Ref 71, 76, 77, 78, and 79). The ultimate goal of the research is to develop theories that will connect the results of LEFM and EPFM tests to the complex mechanisms of microcracking, crack bridging, and crack branching. As this goal is achieved, mature fracture mechanics technology will be realized for CMCs.

Fracture Toughness of Ceramics and Ceramic Matrix Composites

J.H. Miller, Oak Ridge National Laboratory P.K. Liaw, The University of Tennessee, Knoxville

Acknowledgments

Professor P.K. Liaw is kindly and greatly supported by the NSF Division of Design, Manufacture, and Industrial Innovation, under Grant No. DMI-9724476, and the Combined Research-Curriculum Development (CRCD) Program under EEC-9527527 to the University of Tennessee, Knoxville (UTK), with Dr. Delcie R. Durham and Ms. Mary Poats as program managers, respectively. We would like to acknowledge the financial support of the Office of Research and the Center for Materials Processing at UTK. We would also like to express our appreciation to Dr. John Landes, Dr. Allen Yu, and Dr. Ray Buchanan, all from UTK, for their comments and help during the preparation of this article.

This research was performed in cooperation with the UTK under contract 11X-SN191V with the Lockheed-Martin Energy Research Corporation and is sponsored by the US Department of Energy, Assistant Secretary for Conservation and Renewable Energy, Office of Industrial Technology, Industrial Energy Division, under contract DE-AC05-84OR21400 with the Lockheed-Martin Energy Research Corporation.

Fracture Resistance Testing of Brittle Solids

Michael Jenkins, University of Washington; Johnathan Salem, NASA-Glenn Research Center

Introduction

CATASTROPHIC FAILURE best typifies the characteristic behavior of brittle solids in the presence of cracks or crack-like flaws under ambient conditions. Examples of engineering materials that behave as brittle solids include glasses, ceramics, and hardened metal alloys, such as bearing or brake steels. Figure 1 shows the linear-elastic stress-strain curves and abrupt failures of a glass and a ceramic. This behavior is contrasted with the linear/nonlinear stress-strain curves and “graceful” failure of a ductile-like material, such as a metal, or in this case, a continuous fiber-reinforced composite.

Fig. 1 Comparison of stress-strain curves for ceramics and glasses (as examples of brittle solids) and fiber-reinforced composites (as examples of nonbrittle solids). Source: Ref 1

Sometimes under nonambient conditions, materials that normally fail in a ductile manner may fail in a brittle manner (e.g., carbon steel at temperatures less than their nil-ductility) and those materials that normally fail in a brittle manner may exhibit pseudo-plasticity and failure in a ductile manner (e.g., ceramics containing glassy secondary phases at temperatures greater than the glass-softening temperature).

Because catastrophic failure occurs without warning and can occur in any engineering material under the “suitably wrong” conditions, it is important to characterize the fracture behavior of materials in order to produce engineering designs that can accommodate this phenomenon. This article reviews the fracture behavior of brittle solids and the various methods that have been developed to characterize this behavior.

Concepts of Fracture Mechanics as Applied to Brittle Materials

Many assumptions accompany engineering analyses. For example, in fundamental mechanics of materials it is often assumed that materials are linear elastic, homogeneous, uniform, and isotropic from a macroscopic view. These assumptions are more or less appropriate for polycrystalline materials without any crystallographic ordering. Microscopically, of course, these assumptions become tenuous at best, especially for dimensional scales on the order of grain sizes.

In the study of crack and material interactions, fundamental engineering fracture mechanics also makes several assumptions. These include the linear elastic, homogeneous, uniform, and isotropic assumptions of material response. In addition, it is assumed that the change in stored elastic strain energy is used entirely by the fracture process in creating new fracture surfaces and that the crack itself exists in an infinite body and is not influenced by any boundary conditions. Using these assumptions, it is possible to write the original Griffith criterion for fracture in terms of an applied fracture stress (Ref 1, 2, and 3):

$$\sigma_f = \sqrt{\frac{4\gamma_f E}{\pi(1-\nu^2)c}} \quad (\text{Eq 1})$$

where σ_f is the applied stress at fracture, γ_f is the energy required to create a unit of fractured surface area (i.e., fracture surface energy), E is the elastic modulus, ν is Poisson's ratio, and c is the flaw (i.e., crack) dimension (in the case of an internal flaw, the radius). The observed fracture strengths, S_f , of brittle solids (i.e., the applied stress at fracture given by Eq 1 where $S_f = \sigma_f$) are related to the size and distributions of the strength-limiting flaws, c , in the material (assuming γ_f , E , and ν are deterministic material properties). Strength distributions are therefore related to the distributions of these flaws: intrinsic flaws (e.g., those due to processing) are those that can be treated as microcracks (short cracks) and are on the order of the microstructure; extrinsic or induced flaws (e.g., those due to service) are those that can be treated as macrocracks (long cracks) and are on the order of component dimensions. Note that sometimes extrinsic flaws may be of the same dimensional order as intrinsic flaws.

The microcrack-like flaws are randomly distributed in size, location, orientation, and shape (scattered) throughout brittle materials, causing a range of fracture strengths in otherwise identical components or parts. This inherent scatter leads to fracture strengths that are related to the geometric size (i.e., surface area or volume) of the component. In other words, the larger the component is, the greater the probability of a larger (or properly oriented, or properly shaped, etc.) flaw to occur and, hence, the lower the fracture strength is. Therefore, fracture strength is not a deterministic property in brittle materials unless the flaws are extremely uniform and consistent. Factors of safety in the conventional sense cannot be used. Strength values vary significantly with size and shape of the component (or test specimen) and with processing conditions. There may even be batch-to-batch differences as a consequence of material inconsistencies. These factors, coupled with the "inherent" brittleness of the materials, mean that either extremely conservative stress/strength-based deterministic design philosophies or probabilistic reliability methods must be used for components fabricated from brittle materials.

The concepts of engineering fracture mechanics can be applied when a flaw has a measurable crack size. In this case, the stress field at the crack tip is described in terms of stress intensity factor, which can be written as (Ref 4, 5):

$$K = Y\sigma\sqrt{\pi a} \quad (\text{Eq 2})$$

where K is the stress intensity factor, σ is an applied stress, Y is a geometry correction factor, and a is the macrocrack dimension. Three "modes" of fracture are related to the "mode" of loading (Fig. 2). Mode I, the "opening mode," is considered to be the limiting case for the tendency to fracture because a tensile normal stress "opens" the crack with the resulting stresses in the material "carried" at the crack tip (as opposed to partially distribute through interaction of the crack faces as in modes II and III).

Fig. 2 Modes of fracture. Mode I (opening), mode II (sliding), and mode III (tearing). Source: Ref 4

The critical mode I condition for brittle fracture in a component with a crack-like flaw is reached at a combination of the crack/component geometry correction factor, Y ; a sufficiently high tensile, normal stress, σ ; and a sufficiently long, sharp crack, a . If the fracture resistance of the material is not a function of crack length then catastrophic fracture will occur in the component when the stress intensity factor is equal to the critical stress intensity factor at fracture in the component:

$$\text{Brittle fracture if } K_I = K_{Ic} \tag{Eq 3}$$

where K_I is the mode I stress intensity factor and K_{Ic} is the fracture toughness* of the material (i.e., resistance to fracture), which can be related to fundamental fracture behavior of the material through the Griffith approach (Ref 1, 4):

$$K_{Ic} = \sqrt{\frac{2\gamma_f E}{(1-\nu^2)}} \tag{Eq 4}$$

From a practical view, materials scientists often prefer to use the Griffith approach and γ_f (Eq 1) to describe the fracture characteristics of materials and their relation to the fundamental aspects of the material. However, designers and engineers prefer the fracture-mechanics approach and K_{Ic} (Eq 2 and 3) because fracture characteristics of the component can be related to the applied stress and the crack size.

Note that Eq 3 is a necessary, but not sufficient, condition for fracture. From the Griffith fracture criterion, fracture does not occur at the extreme value of the energy balance as a function of crack length, $U = f(c)$, but rather when the derivative of this energy with respect to the crack length, dU/dc , is equal to zero (Ref 3).

If the resistance of the material to fracture is denoted as R , then, according to Ref 3, the conditions for unstable (brittle catastrophic) fracture can be written as:

$$K_I = R \text{ and } \frac{dK}{dc} \geq \frac{dR}{dc} \tag{Eq 5a}$$

Stable (noncatastrophic) fracture is represented as:

$$K_I \leq R \text{ and /or } \frac{dK}{dc} < \frac{dR}{dc} \quad (\text{Eq 5b})$$

where dK/dc and dR/dc are the derivatives of the stress intensity factor, K , and the fracture resistance of the material, R , with respect to the crack length, c , respectively. Equations 5a(a) and 5b(b) can be illustrated as a fracture resistance or R -curve, as shown in Fig. 3. Note that the R term can be further described in parts such that (Ref 3):

$$R = R_0 + R(c) \quad (\text{Eq 6})$$

where R_0 can be considered the intrinsic fracture resistance, and $R(c)$ is the R -curve component. Note that at some finite length of crack extension, R becomes constant and $R(c)$ is no longer a function of c . This “steady-state” value of fracture resistance [$R_\infty \neq f(c)$] corresponds to fully developed “toughening mechanisms” (Ref 1, 3). R -curve behavior in brittle materials typically develops because of microstructural effects, as shown in Fig. 4. R -curve effects often confuse and frustrate attempts to experimentally measure R_0 (or K_{Ic}) because the effects of crack growth history add to experimental scatter if R (or K_{Ic}) is measured and reported outside the context of the crack extension.

Fig. 3 Schematic representation of R -curve behavior

Fig. 4 Microstructural features responsible for fracture resistance as a function of crack length (R -curve effects). Source: Ref 1

Part of the debate surrounding the development of standardized test methods (Ref 7, 8, 9, and 10) for determining the fracture resistance of brittle ceramics has been whether the test method should measure the intrinsic fracture resistance, R_o , or the fully developed fracture resistance, R_∞ . To address this question, the operational aspects of the test method must take into account intrinsic versus extrinsic flaws (or cracks), the degree of crack extension prior to measurement of the fracture resistance, the resulting linearity (or nonlinearity) of the loading curve, features on the fracture surfaces, and other “clues” indicating brittle or nonbrittle fracture.

Typically, brittle materials exhibit low values of fracture toughness ($K_{Ic} = R_o$) ($<1 \text{ MPa}\sqrt{m}$ for many glasses, $<10 \text{ MPa}\sqrt{m}$ for many monolithic ceramics, and $<20 \text{ MPa}\sqrt{m}$ for cast irons and hardened steel alloys). These low fracture toughnesses combined with moderate strengths mean that from a Griffith approach, intrinsic flaw sizes may only be on the order of 1 to 50 μm , which often lead to low, broad strength distributions. From a fracture-mechanics approach, lower fracture toughness combined with detectable macrocrack sizes severely limit the design stresses allowable in components comprised of brittle materials.

Thus, the real utility of measuring the fracture resistance of brittle materials may not be in its direct application to crack- or flaw-based design (e.g., when does $K_I = K_{Ic}$?) through either Griffith or fracture-mechanics approaches. Instead, measures of fracture resistance (e.g., K_{Ic}) may find their greatest utility when combined with other material properties in relative comparison indices, such as those that describe wear or brittleness.

One possible proposed abrasive wear model for ceramics is (Ref 11, 12):

$$\dot{V} \propto P^{1.5} K_c^{-0.5} H^{-0.625} \left(\frac{E}{H} \right)^{0.8} \quad (\text{Eq 7})$$

where \dot{V} is the volume-loss rate of material, P is the applied load, K_c is the fracture resistance, and H is the hardness. Although the exponents in Eq 7 are specific to the application and material, it is apparent from the model that to minimize abrasive wear at high loads, P , the material must possess high K_c , high H , and low E .

A possible proposed erosive wear model for ceramics has the form (Ref 12, 13):

$$\varepsilon_v \propto v^2 \frac{\pi d^4}{12} (E\rho/K_c^2) \quad (\text{Eq 8})$$

where ε_v is the volume of material removed, v is the impact velocity of the particle with diameter d , and ρ is the density of the particle. Again, note that for high velocities of impacting particles, the erosive wear of the material can be minimized by a high K_c , low E , and low ρ .

Finally, the susceptibility of a material to cracking rather than deformation under the action of a concentrated stress can be defined in terms of its brittleness (Ref 14, 15):

$$B = \left(\frac{HE}{K_{Ic}^2} \right) \quad (\text{Eq 9})$$

where B is the brittleness. In this case, in order to decrease the tendency toward brittle behavior (i.e., cracking rather than plastic deformation), B needs to be decreased by decreasing H and E and increasing K_{Ic} .

These examples of relative comparison indices show that quantifying the fracture resistance of brittle solids has direct and important applications other than those conventionally thought of from a fracture-mechanics viewpoint. In addition, as indicated in Eq 7, 8, and 9, depending on the application, the exponent on the fracture-resistance term can have a significant influence on the resulting value of the index being calculated. Thus, accurate and precise measures of the fracture resistance of brittle materials are of paramount importance for making sensible predictions of material behavior using relative comparison indices.

Footnote

* ASTM Committee E08 denotes the symbol K_{Ic} to represent the “plane strain fracture toughness” of a material. Plane strain fracture toughness is defined as: “the crack extension resistance under conditions of crack-tip plane strain... (and)... the value of stress intensity factor designated as K_{Ic} as measured using the operational procedure (and satisfying all validity requirements) specified in ...(ASTM E399)... which provides for the measurement of crack-extension resistance at the start of crack extension and provides operational definitions

of crack-tip sharpness, start of crack extension and crack-tip plane strain” (Ref 6).

Fracture Toughness and *R*-Curve Testing at Ambient Temperature

In 1970, the fracture-mechanics and metals communities developed the premiere fracture—toughness testing standard for determining plane strain fracture toughness of metals: ASTM E 399, “Standard Test Method for Plane Strain Fracture Toughness of Metallic Materials” (Ref 6). ASTM Committee E-8 on “Fatigue and Fracture” has defined the term *fracture toughness* and the symbol, K_{IC} , based on the operational methods of ASTM E 399. This test method includes several necessary aspects for an acceptable fracture test method:

- All test specimens must have atomistically sharp precracks at the onset of fracture
- Precracks must be well characterized and measurable at the conclusion of the fracture measurement
- Crack geometry must have a valid stress intensity factor
- Plane strain conditions must exist at the crack tip for the measurement of plane strain fracture toughness.

ASTM E 399 was developed and is appropriate for measuring plane strain fracture toughness in ductile metals but does not necessarily address the unique aspects of brittle solids (e.g., cyclic fatigue precracking is not easily accomplished in brittle materials). In addition, test specimens are rather large, as are the notches, cracks, and precracks, presumably for ease of implementation as well as to minimize the influence of dimensional variations on the repeatability and reproducibility of the fracture-resistance measurement. In recent years, ASTM committees have developed numerous standard test methods for metals; recently, a “unified” standard test method for fracture testing was introduced (ASTM E 1820, “Standard Test Method for Measurement of Fracture Toughness”) (Ref 16). Although a variety of precracking, crack length, fracture parameter (e.g., fracture toughness, *R*-curve, etc.), gripping, and test-specimen preparation techniques are detailed in these standards, many aspects may not be directly applicable to brittle materials.

Since the introduction of ASTM E 399, standards-writing bodies worldwide have labored to develop similar robust and well-accepted test methods for brittle solids, particularly advanced ceramics (Ref 7, 8, 9, and 10). The following sections, where applicable, discuss general aspects of these test methods for extrinsic flaws (macrocracks) and intrinsic flaws (microcracks) in test specimens. The reader is referred to the standards themselves for specific details when such standards exist and to appropriate references when a useful technique is described.

Standard Test Methods for Fracture Toughness at Ambient Temperature

ASTM Standard for Fracture Toughness of Ceramics. After nearly eight years of focused effort, which included downselecting from five to three operational procedures and the introduction of an interim limited-life (two years) provisional standard (Ref 17), ASTM C 1421 “Standard Test Methods for the Determination of Fracture Toughness of Advanced Ceramics at Ambient Temperature” (Ref 18) was approved as a full consensus standard in early 1999. A technical and historical overview of the evolution of these test methods has been published (Ref 9). Only a summary of the test methods is discussed here.

Generally, the test methods involve the flexural testing of extrinsically flawed bend bars, as shown in Fig. 5. Regardless of test method, a minimum of four valid tests is required to complete a test series.

Fig. 5 Three test-method configurations for fracture-toughness testing of ceramics included in ASTM C 1421. SCF, surface crack in flexure; SEPB, single-edge precracked beam; CNB, chevron notched beam

In the case of the single-edge precracked beam (SEPB) test specimen, prior to fracture testing, a compression bridge anvil is used with the 3 by 4 mm (0.12 × 0.16 in.) cross section “bend bar” test specimen to produce precracks from either a saw notch or a series of Vickers indentations. The precracked test specimen is then fracture tested in either three- or four-point flexure (20 by 40 mm, or 0.8 × 1.6 in., inner/outer spans in four-point flexure is recommended, although outer spans as short as 16 mm, or 0.6 in., in three-point flexure are permissible). Various methods are suggested for determining conditions of instability, stable crack extension, and other anomalies that can affect the test results.

Requirements for the precrack include the following:

- Inclination of the precrack front must be $a_{av} - a_{min} < 0.1 a_{av}$, where a_{av} and a_{min} are the average and minimum precrack lengths, respectively.
- The inclination of the propagation direction on the bottom surface and both sides of the specimen is $\leq 5^\circ$.
- The precrack length is between $0.35W$ and $0.60W$, where W is the test specimen height.

For three-point flexure, the fracture toughness by the SEPB method is calculated as:

$$K_{Ipb} = g \left(\frac{P_{max} S_o 10^{-6}}{BW^{3/2}} \right)^{1/2} \times \left(\frac{3(a/W)^{1/2}}{2(1-a/W)^{3/2}} \right) \quad (\text{Eq 10})$$

where K_{Ipb} is the fracture toughness (in $\text{MPa}\sqrt{m}$) using the SEPB method, P_{max} is the maximum force (in newtons) at fracture, S_o is the outer support span (in meters), B is the test specimen breadth (in meters), W is the test specimen height (in meters), a is the precrack length (in meters), and g is the geometry correction factor that depends on the three-point flexure geometry (Ref 17, 18).

For four-point flexure, the fracture toughness by the SEPB method is calculated as:

$$K_{Ipb} = f \left(\frac{P_{max} (S_o - S_i) 10^{-6}}{BW^{3/2}} \right)^{1/2} \times \left(\frac{3(a/W)^{1/2}}{2(1-a/W)^{3/2}} \right) \quad (\text{Eq 11})$$

where S_i is the inner support span (in meters) and f is the geometry correction factor that depends on the four-point flexure geometry (Ref 17, 18).

In the case of the surface crack in flexure (SCF) test specimen, a Knoop indenter is used to create a semielliptical surface precrack. An essential step in this method is the removal of residual stresses induced by the indenter. Grinding and polishing are recommended whereas annealing is not because it can lead to crack healing and crack tip blunting. The precracked test specimen is then fracture tested only in four-point flexure (20 and 40 mm, or 0.8 and 1.6 in., inner and outer spans, respectively). Post-test fractography is necessary to determine the precrack size for the calculation of the fracture toughness. It has been argued that the SCF

method may give results representative of the intrinsic fracture resistance of the material because the induced flaw can be on the order of the intrinsic flaws (Ref 9).

The fracture toughness by the SCF method is calculated as:

$$K_{Isc} = Y \left(\frac{3P_{\max}(S_o - S_i)10^{-6}}{2BW^2} \right)^{1/2} \quad (\text{Eq 12})$$

where K_{Isc} is the fracture toughness (in MPa \sqrt{m}) using the SCF method and Y is the greater of two possible geometry correction factors:

$$Y_d = \frac{(\sqrt{\pi}MH_2)}{\sqrt{Q}} \quad (\text{Eq 13a})$$

$$Y_s = \frac{(\sqrt{\pi}MH_1S)}{\sqrt{Q}} \quad (\text{Eq 13b})$$

where M , H_1 , H_2 , Q , and S are dimensionless functions based on an assumed half semiellipsed precrack shape (Ref 17, 18).

In the chevron notched beam (CNB) test specimen, a V-shaped notch is cut in the “bend bar” with the tip of the V oriented to the tensile stress during fracture testing. The advantage of the CNB test is that no prior precracking is required. Instead, the crack initiates at the tip of the chevron during testing. The crack then propagates through the chevron in a stable manner because the chevron presents an ever-widening crack front to the propagating crack. Examination of the loading curves provides an indication of stable fracture (e.g., smooth, nonlinear rollover), a necessary requirement for a valid CNB test. Either three- or four-point flexure is allowed for the CNB with allowable test geometry parameters (L , W , S_o , and S_i) dependent on the test configuration chosen (A, B, C, or D) (Ref 18). Valid tests must have chevron notch planes that meet within three notch thicknesses; the tip of the chevron must be less than 2% of the test specimen breadth, B , from the centerline; and the difference between the two chevron length measurements and the average of the chevron length must be less than 2% of the test specimen height, W .

The fracture toughness by the CNB method is calculated as:

$$K_{Ivb} = Y_{\min}^* \left(\frac{P_{\max}(S_o - S_i)10^{-6}}{BW^{3/2}} \right)^{1/2} \quad (\text{Eq 14})$$

where K_{Ivb} is the fracture toughness (in MPa \sqrt{m}) using the CNB method and Y_{\min}^* is the minimum stress intensity factor coefficient for the relevant geometry (Ref 17, 18).

Interferences addressed in ASTM C 1421 include slow crack growth (i.e., environmentally assisted crack growth), R -curve effects, and stability. Other methods considered but not addressed in the standard include indentation strength in bending (ISB), indentation fracture (IF), double cantilever beam (DCB), and single-edge notched beam (SENB). Discussions of why these methods were not included in the ASTM standard are provided elsewhere (Ref 9).

JIS Standard for Fracture Toughness of Ceramics. In 1990, the Japanese Industrial Standards Committee (JISC) adopted the Japanese Industrial Standard (JIS) R1607 “Testing Methods for the Fracture Toughness of High Performance Ceramics” (Ref 19). This standard contains two test methods for the determination of the fracture toughness of ceramics: SEPB and IF.

Similar to the ASTM SEPB method, either Vickers indentations or a straight notch can be used as “starters” in the 3 by 4 mm (0.12 × 0.16 in.) cross section bar prior to the use of the compression bridge anvil. Unlike the ASTM SEPB method, after introducing the precrack, the fracture test is conducted only in three-point flexure using either 16 or 30 mm (0.63 or 1.18 in.) outer spans. Requirements for the precrack include the following:

- The length variation and inclination of the precrack front must be $(a_{\max} - a_{\min})/2 < 0.1$, where a_{\max} and a_{\min} are the maximum and minimum precrack lengths, respectively.
- The inclination of the propagation direction on the bottom surface and both sides of the specimen is $\leq 10^\circ$.

- The precrack length is between 1.2 and 2.4 mm (0.05 and 0.09 in.).

The fracture toughness by the SEPB method is calculated as:

$$K_{Isepb} = \left(\frac{PS}{BW^{3/2}} \right)^{1/2} \left(\frac{3(a/W)^{1/2} Y}{2} \right) \quad (\text{Eq 15})$$

where K_{Isepb} is the fracture toughness (in $\text{MPa}\sqrt{\text{m}}$) using the SEPB method (Ref 19). The average of five valid tests is reported.

For the IF method, a Vickers hardness tester “at a large load” is used to create the impression (cracked from corners), as shown in Fig. 6. Within 10 minutes after the creation of the indentation, both diagonal dimensions (two corner crack lengths combined with the indentation diagonal length) are measured. The corner cracks must satisfy the following conditions:

- Cracks start at the corner of the indentation and propagate in the diagonal direction.
- Lengths of any two cracks normal to each other differ by less than 10% of the average crack length.
- Any crack length is at least 2.5 times the diagonal length of the indentation.

Fig. 6 Two methods for fracture-toughness testing of ceramics contained in JIS R1607-90. Dimensions in millimeters. Source: Ref 19

The quasi-fracture toughness is calculated as:

$$K_c = 0.018 \left(\frac{E}{H_v} \right)^{1/2} \left(\frac{P}{C^{3/2}} \right) \quad (\text{Eq 16})$$

$$= 0.026 \frac{E^{1/2} P^{1/2} a}{C^{3/2}}$$

where K_c is the quasi fracture toughness (in $\text{Pa}\sqrt{\text{m}}$) using the IF method, H_v is the Vickers hardness (in pascals), C is half the average crack length (in meters), and a is half the average diagonal length of the indentation (in meters). There is considerable controversy surrounding the result of the IF for accurate and precise measurements of fracture toughness. Two obvious concerns are the choice of the “calibration constant,”

which is 0.018 in Eq 18 but could be one of over 19 different values (Ref 20, 21) and the highly subjective estimate of the final crack tip. Even JIS R1607 states that the result of the IF method cannot be strictly considered a fracture toughness.

ISO Standard for Fracture Toughness of Ceramics. The International Organization for Standardization (ISO) made significant progress in 1999 when ISO DIS15732, “Fine Ceramics (Advanced Ceramics, Advanced Technical Ceramics)—Test Method for Fracture Toughness of Monolithic Ceramics at Room Temperature by Single Edge Pre-Cracked Beam (SEPB) Method” (Ref 22) was approved. In addition, a new working group has introduced an advanced draft of an SCF fracture testing method (Ref 23). ISO Technical Committee (TC) 206 has oversight of both these efforts, although in this article only ISO DIS15732 is discussed in detail because many of the essential aspects of the current draft of the SCF test method are similar to the SCF test method contained within ASTM C 1421. “Harmonization” of existing national and regional standards, not development of completely new standards, is one of the charter goals of ISO TC206.

ISO DIS15732 is a combination of the two existing national standards containing the SEPB fracture test method: ASTM C 1421 and JIS R1607. Because the proper introduction of the precrack is critical to the success of the SEPB method for both ASTM and JIS standards, explicit directions and illustrations are provided in an annex (Fig. 7). Both three- and four-point flexure are allowed in certain outer and inner support spans, again, as contained in both the ASTM and JIS standards (Fig. 8). Also, as contained in the ASTM and JIS standards, either a row of Vickers (or Knoop) indentations or a saw notch are allowed for the precrack starter. Similarly, the cross section of the beam is 3 by 4 mm (0.12×0.16 in.) with minimum lengths ranging from 18 to 45 mm (0.7–1.8 in.) depending on the testing configuration.

Fig. 7 Illustration of compression bridge anvil for fracture-toughness testing of ceramics in ISO DIS 15732. Source: Ref 22

Fig. 8 Test configurations for ISO DIS 15732. For three-point bend (flexure), S_1 can be 16 or 30 mm (0.63 or 1.18 in.). For four-point bend (flexure), S_1 can be 30 mm (1.18 in.) with S_2 at 10 mm (0.39 in.), or S_1 can be 40 mm (1.57 in.) with S_2 at 20 mm (0.79 in.). Source: Ref 22

Notable additions to ISO DIS15732 not contained in either the ASTM or the JIS standards are sections on determining precrack length and stable crack growth using compliance changes and fractography. Additional sections deal with permissible range of stable crack growth ($\leq 2\%$ of the average precrack length) and permissible relative compliance change ($\leq 10\%$ of the ratio of precrack length to test specimen height). Requirements for the precrack include the following:

- Length variation and inclination of the precrack front must be (similar to JIS R1607) $(a_{\max} - a_{\min})/2 < 0.1$, where a_{\max} and a_{\min} are the maximum and minimum precrack lengths, respectively.
- The inclination of the propagation direction on the bottom surface and both sides of the specimen is $\leq 5^\circ$ for the three-point flexure geometries and $\leq 10^\circ$ for the four-point flexure geometries (mixture of JIS R1607 and ASTM C1421).
- The precrack length is between $0.35W$ and $0.60W$, where W is the test specimen height (similar to ASTM C1421).

Notes are provided regarding R -curve effects (the measured fracture toughness may be “artificially high” if stable crack growth occurs after pop-in of the precrack) and slow crack growth effects (the measured fracture toughness may be reduced because of environmentally assisted crack propagation).

The fracture toughness by the SEPB method is calculated using Eq 15 for the three-point flexure geometries and Eq 11 for the four-point flexure geometries. Five or more valid test results are used in calculating an average fracture toughness value.

CEN Standard for Fracture Toughness of Ceramics. Comité Européen de Normalisation (CEN) is the de facto standards-writing body for the European Union. As of 1999, a pre-Euro Norm Voluntaire (preENV) had been drafted indicating the intent to develop a seven-part fracture-toughness testing standard within CEN Technical Committee (TC) 184 on Advanced Technical Ceramics. The first part of this standard is currently in draft form and provides summaries of the six test methods contained in each of the following six sections, as well as guidance to the user as to choice and application of a particular test method (Ref 24).

A pictorial summary of the six test methods is shown in Fig. 9; a summary and comparison are provided in Tables 1 and 2, respectively. Note that with the exception of the IF method, all six methods use “bend-bar” test specimen geometries. Of the six, the SEPB method is contained in the current ASTM, JIS, and ISO standards. The CNB method is contained in the ASTM standard, as is the SCF method. The IF method is contained in the JIS standard. Two methods not yet standardized are the single-edge V-notch beam (SEVNB) and the indentation strength (IS) methods. These two methods are discussed briefly here.

Table 1 Methods for determining apparent fracture toughness using small test specimens

Method	Description	Calibrations	Uncertainties or difficulties
Single-edge precracked beam (SEPB)	A flexural test in a beam into the tensile side of which a short straight crack has been introduced	Accurate calibrations available for wide range of precrack lengths. Fracture toughness is determined at a defined crack length.	Precracking requires some skill to obtain straight-fronted cracks. Results are influenced by rising fracture-resistance behavior.
Chevron notched beam (CNB)	A flexural test in a beam into the tensile side of which a short straight crack has been introduced	Accurate calibrations	Fracture toughness is calculated at assumed crack length. Crack initiation may be difficult in some materials due to machining residual stresses. Result may be influenced by rising fracture resistance behavior.
Surface crack in flexure (SCF)	A flexural test in a beam into the tensile side of which a short straight crack has been introduced	Accurate calibrations assuming the precrack shape approximates to an ellipse after removal of surface damage region	Requires observation and measurements of precrack dimensions, which may not be clearly visible. Limited to materials in which indentation produces good-quality cracks. Result typical for small cracks
Single-edge V-notch beam (SEVNB)	A flexural test in a beam into the tensile side of which a short straight crack has been introduced	Accurate calibrations assuming sharp crack (same as SEPB)	Assumes that if the tip radius of the sharp notch is of the order of the grain size, then the notch is equivalent to a sharp crack and the SEPB calibration can be used
Indentation fracture (IF)	A flexural test in a beam into the tensile side of which a short straight crack has been introduced	Poor calibrations owing to uncertainties in stress fields developed by indentation methods of cracking. Wide variety of different calibrations available	Effective only in materials that do not chip or flake when indented. Inappropriate for tough or porous materials. Result typical for small cracks
Indentation strength (IS)	A flexural test on a beam into the tensile side of which has been placed an indentation	Poor calibrations owing to uncertainties in residual stress fields developed by indentations that are not removed	Reproducible test if well-defined cracks are developed by indentation. Result typical for small cracks, but may not be indentation-force dependent. Inappropriate for porous materials

Table 2 Comparison of fracture-toughness test methods

Criterion	Test method					
	SEPB	CNB	SCF	SEVNB ^(a)	IF	IS
Confidence in calibration ^(b)	Good	Good	Good	Good	Poor	Poor
Relative ranking of materials	Yes	Yes	Yes	Yes	Possible for similar materials	Yes
Long-crack fracture toughness	Yes	Yes	No	No	No	No
Determine <i>R</i> -curve	Yes	No	No	No ^(c)	No	No

effects						
Short-crack fracture toughness	No	No	Yes	Yes ^(d)	Yes	Yes
Fast-fracture fracture toughness	Yes	No	Yes	Yes	Yes	Yes
Controlled-crack-growth fracture toughness	Possible	Yes	No	No	No	No
Low scatter results	Possible	Possible	Yes	Yes	No	Yes
Fine-grained materials	Yes	Yes	Yes	Yes	Yes	Yes
Coarse-grained materials	Yes	Yes	Unlikely	Yes	Unlikely	Unlikely
OK if $K_{Ic} < 6$ MPa \sqrt{m}	Yes	Yes	Yes	Yes	Yes	Yes
OK if $K_{Ic} > 6$ MPa \sqrt{m}	Yes	Yes	Possible ^(e)	Yes	No	No
Sensitive to crack growth before fracture	Yes	Uses a moving crack front	Yes	Possible	Yes	Yes
Sensitive to notch/precrack geometry	Possible	Probable	Yes	Possible for fine-grained materials	Not appropriate	Not appropriate
Suitable for elevated temperature	Yes ^(f)	Yes	Yes ^(f)	Yes	No	Possible^(f)
Cost of effort to do tests	High	Medium	High	Medium	Low	Medium
Cost of facilities to do tests	Medium	Medium	High	Medium	Low	Medium

(a) Attributes given are for notch root radii of $\leq 5 \mu\text{m}$.

(b) On a fracture mechanics basis alone, the quality of the experimental result is influenced by the nature of the material.

(c) Unless used initially to grow a crack from a notch.

(d) If the notch is considered to have a short flaw at its tip, R -curve effects are avoided.

(e) Increasing likelihood of poor precrack generation with increasing fracture toughness.

(f) Upper temperature limit is crack-tip blunting, crack healing, and/or oxidation. Adapted from Ref 24

Fig. 9 Pictorial summary of test methods contained in CEN TC184 draft fracture toughness standard (Ref 24). SEPB, single-edge precracked beam; CNB, chevron notched beam; SCF, surface crack in flexure; SEVNB, single-edge V-notched beam; If, indentation fracture; IS, indentation strength

The SEVNB method is a variation of the single-edge notch beam (SENB) method, which has been a mainstay of the fracture testing community since before the introduction ASTM E 399. However, in brittle materials, the SEVNB addresses a problem that had long plagued the SENB method: how should a sharp crack at the tip or root of the saw notch be introduced? No matter how thin the diamond saw blade (even 50–100 μm thick), a blunt notch is still not an atomistically sharp crack, and, hence, without the introduction of a precrack at the notch tip (e.g., fatigue precracking or SEPB compression bridge loading), the SENB test does not meet one of the basic requirements for a fracture toughness test: a well-defined, atomistically sharp crack. When compared to sharp-crack methods, blunt-notch methods tend to “overestimate” fracture toughness with results that are often a function of notch thickness (e.g., see Ref 25 for a comparison of results for sharp-crack and blunt-notch techniques for alpha silicon carbide).

What sets the SEVNB method apart from the usual SENB method is that after the initial notch is sawed into the beam, the notch tip is “sharpened” (Ref 26, 27). In the latest rendition of the SEVNB method, a reciprocating (either manual or mechanized) conventional razor blade is used, along with various grits of diamond paste, to create the V at the tip of the saw notch (Ref 27). This V-notching technique tends to create notch root radii (or damage zone) less than those that would make the measured fracture toughness a function of the notch width or geometry. The SEVNB method produces precise and accurate results similar to sharp-crack methods (e.g.,

SEPB and SCF) without the need to precrack the test specimen (Ref 27). In addition, measurement of the notch depth at fracture allows the use of the same well-established equations, such as those used for SEPB method (e.g., Eq 11, 12, and 15) for calculating fracture toughness.

The IS method is based on the applications of Eq 1 and 4 to the flexural strength testing of flexural test specimens that have been indented (either Knoop or Vickers) with ever-increasing indentation forces. The size of the controlled indentation flaw increases with increasing indentation force. Therefore, for a material with a deterministic fracture resistance, the measured flexural strength will decrease with increasing flaw size (or increasing indentation force). The mathematics have been worked out relating fracture resistance, flexural strength, and flaw size for sharp indenters producing median cracks (Ref 3).

The actual mechanics of the conducting test involve first placing one indentation each in a series of standard flexure test specimens (each test specimen receives one indentation at one indentation force), such as those specified in ASTM C 1161 (Ref 28) at ever-increasing indentation forces using either a Knoop or Vickers indenter. A standard flexural strength test is then conducted, preferably in four-point flexure to avoid the necessity of trying to align the small indentation with the nose of the loading support in three-point flexure. For four-point flexure, the flexural strength is calculated as:

$$S_f = \frac{3P_f(S_o - S_i)}{2BW^2} \quad (\text{Eq 17})$$

where S_f is the flexural strength and P_f is the force at fracture (typically maximum force for a brittle material). The fracture toughness using the indentation strength method for the particular test can then be calculated using the relation (Ref 29):

$$K_{\text{IIS}} = 0.59 \left(\frac{E}{H_v} \right)^{1/8} (S_f P^{1/3})^{3/4} \quad (\text{Eq 18})$$

where P is the indentation force.

Obvious advantages of the IS method are that it involves readily available flexure test specimens and test standards for both flexure strength and indentations. In addition, the IS method does not require a subjective measure of crack size (from the viewpoint of the fracture-mechanics community, this is also an obvious weakness) (Ref 2). Another weakness is that hardness and elastic modulus need to be measured separately. A final point is that the constant 0.59 in Eq 18 as determined from logarithmic regression analysis (Ref 2) has an estimated standard deviation of 0.12 (a somewhat large source of variability for a “constant”). While the IS method is attractively simple, relative measurements on a given material “are typically reliable to much better than 20%” (Ref 3), making the results of limited value compared to some of the other methods discussed up to this point.

Other Test Methods for Fracture Toughness at Ambient Temperature

Many other successful methods for determining fracture toughness of brittle materials (not yet standardized) have been introduced and refined over the past several years. Some of the more popular methods are discussed in the following sections. Note that these discussions are limited to sharp-crack methods because of the limitation of methods using blunt notches.

The double torsion (DT) method was once seen as a strong contender for a standard test method (Ref 4, 7, 8, 9, and 10). This method (Fig. 10) allows the use of a variety of basic specimen shapes and test geometries, although the most common is a long, thin plate with a side groove cut along its length to guide and crack (although there is evidence that with good alignment, better results are obtained without the groove (Ref 31). Ball-bearing supports tend to minimize friction and help alignment. Various analyses have shown that the applied stress intensity factor is independent of crack length over the dimensionless crack length range of 0.55 to 0.65 a/W (Ref 4). One formulation for stress intensity factor for determining fracture toughness using the DT method is (Ref 30):

$$K_{\text{Idt}} = PW_m \sqrt{\frac{3}{Wd^3 d_n(1-\nu)\xi}} \quad (\text{Eq 19})$$

where W_m is half the test specimen width minus half the notch width, d is the total thickness, d_n is the notch depth, and ξ is a correction factor for thick test specimens such that $\xi = 1 - 0.6302t + 1.20t \exp(-\pi/\tau)$ where $t =$

$2d/W$ and W is the total width of the test specimen. Although the three-dimensionality of the crack front in the DT test specimen has led to some controversy about whether Eq 19 really represents a mode I stress intensity factor, evidence exists that $K_{I_{dt}}$ for various brittle materials compares well to other sharp-crack mode I methods (Ref 25, 30). Obvious advantages of the DT method include the simple loading configuration, its constant stress intensity factor geometry, simple test specimen geometry, and stable crack propagation configuration. Some disadvantages include the relatively large volume of test material (compared to a simple flexure bar) required for a single test, the more complicated arrangement of ball bearings and other components for supports, the curved crack front, and concerns about the three-dimensionality of the crack tip.

Fig. 10 Schematic illustration and nomenclature for double torsion (DT) fracture-toughness test methods. Source: Ref 30

The double cantilever beam (DCB) test method has been part of fracture mechanics in various forms since the inception of the discipline. Indeed, variations of the DCB method even appear in ASTM E 399 for fracture toughness testing of metals. A unique aspect of the DCB test method applied to brittle materials is the method of load application that can have a variety of forms, as shown in Fig. 11. The applied-load method can be particularly troublesome in brittle materials that are susceptible to tensile forces. However, the compressively loaded wedge-loading method and the compressively loaded applied-moment method are suited to testing brittle materials. Often side grooves are used to guide the crack longitudinally. For the applied-load geometry, the stress intensity factor and subsequent fracture toughness have been formulated as (Ref 4):

$$K_{I_{dcb}} = 3.45 \frac{Pa}{bh^{3/2}} \left[1 + 0.7 \left(\frac{h}{a} \right) \right] \quad (\text{Eq 20})$$

where h is half height of the test specimen, b is thickness of the test specimen, and a is the crack length. Some advantages of this geometry are that for some cases the stress intensity factor is independent of crack length (e.g., tapered DCB or applied moment DCB), test specimen preparation can be simple, material usage is efficient, and the loading configuration can be simple. The primary disadvantage is that a sharp crack needs to be introduced to avoid problems of initiation and propagation of a crack from the blunt notch.

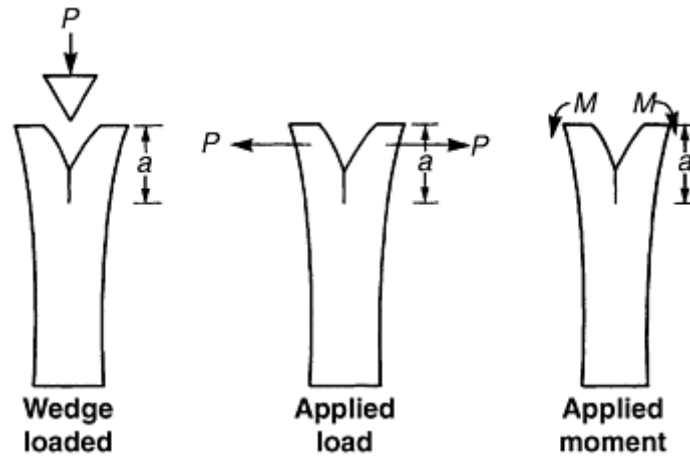

Fig. 11 Double cantilever beam (DCB) fracture test methods

Chevron notched short-rod and short-bar (CNSR and CNSB) test methods (Fig. 12) have many of the advantages of the CNB test method: simple notch preparation, in situ (automatic) crack initiation at the tip of the chevron, and inherent stable crack propagation in the chevron. However, an additional advantage of the CNSR and CNSB geometries is the efficient use of material because the volume of material needed to support a flexural test specimen is avoided. For the CNSB geometry, a suggested formulation for the stress intensity factor and subsequent fracture toughness can be determined as (Ref 4, 32):

$$K_{Icnsb} = \frac{P}{B\sqrt{W}} Y_{min}^* \quad (\text{Eq 21})$$

where P is the applied force, W is length of the test specimen, B is thickness of the test specimen, and Y_{min}^* is the minimum geometry correction factor for the chevron notch geometry. A disadvantage of the CNSR and CNSB test method is the tensile loading required for the fracture test, as shown in Fig. 12.

Fig. 12 Examples of chevron notched short bar (CNSB) and chevron notched short rod (CNSR) test specimens. Source: Ref 4, 32

Fractographic methods (Ref 33, 34) applied to strength tests of intrinsically flawed test specimens involve interpretation of fracture features, quantification of the type and size of the strength-limiting flaws, determination of the applied stress at the flaw suite, and, finally, the calculation of the fracture toughness of the material. It is important to realize that it is usually difficult to directly measure flaws initiating at fracture sites (Ref 35 contains information on fractographic aspects of brittle materials). However, as a consequence of the rapid crack propagation during brittle fracture, the fractured region around flaws often exhibits distinct regions (Fig. 13): flaw origin, fracture mirror (smooth region surrounding the origin), mirror (radial ridges surround the mirror), and hackle (rough ridges surrounding the mirror). Crack branching can exist outside the hackle region as well. A quantitative relationship exists between the stress at the fracture and the distance from the flaw to each of the boundaries of this fracture region such that (Ref 33):

$$\sigma r_j^{1/2} = A_j \quad (\text{Eq 22})$$

where σ is the stress at fracture, r_j is the distance to a particular boundary, and A_j is the corresponding mirror constant such that

$$A_j = \frac{\sqrt{a_{cr} b_{cr}}}{r_j} \quad (\text{Eq 23})$$

where a_{cr} is the failure-initiating flaw depth, b_{cr} is its half depth, and r_j is the relation of fracture mechanics to fractography is given as (Ref 32):

$$K_{If} = \frac{\sqrt{1.2 \pi} \left(\frac{c}{r_j} \right)^{1/2}}{\phi} A_j \quad (\text{Eq 24})$$

where K_{If} is the fracture toughness determined from fractography, $c = \sqrt{a_{cr} b_{cr}}$, as illustrated in Fig. 14, and ϕ is an elliptical integral of the second kind that accounts for degree of ellipticity of the flaw.

Fig. 13 Nomenclature for fracture features. (a) Surface flaws. (b) Volume flaws. Source: Ref 4, 34

Fig. 14 Schematic of fracture surface of brittle materials showing the idealized preexisting flaw of depth a_i and half-width b_i and the failure-initiating critical flaw of depth a_{cr} and half-width b_{cr} . For rapid loading, a_i and b_i should be nearly coincident with a_{cr} and b_{cr} . The fracture-mirror radii boundaries are also shown in the figure: r_i , mirror-mist; r_o , mist-hackle; and r_{cb} , macroscopic crack branching. For some conditions, r_o and r_{cb} cannot be distinguished. σ is the fracture stress. Source: Ref 33

Evaluation of Fracture-Toughness Test Results

Although many examples exist in the literature of small batches of fracture toughness results for fracture resistance testing using a wide variety of methods applied to brittle solids, it is only recently that results are beginning to appear combining statistically significant sample sets of results for well-documented materials fracture tested using accepted and/or approved standardized test methods. For example, ASTM C 1421 (Ref 18) contains a precision and bias section that compares extensive results from various sources (including two round-robin programs sanctioned by the Versailles Advanced Materials and Standards, or VAMAS, organization) (Ref 36, 37) obtained using the test methods SEPB, SCF, and CNB detailed in ASTM C 1421 (although not necessarily the exact procedures). Two materials are highlighted: a sintered silicon carbide [Hexoloy SA, Carborundum (now Ste. Gobain), Niagara Falls, New York] and a hot-pressed silicon nitride [NC132, Norton Co. (now Ste. Gobain), Worcester, Massachusetts]. Each of these materials has a “flat” R -curve and displays little environmental susceptibility at room temperature. The results, graphically illustrated in Fig. 15 and 16, generally show the consistency of the fracture toughness measurements for two brittle materials regardless of sharp-crack technique.

Fig. 15 Comparison of fracture-toughness test results from multiple sources for Hexoloy SA (sintered alpha silicon carbide) using three test methods described in ASTM C 1421. Each bar represents the mean plus or minus one standard deviation. SEPB, single-edge precracked beam; SCF, surface crack in flexure; CNB, chevron notched beam. Adapted from Ref 18

Fig. 16 Comparison of fracture-toughness test results from multiple sources for NC 132 (hot-pressed beta silicon nitride) using three test methods described in ASTM C 1421. Each bar represents the mean plus or minus one standard deviation. SEPB, single-edge precracked beam; SCF, surface crack in flexure; CNB, chevron notched beam. Adapted from Ref 18

A noteworthy use of ASTM C 1421 is to evaluate multiple billets of a standard reference material (SRM 2100, National Institute Standards and Technology, Gaithersburg, Maryland, 1999) known as SRM2100, the same hot-pressed silicon nitride as used in the VAMAS round robin and as shown in Fig. 16. For example, for billet C of the SRM at room temperature, the results were:

Method	Fracture toughness,	No. of valid tests
--------	---------------------	--------------------

	$\text{MPa}\sqrt{m}$	
SCF	$K_{\text{Isc}} = 4.58 \pm 0.16^{(a)}$	26
CNB	$K_{\text{Ivb}} = 4.60 \pm 0.13^{(a)}$	26
SEPB	$K_{\text{Ipb}} = 4.58 \pm 0.10^{(a)}$	19

(a) Mean \pm one standard deviation

This remarkable consistency of fracture toughness results for a single material confirms that the sharp-crack methods contained within ASTM C 1421 have been “optimized” (Ref 9) such that genuine material variability (e.g., billet-to-billet or batch-to-batch) can be discerned and quantified.

R-Curve Behavior at Ambient Temperature

R -curve behavior (i.e., increasing fracture resistance with crack extension, Fig. 3) for brittle materials, as discussed briefly in the introduction, is often a result of interactions of the crack and microstructure. For example, fracture process mechanisms as shown in Fig. 4 can be roughly divided into frontal and wake mechanisms. But why measure *R*-curve behavior in brittle materials? The need to measure *R*-curve behavior can include establishing the unequivocal starting point of the *R*-curve (i.e., intrinsic fracture resistance), R_0 , or it can include determining the final steady-state fracture resistance, R_∞ , or it may include defining the behavior between the extremes of the intrinsic and steady-state fracture resistance, $R(c)$ which may also be a function of crack shape, test specimen geometry, and testing parameters.

In metals, frontal mechanisms—specifically, plastic deformations in a region ahead of and near the crack tip—are responsible for crack closure effects (Ref 38). For engineering analysis, elastic-plastic fracture-mechanics concepts are usually applied, typically using K with a crack-size plasticity adjustment or the J -integral. It is important to realize that *R*-curves are not material properties (unlike fracture toughness), but are instead related to the testing conditions, including test rate and test specimen geometry (e.g., material thickness). Recently, ASTM E 1820 “Standard Test Method for Measurement of Fracture Toughness” (Ref 16) was introduced as a “unified” test method for fracture testing metals at room temperature. The test procedures of five other test methods are contained in ASTM E 1820 to allow extraction of fracture resistance in terms of K , J , and crack-tip opening displacement (CTOD) from a single test at room temperature. Three test specimens (similar to those used in ASTM E 399) are described: SENB, compact tension (CT), and a disk-shaped compact tension (DSCT). All require precracking, usually with cyclic loading, to promote fatigue crack initiation and propagation. Test conditions and procedures are specific to the fracture parameter being measured. However, a compliance method is described to establish in situ crack length during stable crack propagation.

ASTM E 1820 (Ref 16) was developed, and is appropriate, for measuring plane strain fracture toughness in ductile metals but does not necessarily address the unique aspects of brittle solids. In addition, test specimens are rather large, as are the notches, cracks, and precracks, presumably for ease of implementation as well as to minimize the influence of dimensional variations on the repeatability and reproducibility of the fracture resistance measurement.

Since the introduction of ASTM E 1820, standards-writing bodies worldwide have done little to introduce standard *R*-curve test methods for brittle solids, particularly for advanced ceramics. Several possible explanations exist for this:

- No single method for establishing *R*-curve behavior in brittle materials has stood out.
- No methodology has been established on how to use the measured *R*-curve behavior of brittle materials (in engineering or materials design).
- It is not clear if current fracture toughness techniques really can establish the starting point of *R*-curve behavior.
- *R*-curve behavior is not a material property because it is dependent on factors such as test specimen geometry, crack history, test mode, and rate.

However, although no standardized test methods exist for *R*-curve behavior in brittle materials, many unique and novel test methods have been reported. Often these methods focus on quantifying specific mechanisms giving rise to *R*-curve behavior rather than measuring the *R*-curve itself. The following sections, while not

intended to be an exhaustive listing of reported methods, discuss general aspects of these test methods for extrinsic flaws (macrocracks) and intrinsic flaws (microcracks) in test specimens.

Test Methods for *R*-Curve at Ambient Temperature. Regardless of the organization (ASTM, ISO, CEN, or JISC), no standardized test method for *R*-curve behavior of brittle materials has been proposed or approved. In the future, if the need for such standards are established, it will be useful to build on existing standards for fracture toughness testing of brittle materials such as ASTM did in developing E 1820.

Direct adaptation of *R*-curve test methods for metals is one approach that has been successfully used in determining the *R*-curve behavior in brittle materials. As shown in Fig. 17, an SENB test specimen in three-point flexure was used to test Westerly granite (Ref 39). Single fatigue cracks were introduced at the root of the notch by cyclic “loading” at 2.2 Hz under crack-mouth displacement (CMD) control mode with an initial force up to 90% of the breaking force. Both compliance and dye penetration methods were used to determine crack length during the stable crack-extension part of the fracture test. Apparent fracture toughness (K_R) and the *J*-integral (J_R) as functions of crack length were established.

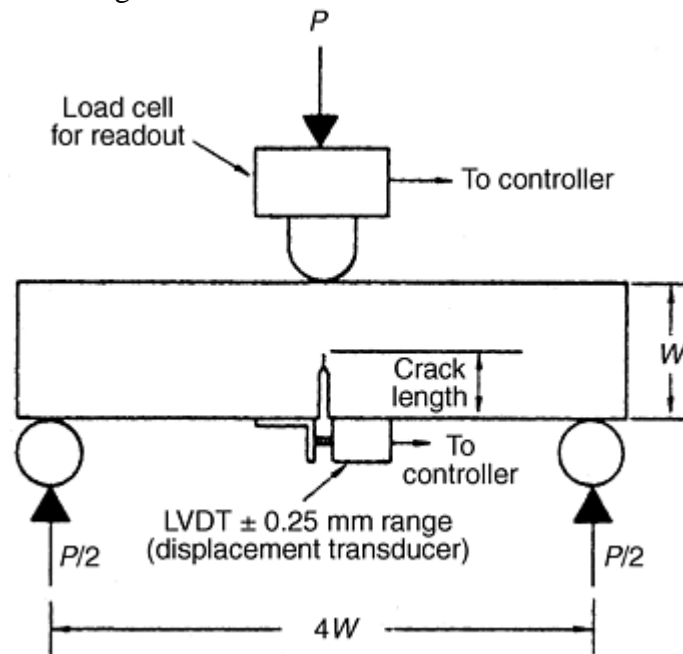

Fig. 17 Single-edge notch beam (SENB) fracture test specimen of Westerly granite used to determine *R*-curve behavior. LVDT, linear variable differential transformer. Source: Ref 39

Using SENB test specimens, but with a slightly different approach for stable crack propagation, the *R*-curve behavior of aluminum oxide ceramics was measured (Ref 40). Although no precrack was initiated at the tip of the notch root, it was reported that the three-point flexure test system was sufficiently stiff to allow stable crack propagation. Different initial notch depths led to the determination of a notch-depth independent intrinsic fracture resistance, while a notch-depth dependent fracture resistance as a function of crack length, $R(c)$, was determined. Both shape and magnitude of the *R*-curve were dependent on test parameters (i.e., test mode, test rate, and test specimen geometry).

A variation of the SENB was used to determine the grain-bridging contributions during *R*-curve testing of aluminum oxide and magnesium aluminate spinel (Ref 41, 42). A “back-notched” SENB test specimen (Fig. 18) was tested in four-point flexure. An aluminum oxide wedge was inserted into the back notch for load support throughout the fracture test. The fracture test was conducted until complete propagation of the crack across the unnotched section of the test specimen. The cracked (but not separated) SENB test specimens were then longitudinally tested in tension to determine the tensile stress-strain response of the fracture process zone. The *R*-curve was inferred from the postfracture tensile test results (Ref 42).

Fig. 18 Single-edge notch beam (SENB) fracture test specimen with back notch and wedge used to determine R -curve parameters from postfracture tensile tests. Source: Ref 41

A further study of R -curve effects in aluminum oxide was carried out using CNSB test specimens (Ref 43) (Fig. 12). The inherently stable crack propagation in the chevron notch geometry was used to incrementally extend the crack before unloading slightly to determine the compliance for calculating the instantaneous crack length. R -curves were plotted as stress intensity factor versus crack extension. A bearing steel was also evaluated using this technique (Ref 44).

R -curves for two brittle materials were determined (Ref 45) using one of the test specimen geometries (CNB) contained in the ASTM standardized fracture toughness method for brittle materials (ASTM C 1421). In this study, three-point flexure was used with square-cross section test specimens (Fig. 19). The tests were conducted monotonically, and the instantaneous compliance (not unloading compliance) was used to determine the instantaneous crack length. Crack mouth opening displacement (CMOD) was measured using a laser interferometric displacement gage.

Fig. 19 Chevron notched beam (CNB) test specimen in three-point flexure for R -curve effects. Four normalized depth ratios (α_0) were included. Source: Ref 45

R -curve evaluation also was performed using the IS method (Ref 46). When the IS method is used to evaluate fracture strength/resistance in Eq 17 and 18, fracture toughness is related to the indentation force as well as the hardness and elastic modulus of the material. This fracture toughness is calculated for each strength test of the indented flexure test specimens (in these cases, the relationship between the flexural strength, S_f , and the indentation force, P , was assumed to be the theoretical: $S_f \propto P^{-1/3}$). However, for determining R -curve behavior and when all the data are fitted [i.e., $S_f = f(P)$], the exponent on P will only be $-\frac{1}{3}$ for materials with flat R -curves. Furthermore, if the R -curve is described as a power-law function of crack length, the result is (Ref 46):

$$K_{IR} = k(\Delta a)^\tau \quad (\text{Eq 25})$$

where k and τ are constants and Δa is the crack extension, then $\tau = 0$ if the R -curve is flat.

If the R -curve is not flat, then the relationship between flexural strength and indentation force is:

$$S_f \propto \alpha P^{-\beta} \quad (\text{Eq 26})$$

where the exponents β can be defined as $\tau = (1 - 3\beta)/(2 + 2\beta)$, and the coefficient α is defined as $K = Y\alpha(\beta\gamma)^{-\beta}(1 + \beta)^{(1 + \beta)}$ where Y and γ are related to the indentation crack geometry. Note that limiting values on τ are 0 for flat R -curve materials and 0.5 for the steepest rising R -curve material that still fractures catastrophically. This technique is illustrated in Fig. 20 where the assumption of flat R -curve ($\beta = -\frac{1}{3}$) obviously does not work. Note

that annealing to relieve the residual stress (*A* and *B* in Fig. 20) caused by the deformation of the indenter can significantly affect the fracture results.

Fig. 20 Indentation strength (IS) fracture test method for *R*-curve behavior where observed flexural strength is a function of indentation force in a series of two experiments. Specimens for *A* included residual stress of indentation; specimens for *B* had the residual stress annealed out at elevated temperature. Source: Ref 46

For design purposes, the utility of this IS fracture test method is not in fracture mechanics-related analyses. Rather, its greater utility is its application to strength-rated analyses. If the strength distribution is described as Weibull (weakest link), then the Weibull shape parameter, m (i.e., Weibull modulus), can be related to the degree of the *R*-curve by (Ref 47):

$$m = \frac{m_o}{(1 - 2\tau)} \quad (\text{Eq 27})$$

where m_o is the Weibull modulus for $\tau = 0$. Equation 27 holds for a range of flaw sizes related to the indentations of the IS method. Equation 27 also shows that as the slope of the *R*-curve increases, so does the Weibull modulus, thus decreasing the scatter in the strength distribution. Note that m can potentially be equal to ∞ for a deterministic strength (i.e., $\tau \rightarrow \frac{1}{2}$).

Examples of *R*-Curve Test Data. Various types and levels of *R*-curves exist for brittle materials. For example, an *R*-curve for Westerly granite is shown in Fig. 21. Note in this case that the *J*-integral is plotted as a function of crack extension. Extrapolation of the *R*-curves to zero crack extension results in determination of J_{Ic} , which, when related to K_{Ic} , gives an agreement within 4% of K_{Ic} determined directly (Ref 39).

Fig. 21 *J*-integral *R*-curve determined from single-edge notch beam (SENB) fracture test specimens of Westerly granite. Source: Ref 39

R -curves in terms of an energy parameter (K_I^2 / E) are plotted in Fig. 22 for an aluminum oxide. Note that both the slopes and the shapes of the R-curves vary with notch depth, although the initial values of the R-curves appear to be independent of notch depth (Ref 40).

Fig. 22 R-curves as a function of crack depth for aluminum oxide. Source: Ref 40

R -curves determined from CNSB test specimens and in terms of stress intensity factors are shown in Fig. 23. Also shown in Fig. 23 is an R-curve determined from the IS method for the same material. Note that the R-curves are dependent on geometry, test method, and type of crack (intrinsic versus extrinsic) (Ref 44), although they do band the same K_I range.

Fig. 23 Comparison of R-curves for aluminum oxide determined from the chevron notched short bar (CNSB) and indentation strength (IS) methods. Source: Ref 44

With the proper testing configuration, even flat R-curves can be measured using the CNB test specimen, as shown in Fig. 24 (Ref 45). These R-curves are not only flat, but the fracture toughness for one of the materials (silicon carbide) is only in the range of $3 \text{ MPa}\sqrt{m}$.

Fracture Toughness and *R*-Curve Testing at Elevated Temperature

Decreasing mechanical properties and performance with increasing temperature are consistently observed for most materials. Complications of tests at elevated temperature include temperature control, environmental effects (both material and test apparatuses), and time-dependent behavior (e.g., creep or oxidation).

In fracture testing, a particularly troubling complication is the effect of material and/or environmental interactions on the crack-tip conditions. A good example of this is crack-tip blunting, which may more easily occur after the trouble of introducing an atomistically sharp precrack in fracture testing specimens.

At this time, no standardized test methods exist for fracture testing at elevated temperature (for metals or nonmetals). As the need increases for such standards, they will no doubt be introduced, not without much controversy and complication.

Test Methods for Fracture Toughness at Elevated Temperature

At this time there are no specific elevated-temperature standards for fracture toughness testing. Apparently, it is assumed that ambient temperature standards will be implemented with due care taken to ensure proper use at elevated temperatures. In most cases, this is a reasonable approach. However, complications that have been noted are crack healing and blunting in those methods that rely on precracking prior to fracture testing.

An early report of this “flaw healing” in SCF tests showed that fracture strength of indented flexure bars made of a silicon carbide increased by a factor of three after annealing in air. This implies that the increase in strength is due to the reduction in the effect of the SCF precrack on the susceptibility to fracture. Annealing in a vacuum caused a similar, but somewhat reduced, effect (Ref 48).

Special caution is advised in extending methods that start with a sharp crack introduced at ambient temperature. These methods include SEPB, SCF, IS, and precracked methods such as SENB and DCB. Methods that form cracks in situ will probably not experience the “flaw healing” phenomenon. These methods include all the chevron notched test specimens (CNB, CNSB, CNSR), SEVNB, and DT. Given the difficulties of properly performing and analyzing the IF method at ambient temperature, it appears doubtful that it could be successful at elevated temperatures.

Examples of Elevated-Temperature Fracture Toughness Test Data

“Flaw healing” can be a particular problem at elevated temperatures for precracked fracture test methods. However, even methods such as the CNB may exhibit difficulties in initiating and propagating cracks under certain conditions (e.g., very high temperatures). An in situ toughened silicon nitride (SN251, Kyocera Corporation, Kyoto, Japan 1990 vintage) was fracture tested using CNB, SEPB, and fine notched (50 μm thickness) SENB (Ref 44). The load-displacement curves for the CNB tests are shown in Fig. 25. The stable curves at 25 and 1200 °C (77 and 2200 °F) provide valid test results according to ASTM C 1421. However, the highly nonlinear behavior at 1371 °C (2500 °F), although stable and valid according to the standard, was ruled an invalid test because a crack initiated and grew only part way before stopping at the tip of the chevron. Instead, the highly nonlinear behavior shown in Fig. 25 was attributed to “plastic hinging” (Ref 44).

Fig. 25 Load displacement curves for stable fracture in chevron notched beam (CNB) fracture tests of an in situ toughened silicon nitride. The test at 1370 °C is an invalid test because a crack never initiated at the tip of the chevron, and plastic hinging occurred. Source: Ref 44

Comparison of fracture toughness results from CNB, SEPB, and sharp notch SENB are presented in Fig. 26. Note that under the proper conditions at 1371 °C (2500 °F) (fast heat up and short hold times), the SEPB method, despite the sharp precrack, gives results similar to the sharp notch SENB method. The CNB method at 1371 °C (2500 °F) under these test conditions tends to overestimate fracture toughness as expected from the nonlinear loading curve shown in Fig. 25.

Fig. 26 Comparison of fracture toughness for in situ toughened silicon nitride (SN251) as functions of temperature for chevron notched beam (CNB), single-edge precracked beam (SEPB), and single-edge V-notch beam (SEVNB) fracture test methods

In a demonstration of the diversity of application of the CNB method, fracture toughness for seven advanced ceramics (from aluminum oxide to silicon carbide to silicon nitride) and eight temperatures (from 20–1400 °C or 68–2600 °F) in ambient air are plotted with error bars in Fig. 27. With the exception of the nonlinear behavior of the in situ toughened silicon nitride, all results are predictable and consistent (Ref 49).

Fig. 27 Fracture toughness results as functions for temperature for seven advanced ceramic materials. Source: Ref 49

R-Curve Testing at Elevated Temperature

Temperature-dependent mechanical properties and performance are consistently observed for most materials. At elevated temperatures complications of fracture testing include temperature control, environmental effects (both material and test apparatuses), and time-dependent behavior.

In *R*-curve fracture testing, the complication of materials and/or environmental interactions on the crack-tip conditions is of concern. For example, crack-tip blunting can occur after an atomistically sharp precrack is introduced in fracture test specimens. Even methods that are successful at in situ crack initiation can exhibit problems with “flaw healing” as the crack propagates through the material during *R*-curve testing.

At this time, no dominant test methods exist for *R*-curve testing at elevated temperature (for metals or nonmetals). If the need develops for such test methods, they will no doubt be introduced, but not without much controversy and complication.

Test Methods for *R*-Curve Testing at Elevated Temperature. Currently, there are no specific elevated temperature standards for *R*-curve testing. Apparently, it is assumed that ambient temperature standards will be implemented with due care taken to ensure proper use at elevated temperatures. In most cases, this is a reasonable approach. However, complications that have been noted are crack healing and blunting in those methods that rely on precracking prior to fracture testing.

One successful method promoted as characterizing the complete fracture history (crack initiation to stable crack propagation to final fracture) of a brittle material in a single test used to CNB test specimen (Ref 49). This method used a monotonic load history combined with a laser-based apparatus to measure CMOD, and it used a compliance method to determine crack length, fracture toughness, *R*-curve, and work of fracture for a range of monolithic and composite advanced ceramics.

Special caution is advised in extending methods that start with a sharp crack introduced at ambient temperature. These methods include SEPB, SCF, IS, and precracked methods such as SENB and DCB. Methods that form cracks in situ will probably not experience the “flaw healing” phenomenon. These methods include other chevron notched test specimens (CNB, CNSB, CNSR), SEVNB, and DT. Given the difficulties of properly

performing and analyzing the IF method at ambient temperature, it appears doubtful that it could be successful at elevated temperatures.

Examples of Elevated-Temperature *R*-Curve Test Data. The use of the CNB method to characterize the complete fracture history of a single test specimen (Ref 45) is an excellent demonstration of the information available to characterize fracture behavior of brittle materials. For example, flat *R*-curves for three materials are shown at two temperatures (20 and 1200 °C, or 68 and 2200 °F) in Fig. 28(a). Nonlinear *R*-curves are shown for four materials in Fig. 28(b). Keep in mind that it has been shown that *R*-curves are not material properties and are highly dependent on test conditions, including test specimen geometry. Thus, the *R*-curves shown in Fig. 28 indicate material response and “toughening mechanisms” in the presence of cracks. However, the information is of questionable use for design purposes.

Fracture Resistance Testing of Brittle Solids

Michael Jenkins, University of Washington; Johnathan Salem, NASA-Glenn Research Center

Summary

The fracture of theoretical brittle solids, while conceptually (and mathematically) rather simple and straightforward, is far from simple in practice. “Real” materials often contain residual stresses, microstructures, and geometric features that can complicate test methods intended to extract what appears to be a fundamental material property: fracture resistance in the form of fracture toughness. Further complicating test methods are differences in fracture behavior because of the type of flaw: intrinsic flaws (i.e., microcracks) often provide information on intrinsic fracture resistance behavior; that is, fundamental behavior without influence of microstructure or history of crack propagation (i.e., *R*-curve) fracture resistance. In contrast, extrinsic flaws (i.e., induced cracks) can be used to measure either the intrinsic or the steady-state fracture resistance, but can also lead to apparently large scatter (actually, differences) in the results if the influence of the microstructure and history of crack propagation are not accounted for.

Standardized test methods for fracture of brittle solids (specifically, advanced ceramics) developed to date (e.g., ASTM C 1421, JIS R1607, and ISO DIS15732) have concentrated on maximizing repeatability and reproducibility of the fracture resistance measurements at the onset of brittle fracture. Minimizing the effects of *R*-curve behavior, environmentally assisted crack growth and variability in testing are primary concerns.

Although *R*-curve behavior is recognized as having a strong influence on the fracture behavior of polycrystalline brittle solids, no standardization activities are currently underway to develop standard test methods. Several reasons may be responsible for this lack of activity:

- Research in this area is still quite active and no dominant methods have emerged.
- It is not clear how to deal with the issue of intrinsic fracture resistance versus steady-state fracture resistance and how this relates to the design methodologies that include probabilistic methods and statistical strength distributions.
- *R*-curve behavior is not a material property because it is dependent on component (i.e., test specimen) geometry, crack shape, crack propagation history, stress levels, and test parameters.

At elevated temperature, methods that involve the creation of sharp precracks at room temperature may become unusable at certain elevated temperatures as crack healing and crack-tip blunting negate the effects of precracks. Methods that use either in situ crack formation or very sharp notches seem to provide better ways to measure either fracture toughness or *R*-curve behavior at elevated temperatures.

For brittle solids, it is clear that the driver behind methods to determine fracture resistance is not necessarily for its use in determining the resistance of the material or design to extrinsic flaws. Instead, the need is to accurately and precisely determine the fracture resistance of brittle solids for use in relative comparison indices for evaluation of material performance in fracture-resistance related (but not fracture-resistance driven) applications.

Fatigue and Fracture Mechanics

Introduction

FATIGUE is the progressive, localized, and permanent structural damage that occurs when a material is subjected to cyclic or fluctuating strains at nominal stresses that have maximum values less than (and often much less than) the static yield strength of the material (Ref 1). This process of fatigue failure can be divided into different stages, which, from the standpoint of metallurgical processes, can be divided into five stages (Ref 1):

1. Cyclic plastic deformation prior to fatigue crack initiation
2. Initiation of one or more microcracks
3. Propagation or coalescence of microcracks to form one or more microcracks
4. Propagation of one or more macrocracks
5. Final failure

This division is defined by the characterization of the underlying fatigue damage of a material. It also clearly defines the requirement of plastic deformation for the onset of crack initiation. In general, three simultaneous conditions are required for the occurrence of fatigue damage: cyclic stress, tensile stress, and plastic strain. If any one of these three conditions is not present, a fatigue crack will not initiate and propagate. The plastic strain resulting from cyclic stress initiates the crack; and the tensile stress (which may be localized tensile stresses caused by compressive loads) promotes crack propagation (Ref 1).

The stages of fatigue can also be defined in more general terms from the perspective of mechanical behavior of crack growth. For example, another division of the fatigue process is defined as follows (Ref 2):

- Nucleation (initiation of fatigue cracks)
- Structurally dependent crack growth rates (often called the “short crack” or “small crack” phase)
- Crack growth rates that can be characterized by either linear elastic fracture mechanics, elastic-plastic fracture mechanics, or fully plastic fracture mechanics
- Final instability

This definition of the stages in the fatigue process is roughly equivalent to the first, except that crack propagation is expressed in terms of crack growth rates, and nucleation is meant to include all processes leading up to crack initiation.

In general, the fatigue process consists of a crack initiation and a crack propagation phase. There is, however, no general agreement when (or at what crack size) the crack initiation process ends, and when the crack growth process begins (Ref 3). Nonetheless, the separation of the fatigue process into initiation and propagation phases has been an important and useful advance in engineering.

Another important engineering advance is the transfer of the multistage fatigue process from the field to the laboratory. In order to study, explain, and qualify component designs, or to conduct failure analyses, a key engineering step is often the simulation of the problem in the laboratory. Any simulation is, of course, a compromise of what is practical to quantify, but the study of the multistage fatigue process has been greatly advanced by the combined methods of strain-control testing and the development fracture mechanics of fatigue crack growth rates. This combined approach (Fig. 1) is a key advance that allows better understanding and simulation of both crack nucleation in regions of localized strain and the subsequent crack growth mechanisms outside the plastic zone. This integration of fatigue and fracture mechanics has had important implications in many industrial applications for mechanical and materials engineering.

Fig. 1 Laboratory simulation of the multistage fatigue process. Source: Ref 2

This introductory article briefly reviews the three basic types of fatigue properties, which are:

- Stress-life ($S-N$)
- Strain life ($\epsilon-N$)
- Fracture mechanic crack growth ($da/dN-\Delta K$)

These three types of fatigue properties each play a role in engineering, and each property is used in the context of an underlying fatigue design philosophy as follows:

Design philosophy	Design methodology	Principal testing data description
Safe-life, infinite-life	Stress-life	$S-N$
Safe-life, finite-life	Strain-life	$\epsilon-N$
Damage tolerant	Fracture mechanics	$da/dN-\Delta K$

The $S-N$ and $\epsilon-N$ techniques are usually appropriate for situations where a component or structure can be considered a continuum (i.e., those meeting the “no cracks” assumption). In the event of a crack-like discontinuity, the $S-N$ or $\epsilon-N$ methods (except through residual life testing) offer little or quantitative basis for assessment of fatigue life.

Another limitation of the $S-N$ and $\epsilon-N$ methods is the inability of the controlling quantities to make sense of the presence of a crack. A brief review of basic elasticity calculations shows that both stress and strain become astronomical at a discontinuity such as a crack, far exceeding any recognized property levels that might offer some sort of limitation. Even invoking plasticity still leaves inordinately large numbers or, conversely, extremely low tolerable loads.

The solution to this situation is the characterization and quantification of the stress field at the crack tip in terms of stress intensity in linear elastic fracture mechanics. It recognizes the singularity of stress at the tip and provides a tractable controlling quantity and measurable material property. The use of the stress intensity as a controlling quantity for crack extension under cyclic loading thus enhances the engineering analysis of the fatigue process.

More detailed information on fatigue and fracture mechanics can be found in *Fatigue and Fracture*, Volume 19 of *ASM Handbook*.

Fatigue and Fracture Mechanics

Infinite-Life Criterion (S - N Curves) (Ref 4)

The safe-life, infinite-life philosophy is the oldest of the approaches to fatigue. Examples of attempts to understand fatigue by means of properties, determinations, and representations that relate to this method include August Wöhler's work on railroad axles in Germany in the mid-1800s. The design method is stress-life, and a general property representation would be S - N (stress versus log number of cycles to failure). Failure in S - N testing is typically defined by total separation of the sample.

General applicability of the stress-life method is restricted to circumstances where continuum, “no cracks” assumptions can be applied. However, some design guidelines for weldments (which inherently contain discontinuities) offer what amount to residual life and runout determinations for a variety of process and joint types that generally follow the safe-life, infinite-life approach. The advantages of this method are simplicity and ease of application, and it can offer some initial perspective on a given situation. It is best applied in or near the elastic range, addressing constant-amplitude loading situations in what has been called the long-life (hence, infinite-life) regime.

The stress-life approach seems best applied to components that look like the test samples and are approximately the same size (this satisfies the similitude associated with the use of total separation as a failure criterion). Much of the technology in application of this approach is based on ferrous metals, especially steels. Steels are predominant as a structural material, but steels also display a fatigue limit or endurance limit at a high number of cycles (typically $>10^6$) under benign environmental conditions. The infinite-life asymptotic behavior of steel fatigue life, thus, provides a useful and beneficial result of S - N testing. However, most other materials do not exhibit this infinite life response. Instead, many materials display a continuously decreasing stress-life response, even at a great number of cycles (10^6 - 10^9), which is more correctly described by a fatigue strength at a given number of cycles.

Assessing Fatigue S - N Properties. Given the extensive history of the stress-life method, substantial property data are available, but beware of the testing conditions employed in producing older data. The usefulness of property data is a critical point due to the numerous variables that influence fatigue results. For example, if a series of tests are conducted at a constant stress ratio ($R = S_{\min}/S_{\max}$), and the alternating stress amplitude (S_a) is used as the other independent dynamic variable, an S - N curve for that situation can be produced, and all dynamic variables can be determined. However, if only one variable is given (e.g., S_a or S_{\max}), there is insufficient information to tell what the test conditions were and the data are virtually useless.

In many cases, insufficient information is available for the effective use of S - N data. Many necessary pieces of data are simply missing. A partial list of important questions might be as follows:

- What were the coupon size and geometry?
- Was there a stress concentration?
- What was the temperature?
- Was an environment other than lab air employed?
- What was the specimen orientation in the original material?
- Does the line represent minimum, mean, or median response?
- How many samples were tested?
- What was the scatter?
- If the plot is based on constant-amplitude data, what were the frequency and waveform?
- Was testing performed using variable-amplitude loading? What was the spectrum?
- What was the failure criterion?
- If there were runouts, how were they handled and represented?

If the data found describe a thin sheet response, it is the wrong data. If the product form is correct, but the plot represents testing done at $R = 0.3$ and fully reversed data are required, the plot may be helpful, but it is not what is desired.

An example of what should be considered important as supporting facts can be found in ASTM E 468, "Presentation of Constant Amplitude Fatigue Test Results for Metallic Materials." It provides guidelines for presenting information other than just final data.

S-N Data Presentation. Stress is the controlling quantity in this method. The most typical formats for the data are plots of the log number of cycles to failure (sample separation) versus either stress amplitude (S_a), maximum stress (S_{max}), or perhaps stress range (ΔS).

Mean stress influences are also very important, and each design approach must consider them. According to Bannantine et al. (Ref 5), the archetypal mean (S_m) versus amplitude (S_a) presentation format for displaying mean stress effects in the safe-life, infinite-life regime was originally proposed by Haigh. The Haigh diagram can be a plot of real data, but it requires an enormous amount of information for substantiation. A slightly more involved, but also more useful, means of showing the same information incorporates the Haigh diagram with S_{max} and S_{min} axes to produce a constant-life diagram. Examples of these are provided subsequently.

For general consideration of mean stress effects, various models of the mean-amplitude response have been proposed. A commonly encountered representation is the Goodman line, although several other models are possible (e.g., Gerber and Soderberg). The conventional plot associated with this problem is produced using the Haigh diagram, with the Goodman line connecting the ultimate strength on S_m , and the fatigue limit, corrected fatigue limit, or fatigue strength on S_a . This line then defines the boundary of combined mean-amplitude pairs for anticipated safe-life response. The Goodman relation is linear and can be readily adapted to a variety of manipulations.

In many cases Haigh or constant-life diagrams are simply constructs, using the Goodman representation as a means of approximating actual response through the model of the behavior. For materials that do not have a fatigue limit, or for finite-life estimates of materials that do, the fatigue strength at a given number of cycles can be substituted for the intercept on the stress-amplitude axis. Examples of the Haigh and constant-life diagrams are provided in Fig. 2 and 3. Figure 3 is of interest also because of its construction in terms of a percentage of ultimate tensile strength for the strength ranges included.

Fig. 2 A synthetically generated Haigh diagram for an alloy steel (620 MPa, or 90 ksi, ultimate tensile strength) based on typically employed approximations for the axes intercepts and using the Goodman line to establish the acceptable envelope for safe-life, infinite-life combinations. The Goodman line represents an unconnected 10^6 estimate at 50% failure (criterion: separation).

Fig. 3 A constant-life diagram for alloy steels that provides combined axes for more ready interpretation. Note the presence of safe-life, finite-life lines on this plot. This diagram is for average test data for axial loading of polished specimens of AISI 4340 steel (ultimate tensile strength, UTS, 860 to 1240 MPa, or 125 to 180 ksi) and is applicable to other steels (e.g., AISI 2330, 4130, 8630). Fatigue and Fracture Mechanics

Finite-Life Criterion (ϵ - N Curves) (Ref 4)

Strain life is the general approach employed for continuum response in the safe-life, finite-life regime. It is primarily intended to address the low-cycle fatigue area (e.g., from approximately 10^2 to 10^6 cycles). The ϵ - N method can also be used to characterize the “long-life” fatigue behavior of materials that do not show a fatigue limit.

From a properties standpoint, the representations of strain-life data are similar to those for stress-life data. However, because plastic strain is a required condition for fatigue, strain-controlled testing offers advantages in the characterization of fatigue crack initiation (prior to subsequent crack growth and final failure). The S - N method is based on just one failure criterion—the total separation of the test coupon. In contrast, any of the following may be used as the failure criterion in strain-controlled fatigue testing (per ASTM E 606): separation,

modulus ratio, microcracking (initiation), or percentage of maximum load drop. This flexibility can provide better characterization of fatigue behavior.

Testing for strain-life data is not as straightforward as the simple load-controlled (stress-controlled) $S-N$ testing. Monitoring and controlling using strain requires continuous extensometer capability. In addition, the developments of the technique may make it necessary to determine certain other characteristics associated with either monotonic or cyclic behavior. Further details on testing are given in the article “Fatigue, Creep Fatigue, and Thermomechanical Fatigue Life Testing” in this Volume.

Fatigue and Fracture Mechanics

Fracture Mechanics Approach (Ref 7)

Fracture of structural and equipment components as a result of cyclic loading has long been a major design problem and the subject of numerous investigations. Although a considerable amount of fatigue data are available, the majority have been concerned with the nominal stress required to cause failure in a given number of cycles—namely, $S-N$ curves. Usually, such data are obtained by testing smooth specimens which, although of some qualitative use for guiding material selection, are subject to limitations caused primarily by the failure to adequately distinguish between fatigue-crack-initiation life and fatigue-crack-propagation life. The existence of surface irregularities and cracklike imperfections reduces and may eliminate the crack-initiation portion of the fatigue life of the component. Fracture-mechanics methodology offers considerable promise for improved understanding of the initiation and propagation of fatigue cracks and problem resolution in designing to prevent failures by fatigue.

Fatigue-Crack Initiation. Initiation of fatigue cracks in structural and equipment components occurs in regions of stress concentrations, such as notches, as a result of stress fluctuation. The material element at the tip of a notch in a cyclically loaded component is subjected to the maximum stress range, $\Delta\sigma_{\max}$. Consequently, this material element is most susceptible to fatigue damage and is, in general, the origin of fatigue-crack initiation. It can be shown that, for sharp notches, the maximum-stress range on this element can be related to the stress-intensity-factor range, ΔK_I , as follows (Ref 8):

$$\Delta\sigma_{\max} = \frac{2}{\sqrt{\pi}} \frac{\Delta K_I}{\sqrt{\rho}} = \Delta\sigma(k_t) \quad (\text{Eq 1})$$

where ρ is the notch-tip radius, $\Delta\sigma$ is the range of applied nominal stress, and k_t is the stress-concentration factor.

Fatigue-crack-initiation behavior of various steels is presented in Fig. 4 (Ref 8) for specimens subjected to zero-to-tension bending stress and containing a smooth notch that resulted in a stress-concentration factor of about 2.5. The data show that $\Delta K_I/\sqrt{\rho}$, and, therefore, $\Delta\sigma_{\max}$ is the primary parameter that governs fatigue-crack-initiation behavior in regions of stress concentration for a given steel tested in a benign environment. The data also indicate the existence of a fatigue-crack-initiation threshold, $\Delta K_I/\sqrt{\rho}_{\text{th}}$, below which fatigue cracks would not initiate at the roots of the tested notches. The value of this threshold is characteristic of the steel and increases with increasing yield or tensile strength of the steel. The data show that the fatigue-crack-initiation life of a component subjected to a given nominal-stress range increases with increasing strength. However, this difference in fatigue-crack-initiation life among various steels decreases with increasing stress-concentration factor (Ref 8).

Fig. 4 Fatigue-crack-initiation behavior of various steels at a stress ratio of +0.1. Source: Ref 8

Finally, fatigue-crack-initiation data for various steels subjected to stress ratios (ratio of nominal minimum applied stress to nominal maximum applied stress) ranging from -1.0 to +0.5 indicate that fatigue-crack-initiation life is governed by the total maximum stress (tension plus compression) range at the tip of the notch (Ref 9). The data presented in Fig. 5 (Ref 10) indicate that the fatigue-crack-initiation threshold, $\Delta K_I/\sqrt{\rho}_{th}$, for various steels subjected to stress ratios ranging from -1.0 to +0.5 can be estimated from

$$\frac{\Delta K_{total}}{\sqrt{\rho}} = 10\sqrt{\sigma_{ys}} \quad (\text{Eq 2})$$

where ΔK_{total} is the stress-intensity-factor range calculated by using the tension-plus-compression stress range, and σ_{ys} is the yield strength of the material.

Fig. 5 Dependence of fatigue-crack-initiation threshold on yield strength

Fatigue-Crack Propagation. Extensive data have shown that the fatigue-crack-propagation behavior of metals is controlled primarily by the stress-intensity-factor range, ΔK_I . The fatigue-crack-propagation behavior of metals can be divided into three regions, as shown in Fig. 6 (Ref 11). The behavior in region 1 exhibits a fatigue-crack-propagation threshold, ΔK_{th} , which corresponds to the stress-intensity-factor range, below which cracks do not propagate under cyclic-stress fluctuations. An analysis of experimental results published on nonpropagating fatigue cracks shows that conservative estimates of ΔK_{th} for various steels subjected to different stress ratios, R , can be predicted (Ref 8) from:

$$\Delta K_{th} = 6.4(1 - 0.85R)$$

for

$$R \geq +0.1 \tag{Eq 3a}$$

and

$$\Delta K_{th} = 5.5 \text{ for } R < +0.1 \tag{Eq 3b}$$

where ΔK_{th} is in $\text{ksi}\sqrt{\text{in}}$.

Fig. 6 Schematic illustration of variation of fatigue-crack-growth rate, da/dN , with alternating stress intensity, ΔK , in steels, showing regions of primary crack-growth mechanisms. Source: Ref 11

Equation 3a and 3b indicates that the fatigue-crack-propagation threshold for steels is primarily a function of the stress ratio and is essentially independent of chemical or mechanical properties.

The behavior in region 2 (Fig. 6) represents the fatigue-crack-propagation behavior above ΔK_{th} , which can be represented by the power-law relationship:

$$\frac{da}{dN} = A(\Delta K_1)^n \quad (\text{Eq 4})$$

where a is crack length, N is number of cycles, and A and n are constants.

Extensive fatigue-crack-growth-rate data for various steels show that the primary parameter affecting growth rate in region 2 is the stress-intensity-factor range, and that the mechanical and metallurgical properties of these steels have negligible effects on the fatigue-crack-growth rate in a room-temperature air environment. The data for martensitic steels fall within a single band, as shown in Fig. 7 (Ref 8), and the upper bound of scatter can be obtained (Ref 8) from:

$$\frac{da}{dN} = 0.66 \times 10^{-8} (\Delta K_1)^{2.25} \quad (\text{Eq 5})$$

where a is in inches and ΔK_1 is in $\text{ksi}\sqrt{\text{in}}$. Similarly, as shown in Fig. 8 (Ref 8), data for ferrite-pearlite steels fall within a single band (different from the band for martensitic steels), and the upper bound of scatter can be calculated from:

$$\frac{da}{dN} = 3.6 \times 10^{-10} (\Delta K_1)^{3.0} \quad (\text{Eq 6})$$

where a is in inches and ΔK_1 is in $\text{ksi}\sqrt{\text{in}}$.

Fig. 7 Summary of fatigue-crack-growth data for martensitic steels. Source: Ref 8

Fig. 8 Summary of fatigue-crack-growth data for ferrite-pearlite steels. Source: Ref 8

The stress ratio and mean stress have negligible effects on the rate of crack growth in region 2. Also, the frequency of cyclic loading and the wave form (sinusoidal, triangular, square, or trapezoidal) do not affect the rate of crack propagation per cycle of load for steels in benign environments (Ref 8).

The acceleration of fatigue-crack-growth rates that determines the transition from region 2 to region 3 appears to be caused by the superposition of a brittle or a ductile-tearing mechanism onto the mechanism of cyclic subcritical crack extension, which leaves fatigue striations on the fracture surface. These mechanisms occur when the strain at the tip of the crack reaches a critical value (Ref 8). Thus, the fatigue-rate transition from

region 2 to region 3 depends on the maximum stress-intensity factor, on the stress ratio, and on the fracture properties of the material (Ref 8).

Fatigue, Creep Fatigue, and Thermomechanical Fatigue Life Testing

Gary R. Halford and Bradley A. Lerch, Glenn Research Center at Lewis Field, National Aeronautics and Space Administration; Michael A. McGaw, McGaw Technology, Inc.

Introduction

THE FATIGUE CRACK INITIATION RESISTANCE of an alloy is determined by conducting a series of tests over a range of values of stress amplitude or strain range. The observed number of cycles to failure is plotted against the stress amplitude or strain range to obtain a fatigue curve. The fatigue properties quoted for an alloy are typically the constants used in the equation(s) that describe the fatigue curve. Fatigue lives of interest may be as low as 10^2 or higher than 10^9 cycles. Because of the enormous scatter associated with fatigue, dozens of tests may be needed to confidently establish a fatigue curve, and the cost may run into several thousands of dollars. To further establish the effects on fatigue life of, for example, the test temperature, environment, alloy condition, mean stress effects, creep-fatigue effects, and thermomechanical cycling, requires an extraordinarily

large and usually very costly test matrix. The total effort required to establish the fatigue resistance of an alloy should not be taken lightly.

Fatigue crack initiation tests are conducted on relatively small—and presumed to be initially crack-free—samples of an alloy that are intended to be representative of the metallurgical and physical condition of the alloy. Generally, samples are smooth and have uniformly polished surfaces within the test section. Some may have intentionally machined notches of well-controlled geometry, but the surface at the root of the notch is usually not polished. The purpose of polishing is to attain a reproducible surface finish. This is to eliminate surface finish as an uncontrolled variable. Test specimens are cyclically loaded until macroscopically observable cracks initiate and eventually grow to failure. Normally, the fatigue failure life of a specimen is defined as the number of cycles to separation of the specimen into two pieces. Alternative definitions are becoming more common, particularly for low-cycle fatigue testing, wherein some prescribed indication of impending failure due to cracking is adopted. Specific criteria will be described later. As a rule, cracks that develop during testing are not measured, nor are the test parameters intentionally altered owing to the presence of cracking. The topic of fatigue crack propagation testing of alloys is discussed in the articles “Fatigue Crack Growth Testing” and “Creep Crack Growth Testing” in this Volume.

Microscopic-sized fatigue cracks tend to nucleate quite early in cyclic life (in the first 1–10%) in the high-strain, plasticity-dominated, low-cycle life regime. In this regime, cyclic plasticity is widespread throughout the specimen test section, and the range of plastic strain is used as a measure of the severity of fatigue “loading.” On the other hand, cracks begin to appear quite late in cyclic life (90–99%) in the very low-strain, elastically dominated, high-cycle life regime. There is a gradual transition between these two extremes of behavior for intermediate strain ranges and cyclic lifetimes. In the high-cycle life regime, the cyclic behavior at the macroscopic, phenomenological level is usually considered by design engineers to be linearly elastic and thermodynamically reversible. It is important to recognize, however, that the micromechanisms of fatigue crack nucleation and growth in metals and alloys are linked directly to the occurrence of reversed cyclic plasticity. Fatigue will not occur without it. Even fatigue cracking that occurs in the range of a billion cycles to failure or more *must involve* reversed plasticity. It is also important to recognize that the fatigue process is a progressively degenerative one. For any given condition of cyclic loading that eventually leads to a fatigue failure, there is some, though minute, permanent change from one cycle to the next. While the macroscopic behavior may appear to be, for instance, linear, reversible, and elastic at the microstructural level, irreversible, nonlinear, inelastic deformations occur in highly localized regions that accumulate until macroscopically observable cracking occurs.

Although the results of crack initiation tests conducted on small specimens do not precisely establish the fatigue life of a large part, such tests do provide useful information on the intrinsic fatigue crack initiation behavior of a metal or alloy. As a result, such data can be utilized to develop engineering design criteria to prevent initiation of fatigue cracks in structural components. The use of small-specimen fatigue test data is the basis of fatigue design codes for pressure vessels; piping components; nuclear reactors; turbine blades; wheels; shafts; complex welded, riveted, or bolted structures; automotive and off-highway equipment; exotic aerospace components; and even soldered joints of lead-free electronic chips.

All alloys and metals in structural elements are susceptible to fatigue crack initiation if the structure is subjected to sufficiently large and numerous amplitudes of cyclic loading.

Following a brief description of the phenomena of crack initiation and early growth, this article examines specimen design and preparation as well as the apparatus used in crack initiation testing. Variables that influence the resistance of alloys to fatigue crack initiation, such as the effect of mean and residual stress, stress concentrations, stress amplitude, and surface properties, are briefly reviewed. The initial portion of this article deals with fatigue testing of alloys in the regime wherein the isothermal temperature of testing is below the range wherein behavior is significantly influenced by time-dependent mechanisms, such as creep, oxidation, and metallurgical transformations. The testing procedures, instrumentation, and hardware must be altered to accommodate creep-fatigue testing and thermomechanical fatigue testing, and these items will be addressed as required throughout this article. Applicable ASTM standards for baseline fatigue testing are listed in Table 1.

Process of Fatigue Crack Initiation and Early Growth

Fatigue crack initiation and early growth require cyclic inelastic deformation. For alloys and metals tested at subcreep temperatures, the nonlinear inelastic behavior is invariably plasticity, that is, the slip associated with dislocation motion along the most densely packed crystallographic planes aligned favorably with the maximum resolved shear stress. In low-cycle fatigue testing, the cyclic plasticity is widely spread throughout the gage portion of the specimen and is readily measured with commercially available strain measuring devices. In this regime, the cyclic stresses will be near or above the conventional offset yield strength of the alloy. Cyclic strain hardening or softening typically also occurs. On the other hand, at very long cyclic lives, cyclic plasticity is still present, although certainly not detectable with conventional strain measurement techniques. Reversed crystallographic slip is highly localized within a few of the most favorably oriented grains or near highly localized stress concentrations. Stress-strain response appears to be totally elastic in this life regime. Because of the extreme localization at the smallest cyclic stresses and strains and, hence, longest lives, the tendency is for only one major crack to initiate and grow to failure in this regime. In the high-strain regime, corresponding to low-cycle fatigue lives, there is a tendency for the material to develop multiple crack initiations and early growth followed by eventual link-up of independent cracks into a single fatal fatigue crack. The transition between low-cycle fatigue and high-cycle fatigue is essentially a gradual one with mechanisms varying more in degree than in kind. The region between low- and high-cycle fatigue is referred to as intermediate-cycle fatigue. With few exceptions, such as rolling-contact fatigue and influences of mechanical or metallurgical surface treatments, cracks initiate at a free surface. Usually the surface is the external surface of the specimen, although it could be an internal surface associated with a void or a debonded internal particle. Cyclic plasticity is less constrained at a free surface due to the fewer nearest neighbors and, hence, fewer atomic bonds available to inhibit dislocation motion. Dislocations also exit and disappear at free surfaces, leaving one atomic-sized step for each dislocation that exists on a particular slip plane. Typically, more than one slip plane is involved. Any given slip plane experiences nonreversed slip, that is, the amount of slip in the slip direction of the plane during one direction of loading is not recovered in the opposite direction when the direction of loading is reversed. Rather, the overall deformation is recovered, but some of it may be on parallel slip planes. The active parallel slip planes are separated by numerous atomic distances and form what are known as slip bands. Within a band the to-and-fro slip is not uniform, resulting in considerable disarray beneath the surface and outcroppings that are highly irregular. These are referred to as persistent slip bands, that is, those deeper than several microns below the free surface. Persistent slip bands remain active throughout the bulk of the cyclic life.

As the number of applied fatigue cycles of cyclic plasticity increase, the severity of the irregularity increases until such time as the outcroppings form extrusion-intrusion pairs within the slip bands. Intrusions are the nuclei or formative stages of atomic-sized fatigue cracks known as stage I cracks (defined as cracking along the crystallographic slip plane). The intrusion grows slowly with continued cycling. Once the depth of the intrusion is great enough, the surrounding material perceives it as a crack that exerts its own highly localized stress-strain field. At this stage of the evolving fatigue process, the stress-strain field of the nucleated crack, which superimposes itself on the applied stress-strain field, becomes the dominant field. The cracking response changes accordingly, and the global crack direction turns to become perpendicular to the maximum principal stress direction immediately in front of the crack. This signals the onset of stage II fatigue cracking, which generally prevails until fatigue failure occurs. Inspection of a fatigue fracture surface with the naked eye generally reveals primarily stage II cracking because stage I cracks are seldom greater than a grain size or two in depth. Cracks may also start at the location of surface irregularities due to grain boundaries, chemical attack, and casting or machining imperfections. Nevertheless, cyclic plasticity is always a necessary ingredient for the nucleation process.

Although the scenario described above is simplified, it provides phenomenological insight into the gradual, progressive nature of the fatigue process that is useful in understanding cyclic testing in the low-, intermediate-, and high-cycle fatigue regimes. There are no sharp demarcations between the three regions when described by

the number of cycles to failure. In fact, the distinction is better founded in terms of the magnitude of the range of cyclic plastic strain than in terms of number of cycles due to the overwhelming influence of the plasticity. As an example, high-ductility, low-strength metals such as copper behave in a low-cycle fatigue manner even at 10^6 cycles to failure, because the cyclic strain range may be half plastic and half elastic even at this life level. By contrast, a low-ductility, high-strength hardened ball-bearing steel exhibits high-cycle-type fatigue behavior at cyclic lives of only 10^3 , owing to the minuscule amount of plasticity that is overwhelmed by the large elastic component of cyclic strain.

Fatigue, Creep Fatigue, and Thermomechanical Fatigue Life Testing

Gary R. Halford and Bradley A. Lerch, Glenn Research Center at Lewis Field, National Aeronautics and Space Administration; Michael A. McGaw, McGaw Technology, Inc.

Fatigue Testing Machines

Numerous types of testing machines have been developed for fatigue crack initiation testing. Fatigue testing machines covered in this article deal with nominally uniaxial normal-stress applications. Multiaxial fatigue loading, including torsional and contact fatigue (e.g., rolling elements, gears, and impact) is covered in the article “Multiaxial Fatigue Testing” in this Volume. Most fatigue testing machines have been developed to a high degree and are marketed commercially to laboratories for conducting a wide variety of fatigue testing. Machines have been developed for various modes of loading that, in turn, dictate the configuration of the test specimen. Considerable variation of specimen geometry can be accommodated by each of the modes as discussed in the following paragraph.

Fatigue Loading Modes

Three basic modes of loading are used: direct axial loading, plane-bending, and rotating-beam loading. Specimens for direct axial stress machines may have a wide range of cross-sectional geometries (solid or hollow) and have a uniform gage length with axial cross sections that are round, elliptical, square, rectangular, or thin sheet. Specimens of nonuniform cross section include sharp notches and low stress concentration, hourglass-shaped specimens for diametral strain control. Bending specimens may have cross sections of uniform width and thickness for three- or four-point loading, or tapered cross sections (designed for constant stress along the length) for cantilevered plane-bending or rotating-beam testing. All bending specimens could be machined with stress concentrations in the form of notches. Examples of standardized fatigue test specimens are presented in the section “Ancillary Equipment and Specimens” in this article.

Classifications of Fatigue Testing Machines

In addition to the loading mode, fatigue testing machines are further classified by their basic drive mechanism and by the test parameter to be controlled. The basic drive system is most often electrical. An electric motor directly drives rotating-beam testing machines. An eccentric cam attached to a drive motor deflects the cantilevered end of a plane-bending fatigue specimen. Eccentric cams coupled with flexure-plate, parallel-motion pivoted lever arms can also drive axially loaded specimens in a direct-stress machine. Direct-stress machines can also be modified with fixturing to perform plane-bending fatigue tests, either in three-point or four-point bending. The rotary motion of an eccentric cam on an electric drive motor can be used to excite a linear oscillating spring-mass system at its resonance point to provide direct-stress loading of a fatigue specimen. Electromagnetic excitation can be used to excite a mass or inertial system to load a specimen in direct stress or plane bending. Ultrasonic fatigue testing is possible at frequencies up to 20 kHz using electromagnetic excitation of a specimen gripped at one end and excited at its natural frequency in the axial direction. Even piezoelectric devices have been used to create small high-frequency displacement excitations for specialized fatigue testing. Electric motors also turn the pumps to pressurize the fluids used in modern

servohydraulic testing machines. The greatest versatility comes with closed-loop, servohydraulic testing systems that offer capability to control any of the primary fatigue variables, provided that that variable can be sensed electronically.

Test parameter control is usually fixed for the simplest and least costly fatigue machines. Rotating-beam testing is generally done under constant bending moment control. Provided the maximum bending stress remains linearly elastic, the elastically calculated stress or strain is presumed to be a controlled constant. However, should a small amount of inelasticity occur at the peak stress of the cycle, the maximum stress will drop due to stress redistribution. This action results in neither a constant pure stress nor strain control, although the strain or displacement will tend to be controlled more consistently than the stress might be. For plane bending, if the loading is performed through a rotating eccentric cam, the control condition is closest to a constant displacement control. If the loading is done with a bending fixture attached to a direct-stress machine that is under load control, then the control mode for the bending specimen is constant bending moment. Servohydraulic direct-stress machines can be operated in constant load, strain, or displacement control depending upon which variable signal is being sensed and fed back into the servocontrolled loop. While the most versatile, such machines typically require higher initial, operating, and maintenance costs.

All fatigue testing machines have a basic loading frame that resists the loads imposed on the test specimen. This frame also supports a number of other components, including the drive mechanism that transmits loading to the specimen through grips, load cells, extensometry, and other measurement devices. If heating, cooling, or environmental chambers are involved, they too have to be supported by the loading frame. Key attributes of the loading frame are to provide accessible space for installing and removing test specimens; once installed, they have very high stiffness relative to the stiffness of the specimen. In other words, the testing machine should undergo as little elastic loading displacement as possible. Ideally, the bulk of the displacement should be absorbed by the specimen. The loading train within the testing machine should also have excellent alignment of the load line with the specimen to prevent premature specimen warping or buckling under high loads. Typical load train components in a modern servohydraulic axial fatigue machine are shown in Fig. 1. Schematic diagrams of the load train components for other common fatigue testing machines are shown in Fig. 2 3 4 5 6 7. Brief descriptions of the various commercially available fatigue testing machines are given in the following sections.

Axial (Direct-Stress) Fatigue Testing Machines. The direct-stress fatigue testing machine subjects a test specimen to a uniform stress or strain through its cross section. For the same cross section, an axial fatigue testing machine must be able to apply a greater force than a static bending machine to achieve the same stress. Axial machines are used to obtain fatigue data for most applications and offer the best method of establishing, by closed-loop control, a controlled strain range in the plastic strain regime (low-cycle fatigue).

Servo-hydraulic closed-loop systems offer optimum control, monitoring, and versatility. These can be obtained as component systems and can be upgraded as required. A hydraulically actuated cylinder typically is used to apply the load in axial fatigue testing. A servovalve governs the flow of hydraulic fluid to the cylinder. The direction and rate of flow is dictated by the electronic control signal to the servovalve through a feedback control loop. Due to the versatility provided by the servo-hydraulic system in control modes (load, strain, displacement, related variables, or computed combinations of these variables such as plastic strain), the same machine can be used for both high-cycle fatigue and low-cycle (stress- or strain-controlled) fatigue testing. A wide variety of grips, including self-aligning (typically tension-tension only) types, are available for these machines.

Electromechanical systems have been developed for axial fatigue studies. The crank and lever machine of Fig. 2(a) is an example of one of the testing systems using this drive mechanism. Forced vibration and resonant systems have also been used extensively. Older machine designs were open-loop systems, but newer machines have closed-loop features to continuously maintain loading levels. An older-style forced-vibration rotating eccentric mass machine with a direct-stress fixture is shown in Fig. 5, and a closed-loop resonant machine is shown in Fig. 6.

In crank and lever machines, a cyclic load is applied to one end of the test specimen through a deflection-calibrated lever that is driven by a variable-throw crank. The load is transmitted to the specimen through a

flexure system, which provides straight-line motion to the specimen. The other end of the specimen is connected to the loading frame. Some machines have a hydraulic piston that is part of an electrohydraulically controlled load-maintaining system that senses specimen yielding. This system automatically restores the preset load through the hydraulic piston. Thus, the static and dynamic loads are applied to opposite ends of the specimen, making it possible to maintain a constant load on the specimen regardless of dimensional changes caused by specimen fatigue.

Electromagnetic or magnetostrictive excitation may be used for axial fatigue testing machine drive systems when low-load amplitudes and high-cycle fatigue lives are desired in short test durations. The ultrahigh-cycle frequency of operation of these types of machines (on the order of 10–25 kHz) enables testing to long fatigue lives ($>10^8$ cycles) within weeks. An example of one of these types of machines is illustrated in Fig. 7. A comprehensive review on all aspects of ultrasonic fatigue testing is given in the article “Ultrasonic Fatigue Testing” in this Volume.

Bending Fatigue Machines. The most highly used type of fatigue machine has probably been the bending fatigue machine. These simple, inexpensive systems have allowed laboratories to conduct extensive test programs with a low investment in equipment. The most common general-purpose bending fatigue machines are cantilever-beam plane-bending (repeated-flexure) and rotating-beam machines.

Cantilever-beam plane-bending machines use flat test specimens that have a tapered width and uniform thickness. This configuration results in a sizable portion of the test specimen volume having a uniform bending stress. Substantially smaller loads are required than for axial fatigue of the same section size. In bending, the stress is highest at the surface, making this test mode advantageous for studying the effects of surface treatments or coatings.

Because of their large displacement, the cam or eccentric principles used in cantilever-beam plane-bending machines typically have a limited cyclic frequency compared to rotating-beam types. Both deflection-controlled and load-controlled types are available and are in use today.

Rotating-beam machines are the earliest type of fatigue testing machine, and they remain in occasional use today. The specimen has a round cross section and is subjected to dead-weight loading while swivel bearings permit rotation. A given point on the circular test-section surface, during each rotation, is subjected to sinusoidal stress variation from tension on the top to compression on the bottom. It is not possible to run mean-stress effects tests with this machine.

Typical rotating-beam machine types are shown in Fig. 3. The R.R. Moore-type machines (Fig. 3a) typically operate at 167 Hz. In all bending-type tests, only the material near the surface is subjected to the maximum stress; therefore, in a small-diameter specimen, only a very small volume of material is under testing. Thus the fatigue strength and lives obtained from small rotating-beam fatigue tests typically are higher than those obtained from axial fatigue tests for specimens with the same cross-sectional area.

Regimes of Operation

The choice of the fatigue testing machine will depend strongly on the fatigue-life regime to be investigated and upon the type of fatigue data desired.

High-Cycle Fatigue. At the high-cycle fatigue (HCF) end of the fatigue spectrum (10^5 to 10^8 and higher), high-frequency cycling is an absolute must. It requires nearly 12 days of cycling at 1000 Hz to reach 10^8 cycles to failure. Even ultrasonic fatigue testing at 20,000 Hz would require 14 hours to reach this life level. Fortunately, in the HCF regime, the cyclic plasticity is so minuscule that specimen heating, while ever present, does not restrict testing. Rise-in-temperature measurements made during high-frequency cycling have, however, been used successfully to help identify high-cycle fatigue endurance strengths (Ref 1). On the macroscopic phenomenological level, specimen behavior is considered to be linearly elastic. Hence, load-controlled testing is entirely adequate and, in practical fact, is virtually dictated. Any conventional fatigue extensometer would be of no added value to testing even if means were found to keep it from being shaken off at higher frequencies.

In the high-cycle fatigue regime, statistical variation in fatigue life is quite large (see the section on statistical aspects of fatigue data). This dictates multiple test results to provide a sufficient database to establish the fatigue resistance of the material. The exceptionally large amount of total testing time in turn requires multiple fatigue testing machines. Consequently, the cost per machine must be relatively low. The simpler fatigue testing machines based on constant loading or displacement in plane bending, rotating bending, and direct stress are used almost exclusively for evaluation of very-high-cycle fatigue resistance of materials. Ultrasonic fatigue

testing is rarely used because the cyclic strain rates are much higher than found in service. This large difference in strain rate may result in different micromechanisms of straining and, hence, fatigue crack initiation mechanisms.

Low-Cycle Fatigue. Conventional low-cycle fatigue (LCF) crack initiation data in the regime of 10 to 10^5 cycles to failure are best obtained under strain cycling conditions, leaving little choice but to use an electrohydraulic direct-stress fatigue machine with an extensometer and servostrain control. The cyclic frequency need not be high. Even at 1 Hz, 10^5 cycles can be reached in just over a day. In fact, higher frequencies would not be desirable at lower life levels where cyclic plasticity could be significant. Energy dissipation due to rapid cyclic plasticity would cause considerable, and highly undesired, specimen heating, assuming the specimen is not already being heated to an elevated test temperature. (If cyclically generated heat is not dissipated, the resultant thermal expansion of the specimen test section creates an “apparent” mechanical strain. Under servocontrolled cyclic straining, thermal expansion would be offset by enforced compression and, hence, compressive mean stress, destroying the original purpose of the test.)

Elevated-temperature fatigue testing, especially low-cycle isothermal creep-fatigue (ICF) and thermomechanical fatigue (TMF), invariably requires servocontrolled, strain-cycling capabilities to avoid undesirable creep or plasticity ratcheting strains. The maximum cyclic rates during TMF cycling are typically quite low due to the relatively low rate at which temperatures of test samples can be changed in a controlled manner. Due to the relatively long testing time per cycle for ICF and TMF tests, and due to the high costs per test and high machine acquisition and maintenance costs, there have been few published investigations of the statistical nature of ICF and TMF; however, proprietary databases exist in some large corporations for certain critical materials applications. High-temperature fatigue testing will be discussed in greater detail in following sections of this article.

Ancillary Equipment and Specimens

A fatigue testing machine typically will have a number of components or accessories added to the basic loading frame. The most common are shown in Fig. 8. Ancillary equipment performs various functions, such as load and strain detection and specimen gripping and alignment, and provides a controlled environment for the specimen. Load cells, grips and alignment devices, extensometry, environmental chambers, furnaces and other methods of heating are briefly discussed below.

Load Application, Measurement, and Control

Hydraulic Cylinder. The forces and displacements in servohydraulic materials testing systems are produced by a hydraulic actuator (Fig. 1b). Many types of hydraulic actuators (cylinders) are in common use in industrial equipment; however, hydraulic cylinders used in materials testing machines are differentiated from others in the following ways: they are fatigue rated so that they may be reliably used in fatigue testing where the duty cycles will be substantial, and they feature specialized seal designs to enable high lateral stiffness to be obtained, which is important in maintaining alignment during testing.

Load Cell. The force-measuring device in a fatigue machine is called a load cell. It typically consists of resistance strain gages bonded to a linear elastic spring element, which carries the same load as the specimen. The gages make up an electrical resistance bridge circuit. Applied load creates a bridge out of balance that is linearly proportional to the load. Load cell design is sophisticated and has evolved over several decades. Load cells must be accurate to within 1% of the applied load (ASTM E 4) and be insensitive to side loads. Load cells should be stiff and stable and have minimal amounts of hysteresis and nonlinearity. Commercially available load cells are insensitive to small thermal fluctuations. However, care must still be taken to ensure that the cell is thermally protected during testing at elevated temperature. In addition, the load cell and cabling should have shielding to prevent electronic noise, particularly as induced from specimen heating systems. Load cells are designed with overload protection, which prevents damage of the cell due to misuse, and must be rated for fatigue testing.

This description applies to load cells used in axial loading as well as some plane-bending loading (three- and four-point loading not discussed herein) wherein the bending loads are imposed by loading in an axial loading frame. Cantilever plane-bending fatigue testing is done in smaller, simpler testing machines, and the load cell used to measure the bending load may differ in detail. For plane cantilever bending using an eccentric drive mechanism, the bending load cell can be built into the grips. Some rotating-bending test machines do not use a load cell, but rather rely on deadweight loading and knowledge of the lever arm distance to determine the applied bending moment. All force-measuring systems require periodic calibration to ensure accuracy. Methods of calibration and the intervals at which they are performed are specified in standards such as ASTM E 4. An excellent review of load cell design can be found in Ref 2.

Most often, the forces and displacements imparted on a test specimen by a testing machine originate from a hydraulic cylinder, the ram displacement of which is controlled by a servovalve (Fig. 1b).

Servo valves (Fig. 8b and 8c) are electromechanical devices that provide a means of controlling the flow of (hydraulic) fluid supplied to a hydraulic cylinder. This is generally accomplished by an electrically actuated element connected to a spool, where the spool is machined in such a manner so as to permit fluid flow to occur in proportion to its position relative to fluid inlet and outlet ports. These devices generally have a transfer function expressed in terms of the current (in milliamperes) required to develop a specific rate of flow. Conventional servo valves (Fig. 8b), as described above, are the most common design in use with servohydraulic materials testing equipment and provide acceptable frequency response for most fatigue testing applications. However, high-frequency servo valves are often used in the economical production of high-cycle fatigue data in excess of 10^6 cycles. One type of high-frequency servo valve used in materials testing applications uses a voice coil to actuate a pilot spool, which in turn ports fluid to a main stage spool, which in turn is used to port fluid to the actuator. This arrangement—in which the pilot spool position, obtained with a linear variable differential transformer sensor, is used in a control loop—provides very-high-frequency capability for materials testing. Other types of high-frequency servo valves, such as the one shown in Fig. 8c, do not use a voice coil to actuate a pilot spool.

Gripping Systems

Well-designed fixturing is required to transmit the applied load through the specimen to the load cell. The grip system must be versatile enough to allow easy installation of the specimen, but must not cause damage to the specimen test section during installation and testing. In addition, the grips must ensure good alignment and be able to withstand the environment associated with the test. The gripping system should have high lateral stiffness to maintain good alignment (more information about alignment can be found in the section “Alignment Considerations” in this article). For uniaxial, tension-compression testing, the specimen and grips must be designed such that there is no backlash while passing through zero load. Modern gripping systems usually consist of a block of high-stiffness metal (typically steel) that attaches to the load train. The body of the grip may be water-cooled to prevent overheating during tests at elevated temperatures. The grip body has some type of insert that aids in specimen installation and accommodates the geometry of the specimen grip ends (Fig. 9). The inserts are typically made of a material with high hardness (such as tool steel) to minimize wear and distortion due to repeated clamping. For elevated-temperature operations, a high-temperature alloy is often chosen.

Fig. 9 Schematic of typical hydraulic wedge grip

To properly grip the specimen, inserts are used in the grip body or directly on the pull rods. These are generally of the collet or wedge type. Some of the more common types of inserts are shown in Fig. 10. Collets can be used for flat and round specimens and are most often used for tension-compression testing. Wedge inserts are used for flat specimens, primarily tested in tension. Both collets and wedges generally operate in a grip, such as the one shown in Fig. 9. The specimen is held in place with friction that is regulated by squeezing the sample within the inserts using hydraulic pressure. This system provides easy specimen installation and maintains excellent alignment. The gripping surfaces of the insert often have a knurled surface or are treated with an abrasive coating to enhance the friction and allow higher axial loads to be applied without the specimen slipping in the grips. Grip surfaces that are too coarse can cause unwanted grip failures.

Fig. 10 Grip insert designs used for axial fatigue testing. (a) Three-piece collet grip for cylindrical specimens. (b) V-grips for rounds for use in wedge grip body. (c) Wedges for flat specimens. (d) Universal open-front holders. (e) Adapters for special samples (e.g., screws, bolts, and studs) for use with open-front holders. (f) Holders for threaded samples. (g) Snubber-type wire grips for flexible wire or cable

When testing at elevated temperatures, the grips must be able to maintain their operating capabilities. There are two basic methods for gripping at high temperatures. The first is to keep the grips out of the hot zone and water cool them to prevent overheating. This is most effective with heating systems where only localized heating (in the gage section) occurs, such as with induction, radiant heaters, and small furnaces. The drawback to cooled grips is that the grips act as a large heat sink, pulling the heat out of the specimen. This can make it difficult to achieve an acceptably low thermal gradient along the length of the specimen test section.

The second method is to employ hot grips. With this gripping system, the grips reside in or near the hot zone. This is commonly used with large muffle-type furnaces. Negligibly low thermal gradients along the specimen test section are easily achieved with hot grips because the grip temperature is similar to that of the test section. The grip material must be of a high-temperature alloy, typically a nickel- or cobalt-base alloy. Care must be taken to ensure that the specimen does not permanently affix itself to the grips. A high-temperature lubricant, such as MoSi_2 or Al_2O_3 , is typically used to prevent this permanent affixation from happening. Hot grips are generally replaced at a greater frequency than cooled grips due to long term deformation (creep) of the grips and oxidation and microstructural instabilities that may weaken and distort the grip material.

Another type of fixture is commonly used for threaded samples. These fixtures consist of a block of material with internal threads to accommodate the specimen. To lock the specimen to the grips, jamb nuts are tightened to preload the specimen grip ends within the grips and eliminate backlash. Care must be taken to avoid applying a torque across the specimen test section during installation. This fixture has an advantage that very small specimens can be used, thus minimizing material mainly due to the relatively short grip section needed compared to wedge or collet grips. The disadvantage of such grips is that alignment can be poor and can vary from set-up to set-up for a given specimen, as well as from specimen to specimen. Also, notch-sensitive materials may tend to break in the threads rather than the test section if the thread diameter is too small compared to the gage section diameter.

Grips for three- and four-point bending carried out in an axial loading frame often take the form of simple rollers that transmit normal forces, but negligible shear forces, to the surface of bending specimens. Care is taken to maintain the orientation and location of the rollers and the specimen relative to the loading frame. Consideration should also be given to surface-initiated cracking from the contact line of the rollers, although this is offset by the compressive Hertzian stresses imposed by the rollers. For bending in both directions, symmetric sets of rollers must be located on the opposite faces of the bend specimen and preloaded to prevent backlash. Three- and four-point bending fatigue tests are used often to test notched geometries or to grow cracks for subsequent fracture toughness testing.

Grips are considerably simpler, and alignment, while still important, is not as critical for cantilever plane bending using an eccentric drive as it is for axial loading. The larger, fixed end of the specimen is typically bolted to a rigid plate on the test frame. The flat plane of the specimen must remain plane and be aligned with respect to the bending axis. Clamping forces must be high enough to prevent relative motion in the grips, but not so high as to introduce clamping stresses that would cause changes to the reduced width and thickness of the test section. Gripping of the cantilevered end of the specimen is relatively unimportant because of the low bending stresses present. However, the gripping and means of force transmittal must freely accommodate the

forced displacement of the end of the specimen that traces the arc of a circle. The specimen must be free of loading along its longitudinal axis and free of all extraneous bending moments. Collet, or lathe, grips are commonly used for rotating-beam specimens and must be designed so that fretting does not occur in the grip. Also, the grip design must prohibit seizure of the specimen, allowing easy specimen removal without damage. Care must be taken that the tightening of the grips does not induce misalignment and, hence, unwanted stresses in the specimen test section.

Extensometry and Strain Measuring Devices

Because fatigue damage occurs as a result of plasticity, it is desirable to measure the deformation occurring within the gage section during a test. The deformation or displacements can be easily tracked using a number of devices. The most accurate methods involve measurement of the strain in the gage section of the specimen. Measurements over larger sections, such as displacement between the crosshead (stroke), should not be used because they include displacement components from the load train as well as the deformation that occurs in the specimen. A number of studies have been conducted in which strain has been measured on specimen ridges outside the gage section (Ref 3, 4), an approach that involves analysis of the deformation in the radius section to determine only the contribution to displacement coming from the gage section. The relative contributions depend on the degree of plastic strain, therefore, a variable calibration is required.

Direct measurements on the gage section are more straightforward and can be performed with a number of devices, such as strain gages, extensometers, and optical devices. The key to any of these devices is that, in addition to taking accurate strain readings, the device cannot affect the fatigue life of the sample. In addition, these devices should not only be able to record displacement, but also be stable enough to be used to close a feedback loop in a strain-controlled mode. Resistance strain gages are very accurate and can be used to both measure strains in any direction and control strain during the test. They are best suited for nominally elastic straining tests. Sustained cyclic strains larger than about 0.75% amplitude may be inappropriate for use of resistance strain gages (Ref 5). Strain gages can be very small in size, and, therefore, many can be applied to a standard test specimen and used to measure bending strains, Poisson's ratio, and strains in various axes. Commercially available gages provide resolutions and accuracies suitable for fatigue testing. Standard texts on strain gage usage (see, for example, Ref 6) can guide the user in this area. The gages should be rated for cyclic use over the range of strains needed for the test. Care must be taken to ensure that specimen surface preparation for gage installation does not induce premature fatigue cracking of the specimen.

Resistance strain gages are used principally at room temperature. However, resistance strain gages are available that have limited use at temperatures as high as 800 °C (1500 °F) (Ref 7, 8). These gages are used where measuring strains in various directions on the specimen is desirable, or where easy access to the specimen by an extensometer is not possible (e.g., in a furnace). However, they are difficult to use, often suffer from long-term drift, and must be individually compensated for each temperature range. More information on these gages can be found in ASTM E 1319.

The most common method of measuring strains in fatigue tests is through the use of a mechanical extensometer. Extensometers employ some method of contact with the specimen that relays the displacement through a lever system to an electronic sensing element. The sensor is generally a strain gage bridge, a capacitance transducer, or a linear variable differential transformer (LVDT). Generally LVDTs are larger and heavier than the other two types.

Extensometers are rated according to their accuracy (ASTM E 83). Like load cells, extensometers should have a linear response and have minimal hysteresis (ASTM E 606). Extensometers require periodic calibration (ASTM E 83) to ensure their accuracy (Ref 5).

Axial Extensometers. For tests at room temperature, clip-on extensometers are generally used, attaching to the specimen using breakaway features, such as springs, sheet metal clamps, and other low-pressure clamping arrangements. Metallic knife-edge probes provide a sharp point of contact and are mechanically set to the exact gage length. Often, small strips of tape are adhered to the specimen to give the knife edges something to “bite into” without damaging the specimen.

When testing at elevated temperatures, the sensing element of the extensometer must be protected from the heat. Moving the sensor away from the heat source by the use of longer probes can accomplish this. However, metal probes are no longer suitable and are replaced with a ceramic material. The probes are rods with a suitable specimen contact geometry, such as knife-edge, V-notch, or conical point geometry, depending on the

specimen material and gage section geometry. The probes must not damage the surface of the specimen, must not be reactive with the specimen material, must remain in stationary contact with the specimen surface, and must not deform (particularly creep) during the test.

The extensometer probes are mechanically preloaded (typically using springs) to hold them in direct contact with the specimen surface. The force must be sufficient to prevent slippage of the probes, but not so high as to deform the specimen (particularly due to creep) or to otherwise influence specimen failure. Commercial extensometers are available with a wide range of contact forces. The extensometer is mounted to a fixture that may also act as a heat shield, further protecting the sensing element. The extensometer-sensing element is usually air or water cooled to maintain temperature equilibrium during the test so that there is no temperature-induced drift in the strain reading.

Where a large furnace is used (generally with hot grips), the sensing element must be moved even further from the specimen, and long probes or rods must be used to transfer the specimen displacement out of the furnace to the sensing device. Systems of this type can be found in Ref 9, 10, and 11.

Optical extensometers are also available. Most are based on lasers. Their major advantage is the zero mass of a laser beam that offers potentially high response to specimen straining. Another advantage, depending on the type of laser detection employed, is elimination of direct attachment of an extensometer to the specimen. This is particularly important for brittle and notch-sensitive materials. Of course, an optical path must be available between the specimen and the laser/detector. This type of extensometer, however, can be expensive to purchase, set up, and maintain. While speckle-pattern and interferometric systems are available, their adaptation for closed-loop servostrain control is quite difficult. For that reason, only the optical target (flag) system will be discussed here. This system uses a laser beam and detector array to scan the displacement of flags that define a gage length. Typically, the laser scans multiple times per second and averages the distance between two flags attached to the specimen. Unfortunately, current scanning rates are too low to achieve high-strain-rate response. Another problem is that the flags have to be specially designed to maintain a sharp edge at temperature, must adhere to the specimen without inducing damage, and must remain on the specimen throughout the duration of the test. A good comparison of the capabilities of a laser/target extensometer with various other types of strain measuring devices can be found in Ref 12.

Diametral extensometers are used to measure the change in diameter of a specimen due to Poisson's contraction. They are used primarily with axially loaded, hourglass fatigue specimens and at large strain ranges where premature cyclic plastic buckling would rule out use of straight gage length specimens. Generally, the design is a hinge and transducer with the extensometer mass supported by wires or self-centering springs, such that very low contact forces are needed. This design avoids some of the problems associated with use of axial extensometers. Diametral strain can be converted into axial strain using equations found in Ref 10, 13, and 14. However, if the load is not constant (a result, for example, of cyclic strain hardening or softening) during a constant diametral strain-range-controlled test, then the longitudinal strain range will vary. However, computer-controlled testing could be used to compensate so as to maintain a constant total axial strain range. Another drawback to the diametral extensometer is that the change in diameter of the specimen during a fatigue test is very small, and high resolution is required for the sensing device. However, this extensometer is typically used for large strain ranges and therefore sensitivity is not critical. Only a small volume of material experiences the full loads and strains during the test, which limits the size of microstructural features that can be effectively sampled. Information on a number of diametral extensometer designs can be found in Ref 13. Diametral extensometers were used extensively prior to the development of the current generation of axial extensometers.

Heating Systems

When fatigue testing is conducted at elevated temperatures, any method that can heat the specimen to the desired temperature and be adaptable to the existing test equipment might be used. The key to choosing the appropriate heating method depends primarily on ease of use and the ability to obtain the desired temperatures and thermal gradients. According to ASTM E 606, the thermal gradient within the gage section must be within 2 °C (3.6 °F) or 1% of the test temperature, whichever is larger. Also, the nominal temperature should not vary during the test by more than ± 2 °C (± 3.6 °F). These requirements are not overly restrictive, but do require some consideration and effort to achieve. There are various heating methods that can easily attain these limits and have proven themselves for use with fatigue testing; these methods are discussed in this section. Test results not meeting ASTM standards should be so indicated and the deviation quantified.

Induction Heating. One of the most versatile methods of heating and probably the most widely used for low-cycle fatigue of metallic materials is direct induction heating. Induction heaters generate either audio or radio frequency electromagnetic fields to induce eddy currents in the near surface of a test specimen. The current is passed from the induction generator into water-cooled copper tubing wrapped into coils, which surround the specimen. These coils can be made to fit any size or shape of specimen, making this system of heating highly versatile. The tubing is normally covered with a high-temperature insulating material to prevent accidental shorting between coils. There is generally no limitation on the maximum temperature that can be obtained using induction heating, provided that the induction generator has sufficient capacity and that adequate cooling is available for the working coils. For the majority of test specimens and materials, a 5 kW induction heater will suffice. These types of heaters have very low thermal mass and are ideal for rapid thermal cycling, such as would be needed for TMF testing. The major disadvantage of induction heating is the difficulty in establishing the required thermal gradient. Localized heating can readily occur with temperatures varying by as much as 20 °C (36 °F) over short distances (e.g., 6 mm, or 0.25 in.). Manipulating the position and proximity of the induction coils can bring these gradients into compliance with requirements. Unfortunately, this process is more art than science. At least one method has been developed (see Fig. 11) that separates the coil into three independent segments (Ref 15). Each segment can be moved while the specimen is at temperature, thereby greatly reducing the time required to establish an acceptable thermal gradient.

Fig. 11 Adjustable work coil fixture for direct induction heating in elevated-temperature fatigue testing

Another disadvantage to direct induction heating is that temperature measurement requires thermocouples to be bonded to the specimen (i.e., welded). If there is poor contact between the specimen and the thermocouple, the thermocouple will be independently heated by the induction field and give erroneous readings. Unfortunately, welding thermocouples onto the gage of the sample may initiate premature cracking. There are at least three ways to work around the thermocouple attachment problem. First, one can weld the control thermocouple to a place other than the gage section, such as the grip. The temperature relation between the gage section and the grip would have to be determined with a calibration specimen and shown to be constant from one specimen to

the next. Second, one can use a noncontacting temperature-measurement device (e.g., optical pyrometer). Third, one can use susceptor heating. In this method, a susceptor material—usually SiC, graphite, or metal—is placed within the induction coil. The induction field heats the susceptor, which in turn radiates heat to the specimen. This method is commonly used for materials that are poor electrical conductors. Even though a susceptor is used, some amount of coupling between the induction field and the specimen can still occur. Also, a susceptor has a larger thermal mass, and the temperature of the specimen cannot be changed as quickly as by direct induction. Therefore, this type of heating may have limited use for TMF testing.

Radiant Heating. Another type of heating, quartz-lamp radiant heating, works particularly well with flat specimens (but has also been used successfully with cylindrical specimens). With this method, radiant energy is focused onto the specimen by means of a parabolic reflector. Because the lamps are designed for a specific focal length, which ensures a certain area of constant temperature, they are not readily adaptable to specimens and test set-ups other than for the purpose for which they were originally designed. The lamps have very fast heating rates and are suited for moderately rapid thermal cycling. Care must be taken to ensure that the specimen is not shadowed by instrumentation.

Radiant heating using wire resistance coils in a hollow furnace is also a common heating method. Muffle furnaces, either split or in one piece, can be used, but these are typically large. Smaller furnaces can be constructed out of banks of individual heating elements or of continuous windings of Nichrome wire for specific applications. Both furnace types can be manufactured in single- or multi-zone configurations. These furnaces provide uniform and constant temperatures with very low thermal gradients and are ideally suited for long-term exposures. Because the area within the furnace is essentially at the same temperature, thermocouples need not be in intimate contact with the specimen. This permits the use of wrap-around and probe-type thermocouples. However, the furnaces are generally large, which increases the distance between the load platens resulting in a less-stiff load train. Also, access to the specimen with instrumentation is difficult and must be considered before the furnace is constructed in order to include a sufficient number of properly sized ports. Finally, the very large thermal mass of these systems makes them poorly suited for rapid thermal cycling. A highly specialized radiant heating system consists of a silicon carbide heating element that is inserted inside a tubular specimen and radiates heat to the inside surface of the specimen. The presence of thermal gradients throughout the wall and along the length is a disadvantage, but this disadvantage is offset by entirely freeing up the external-surface outer diameter of the specimen for any extensometry or other measurement paraphernalia (Ref 14).

Direct resistance heating is another specialty heating technique that has been used to advantage for elevated-temperature fatigue tests including TMF (Ref 16, 17, and 18). The specimen itself becomes the heating element. Although a metallic specimen possesses a low electrical resistance, passing a very high current (on the order of a kiloampere) directly through the specimen will produce heat within the specimen that is proportional to the product of the current times the voltage drop across the length of the specimen. Extraordinarily high rates of heating are attainable. Transverse temperature gradients are inherently small compared to other heating techniques because the heat is generated uniformly within the material. Heat transfer is not necessary to heat the interior, because heat is being generated uniformly throughout the volume of a uniform test section at the same rate as at the surface. Actually, the center of the specimen may be ever so slightly hotter than the surface because of radiation losses and the slightly higher heat flow rate of surface material. Extensive water cooling is necessary to prevent oxidation and contact resistance of all high-current connections, including those of the specimen to its grips. Water cooling assists rapid specimen cooling when TMF tests are conducted. Disadvantages of direct resistance heating include safety concerns regarding large currents and the potential for inadvertent short circuit arcs that could produce instant molten metal and severe burns. Large currents also introduce control difficulties and high magnetic fields, causing interference with sensitive electronic control equipment indigenous to modern fatigue testing systems.

Temperature Control. With all heating methods, temperature is commonly controlled using commercially available, solid-state temperature controllers. These controllers can be purchased with resolutions far superior to what is needed for fatigue testing. Proportional-integral-derivative (PID) control settings can be adjusted to maintain the control temperature to within 0.1 °C of the desired temperature. These controllers can be operated manually or programmed to follow a signal generator output. Hence, temperature cycling can be phased with mechanical strain cycling during a TMF test.

To minimize temperature variations during testing due to air currents in the laboratory, it is recommended that an enclosure be installed around the zone of the specimen. Another important concern for all methods of

specimen heating is unwanted electronic interference created by the temperature controllers. Unless an off-the-shelf engineered testing system is purchased, care is required to shield or filter troublesome signals.

Environmental Chambers

When environments other than still laboratory air are desired, an environmental chamber must be used (Fig. 12). Examples include a vacuum or inert gases (argon, helium) to eliminate effects of oxidation at high temperatures; high pressure; high-temperature gases, such as oxygen or hydrogen to simulate liquid rocket engine environments; radiation from radioactive sources for the study of nuclear reactor components; cryogenic environments for the study of alloys used in super-cold applications; or even corrosive environments that can degrade the fatigue properties of a material. Each environment poses its own set of concerns for the protection of grips, extensometry, and load cells. If, for example, a vacuum or pressurized chamber is required, any parasitic loads transmitted through the structural components required to maintain the environment (e.g., seals, baffles, or bellows) must be eliminated from the load cell signal.

Fig. 12 Environmental chamber for fatigue testing

Careful attention must be given to gaining access to the specimen and grips for installation and removal of specimens, and the attachment and support of extensometry. Viewing ports are also highly desirable. For sealed systems, insulated electrical feed-through connectors are required for transducer signals (e.g., strain, pressure, and temperature).

Representation of Material and Specimen Configurations

A specimen is a representative sample of an alloy and is used to determine and compare the basic fatigue characteristics of a material. In addition to this primary use, specimens can be designed to study the effects on fatigue resistance of several important factors. These factors can be categorized as:

- *Geometric features*, such as stress concentrations including intentional notches, holes, fillet radii, and attachment configurations; unintentional voids or flaws; and damage due to handling or service use

- *Bulk properties*, such as those influenced by degree and orientation of cold working, temperature of testing, thermal exposure, heat treatment, and radiation
- *Surface-related effects*, including mechanical surface finish, shot peening, burnishing, laser shock treatment, residual stresses, environmental interactions, fretting, galling, and coatings
- *Loading-related factors*, such as mean stress, multiaxiality, cumulative damage, temperature of testing, thermal cycling, and creep-fatigue interaction that might occur at low testing frequency and hold times

Nomenclature for a typical fatigue specimen is given in Fig. 13. A test specimen has three sections: the test section, a transition zone, and the two grip ends. The test section is where the quoted stresses, strains, temperature, and environment are measured or controlled and where fatigue cracking and failure are designed to occur. The majority of the specimen deformation occurs in this section. The grip ends are designed to transfer load from the test machine grips to the test section and may be identical at either end, particularly for axial fatigue tests. The transition from the grip ends to the test area is designed with large, smoothly blended radii to minimize stress concentration in the transition, which could otherwise initiate undesired fatigue cracking.

Fig. 13 Nomenclature for a typical fatigue specimen. Ends of round specimens may have smooth shanks, button heads, or threads. Smooth shanks should be long enough to accommodate some type of wedge grip. Rectangular specimens are generally made with smooth shanks, but may be shouldered to contain a hole for a pin bearing.

The design and type of specimen used depends on the fatigue testing machine and the objective of the fatigue study. The test section in the specimen is reduced in cross section to increase the stresses and strains there and, hence, avoid failure in the transition region and in the grip ends. The test section should be proportioned to properly test the material, accounting for adequate sampling of specific microstructural features (e.g., defects and grain size), yet still be small enough that the load capacity of the load frame is not exceeded.

The location from which a test specimen is taken from the initial product form is important because the manner in which a material is processed influences the uniformity of microstructure along the length of the product as well as through its thickness. For example, the properties of metal cut from castings are influenced by the rate of cooling and by shrinkage stresses at changes in section. Generally, specimens taken from the surface of castings are stronger. Many ASTM standards, such as E 8 and B 557, provide guidance in the selection of test specimen orientation relative to the rolling direction of the plate or the major forming axes of other types of products, and in the selection of test specimen location relative to the surface of the product.

Orientation is also important to standardize test results relative to the directionality of properties that often develops in the microstructure of materials during processing. Some causes of directionality include the fibering of inclusions in steels, the formation of crystallographic textures in most metals and alloys, and preferred growth directions in directionally solidified and single-crystal materials.

Specimen Machining and Surface Preparation

Because fatigue crack initiation typically is surface dependent, proper machining and surface preparation of test specimens are critical. Unless care is taken, scatter caused by variable surface conditions will overwhelm the inherent scatter of the material being studied.

Because a primary aim of fatigue testing is comparison of materials, uniform preparation procedures must be established. Machining operations must not alter the surface structure of the metal; thus, heat generation, heavy cutting, and severe grinding are prohibited. Final machining should be parallel to the direction of applied stress. Transition fillets must be blended into the test area without steps or undercutting. Surface polishing using metallographic techniques is preferred for smooth specimens, where machining marks are removed by a sequence of grinding steps. Example procedures for machining of specimens are given in ASTM E 466 and Ref 19.

The final polishing is not a buffing operation, but a cutting operation that uses lapping compounds or aluminum oxide powder in a liquid medium to remove grinding scratches. For flat sheet or plate specimens, edges should be slightly rounded and ground to eliminate nicks, dents, cuts, and sharp edges, which can lead to premature crack initiation. The relationship between surface characteristics and fatigue properties is discussed later in this article.

Test specimens received from a machine shop are expected to meet size specifications provided to the shop. To ensure dimensional accuracy, however, each test specimen should be measured prior to testing. Gage length, fillet radius, and cross-sectional dimensions are easily measured. Cylindrical test specimens should be measured for concentricity. Maintaining acceptable concentricity is extremely important in minimizing unintended bending stresses.

In general, flat specimens are difficult to manufacture without twisting or bending; especially if they are taken from rolled products. The potential warping of thin specimens and their inadequate section modulus lead to ready elastic buckling under compressive loads. Therefore, these types of specimens are usually only tested in tension. Lateral antibuckling guides can be used to prevent buckling of compressively loaded thin flat specimens (Ref 20). However, the buckling guides introduce other problems (surface contact and small amounts of rubbing action at points of contact) that can affect the fatigue properties.

The product form from which the specimen is taken often influences the geometry of a test specimen. Obviously, only flat specimens can be obtained from sheet products. Test specimens taken from thick plates or bar stock may be either round or flat. Occasionally, subscale specimens must be employed if the product form is too small for standard specimen dimensions.

Cylindrical Specimens. Three types of specimens with circular cross sections are commonly used:

- Specimens with tangentially blending fillets between the test section and the grip ends (Fig. 14a and b)
- Specimens with a continuous radius between the grip ends with the minimum diameter at the center (Fig. 14b and d and 15a). These are referred to as hourglass specimens and are commonly used when strain ranges are larger than 2%.
- Specimens for use in cantilever-beam loading with tapered diameters proportioned to produce nominally constant stress along the test section

Fig. 14 Typical fatigue test specimens. (a) Torsional specimen. (b) Rotating-beam specimen. (c) Plate specimen for cantilever reverse bending. (d) Axial loading specimen

The design of the grip ends depends on the machine design and the gripping devices used. Round specimens for axial fatigue machines using grip inserts like those shown in Fig. 10 may be threaded, button-head, or smooth-shank types. For rotating-beam machines, short tapered grip ends with internal threads are used, and the specimen is pulled into the grip by a draw bar. A long, smooth shank end is used on machines with lathe-type collets.

Flat Sheet and Plate Specimens. Generally, flat specimens for either axial or bending fatigue tests are reduced in width in the test section but may have small thickness reductions as well. The most commonly used types include:

- Specimens with tangentially blending fillets between the test section and the grip ends (Fig. 15c). This specimen has a straight gage section and is used in both axial and bending fatigue.

- Specimens with a continuous radius between the grip ends, giving a flat hourglass design (Fig. 15d). These are also used in both axial and bending fatigue test.
- Specimens for use in cantilever reverse-bending tests with tapered widths (Fig. 14c)

Flat specimens generally are clamped in flat wedge-type grips or may be held with a stiff bolted clamp/joint friction grip for reversed axial loading. Pin loading can be used when only tensile loads are encountered. When pin loading is utilized, the holes drilled in the grip end must be designed to avoid shear or bearing failures at the holes, tensile failure between the holes at maximum load, and fatigue cracking at the holes in the grip end. In axial fatigue testing of flat sheet specimens, the test length and cross section must be designed to prevent premature buckling of the specimen.

(b) Round specimen with tangentially blended fillets between test section and grip ends. (c) Flat specimen with tangentially blended fillets between test section and grip ends. (d) Flat specimen with continuous radius between the grip ends

Alignment Considerations

The keys to achieving accurate fatigue data include ensuring that applied loading is aligned with the specimen axis. This is particularly important in axially loaded specimens. Poor and nonreproducible alignment produces bending strains that reduce the fatigue life and increase the scatter in the data. In fact, it has been calculated that the largest contributing factor to scatter in LCF data is due to bending (Ref 21). Bending strains arise when there is a misalignment somewhere in the load train. The axially and concentricity of the actuator, grips, test specimen, and load cell should be verified and corrected if there is a problem. Coarse adjustments can be made by removing the preload and loosening the load train. These components can then be shifted and/or shimmed to gain proper alignment. Once the load train has been retightened, the small bending strains, *which always exist*, must be measured and minimized. This is typically done by using a strain-gaged trial test specimen, which allows bending strains to be calculated as a function of position along the test specimen, using the same material and test set-up as used in the actual test program. This process can be somewhat involved, and ASTM E 1020 describes it, along with many articles (Ref 22, 23, 24, and 25).

During axial loading, the bending strains should be kept below a specified amount, as described in various fatigue testing standards. For example, ASTM E 606 recommends that the maximum bending strain should not exceed 5% of the minimum axial strain range used during the test. If the bending strains exceed these amounts, the test rig must be further aligned. In past years, this was done by a trial and error method similar to the coarse adjustment procedure described above. This process could take days of effort to achieve moderate bending results. Recently, a new device has been developed (Fig. 16), which fits into one end of the load train (Fig. 8) and allows adjustment of both angular and concentric components of bending while the load train is under preload. This reduces the time needed for achieving proper alignment to within a few hours.

Fig. 16 Alignment fixture for minimizing bending strains in axial fatigue testing

The amount of bending strain in the specimen is affected by gripping methods and specimen design. Better alignment can be achieved using collet, wedge, and button-head grips. Threaded specimens generally give poorer alignment with equally poor reproducibility. Likewise, wear and oxidation of the grips can lead to poor alignment.

Graphic Recorders

In addition to software-based digital recording methods, analog recording devices are also commonly employed for materials testing applications. Strip-chart recorders, enabling time-based paper chart records of various control and response variables, are used. Generally, the strip chart record is used to provide a means to diagnose why a test went off-line, if it does so prior to failure, and to record the gross response variable behavior (e.g., load response) at the point of incipient failure under strain control conditions. Most pen-based strip chart recorders are useful for lower-frequency testing applications (e.g., <1 Hz), because their limited frequency response precludes use to higher frequencies. XY recorders are also commonly employed to record material stress-strain (load-displacement) response or hysteresis loop response in fatigue tests. XY and strip-chart recorders often feature a selection of preset gain ranges (e.g., 0.1 V, 1 V, 10 V or 1 V, 2 V, 5 V, 10 V) for use in plotting signals from the test system. For materials testing applications, it is most desirable that the preset gain controls offer ranges that approximately double the value of the previous setting with each subsequent setting (e.g., 1 V, 2 V, 5 V, 10 V). Analog recorders of these types are often used in conjunction with digital controllers and associated software due to the additional flexibility offered.

Fatigue, Creep Fatigue, and Thermomechanical Fatigue Life Testing

Gary R. Halford and Bradley A. Lerch, Glenn Research Center at Lewis Field, National Aeronautics and Space Administration; Michael A. McGaw, McGaw Technology, Inc.

Electronic Test Controls

Electronic test controls (controllers) are used to adjust and maintain the desired control parameter(s) for a given fatigue test. Controllers also provide test termination capabilities for many criteria, for example, failure, load drop-off, deflection, or extension limit excellence. Modern fatigue testing is generally performed using closed-loop servocontrollers, wherein the controlled parameter is continually sensed and compared to the desired command, and the result of this comparison, the error signal, is used to drive the actuator (which may be hydraulic or electromechanical in nature). Sensors for measuring the relevant mechanical quantities (e.g., load cells and extensometers, as discussed elsewhere in this article) provide the feedback, and the control mode of the test is defined by the sensor being used for feedback control. Control is typically effected through a PID strategy wherein the error signal is amplified by gain terms that can be independent of time (proportional gain), as well as dependent on time (integral and derivative gain). A typical closed-loop control system is shown in Fig. 17.

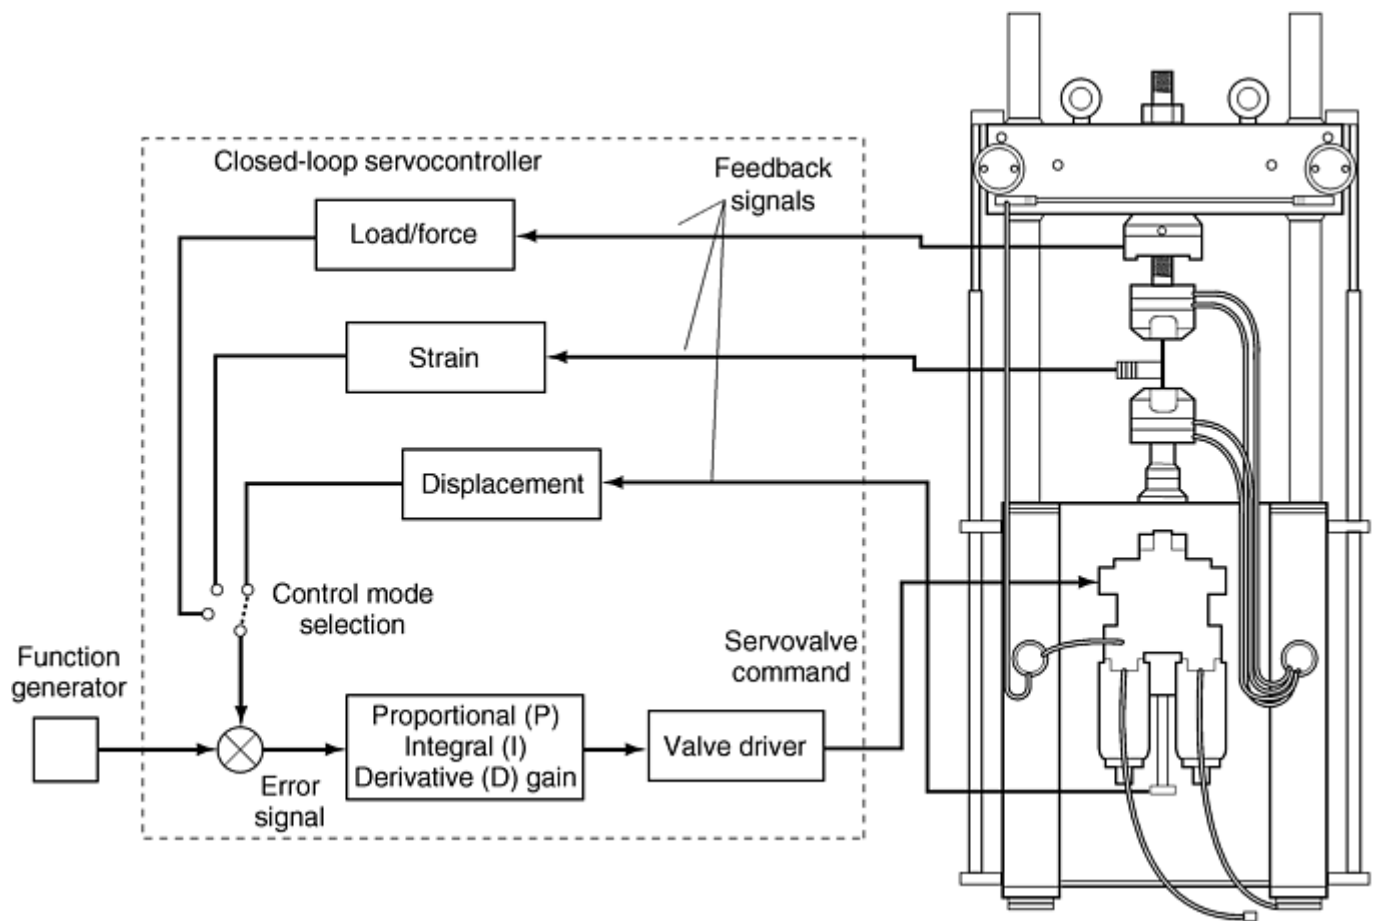

Fig. 17 Typical closed-loop servocontroller system for fatigue testing

A functional fatigue testing machine requires the ability to flexibly define test needs with regard to command waveform generation and data acquisition. A variety of technologies are available to accomplish closed loop control of materials testing systems, in performing standard materials tests, and for the development of custom testing applications. This section discusses these technologies and particularly focuses on the state of the art of software tools for materials testing.

Load Frames: Analog and Digital Controls

Analog controllers are the most commonly used test controllers in fatigue testing laboratories today. Analog controllers have been brought to a high level of refinement, and the latest examples exhibit relatively low noise and reasonably wide-frequency bandwidth. Analog controllers typically provide numerous inputs and outputs that can be used to flexibly adapt to nearly any testing requirement. In addition, materials testing applications software that is designed for analog controllers can be used broadly on many different controller models. The disadvantages of analog controls include the fact that many models do not provide the ability to switch control modes while the test system is energized (under hydraulic pressure), and that calibration of the sensors and the test controller is typically done through trim pot adjustments, a process that can be time consuming.

Digital controllers have been available for the past several years, and the usability of these controllers continues to improve with each new generation. The fundamental difference between an analog controller and a digital controller centers on the summing junction (Fig. 17). A digital controller closes the control loop using a microprocessor instead of continuous-signal analog amplifiers. In a digital controller, the loop closure rate (the rate at which the microprocessor must update the control loop) is directly related to the maximum test frequency performance (i.e., bandwidth) that can be attained. The loop closure rates required for servohydraulic systems demand very-high-performance digital systems. One of the factors driving the development of digital controls is that control mode switching is simpler, as the loop is digital, and many of the problems relating to offset error in analog systems are not present in their digital counterparts. In addition, from a manufacturer's viewpoint, the cost of digital technology continues to drop (for a given level of performance), and the

manufacturing of digitally based products is inherently simpler, owing to fewer required circuit trim adjustments. The chief disadvantages of digital controllers are that changes to the controller organization cannot be done except through software modification of the controller, effectively isolating the user from making any change, and digital controllers generally require software graphical user interfaces. Most digital controller operator interfaces can be labyrinthine to navigate and use, complicating their use and increasing the probability of user mistakes.

Comparison of Analog and Digital Controllers. Both analog and digital control technologies are available for use in performing materials tests, and it is not possible to make definitive statements regarding the superiority of either technology for materials testing needs. The decision as to which controller technology to use may be more prosaic as well: life cycle costs and training costs, among others, must be carefully considered before a choice is rendered. Because analog controllers provide a nearly universal interface for admitting external program command signals, as well as provide high-level conditioned transducer signals for data acquisition, they are easily interfaced to computers for test control purposes. The software created can be generally applied to testing needs regardless of the specific manufacturer's model of the analog servocontroller. Digital controllers, on the other hand, feature software that is based on the "command set" for the specific controller. Thus, materials testing needs that cannot be realized from off-the-shelf software must be custom developed, and any such software is uniquely tied to that specific digital controller model. Finally, analog controllers have a demonstrated longevity, whereas the digital controller will likely have a much more rapid obsolescence, owing to the rapid evolution of digital components.

Furnace Controls

The control of furnaces used in materials testing is largely accomplished using closed-loop temperature controls. Because thermal processes inherently vary slowly (therefore the control loop update rate requirements are relatively modest), and because the costs of microprocessor technology continue to drop, nearly all temperature controllers available today are digitally based. Care must be exercised when selecting a given temperature controller to ensure that it is compatible with the control input requirements of the heating system that is being used. If thermomechanical tests are contemplated, or other nonisothermal temperature requirements are being contemplated, the temperature controller must have facilities for varying the temperature set point, either by means of an external command signal or with a controller command set. Of the two, facilities for accepting an external command signal are preferred, because this provides the greatest flexibility and simplicity in the test apparatus.

Test Program Development and Software

Software systems for performing materials tests have been in use for approximately 25 years (Ref 26). During this period, computer technology has changed dramatically, but, ironically, testing needs have not. Scientists and engineers have a continuing need for flexible and powerful tools to design and conduct materials tests, be they standard tests or unique experiments representative of research and development efforts. Software systems developed to satisfy testing needs have typically been developed along three lines: single application software created uniquely to meet a specific testing requirement (e.g., ASTM E 606), general-purpose testing software designed to provide a flexible set of tools that can be used to implement a broad spectrum of testing requirements, and lastly, custom-written test application software.

Single-Purpose Software. Software for performing standardized tests is widely available from several vendors, operating for both analog and digital servocontrollers. Materials testing engineers charged with conducting standardized materials tests are strongly encouraged to review commercially available offerings before considering custom-application software development. Most specific test requirements (e.g., high-cycle fatigue, low-cycle fatigue, and fatigue crack growth) are well represented by commercially available application software. While the cost of commercial materials testing software is significant, custom-application development is not trivial and is time consuming.

General-Purpose Software. Several examples of general-purpose testing software are readily available from a variety of vendors. Generally, these applications operate on a PC interfaced (in varying degrees of complexity) to a servocontroller, either digital (Ref 27, 28, and 29) or analog and/or digital (Ref 30, 31, 32, 33, and 34). These tools permit the construction of reasonably complicated test sequences and provide for data acquisition

needs. Some systems provide the ability to build test sequences that are limit programmed (e.g., a load-controlled, strain-limited waveform), can offer multimode test control (e.g., dynamically switching control modes during the test), and can provide the ability to perform calculated control of either or both the control variable, as well as the significant waveform parameters (e.g., amplitude, rate, and frequency) (Fig. 18). Examples of the testing applications that can be accomplished with this class of testing software include TMF, biaxial and multiaxial fatigue, creep-fatigue, and bithermal fatigue. These general-purpose systems have grown in sophistication to the point where one must carefully consider one's testing needs before embarking on a custom-application programming project; often, the general-purpose system can provide the quicker solution and at a much more attractive cost.

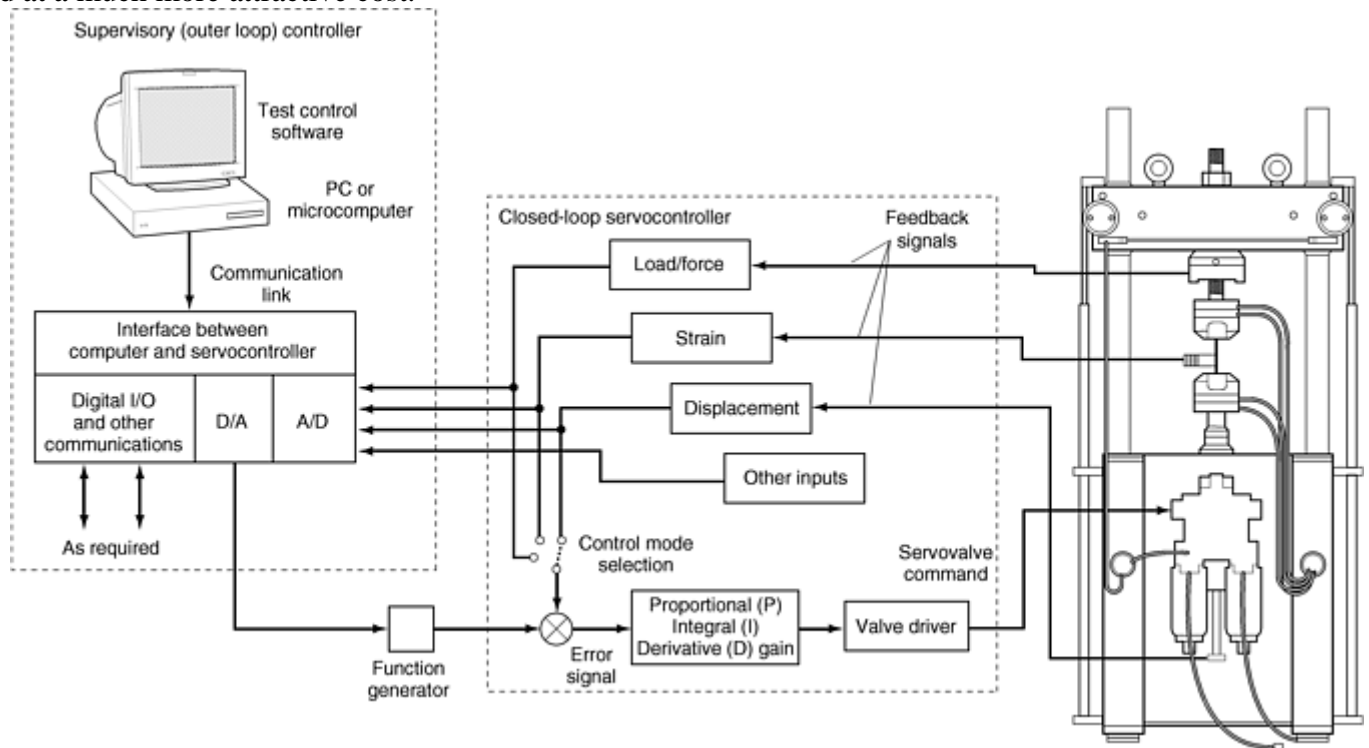

Fig. 18 Typical supervisory (outer loop) calculated-variable controller system for fatigue testing

Custom-Application Software. When testing requirements are very specific and unique, materials testing engineers must often develop their own materials testing application software. The approach taken can vary widely depending on the nature of the test controller and the needs of the application.

Data Acquisition Requirements. Regardless of the approach taken with respect to testing software, certain data acquisition requirements must be met with regard to the amount of data collected, the rate of collection, and the overall accuracy of the data collected. Fatigue tests involving the use of sinusoidal waveforms (commonly used for high-cycle fatigue testing), for example, typically require a data collection rate of fifty points per cycle to enable the cycle to be accurately rendered. A triangular waveform is most often used for low-cycle fatigue testing. Accurately rendering a hysteresis loop in this case requires a data collection rate of up to four hundred points per cycle. When selecting or evaluating data acquisition capabilities for fatigue testing, consideration must also be given to the specific properties of the analog/digital (A/D) system: important characteristics include resolution, accuracy, and noise level. Another important characteristic concerns how the A/D system handles multichannel signal input. Typically, two approaches are taken. The first and most common approach is to simply multiplex the input signals to the A/D system. A concern here is the potential for channel-to-channel data skew: each channel scanned is obtained at a different time than the others. Depending on the conversion rate of the A/D system and the testing frequency being employed, the channel skew can be significant. A second approach for handling multichannel inputs is to use a simultaneous sample and hold amplifier for each channel. In this approach, all channels are sampled and held at the same time and are then multiplexed to the A/D for conversion. Yet other data acquisition systems employ individual A/D converters for each input channel (see ASTM E 1856 for a more detailed discussion of this topic).

Data Analysis. The software available for data analysis largely mirrors that available for testing applications; the standardized test applications generally have built-in data analysis and reporting capabilities, optimized to

report test results in standardized formats. However, test data obtained from general-purpose testing software, and especially data obtained from custom-application programs, must generally be imported into a data analysis program. The most common data analysis programs are the scientific data analysis and plotting applications widely available from many vendors. Another popular method is to import test data into spreadsheet programs. Many of the scientific analysis packages (as well as the spreadsheet programs) provide the ability to develop reasonably sophisticated analysis algorithms (“macros” in spreadsheets, for example), thus providing a convenient and powerful means of data analysis and presentation.

Fatigue, Creep Fatigue, and Thermomechanical Fatigue Life Testing

Gary R. Halford and Bradley A. Lerch, Glenn Research Center at Lewis Field, National Aeronautics and Space Administration; Michael A. McGaw, McGaw Technology, Inc.

Baseline Isothermal Fatigue Testing

It is important to understand the underlying purposes of the testing to be performed. This understanding will aid in selecting a fatigue testing machine and specimen design. Normally, a baseline condition is established from which effects on fatigue life of a wide variety of variables might be assessed. Laboratory ambient conditions of room temperature, atmospheric pressure, and humidity are a commonly accepted condition for baseline testing; however, other choices of, for instance, temperature may be more appropriate. Baseline testing is usually performed with the numerous fatigue life-influencing variables held constant at what would be considered “default” conditions. For example, completely reversed loading (zero mean stress) may be used, or perhaps zero-to-maximum loading is preferred owing to the nominal zero-to-maximum loadings expected in service. Note that rotating-beam machines are incapable of mechanically imposing mean stresses. If mean stress assessment is contemplated for testing beyond the baseline, a different type fatigue machine is required. The acquired baseline database may have value in serving any of several diverse purposes:

- Ranking fatigue resistance of alloys
- Performing micromechanistic studies
- Guiding development of fatigue-life prediction models
- Collecting statistical documentation
- Establishing fatigue design curves
- Conducting failure analysis

Testing Regime. Of additional importance is the fatigue-life regime of interest—low-cycle or high-cycle fatigue. As discussed earlier, the amount of time available for testing, along with the number of companion machines and their cyclic frequency capability, will dictate which type of machine is best suited for the task at hand. For fatigue lives far beyond 10^5 , a high frequency of testing is a necessity. However, at lives well below 10^5 , high frequency is a liability, not an asset. With the exception of very high cyclic lives, servohydraulic direct-stress testing machines offer the greatest possible versatility in testing machines today. Specially designed, and hence costly, commercially available servohydraulic machines can achieve 1000 Hz.

Calibration and Standard Test Procedures. Once equipped with an appropriate fatigue testing machine and a specimen design, it is important to follow applicable standards for testing (e.g., ASTM and ISO standards). The major items covered by ASTM standards include calibration of, for example, load cells, extensometers, other sensors, read-out equipment, and recorders for data storage; alignment of the loading axis of the testing machine with grips and with the test specimen; specimen design, including alignment of the test section with grip ends; surface finish; material quality control from specimen to specimen; and purity of loading command signals. Table 1 lists the currently applicable ASTM standards for baseline (and associated) fatigue testing.

Adhering to testing standards is particularly important in fatigue testing due to the inherently high degree of scatter in fatigue resistance. In creating the standards, efforts were made to ensure uniformity of specimen geometry, surface finish, loading alignment and gripping, temperature and humidity (for alloys sensitive to moisture level), and uniformity in all aspects of the testing machine frame and loading train, its ancillary equipment, controllers, recorders, data storage, and data manipulation.

Generating Fatigue Crack Initiation Data. The loading mode, life regime, test temperature and environmental conditions, mean stress, surface finish, and heat treatment condition, among others, dictate the testing machine and ancillary equipment required. Once these are in place and calibrated and the representative test specimens have been prepared, a baseline fatigue testing program can be conducted. If the program involves several variables, it is wise to first perform a design-of-experiments study to maximize the information to be obtained while minimizing the number of tests and attendant costs. In any event, it should be noted that the cost of specimen preparation is usually not the dominant cost in a fatigue testing program. It is wise to ensure that a sufficient excess of specimens is made to more than adequately cover the initial number required in the program. Having specimens left over from a baseline study is often beneficial, particularly if additional factors are to be studied and if scatter in fatigue lives has been great enough to warrant additional tests to better establish the statistical results. It is generally not possible to duplicate the specimen consistency at a much later date, so it is better to have extra, rather than not enough, specimens to begin a test program.

It is advisable to estimate the expected fatigue life of any test prior to starting the test to avoid excessively long or short test times. Past testing experience with similar materials is valuable in making life estimates. Empirical equations have been published for estimating fatigue resistance based on conventional tensile test data for the material, temperature, and environment of interest. The equations of Manson (Ref 35) and Morrow (Ref 36)

have proven invaluable in this regard (see Eq 1, which follows). In fact, the method of universal slopes (MUS) has been used to bypass fatigue testing (Ref 35). With appropriate factors of safety, the MUS has been used in the establishment of low-cycle fatigue design curves for many of the alloys used in the main engines of the US space shuttle (Ref 37). The fatigue resistance of a large number of alloys in a variety of heat-treated conditions over a range of temperatures and aggressive environments has been established in this manner.

If a broad range of testing times are to be involved, it is also advisable to conduct the shortest-time tests first, then take advantage of these results to govern the loading levels applied for the longest-life tests. One should avoid running tests that must be discontinued. Considerably less information is gained from such “run-outs.”

Sufficient tests should be run to failure over the range of variables studied to permit a statistical assessment of the results. This is particularly true for the baseline results from which other fatigue test results are to be compared.

The extent to which the test data are recorded *during testing* depends on the end use of the fatigue data. In high-cycle fatigue, most alloys behave nominally elastically, and there is little reason to monitor test parameters during the test, as there will be little (if any) change to observe until fatigue failure is imminent. However, in strain-controlled low-cycle fatigue with observable amounts of plasticity, significant changes might occur that warrant recording, for example, cyclic strain hardening or softening, relaxation of mean stress, and even cyclic stress-strain response changes due to crack nucleation. It is quite important to be able to monitor these changes during testing. For example, the hysteresis loop at “half-life” is usually chosen to be the representative loop of the entire fatigue test. This loop provides the values of the stress amplitude, stress range, mean stress, total strain range, inelastic (plastic) strain range, and the elastic strain range that are tabulated along with the number of cycles to failure. Since the number of cycles to failure is not known until after the test has passed the half-life point, it is necessary to monitor and record this information either continuously or at intervals close enough to be able to interpolate to the half-life condition once the test has failed.

Baseline fatigue data are generally tabulated and plotted. Schematic fatigue curves (Ref 38) are shown in Fig. 19(a) for strong, tough, and ductile alloys. The corresponding stress-strain hysteresis loops are depicted in Fig. 19(b). This figure illustrates the common observation that the number of cycles to failure for a 1.0% total strain range is approximately 1000 cycles, regardless of the strength or ductility level of an alloy when there is a trade-off between strength and ductility due to different alloy processing. Presuming an equation form, fatigue data can be analyzed using least-squares curve-fitting analyses. The most common equation form for low-cycle fatigue and for lives to about 10^6 cycles is:

$$\Delta\varepsilon_{\text{total}} = \Delta\varepsilon_{\text{elastic}} + \Delta\varepsilon_{\text{plastic}} = B(N_f)^b + C(N_f)^c \quad (\text{Eq 1})$$

where, $\Delta\varepsilon_{\text{total}}$ is the total mechanical strain range at half-life, $\Delta\varepsilon_{\text{elastic}}$ is the elastic strain range (equal to $\Delta\sigma/E$) at half-life, $\Delta\varepsilon_{\text{plastic}}$ is the plastic (inelastic) strain range at half-life, N_f is the number of cycles to failure, b is the slope of elastic strain-range life line on log-log coordinates, B is the intercept of elastic strain-range life line at $N_f = 1$, c is the slope of plastic strain-range life line on log-log coordinates, C is the intercept of plastic strain range life line at $N_f = 1$, $\Delta\sigma$ is the stress range at half-life, and E is the modulus of elasticity. The method of universal slopes that is used to estimate fatigue curves has the same form as Eq 1. The values of the “universalized slopes” are given by $b = -0.12$ and $c = -0.60$.

(a)

(b)

Fig. 19 Representation of the cyclic strain resistance of idealized alloys (strong, tough, ductile). (a) Fatigue curves. (b) Stress-strain hysteresis loops. After Ref 38

The corresponding values of the intercepts are determined from conventional tensile test results for the alloy at the temperature and environmental conditions of interest: $B = 3.5\sigma_{ult}/E$ and σ_{ult} is the ultimate tensile strength, and $C = D^{0.6}$. True ductility (also true fracture strain) is abbreviated D ; reduction of area in the tensile test is abbreviated RA.

$$D = \ln[(100)/(100 - \%RA)]$$

Morrow's formulation is similar and has seen widespread use in the automotive and off-highway equipment industries. It takes the following specific form:

$$\begin{aligned} (\Delta\varepsilon_{total}/2) &= (\Delta\varepsilon_{elastic}/2) + (\Delta\varepsilon_{plastic}/2) \\ &= (\sigma'_f/E)(2N_f)^b + \varepsilon'_f(2N_f)^c \end{aligned} \tag{Eq 2}$$

where $\Delta\varepsilon_{total}/2$ is the total mechanical strain amplitude at half-life, $\Delta\varepsilon_{elastic}/2$ is the elastic strain amplitude ($\Delta\sigma/2E$) at half-life, $\Delta\varepsilon_{plastic}/2$ is the plastic (inelastic) strain amplitude at half-life, $2N_f$ is the number of reversals to failure ($2 \times N_f$), b is the slope of the elastic strain-amplitude life line on log-log coordinates, σ'_f/E is the intercept of elastic strain amplitude life line at $2N_f = 1$, c is the slope of the plastic strain-amplitude life line on log-log coordinates, ε'_f is the intercept of plastic strain amplitude life line at $2N_f = 1$, and $\Delta\sigma/2$ is the stress amplitude at half-life.

Morrow's fatigue-life equation in its predictive form assumes the slopes and intercepts can be approximated from tensile test properties by $b = n/(5 + n)$, where n is the strain hardening exponent (the cyclic strain hardening exponent, n' , may give better predictions; $n' = b/c$; $c = 1/(5 + n)$); and $\sigma'_f/E = \sigma_f/E$ where σ_f is the true fracture stress (fracture load divided by fracture area). The true fracture strain is equal to the true ductility, D , is equal to ε'_f is equal to ε_f .

The slopes and intercepts from the equations above are referred to as the basic fatigue properties. Reference 39 contains an extensive listing of these fatigue properties, along with corresponding tensile properties, for a wide variety of steels, stainless steels, nickel-base superalloys, titanium alloys, aluminum alloys, weldments, and castings. How the fatigue properties might be affected by factors that influence fatigue behavior is discussed in the section “Testing for Effects of Variables on Fatigue Resistance” in this article.

In the high-cycle fatigue regime, that is, beyond approximately 10^6 cycles to failure, the log-log slopes of the fatigue curves tend to become shallower than at lower life levels. For certain steels and selected body-centered cubic (bcc) alloys, a fatigue or endurance limit of “infinite” life for cyclic stresses below the limit may be observed in laboratory fatigue test results. Such limits may be erased by interspersed low-cycle fatigue loadings that can break up the dislocation pinning by small interstitial atoms in the bcc structure. Under these circumstances, the fatigue curve continues to drop in strength level below the original fatigue limit. Slopes of the fatigue curve in the very-high-cycle fatigue regime may drop to -0.04 or less. Manson (Ref 40) has reported ultrahigh-cycle fatigue life extrapolation procedures.

Criteria for Defining Fatigue Life. The first and most common definition of fatigue life for alloy testing is the number of cycles of loading required for complete fracture of the specimen into two pieces. This definition is unequivocal. It is easy to identify this terminal event in most fatigue tests. (During strain-controlled tests at low strain amplitudes, cracking may reduce the stress level sufficiently so that the specimen never separates; in this case, some other definition of failure must be used.) At fracture, the specimen grips are free to move apart, allowing a mechanically activated switch to be tripped that stops the cyclic drive mechanism and the cycle counter. Electrical continuity of the specimen is also broken permitting direct electrical switching of circuits controlling the machine. Complete specimen separation is typically an acceptable measure of the crack initiation fatigue life for high-cycle fatigue wherein the fatigue crack nucleation portion dominates the total life (perhaps 90–99%). However, because the separation life does include a portion of cyclic crack growth, this quoted life is somewhat larger than the number of cycles to physically initiate a crack. As the fatigue loading levels increase and the cyclic lifetime decreases into the low-cycle fatigue regime, less and less of the life is spent nucleating a crack, and more and more life is spent growing the crack(s) to the critical length for sudden fracture into two pieces. To accurately define the cyclic crack initiation life, particularly in low-cycle fatigue, one ideally would measure the actual crack size (depth and length) as cycling progressed. When a predetermined crack size was reached, the number of cycles to “failure” would be noted and testing stopped. Unfortunately, this is highly impractical for most testing because it cannot be implemented on an automated basis for the large numbers of fatigue tests conducted annually.

The only practical definitions available are those based on measurements that are readily available from the test instrumentation. This is usually in the form of changes in specimen elastic or plastic “stiffness” as determined from stress-strain or load-deflection measurements. As a specimen develops a fatigue crack under completely reversed strain control, its growth causes the load carrying response of the specimen to decrease. Different degrees of drop in the cyclic load range for a fixed strain range have been used to define crack initiation failure for low-cycle fatigue testing. The most commonly used criteria have been the very first indications of an impending drop in the load range (i.e., impending cracking) and a 5% drop in the load range. Obviously other percentage drops (10, 20, and 50) could be defined and used. Unfortunately, it may be difficult to distinguish between load range drop due to cracking and load range drop due to cyclic strain softening of initially work hardened materials. Even cyclic strain hardening could confound the measurement by offsetting the drop due to cracking.

A logical way to separate the effects on load response of cyclic strain hardening or softening from cracking is to track the ratio of the peak tensile load to the peak compressive load (Ref 41). If only hardening or softening occurs, the load range will change, but the tensile/compressive load ratio will be affected very little. As fatigue cracking progresses, the decrease in the tensile load amplitude exceeds that of the decrease of the compressive load amplitude. This is observable in Fig. 20(a) from a load-versus-time trace for a low-cycle, completely reversed, strain-controlled test (Ref 42). As cracking occurs, the change of the load ratio is almost twice as much as the change in the load range, thus making it a more sensitive, as well as a more physically based, measure of cracking. The load response would also be observable in a stress-strain hysteresis loop. In compression, the crack faces close and carry load. This results in a cusp on the hysteresis loop near the compressive peak. In tension, the peak load is carried only by the smaller, uncracked area.

(b)

Fig. 20 Cyclic load response during strain-controlled low-cycle fatigue test of annealed AISI 304 stainless steel in air at 816 °C (1500 °F). Total strain range, 3.26%, 0.056 Hz. (a) Cyclic load response for defining cyclic life to crack initiation. (b) Cyclic load range and ratio of tensile to compressive peak load versus applied cycles. Source: Ref 42

To apply these criteria for defining fatigue crack initiation life, the load ratio must be measured during the precrack nucleation period. Note that the load ratio during this interval may not equal 1.00. It has been observed to vary from as low as 0.9 to about 1.05 depending on material. The ratio, however, is nominally independent of the amount of cyclic hardening or softening that occurs, and, hence, a greater duration of cyclic loading can be used to establish the average value of the ratio before cracking commences. A graphic quantitative example is given by Fig. 20(b) based on the data from Fig. 20(a). Both load ratio and load range are plotted versus applied cycles. The load ratio is relatively constant at 0.96 for the first half of the test, but, by about 100 cycles, it begins to drop steadily. At about 200 cycles, the ratio suddenly and inexplicably rises. This rise signals the end

of useful information from the test. Even though the specimen is still in one piece, the computed stresses and strains are no longer representative of what is going on in the gage length of the specimen. At this point, the dominant crack has grown to a large fraction of the specimen diameter, and the extensometer is subjected to large amounts of bending in addition to axial deformation. The specimen may not have failed completely, but the test has. The corresponding load range is also shown. After considerable initial hardening of 25%, a half-life (“stabilized”) value of 2800 lbf (12.5 kN) is reached. This is followed by an accelerating drop until complete fracture of the specimen occurs at greater than 214 cycles. For the particular test data shown, the load ratio and the load range follow approximately parallel behavior. For this example, a 5% drop in load range and load ratio corresponds to the same number of cycles (~138 cycles). Similarly, a 10% drop in both gives approximately 158 cycles. In this case, either the load range or the load ratio drop criteria would give acceptable definitions of fatigue crack initiation life. This is not expected to be the general case for the following reasons.

For a cyclically stable material with very little strain hardening within a hysteresis loop, a 5% load range drop would correspond to approximately a 10% drop in the load ratio if the only reason for load drop were the presence of a crack. This in turn would imply a 10% loss in specimen cross-sectional area if there were no concentration of stress surrounding the crack tip. However, since there is a concentration of stress in front of the crack, higher stresses are encountered there, thus increasing the tensile load-carrying capacity. Hence, a 10% loss of area would actually correspond to less than a 10% loss of load ratio. Load ratios in the neighborhood of 5 to 8% have been noted.

With modern automated data recording and reduction, it is possible to determine the fatigue life by all of these definitions, including complete fracture into two pieces. In this way, any definition of fatigue crack initiation life can be selected for the purposes at hand. References 41 and 42 contain tabulated fatigue crack initiation lives for several engineering alloys for the four criteria, as discussed above:

N_0	First indication of impending cracking
N_5	5% drop in load range from stabilized range (or at half-life value if stabilization does not occur)
N_i	10% drop in ratio of tensile to compressive load from stabilized range (or at half-life if stabilization does not occur)
N_f	Complete separation of specimen

Similar criteria based on the same concepts could be established for completely reversed, load-controlled tests. Instead of a decrease in load response due to cracking, an increase in strain or deflection response would be measured to define fatigue crack initiation.

Care should be exercised in applying these criteria when multiple cracks initiate parallel to one another. Many shallow cracks will have the same integrated effect on specimen gage length compliance as one deeper crack. In addition, the exact location of the crack(s) relative to the contact points (defining the gage length) of the extensometer can have an appreciable influence on the apparent (measured) compliance. For example, should cracking initiate outside the gage section, the extensometer would not detect a change in compliance. Should cracking initiate within the gage section, the load path would not necessarily remain along the centerline of the specimen, and bending would occur. This, in turn, can cause the extensometer to register different outputs depending on the plane of bending relative to orientation of the extensometer. These confounding influences also affect the load range drop criteria for crack initiation.

Information to be Documented for Baseline Fatigue Tests. Guidelines are presented for what baseline fatigue test information should be documented. Tables 2 and 3, respectively, provide comprehensive listings of pertinent pretest and in-test/post-test information to be considered for inclusion. In preparing Table 3, it was assumed that closed-loop; servostrain-controlled axial fatigue testing was the mode of operation. If other modes of testing are used, the guidelines may have to be altered accordingly. Obviously, the information gleaned from a fatigue test in progress will depend on the extent of instrumentation available, the type of testing machine, and the mode of testing.

Table 2 Pretest information guidelines for baseline fatigue tests including studies of preexisting effects on fatigue

Alloy designation and description	Heat number and composition, forming processes, degree of anisotropy, heat treatment and environmental preexposure conditions, final machining parameters, photomicrographs, hardness, tensile properties
Specimen	Drawing and specifications, orientation of axis to product form, accurately measured

configuration	specimens dimensions (including notch description) and area of cross section (diameter and area for direct stress mode of loading), surface finish and method of preparation, final heat treatment, individual specimen identification number, description of any coating including any processing affecting the surface layer (preoxidation, prefretting, galling, wear erosion, corrosion, carburizing, nitriding, anodizing, shot peening, laser-shock peening, burnishing, and other means of introducing residual stresses, magnitude, and sign of residual stresses, etc.), thickness, orientation of gripped specimen to testing machine
Testing machine	Designation of machine, type of grips, dates of last alignment and calibration of load cell, types of heating and environmental control, type of extensometer, and date of last calibration
Test engineer and operator	Names and dates of set-up and start of test
Test mode, control details, and test conditions	Model of control (e.g., strain, load or deflection), cyclic frequency and waveform including description of mean and alternating components, test temperature and mean of measurement and control, relative humidity and nature of environment, starting date and time error detector limits for shut-down, estimate of test duration and basis for estimate

Table 3 In-test and post-test information guidelines for baseline fatigue tests including studies of preexisting effects on fatigue

Cyclically varying parameters	Value of fixed test control parameters (e.g., stress, strain, or displacement); continuous recording of variations of maximum, minimum, amplitude, range, and mean values of stress and strain as a function of applied cycles; cycles variation of load range variation and ratio of tensile to compressive peak loads to help define failure life and help-life; continuous or periodic recording of variations of stress-strain hysteresis loops
Lifetime information	Cyclic failure lives based on various cyclic failure criteria; failure life (cycles and corresponding time) for criterion adopted; half-life cycles; total, inelastic, and elastic strain ranges at half-life; maximum, minimum, stress amplitude, stress range, mean stress, and mean stress ratio at half-life; degree of cyclic hardening and/or softening from first cycle to half-life (or cycles at stabilization of stress-strain response); description of fracture surface including initiation site(s); location of fracture relative to extensometer probes
Deviations from original test plans	Details of stress and strain history immediately prior to controlled or uncontrolled shut-downs prior to test completion
Data analysis from multiple specimens	Cyclic stress-strain curve and equation constants at half-life (or cycles at stabilization), fatigue curves and equation constants (i.e., fatigue properties)

Example Crack Initiation Fatigue-Life Curves. Fatigue curves are displayed in a variety of forms, although fatigue life is generally plotted on a logarithmic scale. The fatigue loading parameter is usually stress or strain. Stress is most commonly plotted as stress amplitude, stress range, or maximum stress, and the scale may be arithmetic or logarithmic. Examples are given in Fig. 21. These are referred to as *S-N* curves, and an indication of the mean stress ratio should always be given. When strain is the fatigue loading parameter, the total (elastic plus plastic), plastic, or the elastic strain ranges may be plotted. These are usually plotted on logarithmic scales, as shown in Fig. 22, and are referred to as strain-life curves. Unless the fatigue strain cycling ratio is given, it is understood that the curves represent completely reversed loading. The plastic strain-versus-life curve is known as the Manson-Coffin (or Coffin-Manson) low-cycle fatigue curve. The elastic strain range-versus-life curve has come to be known as the Basquin curve (Ref 43). The total strain range-versus-life representation of fatigue data has its origins in the late 1950s and early 1960s. Coffin (Ref 44) originally represented the elastic strain range-versus-life component of the total strain range-versus-life curve as a horizontal line with a strain range value equal to twice the 0.2% offset yield strength divided by the elastic modulus. Langer (Ref 45) used the same basic idea, but replaced the yield strength with the endurance limit strength. He went on to multiply the total strain amplitude by the modulus of elasticity to compute the pseudo-stress amplitude. The resultant fatigue

(*S-N*) curve could then be used in direct conjunction with elastic stress analyses. This representation was adopted by the ASME Code, Section III, for Boiler and Pressure Vessel components.

Fig. 21 Typical *S-N* diagrams for various alloys subjected to completely reversed loading at ambient temperature

Fig. 22 Typical strain-life fatigue curve showing elastic and plastic components, annealed 4340 steel

Manson (Ref 46) and Morrow (Ref 36) carried the fatigue curve representation a step further by recognizing that the elastic strain range-versus-life curve had a negative slope such as first observed by Basquin a half century earlier.

Out of the total strain range-versus-life representation of fatigue resistance comes an important observation and useful concept (e.g., see Ref 40). At some point along the fatigue curve, the elastic strain range and the plastic strain range will be equal. This point defines what is known as the transition fatigue life, $N_{f,trans}$, and the corresponding transition total strain range, $\Delta\epsilon_{total,trans}$, is equal to $2\Delta\epsilon_{plastic}$, which is equal to $2\Delta\epsilon_{elastic}$. Below the transition fatigue life, the behavior is clearly low-cycle fatigue as the plastic strain range dominates over the elastic strain range. Low cycle fatigue actually continues to higher lives beyond the transition life. High-cycle fatigue behavior, in which the elastic strain range overwhelmingly dominates over the plastic strain range, does not begin until at least one order of magnitude in life beyond the transition life.

Fatigue, Creep Fatigue, and Thermomechanical Fatigue Life Testing

Gary R. Halford and Bradley A. Lerch, Glenn Research Center at Lewis Field, National Aeronautics and Space Administration; Michael A. McGaw, McGaw Technology, Inc.

Testing for Effects of Variables on Fatigue Resistance

The fatigue resistance of an alloy is sensitive to a large number of variables. There are too many variables to investigate them all. To do so would require an enormous test matrix, a large number of fatigue testing machines, and a huge budget. Fortunately, similar behavior trends are observed by various classes of alloys. This allows engineers to experimentally document the behavior of many of the more commonly encountered variables using only a limited number of tests. As a prime example, several different models can describe the effects of mean stress on fatigue life. All predict lowered fatigue resistance to tensile mean stress and enhanced life with compressive mean stress. Another example is the correlation between tensile test properties and baseline fatigue resistance as given by Eq 1 and 2, that is, increases in the ductility of an alloy generally enhance low-cycle fatigue life, whereas increases in tensile strength produce greater high-cycle fatigue resistance. These correlations have proven quite valuable. If more accurate assessments of the effects of variables on fatigue are required, they can be determined experimentally. This section discusses the more commonly investigated variables.

The variables affecting fatigue can be categorized into four types: bulk and geometric factors, and surface- and active loading-related factors. Common examples of each type are listed in Table 4. Synergistic interactions may occur among these influences. For example, the loading-related factor of high-temperature testing in air would induce the surface related factor of oxidation. Seldom are surface-related effects of this nature beneficial to fatigue resistance.

Table 4 Significant variables affecting fatigue resistance

Bulk property effects

- **Degree of cold working and/or annealing**
- **Heat treatment**
- **Anisotropy (forming, directional solidification, or single crystal)**
- **Alloy composition**
- **Nuclear radiation**

Surface-related effects

- **Mechanical surface finish (e.g., as-cast, forged, machined, or ground)**
- **Residual stresses**
- **Mechanically induced (e.g., shot peening, burnishing, laser shock peening; machining, or grinding)**
- **Thermally assisted (e.g., rapid surface solidification, welding electrodischarge machining, carburizing, or nitriding)**
- **Environment (oxidation, sulfidation, corrosion, ion transport, or hydrogen embrittlement)**
- **Cavitation**
- **Fretting and galling**
- **Wear and erosion**
- **Coatings (plating, anodizing, ion implantation, oxidation protective, or thermal barriers)**

Geometric effects

- **Notches**
- **Edges and thin sections**
- **Size effects and highly stressed volume**

Active loading-related effects

- **Actively imposed mean stresses and strains**
- **Multiaxiality of stress and strain (proportional and nonproportional)**
- **Cumulative damage (variable levels and types of loading)**
- **Temperature of testing (from cryogenic to high)**
- **Creep-fatigue interaction (low frequency, low strain rate, stress hold times, strain hold, and tensile-versus-compressive hold times)**
- **Thermal fatigue, TMF (continuous temperature strain cycling and bithermal cycling)**

Bulk and surface-related property effects could be further classified as preexisting or concurrent. Geometric effects are generally preexisting with respect to laboratory specimen fatigue testing. Examples of preexisting bulk effects are cold working introduced during the forming process and metallurgical heat treatment of the alloy. Either could significantly alter the strength of an alloy and, hence, alter its fatigue resistance. Concurrent effects can include time-dependent creep, oxidation, or solid-state metallurgical changes, all resulting from exposure of the alloy to high temperature during operational use or specimen testing. Effects on fatigue resistance of preexisting factors can be dealt with by simply considering the alloy as a new material to be evaluated.

Concurrent influences, however, require additional consideration to ensure testing adequately reflects the influences encountered in service. For example, high-temperature service may involve more than an order of magnitude greater exposure time than can be afforded during fatigue testing. Consequently, the testing program must be designed to provide data that can be extrapolated with confidence into the time regime of practical interest. This is a particularly vexing problem in the area of high-temperature fatigue, creep-fatigue, and TMF testing of alloys.

Invariably, engineering models of fatigue behavior are created to allow confident interpolation and extrapolation, particularly for structural applications. Models are calibrated to reflect the influences of a multitude of variables. Many models have been proposed over the past century. Those of greatest value for

engineering design are the ones that are relatively simple, logical, and clearly reflect a cause-and-effect relationship. They are the easiest to remember and use. Those models that reflect a high degree of mechanistic fidelity are naturally of greatest benefit to the material science and failure analysis community. If such models can also be expressed in tractable terms, engineers will also use them for designing in structural durability of machine components. Understanding the root causes of fatigue permits engineers to better guard against this insidious failure mode.

Preexisting Variables

Because of the similarities of testing for preexisting bulk or surface-related effects on fatigue resistance, they will be discussed together. Guidelines for information to be documented from fatigue tests of preexisting variables are contained in Tables 2 and 3.

Bulk Property and Surface-Related Effects. Material with preexisting effects can be evaluated by conducting fatigue tests using the same techniques and procedures as for baseline fatigue testing. The affected material is considered as a new material, but one for which some background knowledge exists. It is not uncommon to see a series of fatigue curves for the same alloy composition wherein each curve reflects differing degrees of cold working, heat treatment, or surface finish. The fatigue results are typically used to select an optimum fabrication method or to indicate material conditions to be avoided. In general, fewer fatigue tests are required, *provided the baseline results are well behaved and well defined*. However, if there were more scatter in the property-affected results, more tests would be required to adequately define the new fatigue curve.

Geometric Effects. The most commonly investigated geometric effects are those of notches and the degree of the theoretical stress concentration, K_t , they impose. Invariably, the fatigue resistance decreases with higher stress concentration factors. The extent of fatigue strength loss for a given fatigue life, however, is never as great as might be suggested by the value of the stress concentration factor. Furthermore, the effectiveness of the stress concentration factor decreases as the root radius decreases and the overall size of the notch decreases. There are several reasons for this behavior that are adequately explained in most textbooks covering fatigue. As discussed earlier, it is of great importance to fatigue testing that uniformity of the notched specimens be maintained to reduce confounding scatter issues. Particular care is required to achieve this goal when dealing with very small notch root radii.

The testing of notched specimens in the high-strain, low-cycle fatigue regime may introduce yielding at the root of the notch. If the cyclic loads are great enough, the yielding will occur on each cycle, despite the fact that the overall specimen appears to behave nearly elastically. The cyclic strain range at the notch root will be larger than indicated by the theoretical stress concentration factor, and the cyclic stress range will be smaller. Analytic approaches are available to describe the stress-strain behavior at the notch root in terms of the applied loading and the cyclic stress-strain curve of the material. See, for example, applications (Ref 47, 48) of Neuber's (Ref 49) and Glinka's (Ref 50) notch analysis approaches. Also of great importance to the fatigue testing of notched specimens is the cyclic relaxation of initial mean stresses at the notch root. For example, for zero to maximum load-controlled cycling, the local notch root stress can relax from an initial zero to maximum condition on the first cycle to a completely reversed condition as cycling progresses. Such changes in the local stress-strain response have a profound influence on the fatigue life of notched specimens. As the cyclic loading level is decreased and longer lives are achieved, there is less and less of a chance for relaxation of the initial cycle mean stress. Consequently, the resultant fatigue curve will exhibit a very low mean stress effect in the low-cycle regime, but will exhibit the full effect of mean stress in the high-cycle regime. Without performing a local stress-strain analysis at the root of the notch, it is nearly impossible to ascertain whether or not a mean stress will relax, and to what extent. The issue of mean stress relaxation becomes critically important in performing cumulative fatigue damage experiments with notched specimens.

Other specimen geometric effects include thin sections and sharp edges. Both can result in fatigue-life reductions due to the fact that there is far less constraint to the motion of dislocations due to the high ratio of surface area to volume. This effect is accentuated at high temperatures wherein creep can occur more readily by grain boundary sliding. Reducing a section thickness to only one or two grain diameters can greatly reduce the normal constraint offered by surrounding grains, thus enhancing creep deformation and increasing the degree of creep-fatigue interaction. When performing fatigue, creep-fatigue, and TMF tests of thin sections, one should caution against having too few grains through the thickness.

Yet another preexisting geometric aspect is the so-called size effect. The smaller the volume and related surface area are for the fatigue-affected zone of a test specimen, the less probability there is of encountering a microscopic flaw leading to early crack initiation. Large specimens with relatively large volumes and high surface areas will invariably exhibit lower fatigue lives than small specimens with relatively small volumes of highly stressed material. While this effect is not an overwhelming one, it should be considered when selecting a particular fatigue specimen for a testing program. In general, the highly stressed volume should be as large as can be tolerated, because many practical machine components have much larger highly stressed volumes than can be accommodated in a corresponding fatigue test specimen.

Concurrent Variables

Concurrent changes of the variables affecting the fatigue resistance are obviously more complex to evaluate. The fatigue resistance being measured is a moving target and quantitatively depends on how much change has accrued over the period of testing. Concurrent changes are due to bulk and surface-related factors, as well as active load-related effects due to mechanical loading and temperature changes during testing. Obviously, the information to be documented for fatigue tests involving concurrent variables is more extensive than shown in Tables 2 and 3.

Bulk Property and Surface-Related Effects. Keep in mind that the laboratory fatigue results are being measured to help assess the structural durability of hardware with specific missions of exposure, loading, temperature, and time, among other factors. Mission loadings often have total durations lasting into years of exposure that cannot be affordably duplicated in laboratory tests. The laboratory coupon results must, therefore, capture the concurrent influences in such a way that they can be generalized and then brought to bear on specific applications. To do so usually requires a physically based model or equation that can relate the laboratory conditions to the mission loading and exposure conditions. An analogy can be made to time-temperature parameters that relate higher-temperature, shorter-time laboratory stress rupture results to longer-time, lower-temperature mission loading exposure. Available time-temperature parameters are generally consistent with the concepts of activation energy for thermally governed time-dependent creep processes. If models are not available for a smooth transition between laboratory and service conditions, extreme or bounding approaches may be necessary.

As an example, suppose the concurrent degradation in service is fretting. Alloy coupons could be prepared with surfaces that have been independently fretted to varying degrees. Subjecting these coupons to subsequent fatigue tests will demonstrate the effects of fretting as though it were a preexisting influence. Testing in this step-wise sequence imposes all of the fretting damage at the beginning of the test, and it could be expected to cause the maximum damage and, hence, a lower-bound fatigue life. This testing philosophy assumes no concurrent synergy between accumulation of fretting damage and accumulation of fatigue damage. Similar evaluations are possible for effects of nuclear radiation on bulk properties (causing, for example, increased strength and decreased ductility) or oxidation on surface-related effects (decreasing surface resistance to cracking). One should not discount the option of testing with a few multiple steps, for example:

- Apply static oxidation to a specimen in a furnace for a time interval.
- Follow this with rapid fatigue cycling for a predetermined block of cycles.
- Remove the specimen from the fatigue machine.
- Reinsert the specimen into the furnace for an additional time interval.
- Reinstall the specimen in the fatigue machine for an additional block of cycles.
- Repeat this process until the specimen fails due to oxidation-accelerated fatigue.

While this procedure is manpower intensive, total testing time in a fatigue machine could be greatly reduced while developing data that are far more relevant to the missions.

Active Loading-Related Effects. A number of active loading variables also fall into the category of concurrent variables. Prime examples of active loading variables are applied mean stresses, multiaxial stress-strain states, cumulative fatigue damage (not constant) loadings, and temperature-related effects such as creep fatigue and TMF. Creep fatigue and TMF are of such significance and require so many changes to conventional fatigue testing procedures that they merit separate discussion.

Mean Stresses. Perhaps the most commonly considered variable for fatigue testing is the mean stress. Mean stress effects on fatigue were recognized by Gerber (Ref 51) as early as the 1870s and have been a source of concern since. One of the most recent thorough reviews of the subject is given by Conway and Sjødahl (Ref 52).

A typical mean stress evaluation test would be conducted under load control of axial or plane bending in the nominally elastic high-cycle fatigue regime. Under plane bending, one surface has a tensile mean stress whereas the opposite surface has a compressive mean stress of equal magnitude. It is not possible to run independent tensile or compressive mean stress bending fatigue tests. Because tensile mean stresses are typically more damaging than compressive mean stresses, the bending specimen would always initiate fatigue cracks from the tensile mean stress surface. The plane-bending fatigue test is inappropriate for studying mean stress effects in the lower cycle-to-failure regime. Once small amounts of inelasticity occur at the outer surfaces, stress relaxation and redistribution occur and the local mean stresses are no longer directly proportional to the imposed mean loads. In fact, the load amplitude and mean will not change as a result of the local changes in stress, and the test engineer will be unaware of any changes to the stresses. Note that it is not possible to conduct mean stress studies under rotating-bending fatigue.

To avoid the problems of bending, axial loading is the recommended mode of testing for mean stress effects. Figure 23 schematically illustrates the decrease in alternating-stress fatigue resistance as the tensile mean stress increases. Frequently, the fatigue curve is displayed in terms of the maximum applied stress in the cycle. Figure 24 shows typical results of the effect of the stress ratio, R (algebraic minimum/algebraic maximum), on the axial fatigue resistance of 2024-T3 aluminum alloy at room temperature over the life range of 10^4 to 10^7 cycles to failure (Ref 52). Care should be taken when mean stresses are applied under load control at very high maximum tensile or compressive stresses. Too high a stress can cause yielding and, hence, cyclic ratcheting in the direction of the mean stress. If in tension, this can lead to eventual excessive tensile strain, subsequent tensile necking (as in a tensile test), and failure long before fatigue cracks have an opportunity to form and grow. Unless an extensometer is employed, small but damaging amounts of ratcheting may escape detection.

Fig. 23 Schematic axial fatigue curve illustrating the effect of tensile mean stress. After Ref 52

Fig. 24 Effect of tensile mean stresses on axial fatigue resistance of 2024-T3 aluminum alloy at room temperature. After Ref 52

Mean loading effects in the low-cycle fatigue regime are best dealt with under strain control. The strain control mode rules out ratcheting, although initial mean stresses imposed by mean straining do have an opportunity to cyclically relax. When imposed strain ranges are large enough that the inelastic strain range is on the order of a tenth of the total or elastic strain range, it is very probable that any initial mean stress will cyclically relax to zero, that is, become completely reversed, even though the straining is not completely reversed (Ref 53). In the high-strain, low-cycle fatigue regime, there is little, if any, effect of mean strain on fatigue life for ductile alloys. However, as the strain range is decreased and the life increases, a nominally elastic condition is reached. Then, a tensile mean strain will be accompanied by a directly proportional tensile mean stress, and the fatigue life will decrease compared to a completely reversed strain cycle. The end result is shown schematically in Fig. 25. Typical data of this nature have been reported for a high-temperature gas turbine engine alloy in (Ref 54).

Fig. 25 Schematic illustration of mean-strain cycling effects on low-cycle fatigue resistance. Mean stresses relax to zero at large strain ranges but remain at low strain ranges, thus reducing life.

Multiaxiality. Investigation of multiaxial stress and strain states on fatigue resistance is a perennial issue because the cyclic stress-strain states at critical locations in machinery components are rarely uniaxial. However, the vast majority of fatigue tests are performed using uniaxial loading. The issues involved are so extensive that the subject has merited a separate article (“Multiaxial Fatigue Testing”) in this Volume and will not be discussed further in this article.

Cumulative Fatigue Damage. Commonly employed cumulative fatigue damage tests involve random, or nonsteady, loading wherein both the amplitude and mean value of the loading vary continuously (Fig. 26a). Such tests are attempts to simulate in the laboratory the detailed loadings encountered in service. The sequence

of loading is commonly referred to as spectrum loading. Also common are simplified, or compressed, loading patterns that have been shown analytically to account for the equivalent amount of fatigue damage that existed in the more complex spectrum loading. These compressed loading patterns capture the basic profile of loading. An illustrative schematic example is shown in Fig. 26(b). In this instance, the simplified loading pattern is arrived at by an equivalent rainflow cycle counting technique (Ref 55). Obviously, reducing the number of loading levels permits simplification of testing. Because a loading pattern may repeat itself, the fatigue loading can be applied in the form of repetitive blocks. Terrestrial-based vehicles, aerospace airframes, and civil engineering structures such as bridges typically experience random loadings during their fatigue crack initiation lifetimes. Greater details on how to approach complex cumulative fatigue damage assessment and testing can be found in Ref 56.

Fig. 26 Nonsteady fatigue loading. (a) Random-appearing original loading pattern. (b) Loading pattern reconstructed by rainflow method of cycle counting. After Ref 55

In the extreme are cumulative fatigue damage tests that involve only two loading levels, one in the low-cycle fatigue (LCF) regime, the other in the high-cycle fatigue (HCF) regime. Using this highly simplified testing pattern, it has typically been observed that LCF cycling (to a fraction of the expected life) followed by HCF cycling to failure reduces overall life, and the reverse loading order increases overall life. This is referred to commonly as the classic loading order effect (Ref 57, 58) and is illustrated in Fig. 27. This effect is not captured by linear damage assessment. Consequently, nonlinear cumulative fatigue damage models have proliferated (Ref 58) since Miner's linear damage rule was published in 1945 (Ref 59). The accuracy and viability of any cumulative fatigue damage rule hinges on the assumption that the physical mechanism of damage does not change as loading levels are changed. Clearly, understanding the damage mechanisms is an important and necessary step in the development of accurate models.

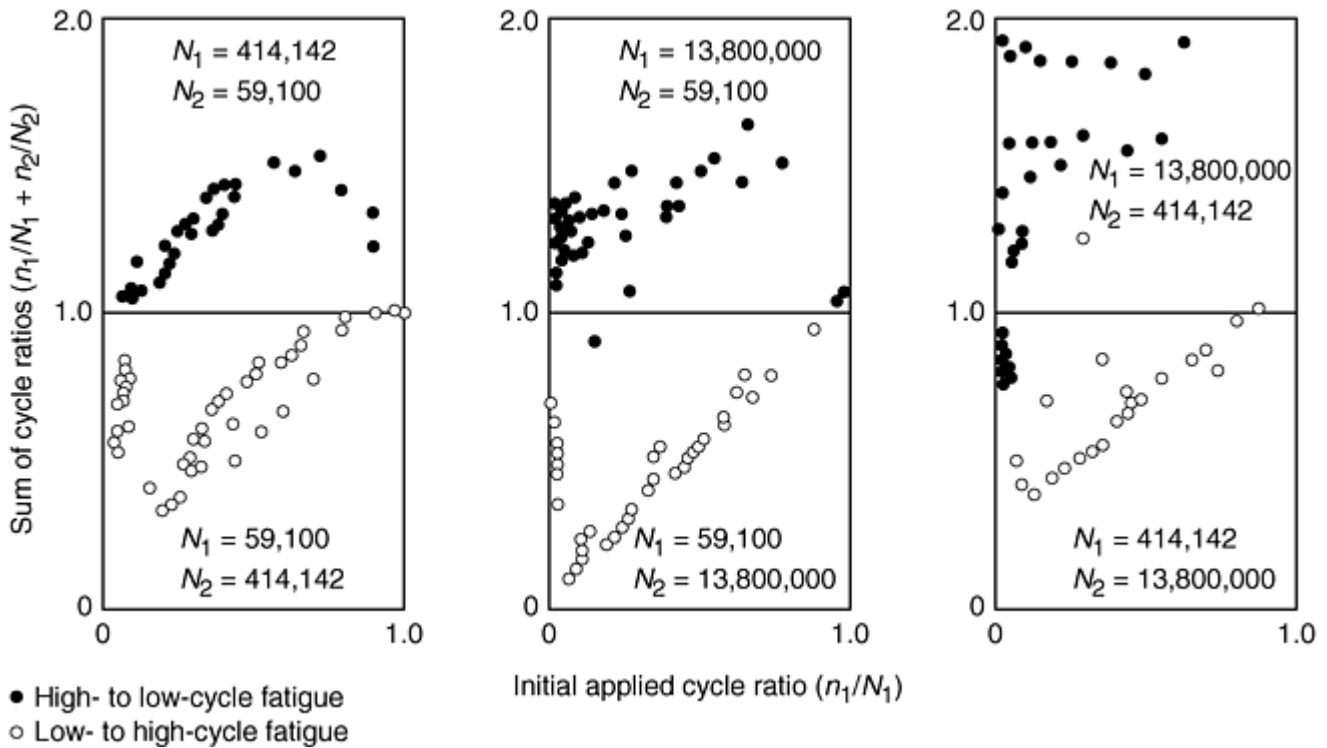

Fig. 27 Examples of classic loading order effect in two load level tests of British aluminum alloy D.T.D. 683. Source: Ref 57

Cumulative fatigue damage testing can also involve more than just loading level variations. Changes in the type of loading—for example, thermomechanical and isothermal (Ref 60), axial and torsion (Ref 61), and fatigue and creep-fatigue (Ref 62)—during testing may also be of importance. Temperature-related effects such as creep-fatigue and TMF are of such significance, and require so many changes to conventional fatigue testing procedures, that they merit separate discussion in the following sections.

Fatigue, Creep Fatigue, and Thermomechanical Fatigue Life Testing

Gary R. Halford and Bradley A. Lerch, Glenn Research Center at Lewis Field, National Aeronautics and Space Administration; Michael A. McGaw, McGaw Technology, Inc.

Creep-Fatigue Interaction

Creep-fatigue interaction testing and modeling have been intense activities since the late 1950s. Interest was spawned by the introduction, and seemingly premature failures, of components in structural equipment operating at elevated temperatures. Examples include aeronautical gas turbine engines; steam turbines; nuclear reactors and pressure vessel and piping components for electric power generation and chemical processing plants; casting and forging dies; railroad wheels subjected to brake-shoe application; automotive cylinder heads, exhaust valves, manifolds, and exhaust piping systems; and reusable rocket engines. In many cases, the elevated temperature of operation is reasonably constant (isothermal) over a period of time while components are under load and can suffer creep or stress-relaxation processes that hasten crack initiation and early growth. The modes of cracking have frequently exhibited creep-like fractures intermixed with cycle-dependent fatigue-type cracking. Hence the descriptive name, creep-fatigue interaction.

Extensive reviews of creep-fatigue interaction were prepared in the early 1980s (Ref 63, 64, 65). Over the intervening decades, more than 100 models or their variations have been proposed to describe creep-fatigue

interaction (Ref 66, 67). As many as a dozen of the models have survived and have been applied to practical situations. The three most widely used are the time- and cycle-fraction rule from the ASME Code Case N-47-23 (Ref 68), strain-range partitioning (SRP) (Ref 69) and its total strain version (Ref 70), and continuous damage mechanics (Ref 71).

The fatigue machines and associated equipment normally used for creep-fatigue experiments are essentially the same as those used for baseline fatigue tests. Current practice calls for axial loading of a uniform-gage length specimen mounted in a closed-loop servocontrolled fatigue testing machine with provisions for heating the sample to elevated temperatures. Closed-loop strain-controlled testing is most commonly used; when it is not used, strain limit control is imposed to prevent creep ratcheting. The major difference between creep-fatigue and baseline isothermal fatigue testing is in the time per cycle. To introduce creep into the cycle, the frequency is reduced by cycling at a lower strain rate or by introducing a hold period at some selected point within each cycle. Most commonly, a hold period is inserted at the peak strains in a cycle, that is, at maximum or minimum algebraic strains, or at both peaks.

Creep-fatigue interaction testing is conducted at a high enough isothermal temperature that thermally activated, diffusion-controlled creep deformation mechanisms can operate under stress as a function of both time and temperature. As a rough rule of thumb, the transition temperature for creep is on the order of half the absolute melting temperature of an alloy. In earlier years, creep-fatigue testing was conducted to simply ascertain the extent of the damaging effect of creep on cyclic (fatigue) life. Today, tests are still run for that purpose, but more often than not, creep-fatigue testing is designed also to evaluate and calibrate the constants in a viable creep-fatigue life prediction model.

The addition of creep to a cycle of normal fatigue loading will invariably reduce the cyclic life, although the clock time to failure may remain constant or actually increase. Conversely, the superposition of fatigue cycling and conventional monotonic creep will also alter the rate of creeping and the time to rupture. Because of the importance placed on knowing the values of stress and time-dependent deformation, it is generally regarded that creep-fatigue testing be done with axially loaded specimens equipped with extensometry. While some interspersed creep-fatigue testing, that is, repeated blocks of brief periods of creep followed by brief periods of fatiguing, has been reported (Ref 62), the most common tests involve repeating cycles of straining with hold periods imposed in tension or compression alone or in combination. The hold periods may be under constant strain or constant stress. If under constant stress, strain limits are generally imposed to preclude ratcheting. Alternatively, creep could be introduced by controlled slow straining rates in tension, compression, or both.

Figures 28 illustrates the various isothermal hysteresis loops that are commonly encountered in fatigue and creep-fatigue testing. Figures 28(a), 28(e), 28(f), and 28(g) were used to generate the data shown in Fig. 29 for AISI type 304 stainless steel (Ref 67). Here the inelastic strain range is plotted against cycles to failure on log-log coordinates. As can be seen, significant cyclic life losses (a factor of 10 or more) are possible with strain hold periods of just 30 minutes per cycle in tension only. Hold periods of up to 180 minutes per cycle do not necessarily further reduce the cyclic life, implying a saturation condition beyond a certain hold period for strain hold (stress relaxation) creep-fatigue cycles. Those cycles that are balanced in nature, that is, the tensile and compressive halves experience the same strain rates or hold times, will not exhibit an algebraic mean stress, whereas the unbalanced cycles will. The mean stress is tensile if the hold period or slow straining rate is in compression and vice versa. Evidence suggests that these mean stresses do not exhibit the classical mean stress effect on cyclic life in the high-strain range, low-cycle fatigue regime (Ref 54), and hence can be ignored. Similar creep-fatigue cycling results for AISI type 304 stainless steel and Incoloy 800 have been reported in Ref 72. These results were analyzed in Ref 73 by both the time- and cycle-fraction rule and the method of strain-range partitioning based on information provided in Ref 72.

Fig. 29 Creep-fatigue interaction effects on isothermal cyclic life of AISI type 304 stainless steel tested in air at 650 °C (1200 °F), normal straining rate of $4 \times 10^{-3} \text{ s}^{-1}$. After Ref 65

Comparison of the two creep-fatigue life prediction models is given in Fig. 30. In this instance, the time- and cycle-fraction rule, which utilizes a stress-based approach to assessing creep damage, does not do an acceptable job of predicting the laboratory results. Cyclic lives can be over-predicted by as much as a factor of 5 and under-predicted by a factor of 20, thus creating a band of uncertainty in predicted life of two orders of magnitude. The method of strain-range partitioning is a strain-based approach and assigns creep damage according to the magnitudes of the creep strains encountered in a cycle. The figure indicates a strain-based approach is superior in this case.

Fig. 30 Predictability of creep-fatigue lives for tensile strain hold time cycles for Incoloy 800 and AISI type 304 stainless steel at elevated temperatures. Source: Ref 70, 71

A viable creep-fatigue model is of great importance to be able to design equipment to operate for long periods of time at elevated temperature. Services lifetimes are typically much greater than the longest affordable creep-fatigue testing lifetimes of laboratory specimens. What a viable model has to offer is increased confidence in the extrapolations to longer times to failure than were used in the model calibration. A physically based model is expected to hold greater promise than simple empirical extrapolation of noncorrelated laboratory data. Because laboratory creep-fatigue measurements are the basic ingredients of the foundation for assessing extrapolated long-time structural durability, it is imperative that accurate measurements and control of the testing variables be maintained. The problem is a much more stringent one than for lower-temperature, fatigue-life extrapolation because of the influence of time and temperature. Creep is sensitive to temperature in a highly nonlinear exponential dependency and sensitive to stress and time of exposure in nonlinear power-law dependencies. The temperature and time dependencies also include the effects of interaction with the environment. Typically, oxygen is the surrounding environment and surface oxidation can greatly influence the susceptibility of exposed surfaces to premature crack initiation and early growth. Most creep-fatigue models are calibrated and used without the benefit of separating the effects of oxidation from the creep effects. A listing of models with the potential for accounting specifically for oxidation or other environmental interaction effects is found in (Ref 67).

Creep-fatigue test results are generally more extensive than simpler fatigue results. Table 5 lists, among other items to be discussed, the additional information that should typically be reported for each creep-fatigue test conducted.

Table 5 In-test and post-test information guidelines for creep fatigue and thermomechanical fatigue

Cyclically varying parameters	Value of fixed test control parameters (stress, strain, temperature, temperature and straining rates, hold times, phasing relation between temperature and strain, as applicable); continuous recording of variations of maximum, minimum, amplitude, range, and mean values of stress, strain, and temperature as a function of applied cycles (or sufficient information for calculation of these parameters); cyclic variation of load range ratio of tensile to compressive peak loads (under strain control) and cyclic variation of strain range and ratio of maximum to minimum strain peaks (under load control) to help define failure life and hence half-life; continuous or periodic recording of variations of stress-strain hysteresis loops and stress versus time and strain versus time; any parameter deemed necessary for evaluation of a particular creep-fatigue or thermomechanical fatigue model (e.g., for strain range partitioning, the amounts of tensile and compressive creep and plastic strains)
Lifetime information	Cyclic failure lives based on various cyclic failure criteria; failure life (cycles and corresponding time) for criterion adopted; half-life cycles; total, inelastic (partitioned strain ranges and method of partitioning if using strain range partitioning), and elastic strain ranges at half-life; maximum, minimum, stress amplitude, stress range, mean stress, and mean stress ratio at half-life; degree of cyclic hardening and/or softening from first cycle to half-life (or cycles at stabilization of stress-strain response); description of fracture surface including initiation site(s); degree of transgranular and intergranular cracking; location of fracture relative to extensometer probes
Deviations from original test plans	Details of stress and strain history and temperature immediately prior to controlled or uncontrolled shut-downs prior to test completion
Data analysis from multiple specimens	Cyclic stress-strain curve and how it varies with strain rate, frequency, cycle time, hold time, and temperature; equation constants at half-life (or cycles at stabilization), that is, the cyclic flow properties; fatigue curves, creep-fatigue curves, and thermomechanical fatigue curves expressed in terms of inelastic strain range, total range, and elastic strain range versus cyclic life; equation constants and how they vary with temperature and some measure of testing time, that is, the cyclic failure

Thermomechanical Fatigue

Thermal fatigue is a structural failure mode in many high-temperature components. Thermal fatigue loading is induced by temperature gradients during transient heating or cooling from one high temperature of operation to another. Thermal fatigue loading can also occur when heating and cooling are present simultaneously and thermal gradients are maintained during steady-state operation. Internally air-cooled high-temperature turbine blades are examples. Thermal gradients produce differential expansion as the hottest material wants to expand more than the cooler, but is constrained from doing so by the cooler and stronger material. The constraint is perceived by the hottest material as a compressive thermal strain that is no different in its effect on the material than would be a mechanically induced strain of equal magnitude. Similarly, the coldest material is forced by the hottest to expand more than normal. The thermally induced strain in the colder material is tensile. Conditions of strain compatibility will be maintained. The corresponding thermal stresses result directly from the thermal strains according to the current stress-strain relation and the necessity to obey the laws of equilibrium. The integrated sum of the internal stresses into forces must always equal zero. Because of the gradients of the primary variables, it is impossible to measure the thermal fatigue properties of a material in the same way that isothermal fatigue or creep-fatigue properties are measured, that is, in terms of holding certain variables constant while the response of the others are measured. To overcome this basic difficulty, TMF tests have been devised.

Thermomechanical Fatigue Testing. The testing machine and specimen set up for TMF testing are essentially the same as used for creep-fatigue testing or baseline high-temperature isothermal fatigue testing. The major distinction is that the temperature of the specimen, instead of remaining constant, must be programmed to vary in a precisely defined manner. Furthermore, the cycling rate must, at times, be rather high, requiring the ability to heat and cool the test specimen as rapidly as possible without creating undue thermal gradients. This requirement virtually rules out the use of conventional clamshell radiation furnaces because of their large thermal inertia. Most commonly, induction heating is used. This is because of the reasonably high rates of heating possible, and because the temperature gradient along the specimen gage length can be controlled better with a three-zone induction heating coil arrangement, as shown in Fig. 11. Induction coils are also more conducive for use of extensometers. Direct resistance heating, although not commonly used, has the capability of heating a sample so rapidly that it could be melted in a matter of seconds. Heating is usually not the limiting factor in governing the cycling rate, rather, cooling is. Forced air cooling has been used successfully. Jets of air are impinged on the specimen surface along the gage length and around the circumference. Excessive cooling induces thermal gradients and, hence, unwanted thermal stress and strains. A balance must be achieved between cooling (as well as heating) rate and the extent of undesired thermally induced stresses and strains. Thermal cycling rates as fast as 3 minutes per cycle are employed on a routine basis. A test run to 12,000 cycles requires 36,000 minutes or 600 hours. This is without consideration of a hold period at the peak temperature. A testing program involving dozens of specimens could thus become extremely expensive and time consuming. Cycling rates as high as 20 seconds per cycle have been achieved through diligence. However, the thermal gradients are quite high and control of the temperature and strain is poor, although reproducible.

Raising the minimum temperature in the laboratory TMF cycle is a commonly used approach to help speed up TMF testing frequency. This can considerably reduce the time needed to cool because cooling follows an exponential decay curve. Removing the last portion of that curve can significantly decrease the cooling time per cycle. However, the range of temperature is reduced in the process, and the measured TMF characteristics are removed further from what occurs in most applications. For most industrial equipment, the minimum temperature in a thermal fatigue cycle is ambient, and is considerably below the minimum temperature usually selected for TMF testing. Normally, the testing conditions of temperature range, minimum temperature, and cycling rate are determined by compromise. Regardless of the minimum temperature selected for testing, there remains the desire to shorten the time per cycle; this leads to higher thermal gradients throughout the test specimen.

Of course, one of the purposes of TMF testing is to intentionally keep thermal gradients negligibly small while the overall temperature of the test volume of the specimen is raised and lowered cyclically. Simultaneously, the magnitude of the uniformly distributed strains (stresses) in the specimen is controlled independently of the temperature change, although a fixed phasing is usually maintained between them. As a consequence, the test specimen could be programmed to experience cyclic thermal and mechanical strains just as the material might at a critical point were it undergoing thermal fatigue in a structural element. In this way, the resistance of a material to thermal fatigue can be experimentally evaluated for a range of phasings and amplitudes of strain (stress) and temperature. Figure 31 illustrates a series of basic TMF strain cycles for the most rudimentary of TMF situations in which mechanical strain and temperature vary in lock step with one another. A triangular waveform is used for the example cycles, although sinusoidal, is also in vogue. When the same waveform is used for both strain and temperature, their time phase shift can be described by a single parameter, the phase angle. In-phase cycling (0° phase shift) is defined as having the maximum algebraic strain occur at the same instant as the maximum temperature and having the minimum algebraic strain occur at the minimum temperature. Out-of-phase TMF cycling (180° phase shift) is just the reverse of in-phase cycling. A phase angle of 90° or 270° corresponds to a diamond-shaped (sometimes referred to as baseball) pattern of mechanical strain versus temperature. The resultant stress-strain hysteresis loop for a diamond cycle will appear as unusual because the maximum and minimum temperatures do not occur at the maximum or minimum mechanical strain. These and other basic cycles (bithermal) to be introduced later serve as excellent uniform types of cycles for characterizing the TMF fatigue resistance of materials.

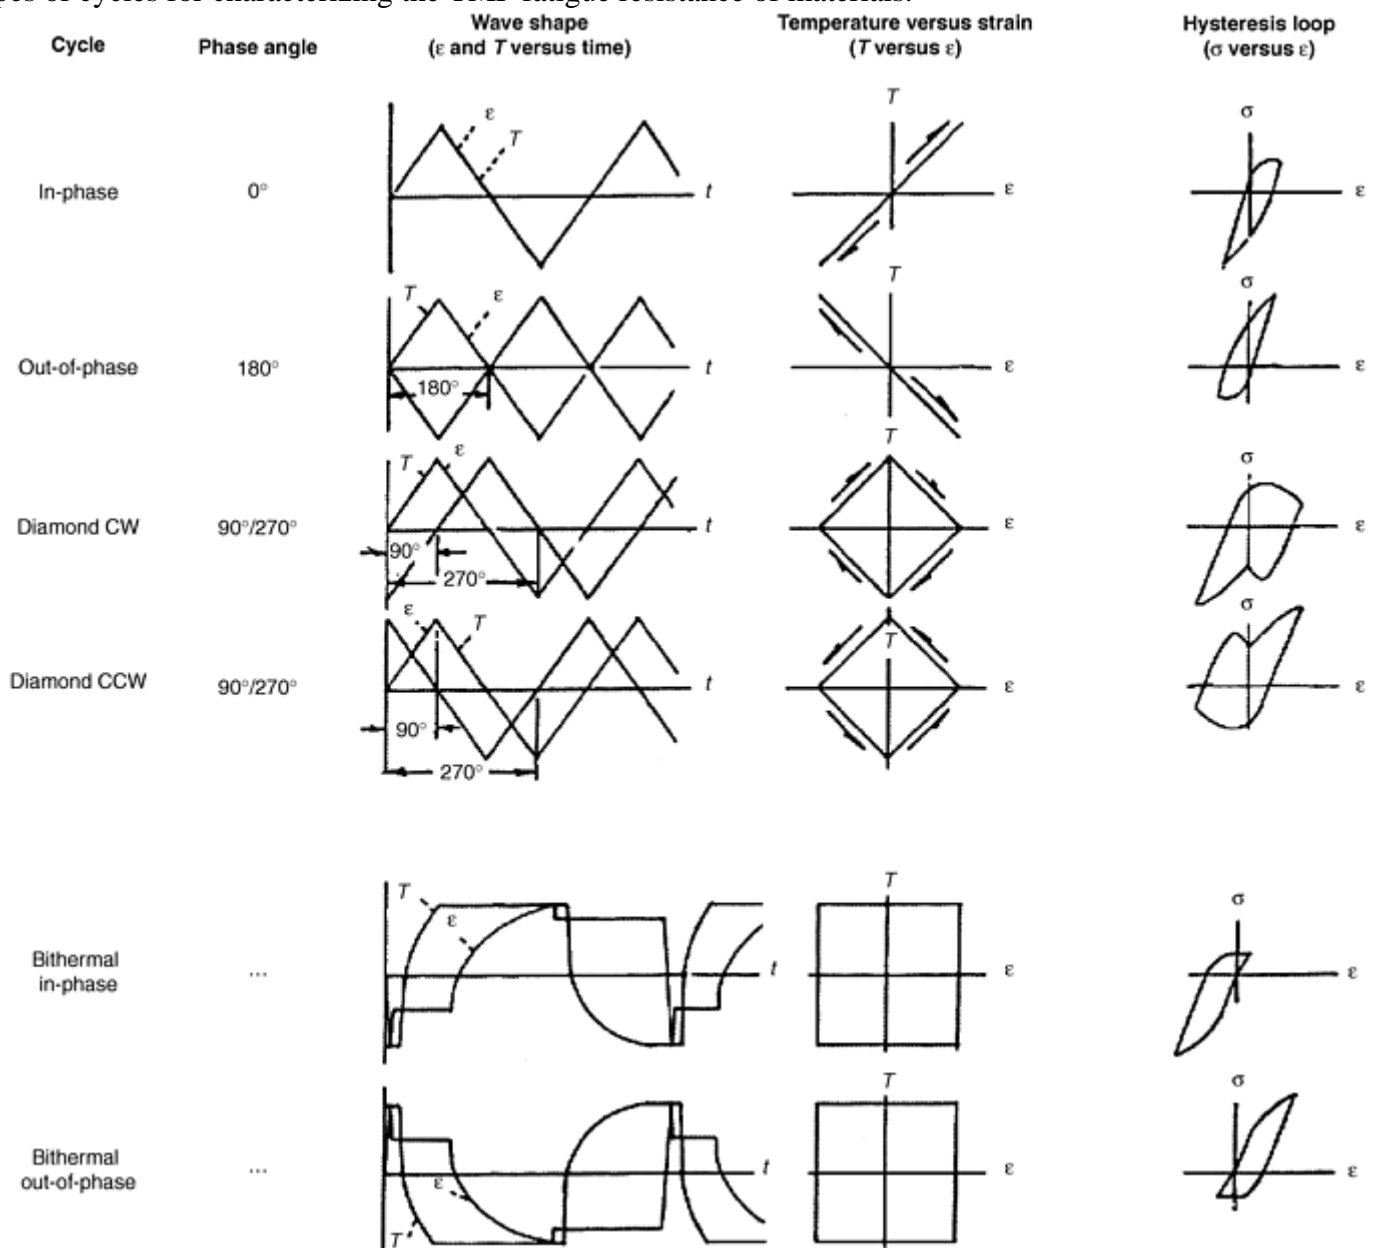

Fig. 31 Basic thermomechanical fatigue strain cycles

Rarely, however, are the simple cycles discussed above encountered exactly in service. Because TMF fatigue life is generally wave-shape dependent, means are required to generalize laboratory characterizations so they may be applied to any unique thermal fatigue cycle encountered in service. This is usually accomplished with a life prediction model. Again, physically based models will have the greatest potential for proper interpolation and extrapolation of results generated. There are spectra of TMF tests of any given type of cycle that could be conducted in a laboratory: phasings could cover the range from in phase to out of phase and all points between, as well as for TMF cycles that are not describable, by quoting a simple measure of phasing; temperature ranges could be very narrow or very wide; the maximum and minimum temperatures could also cover a broad range, as could the mechanical strain range. The frequency (or other measure of the cycling rate and hold periods) is yet another critical variable to be investigated if one is to document the broad range of the thermal fatigue resistance of a material. A complete test matrix that could capture all of the pertinent variables is too large to be practical. Judicious selection of the variables and their combinations and ranges is usually required based on the potential application of the results. ASTM committee E-08 on fatigue is currently crafting a standard for basic TMF fatigue testing (Ref 74) involving simple waveforms (e.g., triangular, sinusoidal) of phased strain and temperature cycling. Once approved and published, the standard will be a valuable document to consult before conducting TMF tests. Table 5 lists in-test and post-test information that should be documented for each TMF test conducted.

As discussed in the reviews of Ref 75, 76, and 77, the thermal fatigue resistance of a material is not necessarily derivable from isothermal fatigue resistance, and it is frequently lower than isothermal fatigue resistance. This is generally observed despite comparisons made to isothermal fatigue resistance measured at the maximum TMF test temperature (i.e., usually thought to be the lowest isothermal fatigue resistance within the span of the TMF temperature range). The basis for comparison of isothermal and TMF fatigue resistance of a material is also important. For example, the TMF resistance may be poorer if the inelastic strain range is used as the basis of comparison, but could be better if the total strain range is used. This apparent dichotomy is a direct result of the differences in the cyclic stress-strain behavior between isothermal and TMF cycling. Comparisons of isothermal and TMF fatigue resistance to inelastic strain for two example alloys (Ref 78, 79) are shown in Fig. 32 and 33.

Fig. 33 Comparison of isothermal and thermomechanical fatigue resistance of AISI 1010 carbon steel.
Source: Ref 76, 77, 79

Thermomechanical Fatigue-Life Modeling. Because of the large number of variables and the inherent problem of not being able to afford to test for all possible combinations of variables, alternate approaches are desirable. One attractive approach is to adopt a TMF life prediction method. By calibrating the constants in equations representing the model, the means are available to calculate behavior under other conditions by interpolation and extrapolation. A variety of TMF life prediction models are discussed in Ref 67, 73, 76, and 77. Among the more frequently used models are the ASME time- and cycle-fraction rule (Ref 68), the continuum damage model of ONERA (the French space agency) (Ref 71), the University of Illinois creep-fatigue-oxidation model (Ref 80, 81), and the NASA Glenn (formerly Lewis) method of strain-range partitioning (SRP) (Ref 82).

The SRP approach for creep-fatigue and TMF life prediction takes advantage of bithermal fatigue testing (Ref 83). As the name implies, bithermal cycling is conducted using two isothermal temperatures within each cycle. The high isothermal temperature represents the maximum temperature of a more complex TMF cycle, while the low isothermal temperature represents the minimum. The impetus for developing bithermal testing was to permit direct measurement of both thermal expansion strain and mechanical strain without them being intermixed. Visual observation of a bithermal hysteresis loop unequivocally identifies these two types of strain. During conventional TMF cycling, thermal and mechanical strains are applied simultaneously and can only be separated by calculation. During bithermal cycling, mechanical straining (and stress) is applied only during the two isothermal halves and not when the temperature is being changed. The stress on the specimen is controlled at zero during any change in temperature, thus providing a clear separation of thermal expansion and mechanical strains.

A schematic bithermal hysteresis loop is shown in Fig. 34. An out-of-phase cycle is shown. All tensile mechanical straining is done at the low temperature, and compressive mechanical straining is done at the high temperature. The loading sequence in traversing a cycle is noted in the table to Fig. 34. The tensile loading from point A to B and unloading from B to C is done at the cold temperature where the elastic modulus is E_{cold} . It is presumed the temperature is low enough and the straining rate is high enough that time-dependent creep is precluded and only plasticity occurs. Hence, the tensile inelastic (plastic) strain is AC and the corresponding elastic strain is CB' , that is, stress at B divided by E_{cold} . At point C the load is held at zero and the specimen temperature raised to the hottest temperature where the elastic modulus is E_{hot} . The specimen expands freely from C to D, a direct measure of the thermal expansion strain over the temperature range. Once thermal stability has been attained, the specimen is strained rapidly into compression until a predetermined stress is reached at point E. The inelastic strain DE'' is time-independent plastic strain. Under the stress at E, compressive creep occurs until the strain limit at point F is reached and the specimen is rapidly unloaded to point G. The amount of compressive creep strain is EF, and the compressive inelastic strain is $DG = DE'' + EF$ (or $E''G$). The corresponding compressive elastic strain is the creep stress (along EF) divided by E_{hot} . Cooling

from point G to point A completes the bithermal loop. The thermal contraction GA should be equal to the expansion CD.

Strain	Type of strain	Temperature	Action
AB	Elastic + plastic	Low	Rapid straining
BC	Elastic unloading	Low	Rapid straining
CD	Thermal expansion	Low-high	Zero stress
DE	Elastic + plastic	High	Rapid straining
EF	Creep	High	Constant stress
FG	Elastic unloading	High	Rapid straining
GA	Thermal constraction	High-low	Zero stress

Fig. 34 Schematic bithermal hysteresis loop (out-of-phase cycle)

It is simple to interpret directly from the hysteresis loop of Fig. 31 the magnitudes of the elastic strains, the inelastic strains, the total strains, and the thermal expansion strains. It is much more difficult to determine these parameters from a continuously varying TMF hysteresis loop. The elastic strain range for the bithermal loop is the sum of the absolute values of the tensile and compressive elastic strains. The corresponding inelastic strain range is the width of the hysteresis loop at zero stress. There are two measures of this strain range, AC or DG. Theoretically, they must be equal; otherwise, cyclic ratcheting takes place. However, the fixed strain limits prevent ratcheting. Since every experimental measurement has some scatter, it is recommended that AC and DG be averaged to determine the value of the inelastic strain range. The total strain range of the bithermal loop is the sum of the elastic and inelastic strain ranges. The loop also reveals the partitioning of the inelastic strains into its creep and plasticity components for use in the strain-range partitioning method for life prediction. An in-phase bithermal hysteresis loop would look just like the out-of-phase loop, except that the loop would be mirror imaged about the strain axis. Thermal fatigue cycles experienced in service rarely have high enough temperatures in both the tensile and compressive halves to suffer creep strains in both directions. Even the 90° or 270° diamond-type cycles tend to experience creep strains predominately in tension or compression only. If, however, the total strain range is very large, all TMF cycles will experience reversed creep. Such cycles rarely, if ever, occur in service situations and are an artifact of TMF testing in the laboratory. By contrast, bithermal tests, for any magnitude of strain range, can be devised that do not experience reversed creep. Commercially available software is available to conduct bithermal tests on a routine basis using computer control.

Laboratory TMF testing is comparatively expensive. Obtaining data from tests of more than a couple of weeks duration (~10,000 cycles) is prohibitively expensive. Accelerated TMF testing is generally not feasible. Hence, application of TMF life prediction methods to long-life structures requires considerable extrapolation of laboratory results. Three primary variables in the laboratory results must be extrapolated: cycles to failure, time to failure, and the mechanical component of the total strain range. Because of the complexity of TMF cycling, it is essential to capitalize on calibrated models for both the failure and the flow (cyclic stress-strain) behavior. Failure behavior can only be calibrated with the longest-life data available, but the flow behavior can be calibrated without carrying tests to the point of failure. Affordable yet realistically long hold times per cycle and small mechanical strain ranges can be applied for just a few cycles to capture the desired flow behavior under anticipated service conditions. Measured flow behavior can then be used to calibrate sophisticated cyclic viscoplastic models (see, for example, Ref 76, 77, and 84) or simpler empirical relations (Ref 82). The latter have been utilized recently for the development of life prediction modeling for long-life automotive exhaust systems (Ref 85). Because cyclic response behavior is so highly dependent on the two major variables of time and temperature, it is imperative that modeling play a vital role in describing practical thermal fatigue cycles and, hence, in extending the direct usefulness of failure data generated at shorter and more affordable lifetimes.

Fatigue, Creep Fatigue, and Thermomechanical Fatigue Life Testing

Gary R. Halford and Bradley A. Lerch, Glenn Research Center at Lewis Field, National Aeronautics and Space Administration; Michael A. McGaw, McGaw Technology, Inc.

Helpful Guidelines for Fatigue Testing

Both novice and experienced fatigue test engineers should find the following operational guidelines valuable. It should also be pointed out that there are a considerable number of commercial fatigue testing laboratories located throughout the world. These laboratories may be equipped to perform certain tests more economically and in a more timely fashion than could be done in a smaller, less-equipped laboratory.

Overall laboratory operation, safety, and training guidelines include the following considerations:

- Operation of modern fatigue testing laboratories has become sophisticated. Hardware and software are complex and require considerable training for safe, accurate, and reliable operation.
- Carelessness is intolerable because serious, maiming accidents can occur in split seconds with fast-responding, high-pressure hydraulic equipment. Noise from hydraulic pumps, valves, and vibrating lines must be attenuated to prevent hearing damage to operators. High-temperature testing also poses a potential burn hazard. Shields, guards, and hazard warning signs are helpful in preventing accidents to laboratory visitors. OSHA regulations, along with other related safety regulations and procedures, should be observed.
- Cleanliness of hydraulic fluid is crucial, and systematic replacement of micron-level filters should be scheduled. Room air cleanliness is also important for reliable operation of all computers and electronic equipment.
- Calibration of all measuring devices, electronics, and computer software should be checked on a regular basis, and a frequency of calibration policy should be established. See ASTM and ISO 9000 standards for maintaining quality systems.
- Basic and advanced training courses for use of testing machines and ancillary equipment are generally available through the respective manufacturers. Skills may be required in several areas, including mechanical and hydraulic systems, electronics and instrumentation, computers and software, thermal management, and environmental control.
- In addition, it is necessary to keep abreast of the latest developments in fatigue behavior and fatigue-life prediction technologies. Short courses are offered by a variety of educational institutions.

Overall Control of Materials to be Tested. A record-keeping system should be set up to keep track of all of the materials being tested. Information on each might include:

- Commercial name or designation
- Nominal (and actual) chemical composition
- Commercial source and dates of production and acquisition
- Product form (e.g., billet, plate, sheet, or bar)
- Method of production (e.g., casting, forging, rolling, or heat treatment)
- AMS, ASM, ASTM, or other specifications
- X-rays and/or NDE results
- Representative micrographs and documentation of anisotropy on material stock
- Proper storage of material stock to avoid any possible contamination
- Reference to mechanical and pertinent physical, thermal, and electrical properties
- Tensile test properties (elastic modulus, Poisson's ratio, yield and ultimate strength, ductility as percent reduction of area and percent elongation)
- Clear designation of material stock (e.g., stamped identification number and color coding)

Overall Control of Specimens. A record-keeping system should be set up to track all specimens made of the above materials. Specimen information might include:

- Diagram of specimen location and orientation relative to material stock
- Specimen drawing(s), dimensions, and specifications for machining
- Specimen final preparation (e.g., heat treatment or surface treatment)
- Specimen dimensions and means of measurement
- Specimen material and individual identification scheme (stamped alphanumeric in visible area near both ends and visible once installed in machine)
- Accessible yet protective specimen storage to prevent damage prior to test
- Document thermocouple attachment techniques and calibration (temp gradients)
- Care exercised in gripping specimens in testing machine
- Orientation of specimen in grips in fatigue machine
- Care to not damage fracture surface prior to machine automatic shut-down
- Care exercised in removing fatigued specimens from testing machine
- Accessible storage system for tested specimens (do not store with fracture surfaces of mating pieces touching)
- Maintain records of metallographic mounts taken from broken specimens

Laboratory Documentation of Set-Ups, Procedures, Calibrations, and Maintenance. One should maintain continuous laboratory documentation books for recording particulars of each new set-up and each new program. Books should be kept, along with fatigued specimens and raw data records, for as long as is practical (then a little longer). Resurrecting old data is far less costly than having to generate new data, and old data are invaluable if untested material specimens are no longer available at a much later date. Data books should be signed and dated by the test engineer(s) and technician(s).

Pretest Checklist. Maintain a checklist to go over prior to the start of each new test. Checklists may consider the following:

- Always predict the cyclic and clock lifetime of each specimen prior to testing.
- All pertinent test information is entered onto any data sheets, paper recorders, computerized data taking and manipulating systems. This information includes fatigue machine number, material, specimen identification number, type of test, temperature, frequency, hold periods, control parameter(s), parameters to be recorded, equipment being used, test engineer, extensometer and load cell ranges of scales employed, ranges of analog recorders, strip chart speeds, computer control programs and data processors utilized, date, time, and any other unique test information.
- An analog X-Y recorder for load cell and extensometer output (stress and strain) is highly recommended even though results can also be recorded electronically. In case of a mishap, the X-Y recording provides

a better vision of what might have gone wrong and how to correct it than do individual load or extensometer signals as a function of time.

- Ensure that each piece of equipment is turned on and functioning properly (e.g., pens of recorders are ready to write and timers and cycle counters are working).
- Ensure that safety limits are set to prevent overload of the specimen and damage of equipment in case of an accident.
- Before actually starting a test, trace a low-amplitude stress-strain hysteresis loop on the X-Y recorder as a check that the recorder is functioning and to check that the modulus of elasticity is close to its expected value. If not, one or more bits of information may be erroneous (e.g., load or extensometer scales, X-Y recorder scales, or specimen dimensions).
- Decide, up front, how to abort a test that is not following the expected response (e.g., abrupt shut down or gradual shut down). During the early stages of a test, be prepared to switch scales of recorders or signal conditioners to better record response signals. For example, large amounts of cyclic strain hardening under strain control may require a switch to a coarser load scale in order to avoid missing measurement of off-scale signals. Do not switch ranges of the control signal during the test.

During the fatigue test the following should be considered:

- As a test progresses, make note of any changes in specimen response (e.g., cyclic strain hardening, softening, relaxation of initial mean stresses under strain control, any strain ratcheting occurring under load control, or any changes in specimen).
- Pay particularly close attention to the progression of failure of the test specimen, marking notes of anything out of the ordinary.
- After specimen failure, and after the machine has been stopped, record the orientation (relative to the specimen and its mounting in the grips and machine) of the initiation location(s) of cracking
- Shut down and rezero all equipment that will not be needed immediately for the next test.
- Record observations of the fracture surface (e.g., single or multiple cracks, multiple planes of cracking, secondary cracking, or angular orientation of cracks to specimen axis).
- Ascertain cyclic lifetime (and, hence, half-life values) at various points along the process of cracking and final fracture using criteria contained in the next of this Section.
- Reduce and tabulate the figure characterization data (e.g., half-life values of total, elastic, and inelastic strain ranges; stress range or amplitude; and mean stress), and compare observed lives with lives predicted prior to testing.
- Add each fatigue data point to the evolving fatigue curve to maintain a current view of the extent of the figure curve. This knowledge may dictate the conditions to be imposed on the next fatigue test

Fatigue, Creep Fatigue, and Thermomechanical Fatigue Life Testing

Ultrasonic Fatigue Testing

Introduction

ULTRASONIC FATIGUE TESTING involves cyclic stressing of material at frequencies typically in the range of 15 to 25 kHz. The major advantage of using ultrasonic fatigue is its ability to provide fatigue-limit and near-threshold data within a reasonable length of time. High-frequency testing provides rapid evaluation of the high-cycle fatigue limit of engineering materials. Fatigue crack growth at extremely slow crack propagation rates is also possible with ultrasonic frequency testing.

Ultrasonic fatigue testing is applicable to most engineering materials, including metals, ceramics, glasses, plastics, and composites. Test data can be used for screening of high-cycle fatigue properties or extending the fatigue data already available from conventional frequency fatigue testing.

This article reviews underlying concepts and basic techniques for performing ultrasonic fatigue tests. It describes test equipment design, specimen design, and effective control over test variables. Results obtained with ultrasonic fatigue test methods are discussed with respect to strain-rate-dependent material behavior. Standardized procedures and test machinery for performing ultrasonic fatigue tests currently are not available.

Historical Perspective

Development of higher-frequency testing machines began early in the 20th century. Prior to 1911, the highest fatigue testing frequency was on the order of 33 Hz, using mechanically driven systems. Electrodynamical resonance systems appeared in 1911 when Hopkinson (Ref 1) introduced a machine capable of 116 Hz. In 1925, Jenkin (Ref 2) tested wires of copper, iron, and steel at 2 kHz, using similar techniques. In 1929, Jenkin and Lehmann (Ref 3) were able to test materials up to 10 kHz using a pulsating air resonance system.

Mason (Ref 4) achieved ultrasonic frequency (20 kHz) in 1950 with the adaptation of magnetostrictive and piezoelectric-type transducers to fatigue testing. This method translated 20 kHz electrical voltage signals into 20 kHz mechanical displacements. A displacement-amplifying acoustical horn and the test specimen were driven into resonance by the transducer. This concept has remained basically unchanged and is the foundation of the practices used in modern ultrasonic fatigue test technology.

In the early 1960s, frequencies as high as 92 and 199 kHz were employed for fatigue tests using Mason's techniques (Ref 5, 6) These extremely high frequencies surpass the upper limits of practicality because of the constraints of specimen size (frequency is inversely proportional to specimen length), machining tolerances, strain amplitude measurements, and energy considerations. A review of the ultrasonic fatigue testing in the 1970s and 1980s shows that the majority of test stands operate at frequencies between 17 and 25 kHz.

This unofficial standard is primarily dictated by the availability of commercial high-power ultrasonic transducers and power supplies. These frequencies are also desirable from a safety viewpoint because they are above the range of normal human hearing. Fatigue testing at 20 kHz proceeds quietly in comparison to testing at 1 to 10 kHz.

Strain Rates, Frequency, and Time Compression

Ultrasonic fatigue testing increases the frequency of stress cycling to reduce the time necessary to accumulate a large number of cycles. Consequently, the strain rate at these frequencies for a given strain amplitude is also increased. In Table 1, strain rate is calculated as a function of frequency and strain amplitude. For typical fatigue strain amplitudes in the range of 10^{-4} to 10^{-3} , the strain rate at 20 kHz ranges from 2 to 20 s^{-1} .

Table 1 Strain rate as a function of test frequency and strain range

Frequency, Hz	Strain rate ($\dot{\epsilon}$), s^{-1} , at strain (ϵ) of:			
	$\epsilon = 10^{-5}$, m/m	$\epsilon = 10^{-4}$, m/m	$\epsilon = 10^{-3}$, m/m	$\epsilon = 10^{-2}$, m/m
10	10^{-4}	10^{-3}	10^{-2}	10^{-1}
100	10^{-3}	10^{-2}	10^{-1}	1
1,000	10^{-2}	10^{-1}	1	10
10,000	10^{-1}	1	10	10^2
100,000	1	10	10^2	10^3

Ultrasonic fatigue techniques are particularly useful for providing fatigue data in applications where strains are being applied and removed at kilohertz frequencies; (e.g., high-frequency loading of turbine blades). In fact, ultrasonic fatigue testing may provide a better simulation of the higher frequency vibrations encountered in service than conventional testing does in these cases. The test method is most applicable when the test material ultimately will be applied in service at frequencies at or near the test frequency. For applications with lower frequency vibrations, the effect of frequency and strain rate on test results must be interpreted.

The time compression per cycle obtained with ultrasonic fatigue is pronounced. For example, a conventional fatigue test at 1 Hz would take 320 years for a 10^{10} cycle test. At 100 Hz, the test would take 3.2 years. At an ultrasonic frequency of 20 kHz, this test would be completed in less than 6 days. The time required to complete fatigue tests at different frequencies is shown in Fig. 1. This time compression is extremely attractive for situations that require high-cycle data.

Fig. 1 Testing time versus number of cycles to complete test as a function of frequency

In comparison to conventional frequency testing, more test conditions and/or replicate tests can be performed in a given period of time at ultrasonic frequency. This provides results and conclusions that are statistically more meaningful for planning and design. On the other hand, the minimum number of cycles that can be measured practically is limited by kilohertz cycling. This limit is 10^5 cycles for open-loop testing, with a testing time of 5 s. Shorter times (~ 1 s) are possible with closed-loop computer control of the test and data acquisition systems. Similar time compression is possible in fatigue crack growth rate testing using ultrasonic fatigue. Figure 2 is a schematic of a typical crack growth rate, da/dN , versus stress intensity curve. The time necessary to measure a crack advance of 0.1 mm (0.004 in.) while testing at 1 Hz or 20 kHz is compared on the right side of the figure. It is obvious that ultrasonic testing is the only practical approach to observe the extremely slow crack growth rates that are characteristic of the threshold regime. Crack growth rate measurements as low as 10^{-11} mm ($4 \times$

10^{-13} in.) have been reported. Again, the practical upper bound of measurable fatigue crack growth rate at 20 kHz is on the order of 10^{-5} mm (4×10^{-7} in.) per cycle due to the rapid cycle accumulation.

Fig. 2 Typical crack growth rate versus stress intensity curve. Difference in time to observe a finite crack growth increment at ultrasonic (20 kHz) and conventional (1 Hz) frequencies is shown.

The testing time compression possible with ultrasonic fatigue is an incentive for applying the technology in a more generic sense, that is, to extend fatigue information obtained at conventional frequencies and lower numbers of cycles to higher-cycle fatigue limits and threshold fatigue crack growth rates. Because this accelerated test method alters testing conditions to produce fatigue in a shorter period of time, the influence of frequency and strain rate on cyclic material behavior must be well understood.

General acceptance of ultrasonic fatigue testing also requires an understanding of how to obtain data free of testing-induced artifacts. Improper execution can have a marked effect on the property data obtained. Much of the skepticism that endures about the use of ultrasonic fatigue stems from earlier testing where questionable techniques were used to measure cyclic strain amplitude and provide adequate cooling of the specimen. Accordingly, the effects of strain rate, frequency, and test technique are the subject of most research on ultrasonic fatigue (Ref 7, 8)

In general, testing by ultrasonic fatigue produces fatigue data that differ only slightly from those observed at more conventional frequencies. Some data reveal a shift in the ultrasonic fatigue stress-life data ($S-N$) for a given stress level toward increased lifetimes relative to conventional-frequency results (Ref 9, 10, and 11) Other reports indicate no shift in the $S-N$ behavior (Ref 12, 13). Most reports indicate that fatigue degradation at ultrasonic frequency occurs by the same sequence of events as at conventional frequencies, namely, saturation of rapid hardening, formation of persistent slip bands, formation and growth of intrusions, and crack propagation.

Materials that exhibit clearly defined endurance limits at conventional frequencies usually exhibit endurance limits at similar cyclic stress amplitudes at ultrasonic frequencies. Similarly, materials that exhibit threshold stress intensities for fatigue crack growth at conventional frequencies also exhibit this behavior at ultrasonic frequencies. Shifts in $S-N$ fatigue behavior to higher stress levels and longer lifetimes or da/dN behavior to slower crack growth rates do not occur for all materials tested at high frequency. Recent testing shows that the effect of frequency on $S-N$ and da/dN performance is primarily a function of the microplasticity and slip character of the material system under test.

It might also be inferred that corrosion fatigue interactions should be negligible at ultrasonic frequency due to the short cyclic period. Again, experimental results illustrate that corrosion fatigue interactions are indeed

observed at ultrasonic frequencies. Recent testing shows that ultrasonic fatigue is an effective method for the evaluation of the degradation of fatigue properties produced by environmental interactions.

Ultrasonic fatigue testing is applicable to most situations in which conventional-frequency fatigue testing has been employed. Examples of a variety of results from ultrasonic fatigue are presented later in this article. As the technique continues to develop, the precise limits of applicability will become more clearly defined.

Ultrasonic Fatigue Testing

Testing Principles

The principles of ultrasonic fatigue testing are quite simple. Ultrasonic fatigue is a resonant test method, in which a large-amplitude displacement wave must be established in a resonant specimen. This wave is generated by a relatively small periodic stimulus at the same frequency as the natural frequency of the test specimen. Resonance is required to achieve the strain amplitude needed to produce fatigue in materials.

Displacement and strain are developed in a bar of material subjected to resonant acoustic loading. Consider a straight bar of material having a uniform diameter and length L (Fig. 3). A sound wave injected longitudinally into one end of the bar travels at a certain velocity through the bar, is reflected from the opposite end, and returns to the point of entrance. The wave velocity, C , is determined by the material properties, the Young's modulus, E , and the density (mass/volume), ρ , by:

$$C = \left(\frac{E}{\rho} \right)^{1/2} \quad (\text{Eq 1})$$

Fig. 3 Distribution of oscillatory displacement amplitude and strain amplitude over the length of a resonant bar of uniform cross section

This velocity is the speed of sound through the material. The time required to travel the length of the bar and return is $2L/C$. If this time is equal to the period of the injected sound wave, the reflected wave will be exactly in phase with the injected wave, standing wave conditions will be established, and the bar will be in resonance. The length, L , of the bar is then exactly equal to the half wavelength of the sound wave. The variation of displacement amplitude of oscillation at a point x along the length of the bar will be:

$$A(x) = A_0 \cos(kx) \quad (\text{Eq 2})$$

where A_0 is the displacement amplitude at the end of the bar, k is $2\pi/\lambda$, and λ is the wavelength of sound at the resonant frequency.

The strain distribution along the bar will be the derivative of the displacement amplitude with respect to distance or:

$$\epsilon(x) = \frac{dA(x)}{dx} = -kA_0 \sin(kx) \quad (\text{Eq 3})$$

Thus, the maximum strain occurs when $\sin(kx) = 1$, or $x = \lambda/4$. The maximum strain varies between $\pm kA_0$ during each cycle. Figure 3 shows the distribution of longitudinal displacement amplitude and strain amplitude along the length of a bar in resonance. The minimum displacement (displacement node) and maximum strain (strain antinode) occur at the center of the bar. Similarly, the maximum displacement (displacement antinode) and minimum strain (strain node) occur at the ends of the bar.

The stress distribution for each point along the bar is obtained by an elastic conversion of the strain distribution:

$$\sigma(x) = E \cdot \epsilon(x) \quad (\text{Eq 4})$$

where E is the dynamic Young's modulus of the material. The dynamic modulus of elasticity must be determined for the appropriate test frequency. Because of the elastic conversion, the stress maximum physically coincides with the strain maximum. Stresses cannot be obtained independent of strains in ultrasonic fatigue testing. Therefore, strict stress-controlled tests cannot be performed. Without independent per-cycle stress and strain information, plastic strain-controlled tests also are not possible at this time. For more information on plastic strain-controlled ultrasonic fatigue testing, see Ref 14.

The example of the uniform resonant bar embodies the basic concepts of ultrasonic fatigue testing. With appropriate geometric modification, these concepts can be used to design the mechanical portion of the converter, the acoustic horns, and the test specimen.

The major difference between a conventional fatigue test specimen and a high-frequency resonant specimen is that the cyclic strain amplitude varies from zero at the ends to a maximum at the center, rather than being constant over its entire length. This confines fatigue damage and, hence, fatigue crack initiation and propagation to the center of the specimen. Because there is minimal strain at the ends of a resonant bar, the requirements for attachment of one resonant bar to another and for gripping the specimen also are minimal.

To produce strain in a bar, only one end of a resonant bar specimen must be in acoustic contact with the source of the sound waves. This permits the testing of thin materials under reversed tension-compression loading without risk of buckling the specimen. Consequently, sheet, tubing, and wire specimens may be subjected to

fully reversed loading during ultrasonic fatigue, whereas more complex gripping and alignment techniques are required to accomplish similar tests at conventional frequencies. The large and cumbersome arrangements for gripping the specimen that often are required in conventional fatigue testing are not needed in ultrasonic fatigue.

A specimen with a free end also provides the ultrasonic fatigue system with a degree of portability that is not easily obtained with conventional-frequency test methods. Fatigue testing can be performed with the specimen in an operating environment by feeding the free end of the wave train through an access port to the environment. Similarly, testing can be performed under the view of an optical or electron microscope without the need of complex load-transmitting stages.

Cyclic straining can be achieved in a bar at any desired resonance frequency by appropriately choosing (tuning) the length of the bar. For a bar with a uniform cross section, the required length for fatigue testing will be $\lambda/2$ at the resonance frequency. For bars with variable cross sections or dumbbell specimen geometries, the resonant length generally is shorter than the resonant length of a uniform bar at the given test frequency. Thus, each component in a resonant testing system must be designed (tuned) to the resonance frequency to transmit the acoustic energy efficiently into the test specimen. The equations developed by Neppiras (Ref 15) are helpful in calculating the appropriate resonant lengths for variable specimen section geometries. These equations are presented later in this article in a section on specimen design.

Testing Equipment and Methods

Packaged ultrasonic fatigue test systems, with one exception, are not commercially available. However, an ultrasonic fatigue test system may be constructed easily from commercially available parts. Tien et al. (Ref 16) describe the construction of a test machine using ultrasonic components normally used in ultrasonic joining processes. This machine, an open-loop test stand, contains the basic equipment needed for testing. Information on test stands with additional capabilities—including double converters, mean loading, electrochemical cells, and computerized control systems—can be found in Ref 17, 18, and 19, and 20. A portable test machine including ultrasonics, external loading frame, environmental system, and test chamber is shown in Fig. 4.

Fig. 4 Portable 20 kHz corrosion-fatigue machine with mean load capability

Figure 5 is a schematic of a typical ultrasonic fatigue test machine. The machine is centered around an acoustic wave train composed of a sonic energy converter, a series of acoustic amplifying horns, and the test specimen. A typical wave train is shown in Fig. 6. The acoustic energy is supplied by a high-frequency power supply. An amplitude-measuring device and a means of dissipating the heat generated by the deformation process are also necessary. This basic equipment is appropriate for stress-life ($S-N$) or fatigue-crack-growth rate (da/dN) testing. A frequency display, cycle counter, and temperature-measuring equipment are used to monitor the test. Additional monitoring equipment is necessary to measure crack length in da/dN testing.

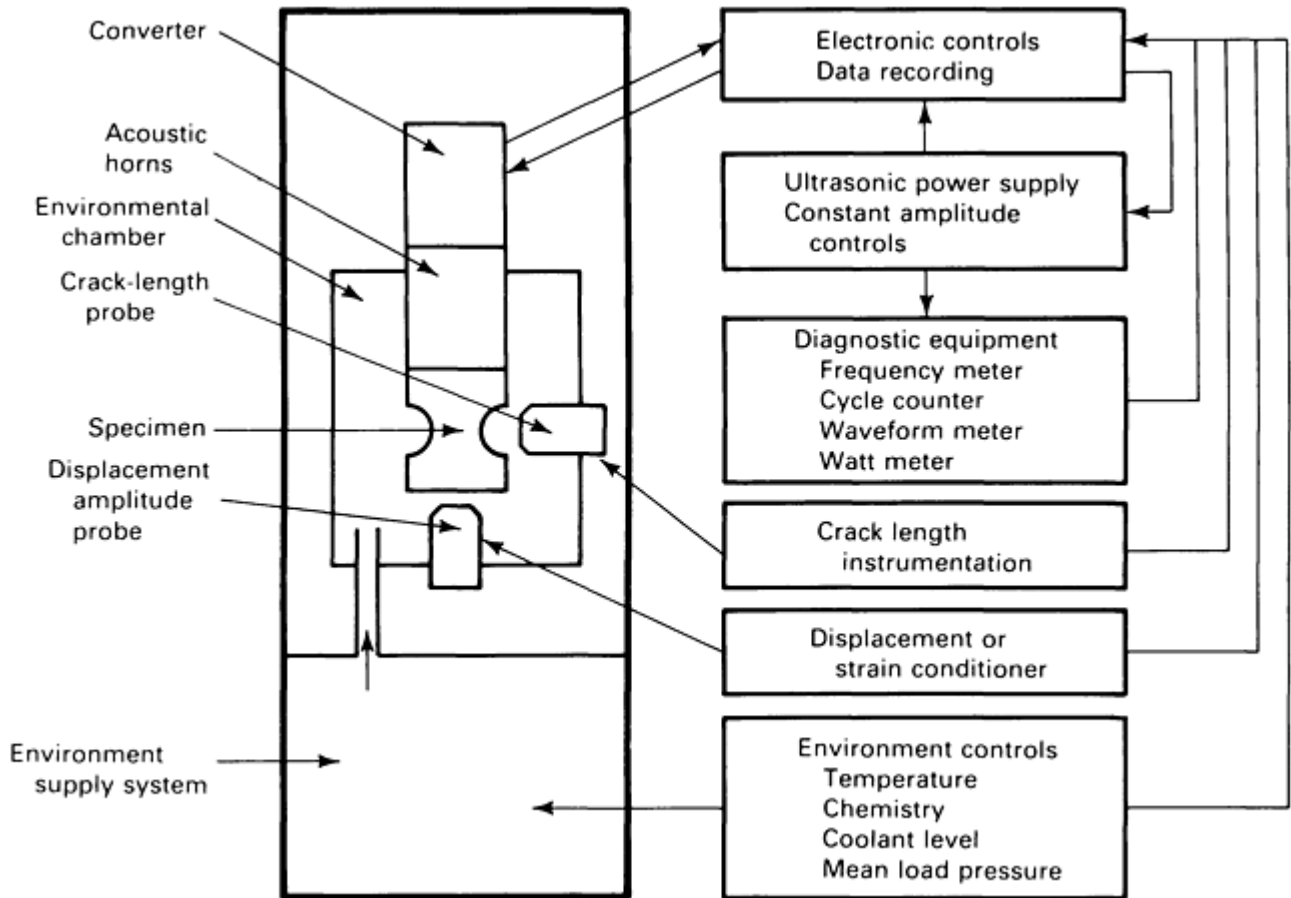

Fig. 5 Schematic of an ultrasonic fatigue test system

Fig. 6 Typical 20 kHz acoustic wave train

Power supplies for ultrasonic fatigue testing typically range from 500 to 4000 W of electrical power. The actual output to the specimen is lower than this during normal resonant operation. Most power supplies have built-in feedback circuits, which produce a constant-amplitude oscillation in the converter. Some power supplies have circuits for automatic shutoff when the specimen or any part of the wave train goes out of resonance. This is useful for *S-N* testing. The fatigue crack at failure will be some fraction of the cross-sectional area when the power supply shuts off. This fraction can range from a few percent to 50% of the cross-sectional area, depending on the automatic shut-off controls.

Sonic Converters. Acoustic resonance is developed in the converter by application of the electrical excitation provided by the power supply. The converter generates a standing acoustic wave that produces a cyclic displacement at the end of the converter. The acoustic wave proceeds down the rest of the resonant wave train to the specimen. Variation of the displacement and strain amplitudes along the wave train is shown in Fig. 7.

Fig. 7 Variation of the displacement and strain amplitudes along the acoustic wave train

Several cycles of application of the electronic stimulus of the power supply are required to achieve the maximum resonant amplitude in the converter and the rest of the wave train. The rise time of the converter should be known when considering a pulsed mode versus continuous-cycling mode of an ultrasonic fatigue system. In a pulsed-mode operation, the specimen is subjected to a series of pulses (~ 1 s) of high-amplitude cycles followed by a cooling period without cycling. Rise time of ultrasonic equipment varies among manufacturers. If rise time is longer than pulse time, variable-amplitude test conditions exist. Pulsed-mode operation has been suggested by some investigators to overcome the rapid heating manifested by high-damping materials upon cycling. Ultrasonic fatigue systems take several cycles for the maximum resonant amplitude to be developed. Hence the tendency to overshoot the desired amplitude setpoint on the first cycle is small.

Converters for generating ultrasonic displacement waves generally are magnetostrictive or piezoelectric devices. Most modern converters use piezoelectric materials for conversion efficiency. Magnetostrictive devices have a low (20%) conversion efficiency. Piezoelectric converters with efficiencies greater than 90% are readily available.

Converter types and designs vary among manufacturers. Some piezoelectric devices use lead-zirconium-titanate (PZT) for the converter material. The end displacement amplitude developed by a 20 kHz PZT converter ranges from 0.010 to 0.020 mm (0.0004 to 0.0008 in.). Piezoelectric plastic materials are being considered for higher-amplitude ultrasonic converters.

A single- or double-converter arrangement can be used to drive the specimen into resonance. In a single-transducer system, one end of the specimen is coupled to the converter and the other end remains free. In a double-converter system, both ends of the specimen are coupled to two coaxial antiphase-driven ultrasonic converters (Ref 17). The advantage of a double-converter system is its symmetry.

A comparison of the displacement, strain, and specific energy parameters for a high-damping perspex (Lucite) test specimen tested with a single- and double-converter system is shown in Fig. 8 (Ref 21). The symmetry of the converters is reflected in the greater symmetry of the displacement and strain distributions produced in a resonant specimen. While equivalent testing conditions can be produced with either single- or double-converter systems through precise design of the acoustic elements, the double converter is less sensitive to small differences between the resonance frequency of the specimen and the driving frequency of the converter. Data also show that the double-converter arrangement is less sensitive to detuning of the specimen due to changes in elastic properties or the growth of a fatigue crack. Fatigue crack growth testing benefits from the longer crack length attainable with a double-converter system before significant frequency degradation occurs.

Fig. 8 Comparison of single- and double-converter systems. Calculated displacement, strain, and specific energy parameters for a highly damped perspex specimen ($L = \lambda/2$) are shown. The single-converter system was excited from the left side. Assumed values for the specimen: $E = 48 \text{ GPa}$ ($6.9 \text{ psi} \times 10^6$); $\rho = 1.2 \text{ g/cm}^3$; frequency = 20 kHz. Source: Ref 21

Acoustic horns transmit the resonance developed by the converter to the specimen. One or more acoustic amplifying horns generally are placed in the wave train to raise the strain amplitude in the specimen to the level required for fatigue. Design of these horns was developed by Mason (Ref 22) and Neppiras (Ref 15).

Acoustic horns are bars of resonant length with cross-sectional areas that change either continuously or discontinuously as distance from the input end varies. To maintain the requirement of continuity of particle velocity along the horn length, the vibrational amplitude must increase in areas of reduced cross-sectional area. This produces displacement and strain amplification. For the simple stepped-down horn shown in Fig. 9(a), displacement and, hence, strains are amplified by the ratio of the cross-sectional areas of the horn:

$$A_o = \frac{\text{Area}_{\text{input}}}{\text{Area}_{\text{output}}} \cdot A_i \quad (\text{Eq 5})$$

where A_o is the displacement amplitude on the output end of the horn, and A_i is the displacement amplitude on the input end of the horn. Conversely, an increase in cross-sectional area causes deamplification. A number of different horn shapes have been designed by detailed mathematical analysis (Ref 23, 24, 25, and 26); typical examples are shown in Fig. 9 along with the particle velocity and stress distribution along their length.

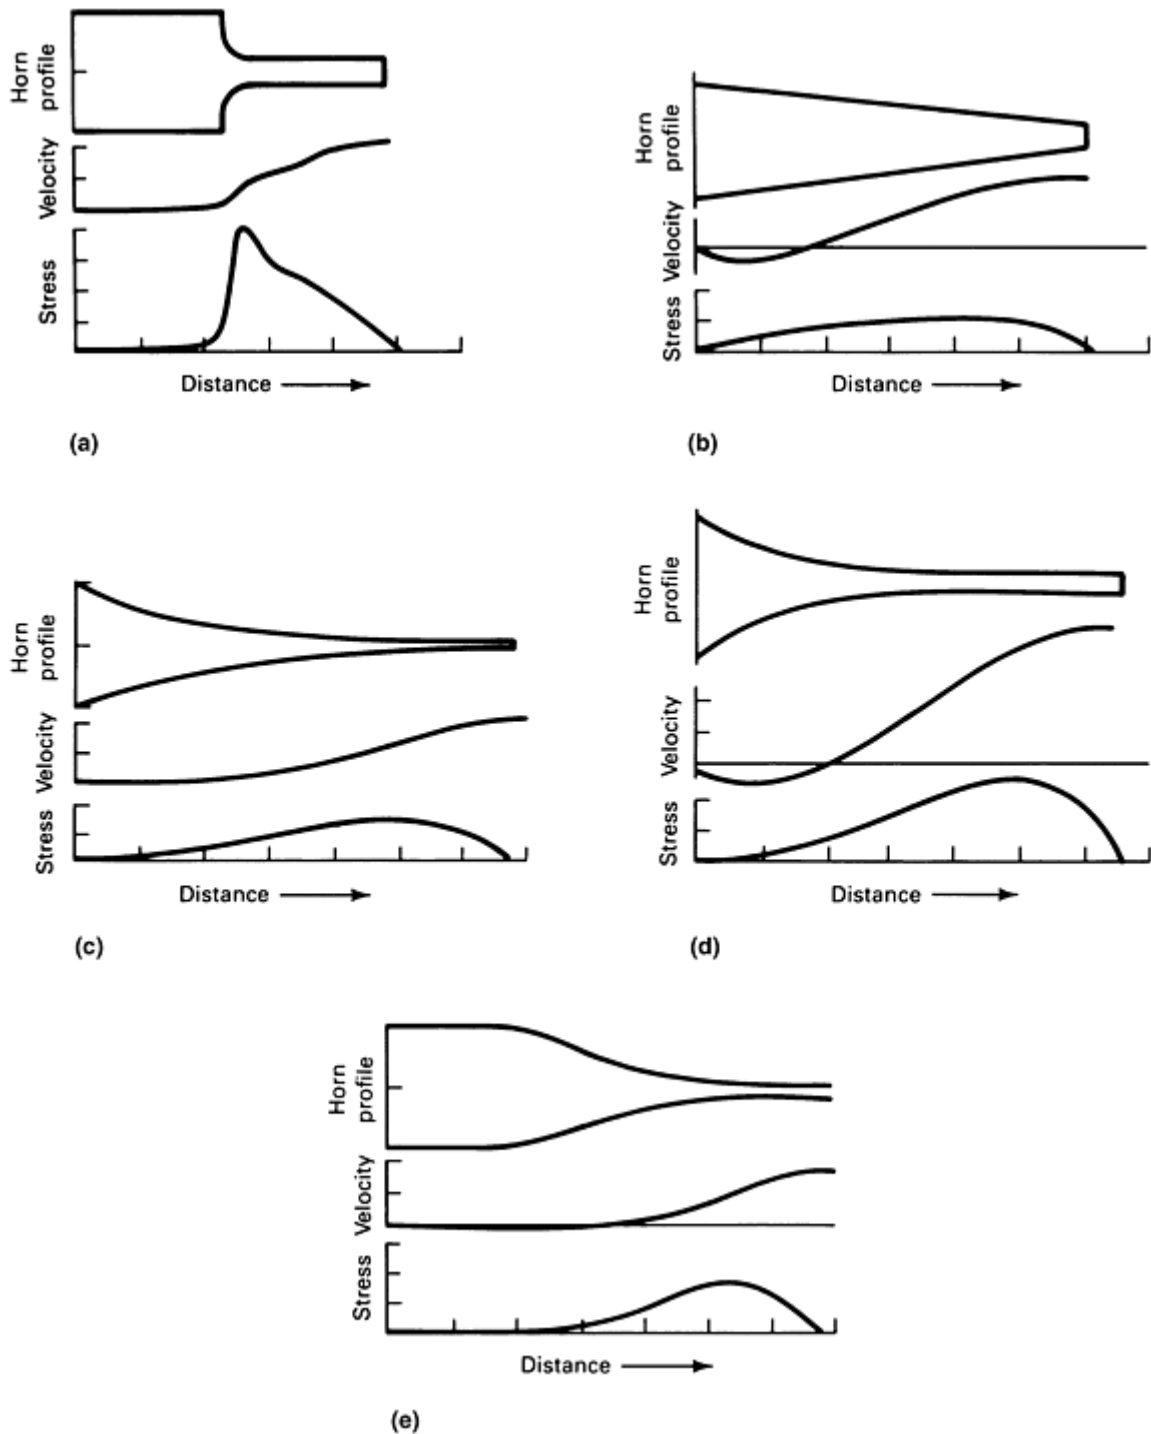

Fig. 9 Profiles of acoustic horns for amplifying converter output. Variations in particle velocity and stress along horns are shown below each profile. (a) Stepped. (b) Conical. (c) Exponential. (d) Catenoidal. (e) Fourier. Source: Ref 23

An obvious problem with the stepped horn is the manifestation of very-high-stress amplitudes at the step. This eventually causes the horn to fail by fatigue at the step. The Fourier horn (Fig. 9e) is the best overall horn design for achieving the highest amplification with the greatest strength and stiffness. Ultrasonic converter suppliers typically carry a variety of acoustic horn designs with amplifications ranging from 1 to 10 to 1. Some manufacturers will design acoustic horns for custom applications, including very high amplifications, special frequencies, or sealing the entrance of an environmental chamber.

Extension Acoustic Horns. The need for extension horns generally arises when the test specimen must be isolated in a controlled environmental chamber, furnace, or external load frame. Typically, a 1 to 1 extension horn is used—that is, a uniform bar of length $\lambda/2$, having been modified with a flange for seating an environmental seal or for attaching the wave train to the external load frame.

It is important to select materials that will not affect the test. Extension horn material should be low damping whenever possible to avoid losses and excessive heating. For corrosive environments, the horn material should be such that a galvanic couple is not set up between the specimen and horn. If high temperatures are to be encountered, the horn material must possess appropriate high-temperature strength. The elastic properties of the material should be determined for the temperature of the desired test. Some properties of materials used for acoustic extension horns are presented in Table 2.

Table 2 Typical 20 kHz resonance properties for acoustic extension horn materials

Material	Density (ρ), g/cm ³	Wavelength of sound at the resonant frequency (λ)		Young's modulus (E)	
		mm	in.	MPa	psi $\times 10^6$
Ra-333	8.3	244	9.61	199,300	28.9
Udimet 710	8.1	264	10.40	224,090	32.5

Amplitude Detection. The accuracy of determining specimen strain depends to a great extent on the accuracy of the measurement of the displacement amplitude at the end of the specimen. Much research has been directed toward the development of sensitive methods for measuring displacement amplitude at ultrasonic frequencies. The simplest, most reliable method is observation of the trajectory of a feature on the specimen surface with a dark-field optical microscope having coaxial lighting and a filar eyepiece.

At magnifications of 500 \times and a reticle scale in hundredths of a millimeter, displacements on the order of 2 to 3 μm can be detected. The trajectory of a point on the specimen surface appears as a bright streak whose length will be the peak-to-peak displacement amplitude. Visual observation of displacement amplitude with a microscope does not lend itself to automated recording of the displacement. However, it is the preferred method for calibrating more automated amplitude detection equipment, because secondary modes of vibration are easily detected. Secondary modes cause the normally linear trajectory of a point to skew or appear to orbit about another point.

Other amplitude detection devices more suitable for automated data acquisition or feedback to a closed-loop fatigue apparatus have also been used. These generally are displacement-measuring devices, which come in many forms, including capacitance gages (Ref 16, 27), permanent magnet-coil arrangements that use eddy currents (Ref 17, 28), a microphone pickup (Ref 29), a photodiode arrangement (Ref 30), and closed-circuit television (Ref 31).

Noncontacting capacitance-type detectors to measure displacement amplitudes at ultrasonic frequency are commercially available with sensitivities on the order of $3 \times 10^2 \mu\text{m}$ and linear frequency response up to 50 kHz. Eddy current probes also are commercially available and are frequently used to measure displacement. Because eddy currents are sensitive to composition and microstructure, eddy current probes require calibration of the output signal versus displacement for each new material that is tested. These devices generally are not useful for measuring displacement of nonconducting or low-permeability materials. When the end of the specimen is inaccessible due to an environment chamber or extension horns, the displacement must be calibrated from the specimen to some other point on the wave train.

Strain can be measured by directly applying strain gages to the specimen and reading the value from a strain conditioner that has a frequency response equivalent to the test frequency. Several problems are associated with strain gages applied directly to the specimen. Strain gages, strain gage leads and the adhesive that holds a strain gage onto the specimen are subject to fatigue loading and have finite cyclic lifetimes. If they are placed at the point of maximum strain on the specimen they generally will fail before the specimen does. Attachment of the gage to the specimen may modify the specimen surface and lower its fatigue properties. The presence of a gage on the specimen can cause additional heating to occur under the gage. These problems can be avoided by placing the gage on an adjacent extension horn where the maximum strains are lower than those on the specimen. The strain in the specimen then can be calibrated to the strain in the extension horn.

It is best to use amplitude detectors that can be located at, or as close as possible to, the specimen. Consideration should be given as to whether the environment that is used will interfere with operation of the device. Some devices give outputs that vary when they are positioned away from the specimen and require calibration for each material; electrodynamic devices operating on eddy currents induced in the vibrating specimen fall into this category. These devices are more difficult to use than capacitance gages, whose output is linear over a known range and does not depend on the properties of the test material. Capacitance gages also need to be calibrated if the working environment changes the dielectric constant.

Crack growth measuring systems for ultrasonic fatigue tests are similar to those used at conventional frequencies. Optical methods can be used because the fatigue crack grows in the plane of maximum strain, which is a displacement node. As a result, the crack will not appear to be vibrating. Optical methods using microscopes on traveling stages can be operated manually or automatically. Automated systems for video monitoring of the crack length are described in Ref 19. Foil-type crack growth gages can be attached to the specimen in the path of the growing crack. These gages develop a linearly varying potential as the crack tears the foil and have been shown to operate linearly under 20 kHz cycling. The usual requirements for monitoring the symmetry of fatigue crack length in double-edge-cracked or center-cracked specimens at conventional frequency also apply for ultrasonic frequency testing.

Cooling Systems. As in conventional fatigue testing, the components of fatigue deformation generate heat within the specimen in an amount equal to the area enclosed by the stress-strain hysteresis loop in each cycle. At 20 kHz, the specific energy input at high stresses can be as high as several hundred watts per cubic centimeter for high damping materials. Large temperature excursions can result if the heat is not removed. These temperature excursions not only change the properties of the test material, but can introduce mean tensile stresses on the surface of solid specimens because of the differential thermal expansion between the core and surface of the specimen.

In most cases, the heat generated can be dissipated by forced cooling if the heat transfer path is not too lengthy. In some cases, the heat generated cannot be eliminated by forced-air cooling, and more efficient external and internal cooling may be necessary. A hollow specimen can be used to decrease the heat-transfer path through the metal.

In specimens of materials with high damping and large cross sections, this heat rise can be extreme. Figure 10(a) shows the temperature contour of a 12 mm (0.48 in.) diam resonant steel bar without cooling (Ref 32). The strain antinode heated to almost 400 °C (750 °F) during ultrasonic-frequency cycling at a stress level of 150 MPa (22 ksi). The highest temperatures are observed at the strain antinode. Efficient cooling of a test specimen would obviously require the greatest volume of coolant to flow over the strain antinode. Large temperature excursions can usually be minimized in practice by the choice of a hollow dumbbell specimen design.

Fig. 10 Infrared thermogram of specimen under 20 kHz excitation without cooling. (a) Resonant specimen exhibiting nodal heating. (b) Localized heating due to thermocouple epoxied to surface of nonresonant specimen. Source: Ref 32

The damping characteristic of the material and the efficiency of the coolant determine the choice of a solid or hollow specimen design for testing. In general, cooling a material with high damping (such as pure copper) with forced-air heat transfer requires a thin-walled hollow specimen to ensure that the temperature rise is acceptably low. At the other end of the damping spectrum, titanium alloys generate so little heat at 20 kHz at modest stress levels that virtually any specimen geometry is compatible with the temperature rise limitations.

Martensitic steel lies somewhere between copper and titanium, and hollow or solid specimens may be selected depending on whether the coolant is forced air or water. Measurement of the temperature rise at the uncooled interior of a hollow type 403 stainless steel specimen (1.25 mm, or 0.05 in., wall thickness, with water cooling at the external surface) revealed a temperature rise of less than 10 °C (18 °F) even during fatigue at stresses high enough to cause failure in 10^7 cycles.

Monitoring the temperature rise is essential to obtaining reliable data, particularly when testing in air. Attaching a thermocouple to the specimen at the maximum strain point presents two basic problems. First, the specimen could be damaged and premature fatigue failure could occur. Second, infrared data show that attachment of the thermocouple to a nonresonant bar causes localized heating in the vicinity of the thermocouple (Fig. 10b).

The localized heating implies that thermocouples may not be reliable for measuring the specimen temperature during ultrasonic vibration. It has been proposed that the localized heating could be caused by vibration of the leads of the thermocouple due to active displacement at all positions of a nonresonant specimen. Hence, placing the thermocouple at the displacement node of a resonant specimen might minimize this local heating. This viewpoint has not yet been verified.

Two alternate temperature-sensing methods that work well in air environments are infrared imaging of the specimen and application of temperature-sensitive paint to the specimen surface. These methods provide only surface temperature information. The subsurface temperature is hotter. In liquid environments, the alternate temperature measurements will not work, and thermocouple data may be the only possible method. In liquid environments, particularly water, temperature control is somewhat easier because the liquid acts as a coolant

and moderates the temperature excursion. Generally, the liquid is controlled to some temperature below the desired temperature so that the excess heat generated from testing will be dissipated in the liquid. For elevated-temperature testing, the furnace temperature must be controlled so that the heat generated in the specimen helps achieve the desired temperature.

A forced-air cooling system with an infrared temperature monitoring system is shown in Fig. 11. Air jets are aimed at the strain antinode. With an air line pressure of 0.5 MPa (72.5 psi) and a venturi-type air cooler in the line, an air jet exit temperature of 0 °C (32 °F) can be obtained. A liquid cooling system requires that the liquid flow over the surface of the specimen.

Fig. 11 Test facility (20 kHz) showing positioning of forced-air cooling, infrared temperature monitor, and external load frame for mean load. 1, converter; 2, booster horn; 3, connecting horn; 4, specimen; 5, capacitance gage; 6, cooling ring; 7, four air inlets; 8, venturi air cooler; 9, air supply; 10, upper and lower support plates; 11, hydraulic pistons; 12, window; 13, infrared camera

The major difference in ultrasonic fatigue testing compared to conventional fatigue testing is that the specimen should not be totally immersed in a bath of coolant. Immersing the specimen could prevent the system from obtaining constant-amplitude resonance. If resonance can be obtained while immersed, cavitation erosion damage may occur at fillets and ends of the specimen. This can be prevented by the application of a thin film of rubber compound, such as carboline neoprene adhesive, to these areas of the specimen. A typical liquid cooling system is shown in Fig. 12. In this system, the liquid flows onto the specimen and drains off to be recirculated. This system can also be used for environmental testing.

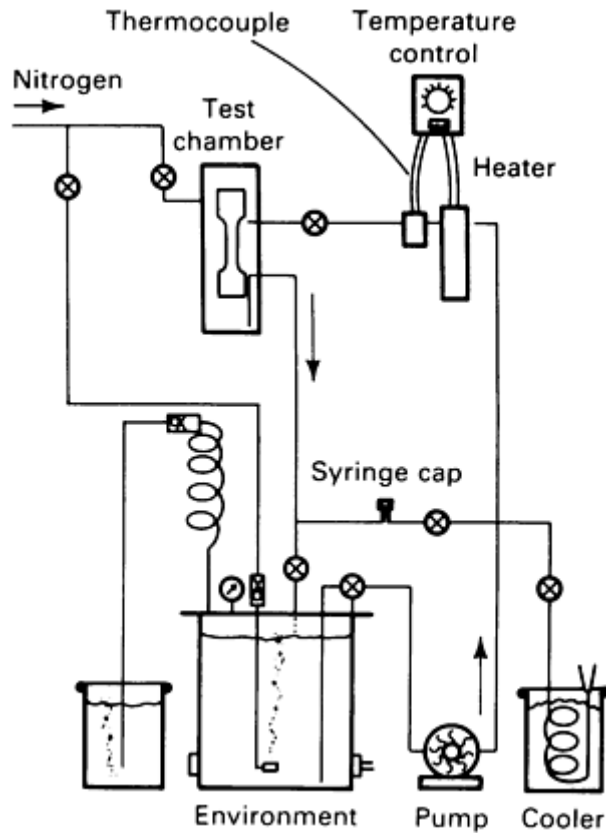

Fig. 12 Environment supply system for liquid cooling or corrosion-fatigue testing

In a liquid cooling system, an inert coolant is necessary to achieve baseline fatigue property data approaching those of air tests. The coolant must not be corrosive to the material and must have a heat capacity large enough to remove the heat from the specimen. Deionized, low-oxygen-content water is a very high-heat-capacity, minimally corrosive coolant for most materials. It is a little more difficult to use low-oxygen deionized water as a coolant because an environmental system is necessary to control the gaseous traces in the water. Acid-free transformer oil is another coolant frequently used for ultrasonic fatigue tests. Liquid cryogen coolants, such as liquid nitrogen, generally are less effective due to their tendency to vaporize on contact with the specimen. The vapor forms a boundary layer at the specimen surface, which reduces effective cooling instead of increasing it. Fatigue property data obtained with a nonaggressive coolant generally are slightly lower than data obtained with air cooling. Baseline data obtained with an inert coolant are usually necessary for the interpretation of corrosion fatigue data.

External Load Frame. The wave train arrangement can be used without further attachment for completely reversed tension-compression testing. The wave train can also be placed in an external load frame, such as a tensile test machine, to provide static mean loading or superposition of large-amplitude low-frequency cycling on top of the high-frequency cycling (Ref 18, 32). The external load frame is attached to the wave train at the displacement nodes on acoustic horns on either side of the specimen, as shown in Fig. 11.

Design of specimens to be subject to superimposed external loads must take two additional factors into account. First, the elongation of the specimen due to external straining must be considered to stay within the bounds of the resonance conditions. Second, there have been observations of softening of metals during simultaneous tensile or compressive mechanical deformation and high-frequency straining, which is known as the Blaha effect (Ref 33). These mechanisms are discussed in more detail in Ref 32. Test engineers should be aware of this effect because it can result in additional plastic deformation of the material during testing.

Environmental Fatigue. Ultrasonic fatigue testing can be performed under most environmental conditions. One possible exception is vacuum, in which testing is narrowed to a few very-low-damping materials at low stress levels. Environmental testing requires the normal ultrasonic fatigue testing apparatus with the addition of an environmental chamber around the test specimen and an environmental supply system.

Elevated Temperatures. For high-temperature testing, the furnace serves as the environmental chamber and supply system. A high-temperature test stand with mean load capability can be constructed by placing a furnace around the specimen in the test system shown in Fig. 11. Some tuning generally is required to design extension

horns that will be resonant in the temperature gradient from the furnace midpoint to the ambient temperature outside the furnace, because the resonant frequency is temperature dependent. For high-temperature fatigue, the specimen displacement amplitude usually will have to be calibrated to a displacement antinode outside the furnace (Ref 34).

Aggressive Liquid Environments. Testing in corrosive liquid environments requires both an environmental chamber and an environmental recirculation system. This is essentially the same equipment needed for inert liquid cooling, as shown in Fig. 12. Additional features are incorporated into the environmental recirculation system to provide control of the solution composition, purity, and temperature. Ports are incorporated so that environment composition samples can be taken for documentation and solution pH can be adjusted. An inert gas overpressure is usually maintained throughout the system to control the dissolved oxygen content of the test solution. Appropriate plumbing and seals are incorporated so that the specimen chamber can be purged of air prior to circulation of the environment.

A controlled-corrosion fatigue chamber is shown in Fig. 13. This chamber exhibits features needed for electrochemical corrosion fatigue study (Ref 20). The chamber is composed of an outer chamber and an inner chamber constructed of Teflon. The inner chamber contains a finite volume of liquid around the gage section of the specimen. A platinum electrode is fitted into the inner chamber for anodic or cathodic polarization of the specimen. A window is placed at the side of the inner chamber to enable viewing of the amount of liquid in the inner chamber. A port is placed in the front of the inner chamber so that a standard reference electrode can be inserted to measure the electrochemical potential of the specimen. The electrodes can be removed for normal corrosion fatigue testing.

Fig. 13 Environmental fatigue test chamber for electrochemical 20 kHz testing

Proper selection of horn material is important in corrosion fatigue testing, because a mismatched specimen and horn material combination may set up a galvanic couple when the joint is wetted with a conductive solution. Depending on the galvanic couple, the horn material may cause the gage of the specimen to be electrochemically more active or passive than normal. This could have a pronounced effect on the corrosion fatigue properties that are being determined. It is advisable to make the specimen and the extension horn out of the same material. If the horn and specimen must be made out of dissimilar metals, care must be taken to ensure that the joint is not exposed to the conductive test solution.

In fatigue crack growth testing in liquid environments, the effect of the liquid inside the growing fatigue crack also must be considered. The effect of the liquid fatigue crack growth rate is currently being investigated. Depending on the fluid properties, the fatigue crack may be wedged open, causing errors in the da/dN and threshold stress intensity range, ΔK_{th} question is whether the environment ever extends to the crack tip. It has been suggested that at high crack growth rates, the environment has little influence on rapid crack growth, and the crack tip behaves as if it were in vacuum (Ref 35).

Test Specimens

Ultrasonic fatigue test specimens must be designed to resonate at the desired test frequency. The first step in designing an ultrasonic fatigue test specimen, acoustic horn, or resonant bar is to obtain the appropriate properties and constants of the materials. The material density, dynamic modulus of elasticity, and the half wavelength of sound in the material at the desired testing frequency must be determined.

Frequency, Wavelength, and Speed of Sound. The longitudinal resonance frequency of a bar test material is measured experimentally, as shown in Fig. 14. A uniform bar of test material is excited by a small converter coupled to a variable-frequency oscillator. The converter can be an electrodynamic vibrator or any other vibrator capable of ultrasonic frequencies. A piezoelectric pickup is placed against the opposite end of the bar to monitor the amplitude of vibration. For most pure metals and alloys, the bar should be about 100 to 150 mm (4 to 6 in.) long and 4 to 10 mm (0.16 to 0.4 in.) in diameter. This diameter is comparable to the diameters of most test specimen gages.

Fig. 14 Experimental measurement of the longitudinal resonance frequency of specimens

The bar should be similar in size to the eventual specimen gage diameter, because measured resonant frequencies vary with large-diameter bars. This directly affects calculation of the dynamic elastic modulus, and ultimately affects calculation of the fatigue stress amplitude. Frequencies on the order of tens of kilohertz should be measured for a bar length in this given range. Sweeping the oscillator through the frequency spectrum produces a large increase in output for some frequency; this is the resonance frequency. The length of the bar is $\lambda/2$ for the experimentally determined resonance frequency. Resonant wavelengths for several pure metals at test frequencies of 20 kHz and 2 MHz are given in Table 3. The resonant wavelength is inversely proportional to frequency. The need for a macroscopic test specimen frequently precludes high-frequency testing in the 2 MHz range. The speed of sound through the material can be calculated by relating the speed of sound, C , to frequency, f , and wavelength, λ :

$$C = \lambda_1 f_1 = \lambda_2 f_2 \quad (\text{Eq 6})$$

Table 3 Resonant specimen lengths for several pure metals

Metal	Young's modulus		Resonant specimen length ($\lambda/2$) at:			
			20 kHz		2 MHz	
	GPa	psi $\times 10^6$	mm	in.	mm	in.
Al	62	9.0	120	4.7	1.20	0.047
Cu	110	15.9	88	3.5	0.88	0.035
Ti	116	16.8	127	5.0	1.27	0.050
Fe	196	28.4	124	4.9	1.24	0.049
Ni	207	30.0	121	4.7	1.21	0.047

The resonance frequency of a bar of arbitrary length, as determined in the previously described experiment, may not be the driving frequency of the converter that will be used for testing. The appropriate wavelength for testing frequency is calculated by assuming that the speed of sound through the material remains constant for a given material and temperature.

The dynamic modulus of elasticity, or dynamic Young's modulus, E , can be determined by combining Eq 1 and 6 to obtain:

$$E = \rho(\lambda f)^2 \quad (\text{Eq 7})$$

The dynamic modulus differs from the static modulus (relaxed modulus) obtained from a tensile test. The static modulus is inadequate for converting the strain amplitude to stress amplitude because it will include anelastic contributions to strain that are absent at ultrasonic frequency. Use of the static modulus gives stress estimates that are too low because the static modulus is typically less than the dynamic modulus.

Stress-Life Specimen Design. Several specimen designs for ultrasonic fatigue stress-life testing are shown in Fig. 15. Although the uniform bar is the most easily produced specimen, it generally is not employed in testing. The stress concentration due to the screw threads used for gripping causes the local stress in the thread to exceed the maximum stress produced at the center of the specimen. Failure in the screw threads rather than in the center of the specimen would result.

Fig. 15 Profiles of specimen designs for ultrasonic fatigue. References cited provide mathematical analyses required to compute stress and strains.

Strain amplification is desirable at the center of the specimen. This is accomplished by reducing the cross-sectional area of the gage section to produce a dumbbell-shaped specimen. By reducing the cross-sectional area, the total power needed to drive the specimen into resonance is reduced. Consequently, the amount of heat produced in the specimen is reduced, which also reduces the cooling requirements.

The choice of specimen design for a particular test depends on many factors, including the amount of material available, maximum amplitude of the wave train, amount and type of cooling available or allowable, minimum diameter to ensure stiffness and eliminate flexural modes, and desired strain level in the gage section. The calculation of the appropriate resonant specimen geometry is the primary task in designing an ultrasonic fatigue specimen. Other considerations for ultrasonic fatigue specimens are the same as those encountered in conventional fatigue testing, including surface finish, minimization of residual stresses, capabilities of the machine shop, and costs of producing the specimen.

Complex Specimen Geometries. More complicated expressions are needed to determine the dimensions and strain amplitude at the point of maximum strain for specimens with nonuniform geometries. A dumbbell-type specimen is resonant at frequency f if Eq 7 and the following equation are satisfied simultaneously (Ref 15):

$$\left(\frac{d_1}{d_2}\right)^2 = \cot\left(\frac{2\pi L_1}{\lambda}\right) \cdot \cot\left(\frac{2\pi L_2}{\lambda}\right) \quad (\text{Eq 8})$$

The variable dimensions L_1 , L_2 , d_1 , and d_2 are shown in Fig. 16. Equations 7 and 8 are the basic design equations for an ideal dumbbell specimen. Using this representation, any three dimensions can be selected; the fourth can be calculated for a given wavelength. The maximum elastic strain on the gage length of the dumbbell specimen shown in Fig. 16 is given by (Ref 15):

$$\epsilon_{\max} = kA_0 \cdot \left[\frac{\cos(kL_1)}{\sin(kL_2)} \right] \quad (\text{Eq 9})$$

where k is $2\pi/\lambda$ and A_0 is displacement amplitude at the end of the dumbbell. Comparing Eq 9 with the maximum strain obtained in a uniform bar shows that the term in square brackets is the magnitude of the amplification of strain amplitude produced by the dumbbell shape. The term in square brackets is often referred to as the strain amplification factor.

Fig. 16 Ideal dumbbell specimen dimensions

Direct measurement of the strain profile from a test specimen has been reported (Ref 41). A contacting probe aids in measuring the displacement and strain distribution for specimens with complex geometries. The displacement and strain amplitudes along the length of a circular, tapered dumbbell specimen are shown in Fig. 17. The amplification of the strain amplitude due to the dumbbell shape is clearly indicated.

Fig. 17 Distribution of displacement and strain amplitudes obtained from a dumbbell-shaped Ti-6Al-4V specimen at 14.2 kHz. Source: Ref 41

If the ideal dumbbell calculations are used, small adjustments to the overall length of the specimen may be necessary during specimen design to achieve the desired test frequency. For example, if a hole is tapped in one

end of the specimen to attach the specimen to the horn, the equivalent mass of material removed for the hole must be replaced in the form of extra length of that dumbbell head. If the attachment stud is the same density as the specimen, then no adjustments are required. However, if a steel stud is used to hold an aluminum specimen, a mass adjustment to the length of the dumbbell head will be needed. Similar tuning considerations should be made when placing fillets between the dumbbell heads and the gage section.

Fillets and Radii. Efficient propagation of acoustic energy along the length of a dumbbell specimen requires that a smooth transition be provided between the heads and the gage section of the specimen. For some specimen designs such as a circular or exponential tapered dumbbell, this smooth transition is the major design element. Specimen designs that use the Neppiras formula (Eq 7 and 8) for an ideal dumbbell must provide a fillet at the transition from head to gage section. Constant-radius fillets are easily machined and can be used if other alternatives are not feasible.

Depending on the choice of radius, some heat will be generated at the fillet because a constant radius fillet does not provide optimal transition in particle velocity. The recommended fillet design is the baud streamline fillet (Ref 42). This design has a continuously varying fillet radius. Its shape is like that of a nonturbulent stream of water as it drains out of a tank with a circular hole. It is highly efficient in providing a smooth transition of particle velocity. This is quite useful for testing high-damping or precipitation-hardened materials. One disadvantage of the baud streamline design is that it requires a tape- or computer-controlled lathe to produce the desired profile.

Notched Bar Specimens. A notched specimen is a special condition of a dumbbell specimen, where L_2 is very small and L_1 is close to $\lambda/4$ to maintain resonance. For a bar containing a narrow notch, the maximum strain in the notch (exclusive of stress concentration factors) is the product of the maximum strain at $\lambda/4$ of a uniform bar without the notch multiplied by the area ratio $(d_1/d_2)^2$ (Ref 39). The L and d dimensions are defined in the ideal dumbbell specimen shown in Fig. 16.

Finite element analysis of the notched bar specimen design shows that, despite differences in the stress distribution along the specimen length between static- and dynamic-loaded specimens, the stress distribution and configuration in the notch region are the same. The complete equation for the maximum stress, σ_{\max} , in a notched resonant member can be calculated by multiplying the maximum strain, $kA_0 \cdot (d_1/d_2)^2$, by the dynamic modulus, E , and the stress concentration factor, K'_t , as:

$$\sigma_{\max} = EkA_0 \cdot \left(\frac{d_1}{d_2} \right)^2 \cdot K'_t \quad (\text{Eq 10})$$

where K'_t is the von Mises stress concentration factor. The von Mises stress concentration factor is used instead of K_t for analyzing high-cycle fatigue results (Ref 43). This is based on the findings that high-cycle fatigue failure is dictated by the alternating von Mises stress, where K'_t is approximately 10% less than K_t . Definition of additional parameters relating to notch fatigue, including notch bar fatigue strength and notch sensitivity, are found in Ref 39.

Design of resonant fatigue crack growth rate specimens is based on physical concepts similar to stress-life specimen design. The major difference is that a sharp crack is introduced into the design at the point of maximum strain. Therefore, the relationships developed for purely elastic deformation are not exactly fulfilled when appreciable plastic deformation occurs at the crack tip, when changes occur in Young's modulus due to localized plastic deformation, or when the specimen is detuned by the growing crack. Discussion of these issues can be found in Ref 44.

The first ultrasonic fatigue crack growth test specimen was a simple resonant bar with an electrodischarge machined slot cut into one side of the bar (Ref 45). Typical geometries of fatigue crack growth specimens are shown in Fig. 18, including single-edge-cracked specimens (Ref 19), double-edge-cracked specimens (Ref 46) with axial loading, center-cracked specimens with axial loading (Ref 47, 48), and single-edge-cracked specimens with transverse loading (Ref 49). Crack length, a , is shown.

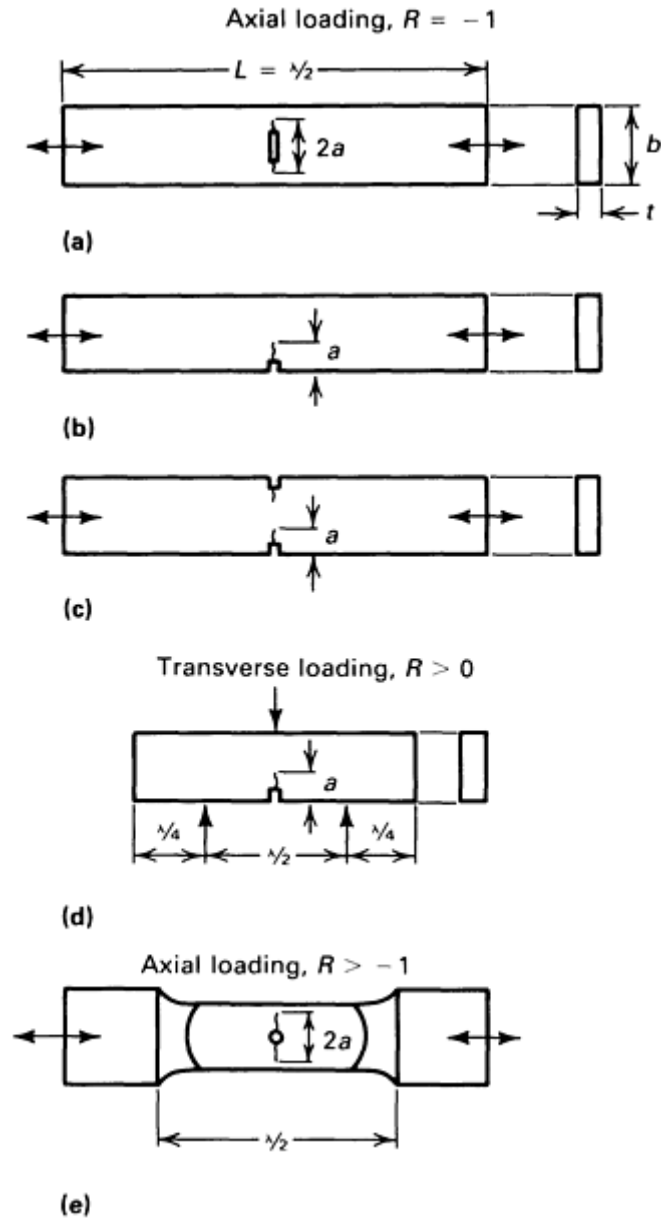

Fig. 18 Specimen geometries for crack growth measurements under high-frequency resonance excitation. (a) Center-cracked specimen. (b) Single-edge-cracked specimen. (c) Double-edge-cracked specimen. (d) Single-edge-cracked specimen. (e) Center-cracked specimen. R , fatigue stress ratio; a , crack length; b , specimen width; t , specimen thickness. Source: Ref 44

Fatigue crack growth test specimen length is controlled by the test frequency, as in the stress-life case. However, the cross-sectional dimensions selected can vary considerably. The current trend in specimen design is to incorporate the relevant criteria of conventional-frequency fatigue crack growth and fracture mechanics into the design. One factor pertains to specimen thickness, d , which should be large in comparison to the plastic zone size at the applied stress intensity range. This is consistent with the pertinent ASTM recommendation:

$$d \geq 2.5 \left(\frac{\Delta K_{\max}}{\sigma_y} \right)^2 \quad (\text{Eq 11})$$

ΔK_{\max} is the maximum stress intensity range, and σ_y is the yield strength of the material. The exception to this rule arises when materials have high damping and produce large quantities of heat. In this case, the specimen must be thin enough to ensure adequate cooling. The specimen also must be thick enough to suppress other modes of vibration, such as flexural oscillations.

The dimension of the starting notch and the permissible fractional length of fatigue crack extension also influences the design of the specimen width, b . For center-cracked specimens, the crack advance should be

limited to a/b ratios of less than 0.4 (Ref 48). For specimens that are wide in comparison to the crack length, flexural contributions due to lateral displacement become significant.

Specimens tested under superimposed static loads (higher R ratios) require regions with cross sections larger than the gage section in order to transmit the required tensile load. The specimen shown in Fig. 18(e) is similar to that specified for conventional fatigue crack growth tests (Ref 50). Currently, specimen choice is equivocal. Standardization of a test specimen will be determined by the ability of a specimen to provide the necessary da/dN and ΔK data. Research is focusing on providing accurate stress intensity values under resonant conditions.

Stress Intensity Concepts. Design of fatigue crack growth rate specimens is useful only if the stress intensity at the crack tip can be calculated. In the simplest method of computing stress intensity range, the nominal stress amplitude is obtained from the displacement amplitude, and the ΔK value is calculated as:

$$\Delta K = \Delta\sigma \sqrt{a\pi} \cdot F_1\left(\frac{a}{b}\right) \quad (\text{Eq 12})$$

where $F_1(a/b)$ is a correction factor to account for the presence of a crack in the finite width of the specimen. This method does not account for the effects of a growing crack on the resonance behavior of the system. It assumes that the relationship between displacement and strain amplitude remains constant with detuning of the specimen due to crack growth. This problem can be avoided by measuring the strain directly with strain gages placed in the crack plane. Additional correction factors to the stress intensity formulism mentioned previously (Eq 12) have been added to account for the growth of the crack by normalizing the measured effective stress to the initial cross section (Ref 51).

A dynamic correction factor for ΔK also has been determined with finite element analysis. This results in a factor that is a function of the ratio of crack length (a) to specimen width (w), specimen width to length (W/L), and the instantaneous frequency (v).

A summary of frequently used correction formulas to calculate ΔK is given in Table 4. Further study must be undertaken to develop a standardized computation procedure for ΔK in resonant specimens.

Table 4 Computation of stress intensity ranges

Specimen geometry (loading mode)	Equation	Ref
Side notch in octagonal bar (longitudinal)	$\Delta K = 1.95 \cdot \Delta\sigma \cdot f\left(\frac{a}{b}\right) \cdot \sqrt{\frac{a}{Q}}$	52
Center-notch flat bar (longitudinal) ^(a)	$\Delta K = \frac{U_o}{W} \cdot E\sqrt{a} \cdot \sqrt{3} \left(\frac{a}{W}, \frac{W}{L}, v\right)$	48
Center-notch flat bar (longitudinal), $a/w < 0.5$	$\Delta K = \epsilon_t \cdot E\sqrt{a}\sqrt{\pi} \cdot f\left(\frac{a}{b}\right) \cdot f\left(\frac{b-a}{b}\right)$	51
Double-side-notch flat bar (longitudinal), $a/w < 0.4$	$\Delta K = \epsilon_t \cdot E\sqrt{a}\sqrt{\pi} \cdot f\left(\frac{a}{b}\right) \cdot f\left(\frac{b-a}{b}\right)$	46
Single-edge-notch thin, flat strip (longitudinal), $a/w < 0.6$	$\Delta K = \Delta\sigma \cdot \sqrt{a}\sqrt{\pi} \cdot f\left(\frac{a}{b}\right)$	19
Single-edge-notch rectangular bar (transverse)^(a)	$\Delta K = \frac{U_o \cdot E}{W} \sqrt{a} \cdot f_2\left(\frac{a}{W}, \frac{W}{L}, v\right)$	48

Note: E , elastic modulus, U_o displacement in the load line.

Specimen Grips. The requirements for gripping an ultrasonic fatigue specimen are minimal. The only gripping requirements in ultrasonic fatigue are maintenance of intimate contact between the specimen and horn to allow good acoustic coupling and the absence of external forces that would disturb the resonance of the remainder of the wave train. Consequently, a fatigue specimen with a 5 mm (0.2 in.) gage can be held in place by a single 6.4 mm (0.25 in.) stud while being fatigued to failure at a stress amplitude of 485 MPa (70 ksi) or more.

Generally, gripping is accomplished by an internal thread arrangement. This arrangement is adequate, even with a specimen that is difficult to grip, such as thin-walled tubing. Gripping can be accomplished by an external screw-down collar, which grips the specimen to an extension horn. This is particularly useful for tests at high mean loads. Gripping can also be accomplished by brazing or welding the specimen to a threaded adapter or directly to an acoustic horn. A holder for wire specimens has been developed that allows multiple specimens to be tested in a batch mode (Ref 53). An interference fit of the specimen with the horn also is satisfactory, as long as good acoustic coupling with the horn is obtained. Attachment of the specimen to the acoustic horn may be accomplished using an adhesive. This is appropriate for fatigue testing of brittle materials, such as glass and ceramics.

Most ultrasonic converter cases are grounded. If metal-to-metal contact is maintained throughout the wave train, the specimen will be grounded also. An electrically floating specimen is needed if electrochemical potential or corrosion current is to be measured during testing. The specimen can be isolated from the horn by using an extension horn made of a nonconducting material, such as Lucite, to grip the specimen. Such grips limit the magnitude of the stress amplitude that can be transmitted to the specimen because of high dissipation of energy or low fatigue strength of these materials.

Ultrasonic Fatigue Testing

Applications

Ultrasonic fatigue testing has been applied successfully to many situations that require fatigue initiation and crack growth data. Testing has been performed under a variety of loading conditions, specimen geometries, and environmental constraints. With perhaps the exception of plastic strain-controlled testing and single-cycle hysteresis testing, ultrasonic fatigue techniques can be readily applied to the problems of fatigue that traditionally have been confronted at lower frequencies.

Plastic strain rate is a function of strain amplitude and waveform as well as cyclic frequency. In ultrasonic fatigue testing, there is some question as to the effect of increased strain rate from testing at ultrasonic frequencies. Experimentation generally is required, but it is also clear that body-centered cubic (bcc) materials exhibit a much larger strain-rate dependence than face-centered cubic (fcc) materials.

The cyclic deformation of bcc materials is quite different from that of fcc materials and can be quite complex. The athermal portion of the flow stress is due primarily to dislocation interactions leading to work hardening. The effective stress is dominated by the lattice friction stress. Thus, strain rate and effect of impurities are extremely important in the deformation behavior of bcc materials.

In general, the strain-rate sensitivity of engineering alloys and materials often requires experimental verification because of the many possible combinations of alloy compositions, properties, and operating environments. Changes in alloy composition affect the activation barriers to deformation, and the high-frequency behavior might be moderated between the paradigms of bcc and fcc materials. Testing in aggressive environments can offset the expected behavior. Additional information on strain-rate-dependent fatigue behavior can be found in Ref 54, 55, 56.

Fretting Fatigue Testing

S.J. Shaffer and W.A. Glaeser, Battelle Memorial Institute

Introduction

FRETTING is a special wear process that occurs at the contact area between two materials under load and subject to slight relative movement by vibration or some other force. Damage begins with local adhesion between mating surfaces and progresses when adhered particles are removed from a surface. When adhered particles are removed from the surface, they may react with air or other corrosive environments. Affected surfaces show pits or grooves with surrounding corrosion products. On ferrous metals, corrosion product is

usually a very fine, reddish iron oxide; on aluminum, it is usually black. The debris from fretting of noble metals does not oxidize.

Under fretting conditions, fatigue strength or endurance limits can be reduced by as much as 50 to 70% during fatigue testing (e.g., see Fig. 1a). During fretting fatigue, cracks can initiate at very low stresses, well below the fatigue limit of nonfretted specimens. In fatigue without fretting, the initiation of small cracks can represent 90% of the total component life. The wear mode known as fretting can cause surface microcrack initiation within the first several thousand cycles, significantly reducing the component life. Additionally, cracks due to fretting are usually hidden by the contacting components and are not easily detected. If conditions are favorable for continued propagation of cracks initiated by fretting, catastrophic failure can occur (Fig. 1b). As such, prevention of fretting fatigue is essential in the design process by eliminating or reducing slip between mated surfaces.

Fig. 1 Effects of fretting. (a) Comparison of fatigue life for 4130 steel under fretting and nonfretting conditions. Specimens were water quenched from 900 °C (1650 °F), tempered 1 h at 450 °C (840 °F), and tested in tension-tension fatigue. Normal stress was 48.3 MPa (7 ksi); slip amplitude was 30–40 μm. (b) Example of catastrophic fatigue due to fretting of a flanged joint

The initiation of fatigue cracks in fretted regions depends mainly on the state of stress in the surface, particularly stresses caused by high friction. The direction of growth of the fatigue cracks is associated with the direction of contact stresses and takes place in a direction perpendicular to the maximum principal stress in the fretting area. After formation due to fretting, cracks propagate initially under shear (mode II) conditions under the influence of the near-surface shear-stress field due to friction of fretting. Beyond that, tensile (mode I) crack propagation under bulk cyclic stresses controls further propagation.

The topics covered in this article are:

- Mechanisms of fretting and fretting fatigue

- Typical occurrences of fretting fatigue
- Fretting fatigue testing
- Prevention methods

Many investigators have contributed to the theoretical and practical research in the field of fretting and fretting fatigue, and the information in this section is derived from their work. Several general texts are available (Ref 1, 2, 3, 4). Reference 5 is another key source for information and illustrations of fretting fatigue failures. In addition, more current discussions and background are provided in the book *Fretting Fatigue* edited by R.B. Waterhouse and T.C. Lindley. The article “On Fretting Maps” by O. Vingsbo and S. Söderberg is another useful general reference on fretting. (See the Selected References for complete bibliographic information.)

As yet, general techniques or models permitting prediction of crack initiation due to fretting are limited. However, an understanding of the factors contributing to fretting fatigue can help minimize the risk and extent of damage. The examples presented in this article from case studies, theoretical work, and laboratory investigations are intended to assist the reader in recognizing the potential for fretting fatigue in design and materials selection. General principles and practical methods for the abatement or elimination of fretting fatigue are summarized in Table 1. More recent information on fretting fatigue testing can be found in ASTM STP 1367 (listed under “Selected References” at the end of this article).

Table 1 Reduction or elimination of fretting fatigue

Principle of abatement or mitigation	Practical method
Reduction in surface shear forces	<ul style="list-style-type: none"> • Reduction in surface normal forces • Reduction in coefficient of friction with coating or lubricants
Reduction/elimination of stress concentrations	<ul style="list-style-type: none"> • Large radii • Material removal (grooving) • Compliant spacers
Introduction of surface compressive stress	<ul style="list-style-type: none"> • Shot or bead blasting • Interference fit • Nitriding/heat treatment
Elimination of relative motion	<ul style="list-style-type: none"> • Increase in surface normal load • Increase in coefficient of friction
Separation of surfaces	<ul style="list-style-type: none"> • Rigid spacers • Coatings • Compliant spacers
Elimination of fretting condition	<ul style="list-style-type: none"> • Drive oscillatory bearing • Remove material from fretting contact (pin joints) • Separation of surfaces (compliant spacers)
Improved wear resistance	<ul style="list-style-type: none"> • Surface hardening • Ion implantation • Soft coatings • Slippery coatings
Reduction of corrosion	<ul style="list-style-type: none"> • Anaerobic sealants • Soft or anodic coatings

Fretting Fatigue Testing

S.J. Shaffer and W.A. Glaeser, Battelle Memorial Institute

Fretting and Fretting Fatigue Mechanisms

In general, fretting occurs between two tight-fitting surfaces that are subjected to a cyclic, relative motion of extremely small amplitude. Although certain aspects of the mechanism of fretting are still not thoroughly understood, the fretting process is generally divided into the following three parts: initial conditions of surface adhesion, oscillation accompanied by the generation of debris, and fatigue and wear in the region of contact. Fretting wear occurs from repeated shear stresses that are generated by friction during small-amplitude oscillatory motion or sliding between two surfaces pressed together in intimate contact. Surface cracks initiate in the fretting wear region. The relative slip amplitude is typically less than 50 μm (0.002 in.), and displacements as small as 10^{-4} μm have produced fretting. Generation of fine wear debris that usually oxidizes is an indication of fretting wear (Fig. 2). The following factors are known to influence the severity of fretting:

- *Contact load*. As long as fretting amplitude is not reduced, fretting wear will increase linearly with increasing load.
- *Amplitude*. There appears to be no measurable amplitude below which fretting does not occur. However if the contact conditions are such that deflection is only elastic, it is not likely that fretting damage will occur. Fretting wear loss increases with amplitude. The effect of amplitude can be linear, or there can be a threshold amplitude above which a rapid increase in wear occurs (Ref 4). The transition is not well established and probably depends on the geometry of the contact.
- *Frequency*. When fretting is measured in volume of material removed per unit sliding distance, there does not appear to be a frequency effect.
- *Number of cycles*. An incubation period occurs during which fretting wear is negligible. After the incubation period, a steady-state wear rate is observed, and a more general surface roughening occurs as fretting continues.
- *Relative humidity*. For materials that rust in air, fretting wear is higher in dry air than in saturated air.
- *Temperature*. The effect of elevated temperature on fretting depends on the oxidation characteristics of the material.

In terms of fatigue, the following three primary variables contribute to shear stresses at the surface and, hence, are important for crack initiation and initial propagation of fretting fatigue cracks:

- Normal load (e.g., contact pressure)
- Relative displacement (slip amplitude)
- Coefficient of friction

The other primary variable is the bulk tensile stresses that control crack propagation beyond the limit of the surface-induced stress field. Secondary factors, including surface roughness, surface contaminants, contact size, debris accumulation, and environment affect fretting fatigue through their influence on the primary variables. Effective lubrication will reduce friction stresses and wear-particle accumulation.

Fretting Modes and Contact Conditions. The oscillatory motion responsible for fretting can be induced by system vibrations or by cyclic loading of one of the components. The relative displacement can be either amplitude controlled or load controlled, or a combination of both. Methods to control fretting fatigue depend on which of these two modes dominates the contact conditions.

Stress Conditions. The nominal macroscopic normal stress between the two surfaces is defined by the normal force divided by the nominal area of contact. Subsurface stress distributions can be computed using Hertzian calculations and the macroscopic contact geometry. The normal stress is also influenced by geometric stress concentrations. The real area of contact is limited to the contacting tips of the microscopic asperities on each of the surfaces, and the local (microscopic) normal stress is dictated by the yield strength of the softer of the two materials. Superimposed on the local normal stresses are shear stresses resulting from the friction of relative displacement of the two contacting members. The magnitude of the shear stresses induced by asperity contact depends on the coefficient of friction (due to adhesive forces between, and interpenetration of, asperities), the local load, asperity geometry, the elastic moduli of the two surfaces, and the amplitude of relative displacement.

Strain Conditions. If the amplitude of oscillation is small, the shear strains are elastic, and the contact condition is one of sticking or *no slip*. Even under microelastic displacements, fatigue cracks can form due to reverse bending at the bases of the contacting asperities. If the amplitude of oscillation is large, depending on the strength and ductility of the asperities in contact, and on the adhesive forces acting between them, the asperities will be forced to pass over one another and *slip* occurs.* With slip, the possibility of wear exists from either adhesion, abrasion, or delamination. All of these material-removal mechanisms lead to a roughening of the surface, the creation of sites for crack initiation, and the generation of wear debris. Cracks can also be initiated by pitting that occurs during fretting.

Conditions for Slip. The local contact conditions may be predominantly displacement controlled or load controlled. In displacement-controlled fretting contacts undergoing full slip, the amplitude of motion is controlled by the external displacements, an example being the relative displacement imposed on adjoining strands of a wire rope passing over a pulley. For force-controlled fretting contacts, the displacement depends on the macroscopic shear force, the normal force, and the coefficient of friction; for example, the mating forces of

a bolted flange or a hub/shaft press fit interface. No slip occurs until the shear stress exceeds the product of the normal force and local coefficient of friction. The condition for slip is met when

$$\tau > \mu\sigma_n \quad (\text{Eq 1})$$

where τ is the local shear stress, μ is the coefficient of friction between contacting surfaces, and σ_n is the local normal stress.

Regions of both slip and no-slip can occur at an interface of contacting solids. This is most easily seen for convex contacts using the elastic stress analysis of a sphere pressed into a plate, as shown in Fig. 3 (Ref 6). The normal (Hertzian) stress field is an elliptical distribution with the maximum stress occurring under the center of the contact. The shear stresses, which promote relative slip, are a maximum at the edges of the contact (limited by yielding) and a minimum in the center. The forces resisting sliding due to the shear stress are given by μN . The condition pictured is known as *partial slip*. As μN is increased, the region of sticking expands, and vice versa. When the shear forces of fretting are superimposed on this stress field, the result is a smaller “stick” area. This analysis can also apply to a cylindrical contact or can be adapted to microscopic asperity contacts.

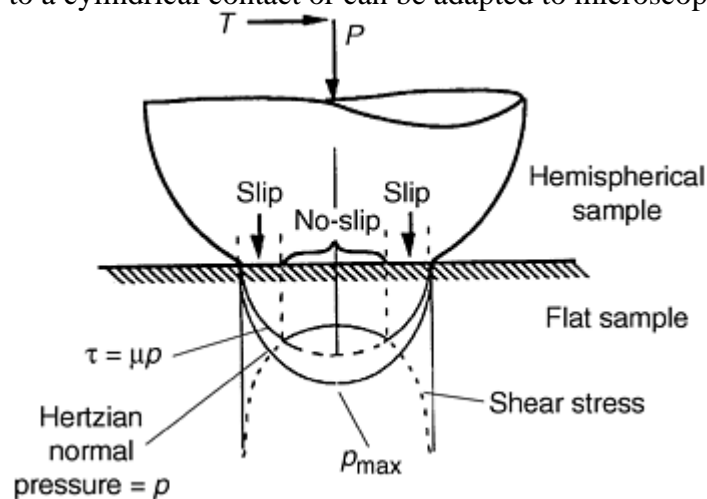

Fig. 3 Stress distribution for hemispherical contact pressed into flat plate. Source: Ref 6

For contact between nominally flat surfaces, the stress state is different, though the slip condition is still defined by Eq 1. The macroscopic stress concentrations for well-defined geometries can be computed using finite-element modeling (FEM) analysis, although wear will change the assumed contact geometry. A general treatment of the subject can be found in Ref 3.

Fatigue-Crack Nucleation from Fretting. Crack nucleation due to fretting must involve a stress concentration or discontinuity. At the microscopic level, examples include: microcracks formed at the base of asperities due to reverse-bending fatigue of the asperities, stress concentrations in the pits left by sheared adhering “cold-welded” asperity junctions, corrosion pits that form due to removal of protective oxides by fretting, grooves due to abrasion, or delamination of a thin surface region whose work-hardening capacity has been exhausted. At the macroscopic level, cracks are proposed to form solely as a result of geometric stress concentrations, usually at the edges of the fretting contact region, where shear stresses are predicted to be highest, at some microscopic inhomogeneity. The two views are not significantly different. The second view is more amenable to modeling and FEM analysis.

The location of crack nucleation depends on the contact conditions. Under *full-slip conditions*, in the absence of stress concentrations at the edge of the contact, cracks can nucleate anywhere in the contact region. The number of asperity interactions per cycle depends on the asperity distribution (surface roughness) and the amplitude of relative motion. Several cracks may be formed. Their stress fields can interact and lead to a decrease in the stress field associated with a single crack. This may explain why multiple nonpropagating cracks are often found in association with fretting. Under *partial-slip conditions*, the cracks always form at the border between the slip and the no-slip regions. In this case, multiple cracks are proposed to result from the movement of the slip/no-slip boundary due to the generation of debris (Ref 7). Though less likely, cracks can also form in the region of *no slip* (full sticking) due to reciprocating subsurface shear stresses associated with reversing elastic deformation of the contacting asperities and stress concentrations at their bases leading to local microplastic deformation and fatigue.

Fatigue-Crack Propagation during Fretting Fatigue. Crack propagation is initially driven by the stress state dominated by the surface shearing. As such, when viewed in cross section, the crack direction initially appears at an angle to the surface of between 35 and 55°. Mode II crack propagation dominates this region. The mode II propagation may depend on material parameters such as grain size, texture, and phase morphology. Because the surface shear stresses fall off rapidly with depth, the crack will either arrest, or, if static or alternating tensile stresses exist in the bulk material, will change direction and run perpendicular to the surface as the driving forces come under the control of the bulk tensile forces (Fig. 4). The depth at which this occurs depends on the magnitude of the surface shear stresses, which depend on the coefficient of friction and normal contact stress. For Hertzian stresses of convex contacts, this depth is on the order of the half-width of the contact area. Beyond this depth, mode I crack propagation analysis can be used to predict the growth rate under the bulk stress state.

Fig. 4 Example of fretting fatigue crack viewed in cross section. Courtesy of R.B. Waterhouse, University of Nottingham

A phenomenon peculiar to fretting is that some of the fatigue cracks do not propagate because the effect of contact stress extends only to a very shallow depth below the fretted surface. At this point, favorable compressive residual stresses retard or completely halt crack propagation. Under full-slip conditions, the wear rate caused by fretting occasionally outpaces the growth rate of surface-initiated fatigue cracks. In this situation, fretting wear preempts fretting fatigue.

Footnote

* In fretting, the term *slip* is used to denote small-amplitude surface displacements. In contrast to *sliding*, which denotes macroscopic displacements. Additionally, in this article *slip* does not refer to the mechanism of fatigue resulting as a consequence of dislocation motion.

Fretting Fatigue Testing

S.J. Shaffer and W.A. Glaeser, Battelle Memorial Institute

Typical Systems and Specific Remedies

Fretting generally occurs at contacting surfaces that are intended to be fixed in relation to each other but that actually undergo minute alternating relative motion that is usually produced by vibration. Fretting generally does not occur on contacting surfaces in continuous motion, such as ball or sleeve bearings. There are exceptions, however, such as contact between balls and raceways in bearings and between mating surfaces in oscillating bearings and flexible couplings. Common sites for fretting are in joints that are bolted, keyed, pinned, press fitted, or riveted; in oscillating bearings, splines, couplings, clutches, spindles, and seals; in press fits on shafts; and in universal joints, baseplates, shackles, and orthopedic implants.

Three general geometries and loading conditions for fretting fatigue are considered in this section:

- Parallel surfaces clamped together with some type of fastener, such as a bolted flange or riveted lap joint
- Parallel surfaces loaded by means of a press or interference fit, such as a gear or wheel on a shaft
- Convex contacts, as found beneath a convex washer, between crossed cylinders such as wire rope strands, or a sphere or a cylinder in a bearing race

Specific remedies to reduce fretting are given for these common examples. When fretting occurs, it often cannot be eliminated but can be reduced in severity.

Parallel Contact with External Loading (Fastened Joints). Bolted flanges in pipe systems are common locations for fretting fatigue. Cracks can occur in the plate either under a bolt head or washer (load controlled), on the inside diameter of the bolt through-hole (displacement controlled), or on the surface of one plate at the point of contact with the end of the other plate (load controlled) (Fig. 5a). Lap joints are found in both heavy plates and thin sheets such as aircraft skins. Fretting can occur in the joint or under the head of a countersunk screw, bolt, or rivet (Fig. 5b).

Fig. 5 Typical location of fretting fatigue cracks in (a) a bolted flange, and (b) a lap joint

For both these geometries, the reduction or abatement of fretting severity depends on whether the motion is load controlled or displacement controlled. If it is displacement controlled, then reducing the contact stress and

minimizing the coefficient of friction at the interface is recommended. For lap joints, however, a reduction in the coefficient of friction may result in insufficient load transmitted by the interface, transferring the load to the fasteners and leading to their failure. For load-controlled motions, it may be possible to increase either the clamping force or the coefficient of friction to completely eliminate relative motion between the two contacting members. While adhesives can be used to eliminate the relative motion, their use complicates future disassembly. If motion cannot be completely eliminated, then minimizing the coefficient of friction may help, although this will likely lead to an increased slip amplitude. Alternatively, a thin compliant layer, such as rubber or other polymer, may be able to absorb the deflection and prevent contact between the two members. For pin joints, fretting can occur on diagonally opposite sides of the pin at the points of contact with the hole due to vibrations or reversing loads. In these cases, White (Ref 8) showed that an increase in fatigue strength can be achieved by machining flats on the sides of the pins to prevent contact at the position of maximum stress, thus removing the region where fretting occurs (Fig. 6).

Fig. 6 Pin joint. (a) Fretting locations. (b) Material removal to eliminate region of highest stress

Parallel Surfaces without External Loading. Hubs, flywheels, gears, and other types of press-fit wheels, pulleys, or disks on shafts are subject to fretting fatigue caused by reverse bending strains compounded by the stress concentration where the shaft meets the disk (Fig. 7a). The introduction of lubricant in the interface can make matters worse by increasing the relative slip. In this case, it is best to attempt a strong interference fit. This can be achieved through cooling the shaft and heating the bore of the hole during assembly in order to produce sufficiently high normal stresses to completely eliminate slip within the interface. After assembly, both surfaces will also be in a state of compressive stress, providing further resistance to fatigue-crack propagation. Finally, if possible, a stress-relieving groove or large radius on the shaft (Fig. 7b) should be incorporated into the design.

Fig. 7 Wheel on shaft. (a) Location of fretting fatigue cracks. (b) Stress-reduction grooves

Gas-turbine rotor-blade roots and other dovetail joints are potential locations of fretting fatigue failures (Fig. 8a). In this case, the loading conditions are variable and depend on the rotational speed. For these situations, stress-relieving grooves can be incorporated into the design (Fig. 8b). Coatings to reduce the coefficient of friction (and hence the surface shear forces) can also help. Experiments by Ruiz and Chen on simulated blade/disk dovetail joints at 600 °C (1112 °F) indicated that shot peening followed by electroplating with a 10 μm (394 μin.) thick Co/C surface layer was effective (Ref 9). Another example is provided in the article by Johnson in Ref 5.

Fig. 8 Dovetail joint. (a) Location of fretting fatigue cracks. (b) Stress-reduction grooves

Convex Surfaces. Fretting fatigue in control cables or wire ropes is caused by small relative displacements between the individual strands as the cable flexes in passing over pulleys, or by varying stresses from wind or water currents (Fig. 9). Stainless steel control cables are particularly susceptible because of the high friction and galling propensity between the strands. Fatigue fractures of the inner strands of the cables make detection by visual inspection virtually impossible until the ends of the fractured strands pop out through the outer strands. Wire rope fretting fatigue in control cables is an example of displacement-controlled contact. As such, large pulley diameters as a function of cable cross section can be specified in the design in order to decrease the displacement and minimize fretting fatigue. Incorporation of lubricant in the cable will reduce strand-to-strand shear forces, but only as long as the lubricant is contained within the rope interior by the outer strands. Takeuchi and Waterhouse report that electrodeposited zinc coatings helped prevent fretting fatigue of wire rope in sea water (Ref 10). The zinc provides both a reduction in the effects of corrosion and a low-shear-strength surface film that reduces friction.

Fig. 9 Examples of fretting on inner strands of drag-line wire rope

In rolling-element bearings, high Hertzian normal stresses occur beneath the contact of bearing balls in their races. Control-system or oscillatory-pivot bearings are often subjected to a low-amplitude, but high-frequency, dithering motion leading to fretting or false brinelling between the balls and the race. (The difference between false brinelling and fretting is discussed in the article “Fretting Wear” in *Friction, Lubrication, and Wear*

Technology, Volume 18 of *ASM Handbook*.) Continuous rotation of one of the races can help prevent fretting under these circumstances (Ref 11).

For convex washers and other convex contacts, a coating, nonmetallic shim, or lubricating film can help reduce the surface shear forces.

Fretting Fatigue Testing

S.J. Shaffer and W.A. Glaeser, Battelle Memorial Institute

Testing, Modeling, and Analysis

When fretting fatigue is encountered or anticipated, laboratory tests are usually required to find a solution. Test results can also be used to develop an empirical model and are required for validation if a model is to be used for design changes. This section presents types of fretting fatigue tests, the forms of results found in the literature, and the effect of variables on fretting fatigue from different research test programs.

Types of Fretting Fatigue Tests. Fretting fatigue tests are designed to accomplish one of three goals. The first is a test to predict or duplicate field failures and evaluate the effect of design changes or treatments based on replication or simulation of service components and conditions. This is most useful if all the service conditions are known and can be replicated or appropriately scaled, but the results will have limited applicability. A second type of test uses a simple geometry and setup. The contact conditions may not be well defined or directly applicable to a specific application, but they are assumed to be the same for every specimen set and many tests can be conducted at a reasonable cost for screening new material combinations. In the third type of fretting fatigue test, well-defined geometries and controlled and/or monitored loads and displacements are used. These more fundamental tests are intended to evaluate the effect of specific variables such as amplitude, clamping loads, reciprocating stresses, environments, or palliative methods, and to develop and validate fretting fatigue models. In order to apply published test results to a specific component, the test parameters must be well defined and understood for each engineering application. At present, work is under way to standardize test methods in order to assist with this endeavor (Ref 2).

For most fretting fatigue testing, fretting pads are positioned on opposite faces of the sample and can be either single or double footprints of flat or convex contact geometry. The relative displacement between the pads and the sample can be driven independently or can be controlled by the loads and motion of the system (Fig. 10). Of the four methods for cyclic loading of fretting fatigue specimens, general trends indicate that torsional

specimens have the smallest drop in fatigue strength, while the largest drop is for tests carried out under rotating-bending or plane-reverse-bending conditions, with plane push-pull testing falling in between (Ref 7).

Fig. 10 Examples of fretting fatigue test configurations. (a) Cantilever beam reverse bending with single pads. (b) Rotating fully reversing bending with double foot-pad bridges and proving ring

The influence of fretting on fatigue strength can be determined by two basic methods. In one method, a sample is subjected to a certain number of cycles of fretting, followed by standard fatigue testing to failure without fretting. Plots of fretting cycles versus total cycles are recorded. This method has been used to determine the number of cycles for fatigue-crack detection under the given geometry, material, normal stress, applied reversing stress, and relative slip amplitude (Ref 12).

Influence of Fretting on $S-N$ Plot. In the second method, the sample is subjected to fretting for the entire test. The fretting fatigue life or strength is determined by plotting the number of cycles to failure on an $S-\log N$ curve where $\pm S$ is the alternating stress. The strength-reduction factor (SRF) is defined by the ratio of the plain fatigue strength to the fretting fatigue strength as shown in Fig. 11 and is attributed to a decrease in crack nucleation time. A shift in cycles to failure at a given strength level is attributed to an increase in crack propagation rate and is often observed under corrosive environments.

Fig. 11 Effect of fretting on fatigue strength reduction through crack initiation. Fatigue strength reduction is equal to the difference between the solid and dashed lines.

The number of cycles to failure can be defined either as full specimen rupture or by initiation of a propagating (into the bulk stress region) crack. Crack length can be determined either from cross-sectional metallography or by specimen compliance methods.

Stress Analysis, Modeling, and Prediction of Fretting Fatigue. Testing, stress analysis, and modeling are complementary techniques required for understanding and predicting fretting fatigue behavior. For well-defined conditions, test results provide input to models. These models aim to predict crack-initiation location, time,

propagation rate, and the effect of changes in variables on these factors. At present, prediction of fretting fatigue is less developed than for plain (unnotched) fatigue. The main limitation is that continuum-mechanics approaches do not consider microstructural inhomogeneities, and crack nucleation is controlled by such factors as well as “short” fatigue-crack propagation.

Most of the early work in stress-field modeling for fretting fatigue uses, as a starting point, analysis similar to that used by Mindlin (Ref 6) of a sphere pressed into a half plane and expands this to consider other geometries and imposed shear loads. If stress fields are computed using FEM analysis, an assumed contact geometry and coefficient of friction are used, and loads are imposed at various mesh locations in order to compute stresses and subsequent strains. Alternatively, displacements can be imposed and strains and stresses computed. To facilitate modeling, the stress singularity associated with an abrupt contact geometry change, such as at the edge of a bolted flange or a hub/shaft interface, is accommodated by plastic deformation, and a limiting stress is assumed. Current models are limited in that changes in contact geometry due to wear and variations in coefficient of friction due to lubrication or debris accumulation are difficult to take into account.

Experiments have been undertaken and models have been proposed for both the full- and partial-slip regimes and are based on empirical observations. Full-slip and partial-slip conditions can be achieved by varying the test configurations.

In addition, while most fretting contacts are some combination of load- and displacement-controlled conditions, laboratory experiments can be designed either to drive the fretting pads independently (displacement controlled) or to allow them to move as a consequence of the clamping force and displacement of the “beam” sample (load controlled).

For fretting under conditions of full slip, two early models predict the SRF due to fretting. Nishioka and Hirakawa (Ref 13) derived the following equation to describe the fretting fatigue strength limit determined using their displacement-controlled experiment setup with full-slip conditions under the fretting pads (Fig. 10).

$$\sigma_{fw1} = \sigma_{w1} - \mu p_o \{1 - e^{(-\delta/K)}\} \quad (\text{Eq 2})$$

where σ_{fw1} is the fretting fatigue strength, σ_{w1} is the plain fatigue strength, p_o is the clamping pressure, δ is the slip amplitude (in mm), and K is a constant dependent on the material and surface condition (on the order of 3.4×10^{-3} mm, or 1.34×10^{-4} in., in Ref 13).

In later work of Wharton et al. (Ref 14), a similar form was developed in which notch sensitivity of the base material was taken into account. The reduction in fatigue strength due to fretting was then proposed to also be proportional to the shear stress resulting from the contact pressure of the cylindrical fretting pads, inversely proportional to the contact width, and given by the equation:

$$\sigma_{wf} = \sigma_{wo} - q(8\mu P/\pi b) \quad (\text{Eq 3})$$

where σ_{wf} is the fatigue strength with fretting, σ_{wo} is the fatigue strength without fretting, q is the notch sensitivity factor, P is the load per unit length, and b is the contact width under the fretting pads (mm). Note that both these predictions show that SRF is worse as μP or μP_o is increased.

For probable location of fretting fatigue crack nucleation in the partial-slip regime, the approach of Ruiz and Chen (Ref 9) can be used. In their analysis of a dovetail interface, a fretting parameter representing the energy available for causing fretting damage, and given by the product of the slip amplitude, δ , and shear stress, τ , at points under the interface, was computed. Next, the product $\sigma\tau\delta$, called the fretting fatigue parameter, is computed, where σ is the maximum surface tensile stress (resulting from the bulk cyclic loading). A fretting fatigue crack is predicted to occur where the local value of $\sigma\tau\delta$ in the interface exceeds an empirically determined critical value, or, fretting occurs when:

$$\sigma\tau\delta \geq \sigma\tau\delta_{crit} \quad (\text{Eq 4})$$

If $\sigma\tau\delta$ and $\sigma\tau\delta_{crit}$ can be experimentally determined, then the designer can use this value as a design guide. Note that both the slip amplitude and the shear stress depend on the coefficient of friction (with opposite responses) and the imposed loading. Analysis by Nowell and Hills (Ref 15) of this work provided a theoretical justification and a possible method for predicting “initiation” (or nucleation) time based on the total accumulated incremental strain. With further effort, it appears that the composite parameter approach can be applied to fretting fatigue in the full-slip regime and can be expanded to include plasticity.

Other models may be used to determine whether the conditions at the interface will be of full or partial slip and to predict the location of the partial slip. These are generally FEM studies and make use of assumed macroscopic contact conditions and bulk material properties. The text by Hills and Nowell covers this area; yet

it is claimed that no current models exist that can predict crack-initiation times strictly from the knowledge of the states of stress, strain, and displacement on a macroscopic scale (Ref 16). Though experiments are required to determine $\sigma\tau\delta_{crit}$, the most probable location of cracking may be predicted using FEM analysis and the criteria of Ruiz and Chen (Ref 9). If conditions are sufficiently well defined, the slip characteristics of the interfaces may also be predicted. Whether the interface is in full slip or the extent of partial slip will help guide the choice of palliative. This article presents some palliatives that have been applied successfully in the past for fretting abatement. However, the designer is advised to apply discretion in applying techniques listed because results depend on the particular condition. In their review, Gordelier and Chivers (Ref 17) attribute contradictory effects of similar treatments on fretting fatigue to the differing effects on the base materials and to the different contact conditions.

Fretting Fatigue Testing

S.J. Shaffer and W.A. Glaeser, Battelle Memorial Institute

Variables Investigated during Fretting Fatigue Tests

Of the dozens of variables that can potentially affect fretting (Ref 18), the three primary variables that control fatigue-crack initiation are surface contact stress, slip amplitude, and coefficient of friction. All other variables are secondary and affect fretting and fretting fatigue through their influence on the primary variables. Unfortunately, many contradictory data appear in the literature (Ref 17). The contradictions concern whether

the fretting conditions were displacement controlled or load controlled and the interactions of the secondary variables between each other and the primary variables. This section presents the results of various investigations into the effect of variables on fretting fatigue.

Contact Stress and Alternating Stress. Contact stresses include both normal and shear stresses imposed at the sample surface. The cyclic shear stresses at the surface are the cause of crack nucleation (where the propensity to cracking from the stress state is also affected by pits, corrosion, and other forms of surface degradation). The magnitude of shear stresses depend on the imposed forces and displacements, the coefficient of friction, macroscopic stress concentrations, and local asperity geometries and distribution. Nishioka and Hirakawa (Ref 19) reported that fretting fatigue strength based on fatigue-crack initiation (or nucleation) was found to decrease linearly with increasing normal force. For fretting fatigue strength based on fracture, they found a critical contact pressure, above which no further degradation occurred. Although their experiments did not reach this level, a sufficiently high normal force can sometimes result in the closure of cracks initiated by fretting through the superposition of a compressive stress.

Alternating stress is the stress imposed on the bulk sample, characterized by an amplitude and a mean stress. For fully reversing bending (which occurs on a rotating shaft), the mean stress is zero. Nishioka and Hirakawa performed experiments in reverse bending on annealed and induction-hardened medium-carbon steel under displacement-controlled conditions (full slip). They found that the mean stress did not affect the range of alternating stress amplitude for fatigue-crack initiation due to fretting, but that it did affect crack propagation (Ref 19).

Wharton et al. also found that the percentage of fatigue life reduction due to fretting, defined by crack propagation to failure, was independent of applied alternating stress level for 70/30 brass and for a 0.7% carbon steel (Ref 20). These experiments were performed in rotating bending using flat fretting pad contacts (Ref 21, 22). Ruiz and Chen found that peak contact stress was important at 600 °C (1112 °F), but at room temperature the fretting parameter, $\tau\delta$, dominated (Ref 9). This was attributed to the nature of the oxide and the influence of the wear debris.

Displacement (Slip Amplitude) and Direction. For conditions of full slip, there is general agreement in the literature that the effect is most severe for slip amplitudes of 20 to 25 μm (787–984 $\mu\text{in.}$). In work on 4130 steel, Gaul and Duquette (Ref 23) found that for clamping pressures of 20 to 41 MPa (3–6 ksi), a minimum in the fatigue life at a given alternating stress occurred at a slip amplitude of 20 μm (787 $\mu\text{in.}$). At amplitudes higher than this, the wear rate due to fretting exceeded the rate of crack growth rate just after initiation and the fretting fatigue strength increased. A similar critical amplitude of relative slip, on the order of 15 to 20 μm (590–787 $\mu\text{in.}$), was found by Nishioka and Hirakawa (Ref 13) for both induction-hardened and quenched-and-tempered medium-carbon steel samples. Clamping pressures of 120 MPa (17 ksi) were used in their work. They also concluded that the fatigue strength-reduction factor due to fretting can be minimized if the fretting amplitude (relative slip) can be kept below 5 μm (197 $\mu\text{in.}$).

An effect related to slip amplitude is that of contact width. Experiments showed that larger-diameter cylinders had a greater detrimental effect on fretting fatigue life for the same line contact stress than small-diameter cylinders (Ref 24). This may be caused by increased partial slip or more asperity contacts per stress cycle.

Nowell and Hills (Ref 15) looked at the effect of slip amplitude through elastic modeling of fretting fatigue in the partial-slip regime. In low-amplitude fretting experiments using cylindrical-radii fretting pads pressed against an in-plane tension/compression loaded Al-4Cu alloy sample, they found a critical contact width for fretting fatigue damage. They also found that a transition between long and short fatigue lives occurred for microslip amplitudes of 0.9 to 1.2 μm (35–47 $\mu\text{in.}$) in the slip zones. This is considerably smaller than the maximum damage displacement of 20 to 30 μm (787–1181 $\mu\text{in.}$) found by Nishioka and Hirakawa and others in their full-slip experiments on steel samples.

The results of work by Collins and Tovey (Ref 25) indicate that fretting motion in the same direction as the cyclic stress has a greater effect than fretting in the perpendicular direction. They used this result to conclude that cracks are nucleated by adhesive wear rather than by abrasive plowing via the expected orientation from each mode.

Coefficient of Friction. The coefficient of friction probably has the greatest influence on fretting fatigue. It influences both slip amplitude and shear stress, though in opposite ways. The influence of different material combinations on fretting fatigue life has been reported to be due to the coefficient of friction (Ref 14). For load-controlled fretting, an increase in coefficient of friction can prevent slip over the whole contact region and reduce or eliminate fretting fatigue. For amplitude-controlled fretting, the opposite effect can be expected, and a

reduction in the coefficient of friction is desired because the surface shear stresses are reduced. Reduction in the coefficient of friction for clamped (bolted or riveted) joints has been shown to be detrimental in some cases because the lower coefficient of friction between the overlapping plates increases the load-carrying requirements of the bolts or rivets leading to failures initiating at the hole edges (Ref 17).

High Temperature. Fretting fatigue strength decreases with increasing temperature for titanium alloys (Ref 26), but was found to increase for the nickel-base alloy Inconel 718 (Ref 27) due to the formation of a protective oxide glaze. Such glazes typically lower the coefficient of friction. For iron-base alloys, both hard and soft flame-sprayed coatings based on molybdenum have shown success in improving the fretting fatigue strength at 300 °C (572 °F). Overs et al. (Ref 28) attribute the improvement to MoO₂ glaze formation.

Environment and Corrosive Media. The effect of environment on fretting fatigue depends on the material and its corrodibility. Fretting action readily destroys passivating films on materials that are normally corrosion resistant. Poon and Hoepfner found that when fretting and corrosion occur simultaneously, the effect of corrosion on fatigue is dominant (Ref 29). As such, many palliatives or remedies for fretting fatigue can be viewed in terms of their effectiveness on corrosion fatigue.

In mildly corrosive aqueous environments, such as weak sodium-chloride solutions representative of human body fluids, the fretting fatigue strength of materials not resistant to corrosion is reduced compared with fretting fatigue in air. Corrosion-resistant materials, such as austenitic stainless steel and titanium, have reduced fretting fatigue strengths in both environments due to the disruption by fretting of the otherwise protective oxide (Ref 30).

Endo found that ductile carbon steels are not affected by water vapor in fretting fatigue (Ref 31). Nishioka and Hirakawa found corrosion to be a secondary factor in fretting fatigue in their work on medium-carbon steels by comparing test data from argon and air experiments (Ref 32). Somewhat in contrast, Endo found that the fretting fatigue strength of carbon steel was higher in argon than in air, explaining that while the crack initiation rate is almost the same, the crack propagation rate is lower in argon (Ref 31).

Aluminum alloys are known to be very sensitive to water corrosion under dynamic conditions. Endo found that both crack initiation and propagation are accelerated by traces of water vapor due to corrosive attack, but not by oxygen. In the case of argon versus air experiments, the removal of oxygen was found to decrease the tangential stress due to soft aluminum wear debris accumulating between the mating surfaces (Ref 31). The alumina formed on aluminum would, if broken, be expected to be more abrasive and give rise to higher shear stresses than soft metallic wear debris.

Compared with tests in air, Ti-6Al-4V alloy was found to be adversely affected by corrosive atmospheres of humid argon and 1% NaCl at alternating stress levels above 120 MPa (17 ksi), but improved fatigue life was observed below 90 MPa (13 ksi) (Ref 33). The nature of the corrosion product was proposed to play a major role, in some cases forming a compacted layer that shielded the metal against crack initiation. Hoepfner reports that steel does not exhibit such a strong dependence on corrosion product (Ref 34).

Corrosion or oxidation are not required in the fretting process. Metallic fretting debris will form with gold or platinum contacts or other nonoxidizable materials (Ref 35).

Microstructure and Material. If the design requirements permit their use, annealed materials were found to be less susceptible to fretting fatigue than materials in the work-hardened state (Ref 20). Similarly, cast structures were less susceptible than forged structures (Ref 36). These results imply that if fatigue-crack nucleation takes place through a wear mode involving exhaustion of work hardening, then prior-worked materials have a significantly shorter nucleation period.

Reeves and Hoepfner (Ref 37) found that carbon steel in the martensitic condition is more resistant to fretting fatigue than in the normalized (ferrite-plus-pearlite) steel due to the higher hardness and wear resistance of the martensitic steel. Nishioka and Hirakawa also found the fatigue limit to be higher on induction-hardened versus annealed steel (Ref 19). These results imply that more wear-resistant materials have better fretting fatigue properties.

Copper-Base Alloys. Wharton et al. (Ref 20) found that 70/30 brass does not show a strength limit in either plain fatigue or fretting fatigue. However, they found that the fretting fatigue strength at a given number of cycles is reduced by a fixed proportion over the plain fatigue strength for two microstructural conditions, independent of applied stress. The reduction was 61 and 74%, for annealed and work-hardened brass, respectively.

Ferritic Alloys. Endo and Goto (Ref 38) found that fatigue cracks generally initiate in ferrite grains, and propagate perpendicular to the sliding direction through a pearlitic region, irrespective of the orientation of the

pearlite plates. Their experiments were performed under reverse bending. They also reported that for two-stage tests on a medium-carbon steel (ferrite-plus-pearlite microstructure), no further reduction in fatigue life occurred if the fretting was continued for the entire test or was stopped after one-quarter of the total life. They concluded that the saturation point in the curve representing fretting cycles versus total fatigue cycles corresponds to the point at which cracks that were initiated during fretting had grown to a depth where they propagated solely due to the macroscopic repeated stress (Ref 38).

Titanium Alloys. For three alpha + beta titanium microstructures, a fine or acicular microstructure was found to be more resistant to damage, defined by the number of propagating cracks found after a given number of cycles at a fixed stress, than a coarser-annealed structure (Ref 7). The finer alloy structure also had a lower SRF.

Fretting Fatigue Testing

S.J. Shaffer and W.A. Glaeser, Battelle Memorial Institute

Prevention or Improvement

Fretting can be minimized or eliminated in many cases by one or more of the methods outlined in Table 1. Additional techniques in the design stages to diminish the effect of fretting on fatigue are discussed in more detail in this article in terms of:

- *Modification of the surface stress state* by introduction of compressive stresses, reduction of surface shear stresses, or elimination or reduction of relative motion

- *Application of principles for wear and fracture toughness* in selection of materials, coatings, and lubricants

Surface Stress Modification

Design for Introduction of Residual Compressive Stress. The only treatment or remedy that has been shown to be universally effective in improving fretting fatigue is the introduction of residual compressive stresses. The compressive stress will reduce the driving force for both crack initiation and propagation. Residual compressive stresses can be imparted through high and uniform clamping forces or interference fits, plastic deformation of the surfaces, phase changes, and precipitation or diffusion/thermal treatments. If sufficiently deep, superposition of the compressive stress can also decrease the tensile stress field on the propagating crack in the base material.

Plastic deformation by means of shot peening, surface rolling, or ballizing the inside diameter of through-holes has the secondary effect of work hardening of the surface. In some cases, this work hardening leads to higher resistance to fretting wear. Waterhouse and Saunders (Ref 39) have attributed the increase in fretting fatigue strength of austenitic stainless steels by shot peening to an increase in surface hardness to 400 HV, compared to 150 HV for the bulk material, resulting in an increase in the fretting fatigue strength to that of the plain fatigue strength without fretting. In contrast, Leadbeater et al. (Ref 40) found that the improved fretting fatigue life in an aluminum 2014A alloy by shot peening was most likely due only to residual compressive stresses. They determined that while increasing surface roughness had a small beneficial effect, work hardening did not influence fretting fatigue properties.

Cold-working methods are not effective in applications where temperatures during service, or those generated locally due to fretting, would lead to annealing of the previously work-hardened surface.

Nitriding is a very effective palliative for steels. It introduces residual compressive stresses in the surface, and local hardening through solid solution strengthening can decrease the areas of real contact of self-mated ferrous material couples. Both chemical and ion implantation nitriding methods can be used. The effectiveness of carburizing will vary. Although the strength and hardness of the surface will be increased, the heat treatment required to create the martensitic transformation, carburizing, can produce either compressive or tensile residual stresses depending on the section size and shape. Tensile stresses, of course, would be detrimental.

Avoidance of Stress Raisers. Reducing geometric stress raisers in the vicinity of the contact will help prevent fretting fatigue-crack nucleation. Examples were presented in the section “Parallel Surfaces without External Loading” and in Fig. 7 and 8. Local stress raisers due to pitting by wear or pits caused by corrosion can be prevented by corrosion-resistant coatings, such as zinc, or by cathodic protection.

Spacers or Shims. If the amplitude of relative displacement is small, it may be possible to absorb all of the transmitted shear stresses through the elasticity of a thin, flexible layer such as rubber. The effectiveness of this method depends on the modulus of the layer, its thickness, the severity of the normal load, and whether the relative motion is displacement controlled. For aluminum alloys used for aircraft skins at temperatures up to 150 °C (302 °F), Taylor reports in work by Harris (Ref 41) that several investigations have shown the success against fretting fatigue of a joint bonded with isocyanate epoxy resin loaded with MoS₂. It is likely that the solid lubricant lowered the transmitted shear stresses while the resin prevented metal-to-metal contact. It has also been reported that both pure aluminum and copper are effective shim materials to be used against steel for reducing the transmitted shear stresses (Ref 24).

Lubricants. By using lubricants to lower the coefficient of friction, shear stresses resulting from the normal load will be decreased. Again, the amplitude of displacement may be increased. Oils and greases tend to be forced from the interface. Rough surfaces, such as those left by a shot-peening operation, can help retain liquid lubricants. Surface finishes that deliver oil to the fretting site are beneficial. Liquid lubricants can be effective on wire rope, where there is some containment of the lubricant due to the outer strands. Solid lubricants tend to be worn away over time and therefore have limited effectiveness.

Relative Motion. If the relative motion of the two members can be eliminated, the fatigue life can then be computed using standard methods found elsewhere in this Volume. The design concern then shifts to minimizing the stress concentration at the edges of the contact. Methods for eliminating motion include increasing the normal load and/or increasing the coefficient of friction of the interface to expand the region of no slip to the entire contact.

Surface Roughness. Surprisingly, a deliberately rough surface finish may be the best for minimizing fretting fatigue damage. Waterhouse suggests machining grooves in the surface of one of the two contacting members, preferably the one that is not subjected to the major cyclic stresses (Ref 42). It was suggested that the benefit found in this work on aluminum was due to a minimization of the extent of any one contact area. An alternative explanation is that the debris generated during fretting may be more readily trapped in the grooves, thus promoting both a lubricating effect and a reduction in the local stresses due to support by the compacted debris.

Wear and Cracking Resistance

Material Selection for Fretting Fatigue Resistance. Two guides for materials selection choices should be used. The first is based on materials and treatments selected for avoidance of fretting damage, hence minimizing crack nucleation (see Table 2). Materials with low propensity for adhesion are described by Rabinowicz (Ref 44) in terms of the inverse of metallurgical compatibility. Typically, dissimilar couples are preferred. Self-lubricating components, such as porous metal washers impregnated with lubricant, can be used. Materials with high work-hardening capacity or dynamic recrystallization characteristics can also minimize fatigue-crack initiation.

Table 2 Relative fretting resistance of various material combinations

Combination	Fretting resistance
Aluminum on cast iron	Poor
Aluminum on stainless steel	Poor
Bakelite on cast iron	Poor
Cast iron on cast iron, with shellac coating	Poor
Cast iron on chromium plating	Poor
Cast iron on tin plating	Poor
Chromium plating on chromium plating	Poor
Hard tool steel on stainless steel	Poor
Laminated plastic on cast iron	Poor
Magnesium on cast iron	Poor
Brass on cast iron	Average
Cast iron on amalgamated copper plate	Average
Cast iron on cast iron	Average
Cast iron on cast iron, rough surface	Average
Cast iron on copper plating	Average
Cast iron on silver plating	Average
Copper on cast iron	Average
Magnesium on copper plating	Average
Zinc on cast iron	Average
Zirconium on zirconium	Average
Cast iron on cast iron with coating of rubber cement	Good
Cast iron on cast iron with Molykote lubricant	Good
Cast iron on cast iron with phosphate conversion coating	Good
Cast iron on cast iron with rubber gasket	Good
Cast iron on cast iron with tungsten sulfide coating	Good
Cast iron on stainless steel with Molykote lubricant	Good
Cold-rolled steel on cold-rolled steel	Good
Hard tool steel on tool steel	Good
Laminated plastic on gold plating	Good

Source: Ref 43

The second materials selection guide is the use of alloy compositions and thermomechanical treatments for existing alloys that improve their fatigue-crack propagation resistance, as described elsewhere in this Volume and in a variety of mechanical properties handbooks (Ref 45, 46, and 47).

Soft coatings provide a “sacrificial,” low-shear strength layer that reduces the magnitude of the oscillatory shear stresses transmitted into the substrate. Both a lower coefficient of friction and a lower shear strength contribute. A coating that dynamically recrystallizes under service conditions would be expected to be effective. Situations that result in creep of the soft coating must be avoided, as the introduction of excessive clearance or a decrease in preload on bolts or washers can occur. In addition, low friction of soft coatings can lead to larger relative displacements for load-controlled fretting.

Diffusion treatments, such as sulfidized coatings on steel, were shown to be effective in delaying the initiation of a propagating fatigue crack in carbon steels in the laboratory when impregnated with a suitable oil-in-water emulsion (Ref 48) and subsequently applied successfully to compressor-blade roots (Ref 42).

Hard coatings minimize the areas of real contact and penetration by opposing asperities and are less prone to adhesive wear. However, hard coatings have high friction coefficients. As such, high shear stresses are transmitted into the coating, which can limit their effectiveness. Care must be taken in design of coating thickness to avoid high shear stresses at the depth of the coating/substrate interface, which is typically a plane of weakness.

Additionally, hard coatings, such as chromium platings, are often filled with cracks; sprayed molybdenum coatings usually contain pores. These defects in the coatings can serve as initial sites for fatigue cracks to develop and propagate into the substrate. Postcoating shot peening is recommended. Improvement in both electrodeposited chromium and nickel coatings was achieved by thermal diffusion processing followed by shot peening (Ref 42).

While hard coatings can reduce the overall fatigue strength compared with that of samples tested without prior fretting, under fretting fatigue conditions they typically show an improvement over uncoated materials. A pretreatment, such as shot peening or vapor blasting, may be required to compensate for the reduction in normal fatigue strength due to the hard coating. In the case of carbon steel, sprayed molybdenum coatings were found to increase the fretting fatigue strength from 33 to 72% of the normal fatigue strength compared with uncoated samples (Ref 49).

Nonmetallic coatings offer improvement in fretting fatigue resistance by lowering the coefficient of friction and preventing metal-to-metal welding at asperity contacts. The same types of substances that are considered solid “boundary” lubricants for wear control can be used. Conversion coatings produced by phosphating and anodizing, polymer sheets of nylon or polytetrafluoroethylene, and polymerized epoxy resins can all be used. In the case of porous coatings, impregnation with oils or greases can provide effective means of reducing or eliminating the occurrence of fretting fatigue when operating in the full-slip regime over the supply life of the lubricant.

Fatigue Crack Growth Testing

Ashok Saxena, Georgia Institute of Technology; Christopher L. Muhlstein, University of California, Berkeley

Introduction

FATIGUE is generally understood to be a process dominated by cyclic plastic deformation, such that fatigue damage can occur at stresses below the monotonic yield strength. The process of fatigue cracking generally begins from locations where discontinuities exist or where plastic strain accumulates preferentially in the form of slip bands. In most situations, fatigue failures initiate in regions of stress concentration, such as sharp notches, nonmetallic inclusions, or at preexisting cracklike defects. Where failures occur at sharp notches or other stress raisers, cracks first initiate and then propagate to critical size, at which time sudden failure occurs. The fatigue life consists of crack initiation as well as crack propagation. On the other hand, when fatigue failures are caused by large inclusions or preexisting cracklike defects, the entire life consists of crack

propagation. Such situations are commonly encountered in service failures. A typical example of such a failure in a railroad track is shown in Fig. 1. The light area in the photograph is the region of fatigue crack growth, and the surrounding darker area is the region of fast fracture. The dark spot within the light area is the origin of the failure, which is a preexisting defect due to a hydrogen flake.

Fig. 1 Fatigue failure of a railroad track

Testing of smooth or notched specimens generally characterizes the overall fatigue life of a specimen material. This type of testing, however, does not distinguish between fatigue crack initiation life and fatigue crack propagation life. With this approach, preexisting flaws or cracklike defects, which would reduce or eliminate the crack initiation portion of the fatigue life, cannot be adequately addressed. Therefore, testing and characterization of fatigue crack growth is used extensively to predict the rate at which subcritical cracks grow due to fatigue loading. For components subjected to cyclic loading, this capability is essential for life prediction, recommendation of a definite accept/reject criterion during nondestructive inspection, and calculation of in-service inspection intervals for continued safe operation.

Fatigue Crack Growth Testing

Ashok Saxena, Georgia Institute of Technology; Christopher L. Muhlstein, University of California, Berkeley

Linear elastic fracture mechanics (LEFM) is an analytical framework that relates the magnitude and distribution of stress in the vicinity of a crack tip to the nominal stress applied to the structure; to the size, shape, and orientation of the crack or cracklike imperfection; and to the crack growth and fracture resistance of the material. The approach is based on the analysis of stress-field equations, which show that the elastic stress field in the region of a crack tip can be described by a single parameter, K called the stress-intensity factor. This same approach is also used to characterize fatigue crack growth rates (da/dN) in terms of the cyclic stress-intensity range parameter (ΔK).

When a component or specimen containing a crack is subjected to cyclic loading, the crack length (a) increases with the number of fatigue cycles (N) if the load amplitude (ΔP), load ratio (R), and cyclic frequency (ν), are held constant. The da/dN increases as the crack length increases during a given test. The da/dN is also higher at any given crack length for tests conducted at higher load amplitudes. Thus, the following functional relationship can be derived from these observations:

$$\left(\frac{da}{dN}\right)_{R, \nu} = f(\Delta P, a) \quad (\text{Eq 1})$$

where the function f is dependent on the geometry of the specimen, the crack length, the loading configuration, and the cyclic load range. This general relation is simplified with the use of the ΔK parameter as summarized below.

Correlation between da/dN and ΔK . In 1963, Paris and Erdogan (Ref 1) published an analysis with considerable fatigue crack growth rate (FCGR) data and demonstrated that a correlation exists between da/dN and the cyclic stress intensity parameter, ΔK . They argued that ΔK characterizes the magnitude of the fatigue stresses in the crack-tip region; hence, it should characterize the crack growth rate. Such a proposition is in obvious agreement with the functional relationships of Eq 1. The parameter ΔK accounts for the magnitude of the load range (ΔP) as well as the crack length and geometry. A number of later studies (Ref 2) have confirmed the findings of Paris and Erdogan. The data for intermediate FCGR values can be represented by the following simple mathematical relationship, commonly known as the Paris equation:

$$\frac{da}{dN} = C (\Delta K)^n \quad (\text{Eq 2})$$

where C and n are constants that can be obtained from the intercept and slope, respectively, of the linear $\log da/dN$ versus $\log \Delta K$ plot. This representation of FCGR is a useful model for midrange FCGR values (Fig. 2).

Fig. 2 Fatigue crack growth regimes versus ΔK

It has been shown and it is generally believed that specimen thickness has no significant effect on the FCGR behavior (Ref 3). The ability of ΔK to account for so many variables has tremendous significance in the application of the data. Thus, the FCGR behavior expressed as da/dN versus ΔK can be regarded as a fundamental material property analogous to the yield and ultimate tensile strengths and plane strain fracture toughness, K_{Ic} . From the knowledge of this property, prediction of the crack length versus cycles behavior of any component using that material and containing a preexisting crack or cracklike defect can be obtained, as

long as the fatigue stresses in the component are known and a K expression for the crack/load configuration is available.

Crack-Tip Plasticity during Fatigue. The cyclic stress-intensity parameter, ΔK , is based on LEFM, and it characterizes only the elastic stress field beyond the plastic zone. However, fatigue is a process dominated by cyclic plastic deformation. Even when fatigue damage occurs at stresses below the monotonic yield strength, the process of fatigue cracking begins from locations where there are discontinuities, such as nonmetallic inclusions, or from surfaces where plastic strain accumulates preferentially in the form of slip bands (Ref 4). Therefore, a brief explanation is given for why ΔK can characterize fatigue crack growth behavior.

When a cracked body is subjected to cyclic loading, a monotonic plastic zone develops at the crack tip during the first loading cycle. If predominantly linear elastic conditions are maintained during loading, as are necessary for ΔK to be a valid crack-tip parameter, compressive stress develops within this plastic zone during unloading. Compressive stress develops, because the elastic forces in the overall body tend to restore the original shape (Ref 2). The magnitude of the maximum compressive stress increases as the crack tip is approached. In a small region within the monotonic plastic zone, the maximum compressive stress exceeds the yield strength, resulting in plastic flow in compression. This small region of reversing plastic flow is called the cyclic plastic zone. A simple estimate of the size of this zone was made by Paris (Ref 2) and Rice (Ref 5) for nonhardening materials by substituting $2\sigma_{ys}$ in place of σ_{ys} in the expression for monotonic plastic zone size and by replacing K with ΔK :

$$r_{cp} = \frac{1}{\pi} \left(\frac{\Delta K}{2\sigma_{ys}} \right)^2 \quad (\text{Eq 3})$$

where r_{cp} is the cyclic plastic zone size under plane-stress conditions. For materials that undergo cyclic hardening or softening, a first-order estimate of the fatigue plastic zone size can be obtained by replacing σ_{ys} with the cyclic yield strength (σ_{cys}) in Eq 3.

General Crack Growth Behavior. When crack growth rates over six to seven decades are plotted against ΔK , the behavior is no longer a straight line on a log-log plot. Results of FCGR tests for nearly all metallic structural materials have shown that the da/dN versus ΔK curves have three distinct regions. The behavior in region I (Fig. 2) exhibits a fatigue crack growth threshold, ΔK_{th} , which corresponds to the stress-intensity factor range below which cracks do not propagate. Equation 2 is applicable in the midrange of da/dN values for FCGR (region II, Fig. 2). Typically, the validity of Eq 2 is limited over a range of two to four decades for midrange crack growth rates.

At high ΔK values (region III, Fig. 2), the K_{max} approaches the critical K for instability, K_c , and the crack growth rate accelerates. In some instances, K_c may be equal to K_{Ic} , but this situation cannot be generalized because the FCGR specimens or even actual components may not always satisfy size requirements for valid linear elastic plane-strain conditions. In some materials, there is also an effect of prior fatiguing on the K value at which instability occurs (Ref 6). In such situations, K_c will not be equal to the K_{Ic} of the material.

At low ΔK values (region I, Fig. 2), the crack growth rate decreases rapidly with decreasing ΔK , and ultimately ΔK approaches a threshold value, ΔK_{th} , when the crack growth rate approaches zero. In high-cycle fatigue applications, ΔK_{th} is an important design parameter. The above definition of ΔK_{th} is an idealized definition; for practical usage, it is important to define its value unambiguously. An operational value of ΔK_{th} is frequently defined as the ΔK value at a da/dN of 10^{-10} m/cycle (Ref 7).

FCGR under Elastic-Plastic Conditions. There are applications when fatigue crack growth occurs under conditions of gross plastic deformation, or at least under conditions for which dominant linear elasticity cannot be ensured. As a crack tip parameter, ΔK breaks down under these conditions and can no longer be expected to uniquely characterize FCGR behavior. Dowling and Begley have defined a cyclic J -integral, ΔJ , which is determined utilizing the loading portion of the load-displacement diagram during cyclic loading (Ref 8, 9).

Metals and alloys can be assumed to deform according to the cyclic stress-strain law given by:

$$\Delta \epsilon = \frac{\Delta \sigma}{E} + D' \left(\frac{\Delta \sigma}{2\sigma_{cys}} \right)^{m'} \quad (\text{Eq 4})$$

where $\Delta \epsilon$ is the cyclic strain range, $\Delta \sigma$ is the cyclic stress range, E is the elastic modulus, and D' and m' are empirically determined material constants. The value of ΔJ for such materials can be defined (Ref 10):

$$\Delta J = \int_{\Gamma} (\Delta W) dy - \Delta T_i \left(\frac{\partial \Delta u_i}{\partial x} \right) ds \quad (\text{Eq 5})$$

The term ΔJ in Eq 5 is a path-independent integral along any given path Γ that originates at the lower crack surface and ends on the upper crack surface traversing along the contour in a counterclockwise direction. The definition of ΔJ is written as a direct analogy to Rice's J -integral (Ref 11), used extensively in characterizing fracture under monotonic loading conditions. The term ΔW in Eq 5 is defined as follows:

$$\Delta W = \int \Delta \epsilon_{ij} \sigma_{ij} d(\Delta \epsilon_{ij}) \quad (\text{Eq 6})$$

Other terms in Eq 5 and 6 are:

- ΔT_i is the range of the traction vector
- Δu_i is the range of displacement
- ds is an element along the contour Γ
- $\Delta \sigma_{ij}$ and $\Delta \epsilon_{ij}$ are the ranges of the stress and strain, respectively

All range quantities are calculated by subtracting the values at minimum load from the corresponding values at maximum load. When ΔJ is defined in the above manner, its value characterizes the crack-tip stress and strain ranges according to the Hutchinson (Ref 12) and Rice and Rosengren (Ref 13) relationships. It must also be noted that for linear elastic conditions, Eq 5 will yield the following relationship:

$$\Delta J = \frac{\Delta K^2}{E} \quad (\text{Eq 7})$$

From the above relationship, the data from linear elastic tests and elastic-plastic or fully plastic tests can be combined into a single plot of da/dN with ΔK or $\sqrt{E\Delta J}$. Similarly, the data can be correlated with $\Delta K^2/E$ or ΔJ . Figure 3 shows the FCGR data for A533 and for 304 stainless steel in this manner (Ref 9, 14). These data were developed on specimens of two geometries and, more notably, with varying sizes within those geometries. Thus, small specimens exhibited considerable plasticity, and the large specimens were under dominantly elastic conditions. Despite the enormous differences in the scales of plasticity among the various tests, the FCGR data lay in a single scatter band.

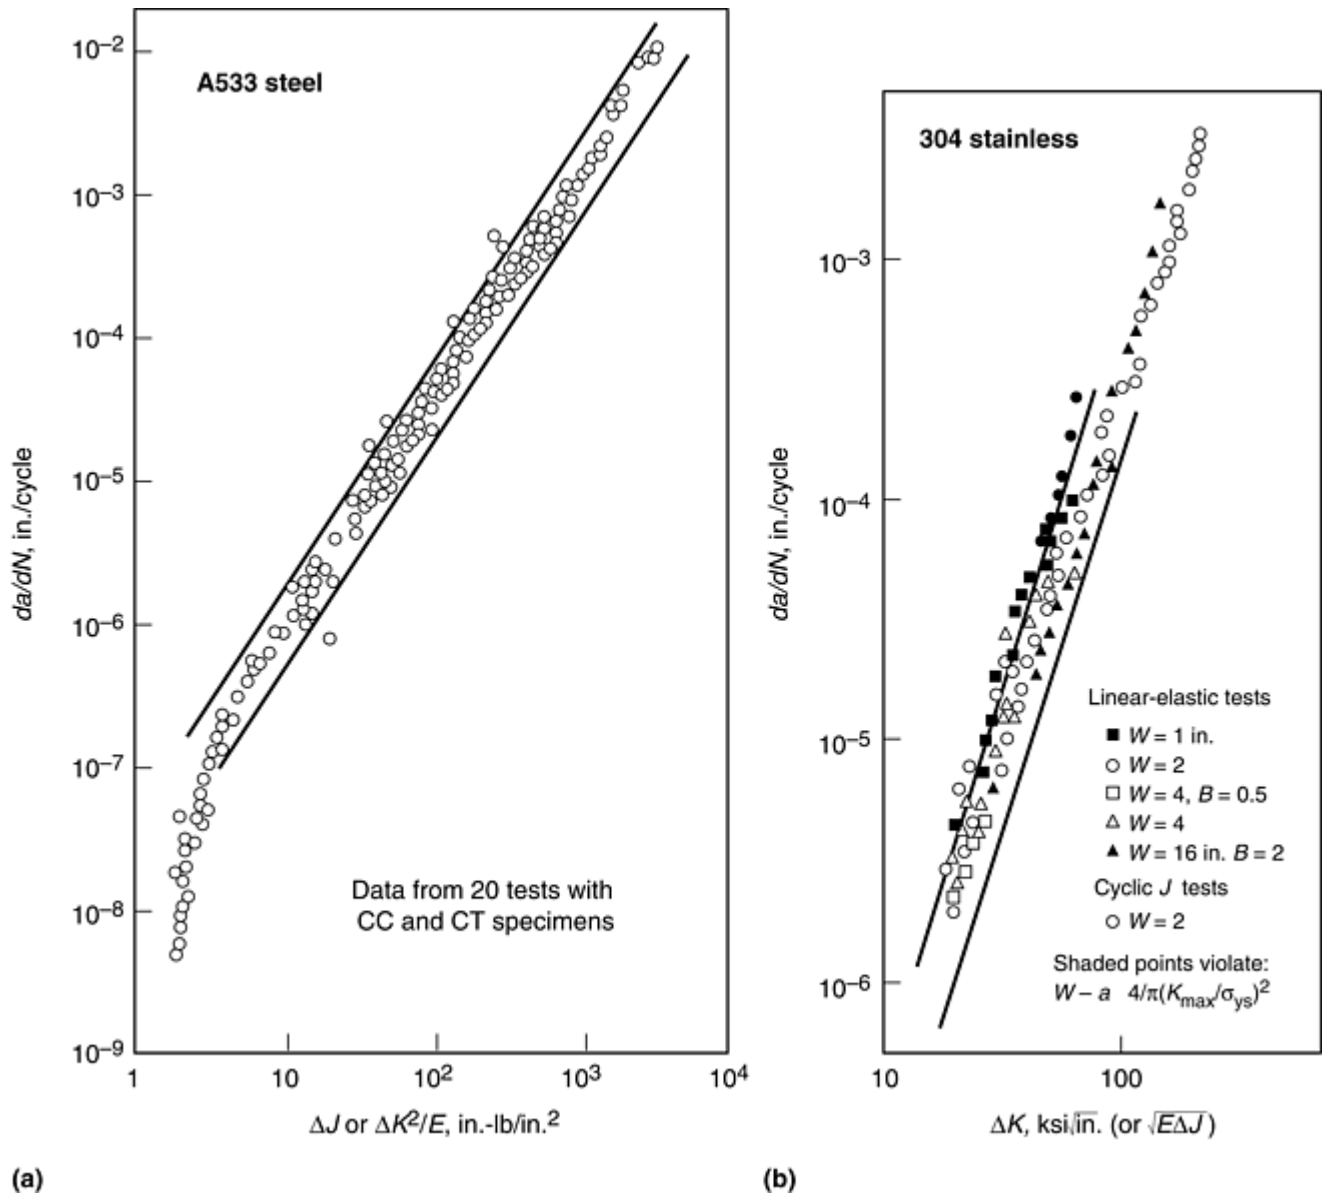

Fig. 3 Fatigue crack growth rate obtained under linear elastic and elastic-plastic conditions in (a) A533 steel and (b) 304 stainless steel. CC, center-cracked specimen; CT, compact-type specimen. Source: Ref 9, 14

Crack Closure. The concept of crack closure was first introduced by Elber (Ref 15, 16) as an effect from a zone of residual deformation left in the wake of a growing fatigue crack. According to this concept, crack surfaces at the crack tip might stay closed during a portion of the fatigue cycle due to compressive residual stress acting at the crack tip. Elber further postulated that this portion of the loading cycle is ineffective in growing the fatigue crack; thus, the corresponding load should be subtracted from the applied ΔP to determine the effective value of ΔK .

Figure 4 presents a series of schematic sketches that show the stress and strain distributions at the crack tip at maximum and minimum load. At the maximum load, *A*, all the load is borne by the uncracked ligament, because cracks are unable to transmit the load. At the minimum load, *B*, there are compressive stresses to the left of the crack tip, because there is contact between opposing crack surfaces within the zone of residual plastic deformation. This contact causes the effective stiffness of the cracked body to change, which manifests itself in the load-displacement diagram. Thus, the crack closure load can be defined as the load at which this change in stiffness occurs.

Fig. 4 Schematic of crack-tip conditions during crack closure

Figure 5(a) shows a schematic load-deflection diagram and the crack closure point. Figure 5(b) plots only the deviation between the total deflection and the linearly predicted deflection, thus highlighting the crack closure point.

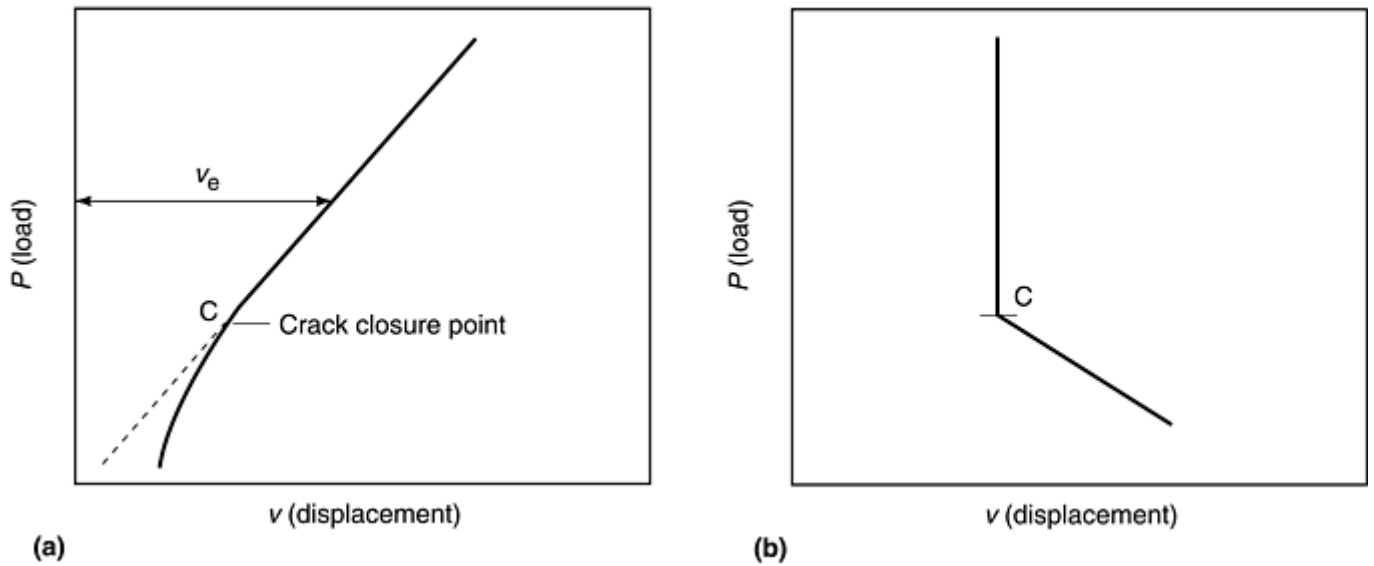

Fig. 5 Load versus displacement diagrams. (a) Diagram showing a change in stiffness at the crack closure point. (b) A plot of total deflection minus the elasticity calculated deflection amplified to highlight crack closure. v_e , elastic displacement

The importance of crack closure varies with the crack growth regime, crack tip material-microstructure interactions, and the extent of plasticity. Crack closure is more significant in the near-threshold regime (region I, Fig. 2) than in region II (Fig. 2). Materials in which the crack path is such that rougher crack surfaces are produced usually exhibit enhanced crack closure levels. The crack closure levels can also increase with plasticity. For example, during fatigue crack growth in the elastic-plastic regime, crack closure levels take on added significance (Ref 8, 9).

Fatigue Crack Growth Testing

Ashok Saxena, Georgia Institute of Technology; Christopher L. Muhlstein, University of California, Berkeley

Test Methods and Procedures

ASTM standard E 647 (Ref 7) is the accepted guideline for fatigue crack growth testing and is applicable to a wide variety of materials and growth rates.

FCGR testing consists of several steps, beginning with selecting the specimen size, geometry, and crack-length measurement technique. When planning the tests, the investigator must have an understanding of the application of FCGR data. Testing is often performed in laboratory air at room temperature; however, any gaseous or liquid environment and temperature of interest may be used to determine the effect of temperature, corrosion, or other chemical reaction on cyclic loading (see the appendix “High-Temperature Fatigue Crack Growth Testing” at the end of this article). Cyclic loading also may involve various waveforms for constant-amplitude loading, spectrum loading, or random loading.

In addition, many of the conventions used in plane-strain fracture toughness testing (ASTM E 399, Ref 17) are also used in FCGR testing. For tension-tension fatigue loading, K_{Ic} loading fixtures frequently can be used. For this type of loading, both the maximum and minimum loads are tensile, and the load ratio, $R = P_{\min}/P_{\max}$, is in the range $0 < R < 1$. A ratio of $R = 0.1$ is commonly used for developing data for comparative purposes.

Cyclic crack growth rate testing in the threshold regime (region I, Fig. 2) complicates acquisition of valid and consistent data, because the crack growth behavior becomes more sensitive to the material, environment, and testing procedures. Within this regime, the fatigue mechanisms of the material that slow the crack growth rates are more significant.

It is extremely expensive to obtain a true definition of ΔK_{th} , and in some materials a true threshold may be nonexistent. Generally, designers are more interested in the FCGR in the near-threshold regime, such as the ΔK that corresponds to a FCGR of 10^{-8} to 10^{-10} m/cycle (3.9×10^{-7} to 10^{-9} in./cycle). Because the duration of the tests increases greatly for each additional decade of near-threshold data (e.g., 10^{-8} to 10^{-9} to 10^{-10} m/cycle), the precise design requirements should be determined in advance of the test. Although the methods of conducting fatigue crack threshold testing may differ, ASTM E 647 addresses these requirements.

In all areas of crack growth rate testing, the resolution capability of the crack measuring technique should be known; however, this knowledge becomes considerably more important in the threshold regime. The smallest amount of crack-length resolution is desired, because the rate of decreasing applied loads (load shedding) is dependent on how easily the crack length can be measured. The minimum amount of change in measured crack growth should be ten times the crack-length measurement precision. It is also recommended that for noncontinuous load shedding testing, where, $[(P_{\max 1} - P_{\max 2})/P_{\max 1}] > 0.02$, the reduction in the maximum load should not exceed 10% of the previous maximum load, and the minimum crack extension between load sheds should be at least 0.50 mm (0.02 in.)

In selecting a specimen, the resolution capability of the crack measuring device and the K -gradient (the rate at which K is increased or decreased) in the specimen should be known to ensure that the test can be conducted appropriately. If the measuring device is not sufficient, the threshold crack growth rate may not be achieved before the specimen is separated in two. To avoid such problems, a plot of the control of the stress intensity (K versus a) should be generated before selection of the specimen.

When a new crack-length measuring device is introduced, a new type of material is used, or any other factor is different from that used in previous testing, the K -decreasing portion of the test should be followed with a constant load amplitude (K -increasing) to provide a comparison between the two methods. Once a consistency is demonstrated, constant-load amplitude testing in the low crack growth rate regime is not necessary under similar conditions.

Fatigue Crack Growth Testing

Ashok Saxena, Georgia Institute of Technology; Christopher L. Muhlstein, University of California, Berkeley

Specimen Selection and Preparation

The two most widely used types of specimens are the middle-crack tension, MT, and the compact-type specimen, CT (Fig. 6, 7). However, any specimen configuration with a known stress-intensity factor solution can be used in FCGR testing, assuming that the appropriate equipment is available for controlling the test and measuring the crack dimensions.

Center-cracked tension specimens ΔK :

$$\Delta K = \frac{\Delta P}{B} \sqrt{\frac{\pi \alpha}{2W}} \sec \frac{\pi \alpha}{2}$$

$$\text{where } \alpha = \frac{2a}{W}; \text{ expression valid for } \frac{2a}{W} < 0.95$$

Fig. 6 Standard center-cracked tension (middle-tension) specimen and ΔK solution. Specimen width (W) ≤ 75 mm (3 in.). $2a_n$ machined notch; a , crack length; B , specimen thickness

Compact-type specimens ΔK value:

$$\Delta K = \frac{\Delta P (2 + \alpha)}{B \sqrt{W} (1 - \alpha)^{3/2}} (0.886 +$$

$$4.64\alpha - 13.32\alpha^2 + 14.72\alpha^3 - 5.6\alpha^4), \text{ where}$$

$$\alpha = \frac{a}{W}; \text{ expression valid for } \frac{a}{W} \leq 0.2$$

Fig. 7 Standard compact-type specimen and ΔK value (per ASTM E 674). Allowable thickness: $W/20 \leq B \leq W/4$. Minimum dimensions: $W = 25 \text{ mm (1.0 in.)}$; machined notch size (a_n) = $0.20W$

Specimens used in FCGR testing may be grouped into three categories: pin-loaded (Fig. 6, 7), bend-loaded (Fig. 8a) and wedge-gripped specimens (Fig. 8b – d). Precisely machined specimens are essential, and ASTM E 647 specifies the recommended tolerances and K -calibrations for CT and MT geometries. Single-edge bend, arc-shaped, and disk-shaped compact specimen geometries and the corresponding K -calibrations are discussed in ASTM E 399. Comparable tolerances should be specified for “nonstandard” specimens. The selection of an appropriate geometry requires consideration of material availability and raw form, desired loading condition, and equipment limitations.

Fig. 8 Alternative crack growth specimen geometries. (a) Single-edge-crack bending specimen. (b) Double-edge-crack tension specimen. (c) Single-edge-crack tension specimen. (d) Surface-crack tension specimen

Crack Length and Specimen Size. The applicable range of the stress-intensity solution of a specimen configuration is very important. Many stress-intensity expressions are valid only over a range of the ratio of crack length to specimen width (a/W). For example, the expression given in Fig. 7 for the CT specimen is valid for $a/W > 0.2$; the expression for the middle-tension (MT) specimen (Fig. 6) is valid for $2a/W < 0.95$. The use of stress-intensity expressions outside the applicable crack-length region can produce significant errors in data. The size of the specimen must also be appropriate. To follow the rules of LEFM, the specimen must be predominantly elastic. However, unlike the requirements for plane-strain fracture toughness testing, there are no specific requirements of minimum specimen thickness. The thickness is considered to be a controlled test variable and depends on the application. The material characteristics, specimen size, crack length, and applied load will dictate whether the specimen is predominantly elastic. Because the loading modes of different specimens vary significantly, each specimen geometry must be considered separately.

For the MT specimen, the following is required:

$$W - 2a \geq \frac{1.25P_{\max}}{B\sigma_{ys}} \quad (\text{Eq 8})$$

where $W - 2a$ is the uncracked ligament of the specimen (see Fig. 6) and σ_{ys} is the 0.2% offset yield strength at the temperature corresponding to the FCGR data.

For the CT specimen, the following is required:

$$W - a \geq \frac{4}{\pi} \left(\frac{K_{\max}}{\sigma_{ys}} \right)^2 \quad (\text{Eq 9})$$

where $W - a$ is the uncracked ligament (Fig. 7). For the CT specimen, the size requirement in Eq 9 limits the monotonic plastic zone in a plane-stress state to approximately 25% of the uncracked ligament. For both Eq 8 and 9, ASTM E 647 recommends the use of the monotonic yield strength. The size requirements in Eq 8 and 9 are appropriate for low-strain hardening materials ($\sigma_{\text{uts}}/\sigma_{ys} \leq 1.3$), where σ_{uts} is the ultimate tensile strength of

the material. For higher-strain-hardening materials, Eq 8 and 9 may be too restrictive. In such situations, the criteria may be relaxed by replacing the yield strength, σ_{ys} , with the effective yield strength, σ_F :

$$\sigma_F = \frac{(\sigma_{ys} + \sigma_u)}{2} \quad (\text{Eq 10})$$

Specimen Thickness. While fatigue crack growth rates have been shown to be relatively insensitive to stress state (i.e., plane-stress versus plane-strain, Ref 3), there are some practical limitations on specimen thickness. ASTM E 647 recommends that generally CT specimen thickness (B) range between 5 and 25% of width ($W/20 \leq B \leq W/4$). Middle-tension specimens may have thicknesses up to 12% of width ($\leq W/8$). When other specimen geometries are used, similar ranges for thickness should be employed.

Although a wide variety of specimen thicknesses are permitted, the amount of crack curvature in the specimen will increase as the thickness increases. Because stress-intensity solutions are based on a straight through-crack, a significant amount of curvature, if not properly considered, can lead to an error in the data. Crack-curvature correction calculations are detailed in ASTM E 647. The minimum allowable thickness depends on the gripping method used; however, the bending strains should not exceed 5% of the nominal strain in the specimen.

Material Form and Microstructure Considerations. The material and its microstructure play an important role in the selection of an appropriate specimen geometry. Materials with anisotropic microstructures due to processing, such as rolling or forging, may show large variations in FCGR in different directions (Ref 18). If the experimental crack growth rate data are to be used for life estimates, the orientation of the specimen should be selected to represent loading orientations expected in service.

In order to eliminate grain size effects, it is usually recommended that the specimen thickness (B) be greater than 30 grain diameters (Ref 19, 20). In some instances, such as in large-grain (~ 3 mm) lamellar γ - α_2 Ti-Al intermetallic or α - β titanium alloys, the required specimen sizes would be prohibitively expensive, test loads would be very high, and the component dimensions would probably be less than 30 times the grain size. In such instances, testing should be performed on thicknesses representative of the component. Curvature of the crack front and side-to-side variation in crack length due to excessive thickness can also be a problem in thick specimens, as discussed below.

Loading Considerations. The desired loading conditions play an important role in the specimen geometry and size selection process. Loading considerations include load ratio, R , residual stresses, K -gradients, and maintaining small-scale yielding. All specimen geometries are well suited for tension-tension ($R > 0$) testing. However, tests that call for negative R (i.e., those with minimum loads less than 0) are restricted to symmetric, wedge-grip loaded specimens, such as the MT specimens. This limitation is due to questions about the crack-tip stress field under compressive loads (Ref 7) and difficulties moving through zero load with pin-loaded specimens.

Residual stresses in the material also have a marked effect on FCGR. Depending on the orientation of the residual stresses, specimen dimensions or geometries should be altered. Residual stresses through the thickness of the specimen (i.e., perpendicular to the direction of crack growth) may accelerate or retard crack growth. When these stresses are not uniform, ASTM E 647 recommends a reduction of the thickness-to-width ratio (B/W).

The rate at which K increases as the crack extends at a constant-load amplitude is given by the geometry function $f(a/W)$ and may be a consideration when selecting the most appropriate specimen geometry. Figure 9 shows the effect of geometry on the K -gradient through a variety of specimen geometries. Specimens with shallower K -gradients are preferable for brittle materials, while the opposite is true for ductile materials.

Fig. 9 K -gradients for a number of fatigue crack growth specimens. Source: Ref 7, 17

Equipment Considerations. Specimen size and geometry also can be influenced by laboratory equipment, such as the loadframe, loadcell, existing loading fixtures, testing environment, and even the crack-length measurement apparatus. To minimize cost, specimen sizes and geometries should be selected to use existing clevises, pins, and other hardware.

Most modern mechanical testing laboratories exclusively use electroservohydraulic loadframes for FCGR investigations. Current controls and data acquisition technology have hydraulic loadframes more versatile than the electromechanical systems used previously. When selecting a specimen geometry and size, it is important to be aware of the load capacity of the actuator and loadframe. Loads that are too high cannot be applied, and those loads that are too low cannot be controlled with the required accuracy ($\pm 2\%$). In addition, the load cell to be used during testing must be able to measure the maximum applied load and resolve the lowest expected amplitudes, as specified in ASTM E 4.

When testing in environments, specimens fit inside ovens, furnaces, or other chambers with ample space left for clevises, cantilever beam clip gages, and other hardware. Special notch geometries or knife-edge attachment locations are often necessary for attaching clip gages or other types of extensometers for nonvisual crack-length measurements using compliance techniques.

Notch and Specimen Preparation. The method by which a notch is machined depends on the specimen material and the desired notch root radius (ρ). Sawcutting is the easiest method but is generally acceptable only for aluminum alloys. For a notch root radius of $\rho \leq 0.25$ mm (0.010 in.) in aluminum alloys, milling or broaching is required. A similar notch root radius in low- and medium-strength steels can be produced by grinding. For high-strength steel alloys, nickel-base superalloys, and titanium alloys, electrical discharge machining may be necessary to produce a notch root radius of $\rho \leq 0.25$ mm (0.010 in.).

The specimen is polished to allow measurement of the crack during the precracking and testing phases of the experiment. Many specimens can be polished using standard metallography practices. In some instances, etching of the polished surface may provide better contrast for viewing of the crack. If the specimen is too large or small to be handled, then hand grinders, finishing sanders, or handheld drills can be used with pieces of polishing cloth to locally apply the abrasive and create a satisfactory viewing surface. These techniques are quick and easy to apply, and they are often used when visual measurements are made only during precracking and subsequent measurements are made by automated techniques, such as electric potential or compliance.

Precracking. The K -calibration functions found in ASTM E 647 and E 399 are valid for sharp cracks within the range of crack length specified. Consequently, before testing begins, a sharp fatigue crack that is long enough to avoid the effects of the machined notch must be present in the specimen ($0.1B$, or $0.1H$, or 1 mm [0.040 in.], whichever is greatest). The process that generates this crack is termed precracking. In general, loads for precracking should be selected such that the K_{\max} at the end of precracking does not exceed levels expected at the start of a test.

For most metals, precracking is a relatively simple process that can be performed under load or displacement control conditions. Moderate growth rates (1×10^{-5} m/cycle) can be selected by estimating the necessary ΔK from growth curves in the literature. Precracking of a specimen prior to testing is conducted at stress intensities sufficient to cause a crack to initiate from the starter notch and propagate to a length that will eliminate the

effect of the notch. To decrease the amount of time needed for precracking to occur, common practice is to initiate the precracking at a load above that used during testing and to subsequently reduce the load.

Load generally is reduced uniformly to avoid transient (load-sequence) effects. Crack growth can be arrested above the threshold stress-intensity value due to formation of the increased plastic zone ahead of the tip of the advancing crack. Therefore, the step size of the load during precracking should be minimized. Under these circumstances, the loads should be shed no faster than 20% (per increment of crack extension, as discussed below) from the previous load increment (Ref 7), which eliminates load-sequence effects on growth rates. As the crack approaches the final desired size, the percentage can be decreased.

The amount of crack extension between each load decrease must also be controlled. If the step is too small, the influence of the plastic zone ahead of the crack may still be present. To avoid transient (load-sequence) effects in the test data, the load range in each step should be applied over a crack-length increment of at least $(3\pi)(K'_{\max}/\sigma_{ys})^2$, where K'_{\max} is the terminal value of K_{\max} from the previous load step. This requirement ensures that the crack extension between load sheds is at least three plastic zone diameters.

The influence of the machined starter notch must be eliminated so that the crack tip conditions are stable. For CT and MT specimens, this condition requires that the final precrack be at least 10% of the thickness of the specimen or equivalent to the height of the starter notch, whichever is greater (Ref 7).

Two additional considerations regarding crack shape are the amount of crack variation from the front and back sides of the specimen and the amount of out-of-plane cracking. Due to microstructural changes through the specimen thickness, residual stresses (particularly in weldments), or misalignment of the specimen in the grips, the crack may grow unevenly on the two surfaces. If any two crack-length measurements vary by more than $0.025W$ or by more than $0.25B$ (whichever is less), the precracking operation is not suitable, and test results will not be valid. If a fatigue precrack departs more than $\pm 5^\circ$ from the plane of symmetry, the specimen is not suitable for subsequent testing.

Precracking of Brittle Materials. Brittle materials, such as intermetallics and ceramics, can be very difficult to precrack. It is not uncommon to initiate a flaw that immediately propagates to failure. This transformation is due, in part, to the increasing K -gradient found in FCGR specimens and the relatively narrow range of ΔK for stable crack growth.

To improve the chances of successful precracking of brittle materials, chevron notches are advised. Chevron-notched specimens (Fig. 10) are used for determining the fracture toughness of brittle materials that are difficult to fatigue precrack. Chevron notches generate decreasing K -gradients at the start of precracking and may be machined as part of the specimen, or they may be added just prior to testing using a thin diamond wafering blade. The maximum slope of the chevron notch should be 45° . Precracking of brittle materials should be performed under displacement control conditions, so that as the crack extends, the load and the applied K decrease. Lastly, the loads should be increased slowly from low levels due to the stochastic nature of crack initiation in these materials. If initiation is especially difficult, compressive overloads may assist the process. It is also helpful to monitor the initiation process with a method other than optical observation. Electric potential techniques (bulk and foil) and back face strain (BFS) compliance techniques are very effective.

Fig. 10 Schematic of chevron notches in fracture mechanics specimens. Area b is the crack area.

Once precracking has been completed, an accurate optical measurement of the initial crack length, a_0 , must be made on both sides of the specimen to within 0.10 mm (0.004 in.) or $0.002W$ (whichever is greatest), or to within 0.25 mm (0.01 in.) for specimens where $W > 127$ mm (5 in.). If the crack lengths on the two surfaces differ by more than $0.25B$, then the test will not be valid, because K -calibration functions presume the existence of a straight crack front. Middle-tension specimens further require that both halves of the precrack be the same length to within $0.025W$. In addition, ASTM E 647 requires that cracks lie on the centerline such that the crack is no more than $\pm 20^\circ$ from a centerline over a distance $0.1W$. Once the precrack has been measured and side-to-side variation and distance from centerline have been established, testing may begin.

Gripping of the specimen must be done in a manner that does not violate the stress-intensity solution requirements. For example, in a single-edge notched specimen, it is possible to produce a grip that permits rotation in the loading of the specimen, or it is possible to produce a rigid grip. Each of these grips requires a different stress-intensity solution. In grips that are permitted to rotate, such as the CT specimen grip, the pin and hole clearances must be designed to minimize friction. It is also advisable to consider lateral movement above and below the grips.

When appropriate, the use of a lubricant is recommended to reduce friction. In thick samples, the amount of bending in the pins should be minimized. Finally, the alignment of the system should be checked carefully to avoid undesirable bending stresses, which generally cause uneven cracking. Alignment can be easily checked using a strain gage specimen of a geometry similar to that used in the test program. Generally, bending strains should not exceed 5% of the nominal strain to be used in the test program.

Gripping arrangements for CT and CCT specimens are described in ASTM E 647 (Ref 7). For a CCT specimen less than 75 mm (3 in.) in width, a single pin grip is generally suitable. Wider specimens generally require additional pins, friction gripping, or some other method to provide sufficient strength in the specimen and grip to prohibit failure at undesirable locations, such as in the grips.

Fatigue Crack Growth Testing

Ashok Saxena, Georgia Institute of Technology; Christopher L. Muhlstein, University of California, Berkeley

Crack-Length Measurement

Precise measurements of fatigue crack extension are crucial for the determination of reliable crack growth rates. ASTM E 647 requires a minimum resolution of 0.1 mm (0.004 in.) in crack-length measurement. Crack extension measurements are recommended at intervals 10 times the minimum required resolution.

Various crack measurement techniques have been applied, including optical (visual and photographic), ultrasonic, acoustic emission, electrical (eddy current and resistance), and compliance (displacement and BFS gages) methods. Optical, compliance, and electric potential difference are the most common laboratory techniques, and merits and limitations are reviewed in detail in the following sections. Other references are listed in “Selected References” at the end of this article.

Optical Crack Measurement

Monitoring of fatigue crack length as a function of cycles is most commonly conducted visually by observing the crack at the specimen surfaces with a traveling low-power microscope at a magnification of 20 to 50 \times . Crack-length measurements are made at intervals such that a nearly even distribution of da/dN versus ΔK is achieved. The minimum amount of extension between readings is commonly about 0.25 mm (0.010 in.).

For planar specimens, the crack length is measured on one or both surfaces, depending on the section thickness. For example, ASTM E 647 (Ref 7) specifies a B/W value of 0.15 as the limit; measurements on only one side are sufficient if $B/W < 0.15$.

Through-thickness variations in crack length must be considered and corrected if too severe. Typical behavior is for the crack length to lead at the midplane (crack tunneling). Because this situation cannot be observed in situ by visual monitoring, posttest observations must be made. Rough alignment of the traveling microscope can be easily achieved by shining a pen light through the eyepiece on the crack-tip region. To ensure accurate crack measurements, obliquely incident light on a well-polished specimen surface is an effective means of highlighting fine cracks. High-intensity strobe lights with adjustable function generators are used to allow “motion free” viewing of cracks during high-frequency tests. The development of extra-long focal length optics has added new functionality to optical techniques. These microscopes allow the in situ observation and image analysis of crack-tip processes while keeping the instruments a reasonable distance (>381 mm, or 15 in.) from the specimen and other testing hardware.

To account for through-thickness crack-length variation, ASTM E 647 recommends measuring the crack length at five points along the crack front contour and averaging the five readings. If the average of the five points exceeds the surface length by more than 5%, the average length is used in computing the growth rate and K .

The optical technique is straightforward and, if the specimen is carefully polished and does not oxidize during the test, produces accurate results. However, the process is time consuming, subjective, and can be automated only with complicated and expensive video-digitizing equipment. In addition, many FCGR tests are conducted in simulated-service environments that obscure direct observation of the crack. The trend toward laboratory automation has resulted in the development of indirect methods of determining crack extension, such as specimen compliance and electric potential monitoring.

Compliance Method

Under linear elastic conditions for a given crack size, the displacement, v , across the load points or at any other locations across the crack surfaces is directly proportional to the applied load (P). The compliance, C , of the specimen is defined:

$$C = \frac{v}{P} \quad (\text{Eq 11})$$

The relationship between dimensionless compliance, BEC , where B is the thickness and E is the elastic modulus, and the dimensionless crack size, a/W , where W is the specimen width, is unique for a given specimen geometry (Ref 21). Thus:

$$BEC = f\left(\frac{a}{W}\right) \quad (\text{Eq 12})$$

The inverse relationship (Ref 21) between crack size and compliance can be written as $a/W = q(u)$, where $u = [1 + BEC]^{-0.5}$. This relationship may be determined numerically using finite element techniques or by experiment. ASTM E 647 also specifies these relationships for CT and MT specimens.

The compliance of an elastically strained specimen (expressed as the quotient of the displacement, v , and the tensile load, P , per Eq 11) is determined by measuring the displacement along, or parallel to, the load line. Figure 11 illustrates that the more deeply a specimen is cracked, the greater the amount of v will be measured for a specific value of tensile load. Additional information on the method and calculation of compliance can be found in the "Selected References" at the end of this article.

Fig. 11 Schematic of the relationship between compliance and crack length. (a) $C(a_0) = v_0/P$. (b) $C(a_1) = v_1/P$

Instrumentation. The displacement usually is measured across the crack mouth opening using cantilever beam clip gages, optical (laser and white light) extensometry, or BFS gages. Linear variable differential transducers have been used, but hysteresis in the response can sometimes be a problem. Each technique has its own advantages and may be used to continuously monitor crack length. An additional benefit of compliance techniques is that the same signal can be used for determining crack closure, as discussed below.

Cantilever beam clip gages, based on resistive and capacitance strain gage technology, are well suited for elevated (<370 °C) and high-temperature tests (up to 1200 °C), respectively. Deflection of the arms is measured by the output of the strain gages mounted on the clip gage arms. Extensometer and transducer design theory is well established in the literature (Ref 17, 22). Attachment of clip gages to the specimen is achieved through integral, machined knife edges or by knife-edge blocks bolted to the front face of the specimen across the crack plane.

Optical extensometry techniques include those based on fiber optics and laser technology. There are two main types of optical extensometry used in compliance measurement. The first type is an advanced laser system that tracks the motion of spots projected on the specimen. In this instance, the transmitter and receiver are located

on the same side of the specimen. A second group of extensometers measure the width of the notch using a transmitter and receiver on opposite sides of the specimen. Laser and white light systems based on these principles are available commercially. Optical systems may have restrictions on frequency response. Like optical crack-length measurement techniques, most optical extensometry techniques are difficult to use when testing at elevated temperatures or in environmental chambers.

An electrical resistance strain gage mounted opposite the notch on the back face of the fatigue specimen is termed a back face strain (BFS) gage. Just as with the clip gage, the load-strain signal from the BFS gage may be used to determine the crack length in the specimen. While conventional strain gages are limited to elevated temperatures (<370 °C) in gaseous or aqueous environments, they have the advantage of directly measuring strain without the application of force. The direct measurement of strain eliminates frequency limitations associated with clip gages at the expense of having no geometric amplification of the strains or the sensitivity benefits of a four active leg Wheatstone bridge (Ref 22). A BFS gage is especially useful for nonmetallic materials where integral knife edges and tapped holes for knife-edge blocks are difficult to machine.

The required sensitivity of the system depends on specimen geometry and sizes. In general, noise-free, amplified output of about 1 V direct current (dc) per 1 mm (0.04 in.) of deflection is satisfactory. Similarly, for the load range applied to the specimen, an approximately 1 V dc change in signal from the load cell is required for accurate calculation of the compliance.

Attachment of Displacement Measurement Hardware. One of the most important factors affecting the accuracy of crack-opening displacement measurements is the manner in which the displacement transducer is attached to the test sample. Transducers for measuring the crack-opening displacement commonly consist of cantilevered arms affixed across the crack. When the crack is opened, deflections either in the arms, or in a flexure attached to the arms, induces measurable strains, which are ultimately converted to displacements.

To prevent slipping of the gage during testing, the gage must have an adequate, well-documented clamping force (~2500 g). This force must be added to the mean tensile load applied to the specimen by the gage during data analysis. For thin or small specimens, the gage-induced mean load may be high enough to preclude testing at the desired load levels. Even with high clamping forces, there will be a limitation on the maximum testing frequency for the gage due to the excitation of resonant modes in the gage or inadequate clamping force. If necessary, higher frequencies can be achieved by bolting the clip gage to the specimen.

The transducer can be bolted across the crack opening at the point of testing, or it can be attached to the specimen through hardened knife-edge pivots that are mechanically or adhesively affixed to the specimen. The transducer can also be affixed via knife-edge contacts machined into the test sample. For elevated-temperature testing, feed-rod systems are frequently used.

The bolt-on system of attaching the transducer to the test specimen (Fig. 12) is capable of reacting to high acceleration loads. These loads result from higher-frequency dynamic testing when the rocking movement generated by the mass of the transducer is carried to the bolt-on attachment through the transducer frame. This attachment system is preferred when a transducer has high mass or an effective mass center located a great distance from the specimen contact pads.

Fig. 12 Bolt-on attachment of crack-opening displacement transducer to fatigue test specimen

The bolt-on system also provides accurate crack-opening displacement measurements on specimens tested under environments not conducive to the use of knife edges, such as elevated-temperature or corrosive environments. In addition, the bolt-on attachment system allows the use of stiffer cabling without disturbing the measurement. For example, a displacement transducer with relatively rigid stainless steel-jacketed cabling can be used to make measurements in pressurized high-temperature water/steam environments.

Hardened knife-edge pivot contacts (Fig. 13) provide a measurement system with minimal sliding action; the knife-edge rocks in a hardened seat in the transducer arm. This condition allows measurements to be made with very low hysteresis levels. Contact and seat-ramp angles can be designed for optimal tradeoffs between static and dynamic measurement accuracy, dynamic stability, and contact durability. Male knife-edge contact replacements are relatively low in cost, and various configurations are available, such as three-point contact, line contact, large radius, and small radius.

Fig. 13 Bolt-on hardened knife-edge attachment of crack-opening displacement transducer to fatigue test specimen

Knife-edge contacts machined into the test sample (Fig. 14) eliminate the possibility of knife-edge screws loosening, resulting in slippage and hysteresis. The compressed initial gage length can be machined to the required tolerance.

Fig. 14 Attachment of crack-opening displacement transducer to specimen by machined knife-edge contacts

Computing Normalized Compliance. When measuring the compliance of a fatigue specimen, the usual practice is to compute a normalized compliance ($EB\delta/P$). This normalized compliance is plotted against a normalized crack length, a/W . For standard geometries, such as a CT specimen, this relationship has the form shown in Fig. 15. Thus, from the measured compliance, a crack length can be obtained from the known analytical

relationships, as shown in Fig. 15 (Ref 21). Note that when the crack is short ($a/W \sim 0.2$ to 0.4), the compliance is less sensitive to changes in crack length than when the crack length is long ($a/W > 0.5$). Thus, the sensitivity of the compliance method is significantly improved for the longer crack lengths, both because of this relationship and because the amount of crack mouth opening and the resulting displacement gage signal are larger. The amount of displacement or measured crack mouth opening is a strong function of the location of the line of measurement of the gage with respect to the load line, which is the reference point for crack extension. The farther away from the crack tip the measurement can be made, the more displacement that will be incurred, and the sensitivity of the method will be improved proportionately.

Fig. 15 Comparison of predicted and experimental compliance for a compact-type fatigue specimen

Data Acquisition and Processing. The signals from the load cell and displacement gage must be obtained simultaneously in order for this method to work to its best advantage. In the most direct instance, the two signals can be fed to an x - y recorder, with the load applied to the y -axis and displacement to the x -axis. At various intervals during the test, a trace of the two signals can be made. If the test is being conducted at a reasonably high frequency (>1 Hz), then the frequency will have to be reduced so that the slow rate of the recorder can keep up with the changing voltage. This maintenance is not a problem if a transient recorder is used and the results from the two channels (load and displacement) are co-plotted. The slopes of the recorder traces can be measured, multiplied by suitable calibration factors, and used in the compliance to crack-length relationship.

A more sophisticated method uses a computerized data acquisition system to obtain load displacement data. These systems are usually faster and, thus, can accept data from rather high-frequency waveforms. In addition, software can be developed to perform the calculations involved in processing the compliance data to crack length. Software to perform FCGR measurements is generally available from manufacturers, but most

researchers write their own data acquisition packages, perhaps using some of the manufacturer-supplied subroutines specific to the hardware involved.

Additionally, data should be taken between about 10 and 90% of the load range. Eliminating the top and bottom fractions of the load range avoids problems of crack closure (at loads approaching zero) or incipient plasticity (near the load maximum, at longer crack lengths). The sets of load-displacement pairs are fitted to a straight line; the slope of which is used in the compliance expression.

Electric Potential Difference Method

The electrical potential, or potential drop, technique has gained increasingly wide acceptance in fracture research as one of the most accurate and efficient methods for monitoring the initiation and propagation of cracks. This method relies on a disturbance in the electrical potential field about any discontinuity in a current-carrying body, and the magnitude of the disturbance depends on the size and shape of the discontinuity.

For the application of crack growth monitoring, the electrical potential method entails passing a constant current (maintained constant by external means) through a cracked test specimen and measuring the change in electrical potential across the crack as it propagates. With increasing crack length, the uncracked cross-sectional area of the test piece decreases, its electrical resistance increases, and the potential difference between two points spanning the crack rises. By monitoring this potential increase, V_a , and comparing it with some referencing potential, V_0 , the ratio of crack length to width, a/W , can be determined through the use of the relevant calibration curve for the particular test piece geometry concerned. The crack length is expressed as a function of the normalized potential (V/V_0) and the initial crack length (a_0), as shown in Fig. 16.

Fig. 16 Potential response for a compact-type specimen

Accuracy of electrical potential measurements of crack length may be limited by a number of factors, including the electrical stability and resolution of the potential measurement system, electrical contact between crack surfaces where the fracture morphology is rough or where significant crack closure effects are present, and changes in electrical resistivity with plastic deformation. Another key factor is the determination of calibration curves relating changes in potential across the crack (V_a) to crack length (a). In most instances, experimental calibration curves have been obtained by measuring the electrical potential difference across the machined slots of increasing length in a single test piece; across a growing fatigue crack, where the length of the crack at each point of measurement is marked on the fracture surface by a single overhead cycle or by a change in mean stress; across a growing fatigue crack in thin specimens, where the length of the crack is measured by surface observation.

Other experimental calibrations have been achieved using an electrical analog of the test piece, where the specimen design is duplicated, usually with increased dimensions for better accuracy, using graphitized analog paper or thin aluminum foil, and where the crack length can be increased simply by cutting with a razor blade. Such calibration procedures, however, are relatively inaccurate, particularly at short crack lengths, and are tedious to perform. Furthermore, where measurements of crack initiation and early growth are required ahead of short cracks or notches of varying acuity, such procedures demand a new experimental calibration to be obtained for each notch geometry.

Electric potential response may be determined empirically (Ref 23, 24, and 25) or using numerical methods, such as finite element or conformal mapping techniques (Ref 26, 27, 28, 29, and 30). Johnson's analytical solution of the MT geometry is widely used in experimental work due to its flexibility (Ref 28):

$$a = \frac{W}{\pi} \cos^{-1} \left[\frac{\cosh[(\pi/W) \times Y_0]}{\cosh \left[\frac{V}{V_0} \times \cosh^{-1} \left[\frac{\cosh[(\pi/W) \times Y_0]}{\cosh[(\pi/W) \times a_r]} \right] \right]} \right] \quad (\text{Eq 13})$$

$$\text{for } 0 \leq 2 \frac{a}{W} \leq 1$$

where a is the crack size, a_r is the reference crack size from another method, W is the specimen width, Y_0 is the voltage measurement lead spacing from crack plane, V is the measured electric potential difference, and V_r is the measured voltage corresponding to a_r . With minor modifications, Eq 13 can be applied to edge-cracked geometries by treating them as half of a MT geometry. Third- or higher-order polynomial expressions with coefficients obtained from regression analysis can be used to describe the potential response of the specimens when simplified expressions are required or Eq 13 does not apply.

A schematic diagram of a typical experimental setup for electrical potential crack monitoring measurements is shown in Fig. 17. The technique can be used with alternating current (ac) or dc power supplies. Alternating current systems have lower power requirements and do not suffer from the thermally induced potentials that plague dc systems. On the other hand, dc systems are widely used because of the relative simplicity. Consequently, this discussion of typical experimental setups is restricted to dc systems.

Fig. 17 Schematic of the direct current electrical potential crack monitoring system

The main component of a dc electric potential system is a power supply capable of producing a large, stabilized constant current. Applied currents range from 5 to 50 A with output voltages from 0.1 to 50 mV. Power supplies must be stable to 1 part in 10^4 or better, and nano- or microvoltmeters with a resolution of 0.05 to 0.5 μV are used (Ref 7). It is crucial that all dc potential measurement equipment (power supplies, voltage meters, etc.) and the loadframe itself be properly grounded. Before a power supply or nearby electromagnetic field

(EMF) source (e.g., induction heater) is faulted for poor performance of the electric potential technique, researchers are reminded to check that all equipment is properly grounded. In some instances, EMF shielding may be required.

High-resolution, stable, properly grounded equipment does not guarantee reliable performance and high resolution for the dc potential difference technique. Proper selection and use of current and potential leads are essential. High-current (welding) cable is ideal for current input leads, which are usually bolted to the specimen. To reduce noise, the potential leads should be firmly attached to the specimen, shielded, and twisted together. To ensure that current will pass through the specimen, the ratio of the loadtrain resistance to that of the specimen must be on the order of 10^4 . If this ratio cannot be achieved, the specimen must be electrically isolated using nonconducting (e.g., alumina) pins and washers or sleeves. The current applied to the specimen should be large enough to produce a measurable potential. Table 1 lists typical current and output voltages for CT specimens of aluminum, steel, and titanium. Excessive current (>10 A) can cause heating of the specimen and should be avoided. Potential leads should be made from fine wire of the same material as the specimen to reduce thermally induced EMF. Potential measurement leads and equipment should be kept away from EMF sources, such as transformers, to further reduce noise.

Table 1 Typical electric potential difference (EPD) voltages as measured on a standard compact-type specimen

Material	Approximate EPD, mV	Approximate change in crack length for 1 μ V change in EPD, μ m
Aluminum	0.1	300
Steel	0.6	50
Titanium	3.5	9

Based on $a/W = 0.22$, $B = 7.7$ mm, and $W = 50$ mm. Lead geometry per Ref 7 and direct current of 10 A. Crack tip processes, such as fatigue crack closure (see the section “Crack Closure” in this article), can reduce the potential of the specimen as the crack faces come together, effectively shortening the crack. This situation is especially a problem when testing materials that do not form protective, nonconducting oxide layers in the environment of interest. The solution to this problem is to measure the potential output at the peak load. In addition to crack closure, crack-tip plasticity and distributed damage, such as microcracking, must be considered. Large plastic zones, such as those encountered under elastic-plastic conditions, disturb the equipotential lines much like the crack (Ref 31). Distributed damage processes can also complicate measurements by making it difficult to define a continuous crack. Hence, optical measurements of the crack should be made to ensure that the electric potential difference technique provides a realistic representation of crack length. Changes in the electrical properties of the material can also limit the effectiveness of dc potential systems.

Changes in conductivity can complicate electric potential measurements. When high-conductivity materials, such as aluminum, are tested, temperature fluctuations of ± 1 °C will cause a change in potential on the order of a few μ V due to the temperature dependence of conductivity, and this change may vary with time. This condition can limit the crack extension resolution. Environmental chambers are useful with high-conductivity materials, even when testing at room temperature.

The primary difficulty with the dc electric potential technique is the junction potentials created at points of current and potential lead attachment. When dissimilar materials are in contact, a potential is generated due to the thermocouple effect, and it may be of the same order of magnitude as the potential generated by the specimen. This thermally induced potential, also known as the thermal voltage, may not be constant. Consequently, care must be taken to separate changes in potential due to fluctuations in thermal voltage from changes due to crack extension. This concern is especially important when measuring the slow growth rates found in the near-threshold regime (region I, Fig. 2).

There are three common approaches to account for the thermal voltage. The first method is to periodically turn off the power supply, note the value of thermal voltage, and subtract it from the output of the specimen with the current applied. This approach is acceptable for manually run tests, but it is not very useful when a continuous signal is required for computer-controlled tests. One alternative to manual measurement of the thermal voltage

is to apply a current to an uncracked specimen with no applied load in the same environment as the test specimen in the “reference potential” technique. The tendency of the thermal voltage to drift should be the same in both the cracked and uncracked specimens. The drift can then be monitored, and the thermal voltage simply becomes an offset. Attempts have been made to apply the reference potential technique to a single specimen by measuring potentials in areas of the specimen that are “insensitive” to crack extension. The development of high-current-capacity solid-state switches has made the use of fully reversed electric potential drop systems a third method for dealing with thermal voltages. If the direction of current flow is periodically reversed, the thermal voltage, which has a fixed polarity, will shift the maximum and minimum output potentials but will not influence the range or amplitude of the signal. Thus, the amplitude of the output potential can be used to determine the length of the crack.

The electric potential technique may also be applied to nonconducting specimens with the use of conducting thin foils. The foils, applied prior to testing, crack with the underlying specimen. Current is applied to the foil instead of to the specimen, and the calibrated response of the foil may be used to monitor the growth of the crack. This technique may be used for room- and elevated-temperature tests, provided that the foil accurately reflects the growth of the crack. Polymer-backed gages sold under the trade name KrakGage (Hartrun Corp., St. Augustine, FL) require special hardware for mounting and use and may be used with conducting or nonconducting specimens. It is also possible to vapor deposit gages directly to nonconducting specimens or to nonconducting oxide films on conducting or nonconducting (e.g., SiC) materials. The drawback of electric potential foils is the tendency for cracks with small opening displacements to “tunnel” under the gage. This crack extension without breaking the foil will lead to inaccurate growth rates.

Optimization Parameters. In any specimen geometry, there are numerous locations for both the current input leads and the potential measurement probes. Optimization of the technique involves finding the best locations, considering accuracy, sensitivity, reproducibility, and magnitude of output (measurability).

In practice, the accuracy of the electrical potential technique may be limited by several factors:

- Electrical stability and resolution of the potential measurement system
- Crack front curvature
- Electrical contact between crack surfaces where the fracture morphology is particularly rough
- Electrical contact between crack surfaces where significant crack closure effects are present
- Changes in electrical resistivity with plastic deformation, temperature variations, or both

Reproducibility refers to inaccuracies produced by small errors in positioning the potential measurement leads. Such leads are generally fine wires spot welded or screwed to the specimen, and accurate positioning is typically no better than within 0.5 mm (0.02 in.). To maximize reproducibility, these leads should be placed in an area where the calibration curve is relatively insensitive to small changes in position—that is, where dV/dx and dV/dy are small, where x and y are position coordinates—with the origin at the midpoint of the specimens. This position is often at variance with sensitivity considerations for measuring small changes in crack length.

To optimize measurability (i.e., signal-to-noise ratios), current input and potential measurement lead locations are chosen to maximize the absolute magnitude of the output voltage signal, V_a . As output, voltages are generally at the microvolt level and because of the high electrical conductivity of metals, a practical means of achieving measurability is simply to increase the input current. However, there is a limit to this increase, because when the current is too large (typically exceeding 30 A in a 12.7 mm, or 0.5 in., thick 1T steel CT specimen), appreciable specimen heating can result from contact resistance at current input positions.

Studies have shown that there must be a compromise between the sensitivity, reproducibility, and magnitude of the output signal when using electric potential techniques. In the instance of CT specimens, it has been shown that potential leads are best placed on the notched side of the specimen, as close to the mouth as possible, as recommended by the ASTM E 647. When using nonstandard geometries, the above references should ensure a sound basis for lead placement.

Fatigue Crack Growth Testing

Ashok Saxena, Georgia Institute of Technology; Christopher L. Muhlstein, University of California, Berkeley

Loading Methods

The goal of a FCGR test is to generate a record of a versus N under specified loading conditions. This information can be generated by applying cyclic varying loads of specified amplitude and frequency.

The frequency of the test should, when possible, be kept constant; however, it may be necessary to reduce the frequency of a test in order to make crack-length measurements. Frequency effects are usually not observed in metals in laboratory air at room temperature over the range of typical testing frequencies (1 to 100 Hz). Although higher-frequency tests finish more quickly, specimen and loadtrain stiffness, as well as load range, impose a practical limit on the maximum testing frequency. Steel specimens 50 mm wide can be run on a typical 90 kN (1 tonf) capacity loadframe at 25 to 50 Hz. If compliance methods are being used to control the test or monitor crack extensions, the frequency response of the clip gage and recording instruments may limit the maximum frequency for testing.

The waveform to be used during a test is usually a sine or sawtooth (ramp) shape. Both waveforms will generate similar data at room temperature in benign environments. However, sine waveforms are easier for servohydraulic systems to control. Ramp waveforms should be used when elevated-temperature FCGR and creep-fatigue interaction are of interest (see appendix to this article, “High-Temperature Fatigue Crack Growth Testing”) or when testing in aqueous environments (Ref 32).

Five types of FCGR tests are used in laboratories today. How the specimen is loaded defines the type of growth rate test. Different types of tests are often conducted in series to confirm growth rates and to use as much of the

specimen as possible. To avoid load sequence effects, tests conducted in series should adhere to the same guidelines specified for precracking.

The simplest test type is one in which the load amplitude is kept constant and the applied ΔK increases as the crack extends. The simplicity of the test is its advantage. However, this test is essentially impractical for crack growth rates below 1×10^{-8} m/cycle. In a second type of test, loads are shed manually at increments of 10% or less. Although cumbersome because they require constant attention, these tests allow the generation of data for slower crack growth in a more time-efficient manner than the constant-load-amplitude test. The prevalence of personal computers and modern controls technology in current laboratories has popularized the remaining three types of so-called “continuous loadshedding” or “ K -controlled” experiments.

Continuous loadshedding tests are those in which loads are shed at steps of 2% or less for a predetermined increment of crack extension. During these tests, the crack length is continuously monitored by electric potential, compliance, or another suitable technique. Loads are shed or increased according to the following relation proposed by Saxena et al. (Ref 33):

$$\Delta K = \Delta K_0 \exp[c(a - a_0)] \quad (\text{Eq 14})$$

where ΔK is the applied range of ΔK , ΔK_0 is the initial range of ΔK , c is the normalized K -gradient, a is the current crack length, and a_0 is the initial crack length. The normalized K -gradient is defined as:

$$c = \frac{1}{K} \left(\frac{dK}{da} \right) [L^{-1}] \quad (\text{Eq 15})$$

The use of Eq 14 for changing fatigue loads is ideally suited for personal computers, and it allows testing under K -controlled conditions. If the normalized K -gradient is less than zero, the applied ΔK will be decreased as the crack extends. These tests are termed K -decreasing tests. Conversely, $c \geq 0$ will lead to increasing ΔK as the crack extends.

The appropriate value of c for a decreasing ΔK test is that which avoids the anomalous growth rates caused by shedding loads too quickly. Investigators have determined that $c = 0.08 \text{ mm}^{-1}$ (-2 in.^{-1}) is an appropriate value for decreasing ΔK tests on most metals (Ref 34). This value of c was derived to eliminate load-interaction effects caused by crack-tip plasticity in metals. The same value of c for a K -decreasing test in intermetallics and ceramics is recommended. This value ensures that sufficient data can be obtained over the narrow range of stable crack growth, even though plastic zones are considerably smaller or nonexistent in these materials (Ref 35, 36).

Increasing ΔK tests (i.e., $c > 0$) are usually conducted to confirm the growth rates measured during the previous K -decreasing portion of the test. Increasing ΔK tests may, if necessary, be conducted with larger normalized K -gradients. It is important to note that during an increasing ΔK test, loads may have to be decreased as the crack extends, which could lead to difficulties with control. Hence, it is preferable to use the simple constant-amplitude test instead of a controlled increasing ΔK test.

The first type of continuous loadshedding test is where the load ratio (R) is held constant. Constant- R tests generate the same type of information as constant-amplitude tests. Low- and high- R ($R = 0.1$ and 0.5 , respectively) tests are usually conducted for comparison purposes.

Another type of K -controlled test is a constant- K_{\max} test, which is essentially a variable- R test. When K_{\max} is held constant as the crack extends, R will vary as shown schematically in Fig. 18. Once again, the value of ΔK to be applied to the specimens is dictated by Eq 14. The advantage of this test is that it quickly establishes the role of R on crack growth rate. For decreasing ΔK in constant- K_{\max} tests with negative c , the lower crack growth rates are at very high values of R . The behavior of threshold cracks under these conditions has been used as a measure of “closure free” fatigue crack growth, reflecting the “intrinsic resistance” of the material to fatigue (Ref 37).

Fig. 18 Constant K_{max} test load ratio

The last type of continuous loadshedding fatigue test is a constant- K_{mean} test. Much like the constant- K_{max} test, a constant- K_{mean} test can be used as a comparison with constant K_{max} to help establish the role of K_{mean} versus K_{max} on fatigue crack growth rates. Constant- K_{max} and - K_{mean} tests have been popular in the testing of brittle materials where definitive mechanisms for crack advance have yet to be established.

Once testing is complete, the final crack in the specimen should be measured optically on both sides of the specimen. This measurement will be compared to the terminal crack length predicted by other measurement techniques in the analysis of the investigation.

Electromechanical Fatigue Testing Systems. The primary function of electromechanical fatigue testers is to apply millions of cycles to a test piece at oscillating loads up to 220 kN (2.5 tonf) to investigate fatigue life, or the number of cycles to failure under controlled cyclic loading conditions. Variables associated with fatigue-life tests are frequency of loading and unloading, amplitude of loading (maximum and minimum loads), and control capabilities. The fundamental data output requirement is the number of cycles to failure, as defined by the application.

A variety of electromechanical fatigue testers have been developed for different applications. Forced-displacement, forced-vibration, rotational-bending, resonance, and servomechanical systems are discussed in this article and are compared in Table 2. Other specialized electromechanical systems are available to perform specific tasks.

Table 2 Comparison of electromechanical fatigue systems

Parameter	Forced displacement	Forced vibration	Rotational bending	Resonance	Servomechanical
Tension	Yes	Yes	No	Yes	Yes
Compression	Yes	Yes	No	Yes	Yes
Reverse stress	Yes	Yes	Yes	Yes	Yes
Bending	Yes	Yes	Yes	Yes	Yes
Frequency range	Fixed	Fixed, 1800 rpm	0–10,000 rpm	40–300 Hz	0–1 Hz
Load range	Typically <450 N (<100 lbf)	Up to 220 kN (50,000 lbf)	...	Up to 180 kN (40,000 lbf)	Up to 90 kN (20,000 lbf)
Type Control	Open-loop	Open-loop	Open-loop	Closed-loop	Closed-loop
Mode	Displacement	Load	Rotation/bending	Load	Load, displacement, strain
Maximum	...	25.4 mm	...	1.0 mm (0.040)	100 mm (4 in.)

deflection		(1.00 in.)		in.)	
Advantages	Simple, straightforward	Versatile, efficient, durable	Efficient, durable, simple	Fully closed-loop, extremely efficient	Fully closed-loop, high precision
Disadvantages	No load control, very limited applications (soft samples)	Fixed frequency, limited control (open-loop)	Rotational bending only, limited applications	Operating frequency directly proportional to sample stiffness	Low frequency only

Servohydraulic testing machines are particularly well suited to provide the control capabilities required for fatigue testing. Extreme demands for sensitivity, resolution, stability, and reliability are imposed by fatigue evaluations. Displacements may have to be controlled (often for many days) to within a few microns, and forces can range from 100 kN (1 tonf) to just a few newtons. This wide range of performance can be obtained with servomechanisms in general and, in particular, with the modular concept of servohydraulic systems.

Usually, the problem of selecting the appropriate system is simply a matter of optimizing the various components to form a system best suited to the given testing application. With any type of control system, the objective is to obtain an output that relates as closely as possible to the programmed input. In a fatigue testing system, it may be desired to vary the force on a specimen in a sinusoidal manner, at a frequency of 1 Hz over a force range of 0 to 100 kN (0 to 1 tonf). The only practical means of precision accomplishment is through the use of a negative-feedback closed-loop system.

Fatigue Crack Growth Testing

Ashok Saxena, Georgia Institute of Technology; Christopher L. Muhlstein, University of California, Berkeley

Analysis of Crack Growth Data

The two major aspects of FCGR test analysis are to ensure suitability of the test data and to calculate growth rates from the data. In addition to growth rate calculations, analysis also may require the calculation of fatigue crack closure levels and the characterization of fracture surface and metallographic features, as discussed in this

section. Combining the results from all of these areas is necessary to develop an understanding of the FCGR behavior of the material. Finally, the reliability of “real time” analysis by personal computers must be verified, and the sophisticated tests performed in modern laboratories must undergo some degree of analysis. Hence, it is essential that computer-controlled tests generate records of a versus N as well as FCGR.

Validity of the Test Data. The first step is to ensure the validity of the test data and make corrections to the crack length, if necessary. Crack measurement intervals are recommended in ASTM E 647 according to specimen type. For CT specimens:

$$\Delta a \leq 0.04W \text{ for } 0.25 \leq \frac{a}{W} \leq 0.40$$

$$\Delta a \leq 0.02W \text{ for } 0.40 \leq \frac{a}{W} \leq 0.60$$

$$\Delta a \leq 0.01W \text{ for } \frac{a}{W} \geq 0.60$$

For MT specimens:

$$\Delta a \leq 0.03W \text{ for } \frac{a}{W} < 0.60$$

$$\Delta a \leq 0.03W \text{ for } \frac{a}{W} > 0.60$$

At the end of the test, the final crack length is measured on both sides of the specimen. A comparison should be made between optical measurements and the final predicted crack length by any nonoptical techniques used. Differences between the measured crack lengths should be corrected using a linear relationship. In other words, the error between the final measured and predicted crack size is linearly distributed over the crack extension range. If periodic optical measurements were made during the test, other more appropriate correction procedures can be used.

Thicker specimens should be fractured after testing to determine the degree of crack front curvature. Cooling the specimen to liquid nitrogen temperatures allows the brittle fracture of most metallic materials and reveals a clear demarcation between the fatigued and fractured portions of the specimen. Five evenly spaced measurements of crack length should be made across the crack front. The average length should then be used as the final crack length, and the corrections should be applied using this value instead of the surface measurements.

Crack Growth Rate Calculation. A number of different numerical techniques have been used to calculate crack growth rates from the set of (a_i, N_i) data points of a given crack growth rate test (Table 3). The secant and incremental polynomial methods are the most widely used. When the data are processed to a final smoothed $da/dN = f(\Delta K)$ format, these methods provide approximately equivalent results. However, the scatter of individual da/dN values about the average depends greatly on the data reduction method.

Table 3 Methods for calculating crack growth rates

Incremental polynomial method:

A least-squares, second-order polynomial is obtained for successive sets of $(2k + 1)$ data points:

$$\hat{a}_i = b_0 + b_1 \left(\frac{N_i - C_1}{C_2} \right) + b_2 \left(\frac{N_i - C_1}{C_2} \right)^2$$

where $C_1 = (N_{i+k} + N_{i-k})/2$ and $C_2 = (N_{i+k} - N_{i-k})/2$ are centering and scaling constants, respectively, that are introduced to prevent numerical problems in obtaining the least squares fit. The crack growth rate at a_i , the predicted central crack length at N_i , is given by the derivative:

$$\left. \frac{da}{dN} \right|_{\hat{a}_i} = \frac{b_1}{C_2} + 2b_2 \frac{(N_i - C_1)^2}{C_2}$$

Typical values of k are 1, 2, or 3, resulting in the second-order polynomial being estimated on the basis of 3, 5, or 7 successive data points. The estimated crack growth rate function loses k data points at each end.

Less apparent scatter is obtained for larger k values.

Secant method:

In the secant method for differentiating the a versus N data, the average crack extension per cycle is calculated for each pair of data points, and ΔK is calculated at the midpoint of the crack lengths:

$$\left. \frac{da}{dN} \right|_{\hat{a}_i} = \frac{a_{i+1} - a_i}{N_{i+1} - N_i}$$
$$\hat{a}_i = \frac{a_{i+1} + a_i}{2}$$

This method is simple but exhibits the most scatter in da/dN values.

Modified difference methods:

These methods are finite difference techniques for estimating the derivative at the midpoint of a data set. These methods use numerical derivatives. The formula for estimating the derivative at the midpoint a_i of three successive data points is given by:

$$\left. \frac{da}{dN} \right|_{a_i} = \frac{a_i - a_{i-1}}{N_i - N_{i-1}} + \left[\frac{N_i - N_{i-1}}{N_{i+1} - N_{i-1}} \right] \left[\frac{a_{i+1} - a_i}{N_{i+1} - N_i} - \frac{a_i - a_{i-1}}{N_i - N_{i-1}} \right]$$

The secant method fits a line between adjacent data points. The slope of the line is the crack growth rate, da/dN . The load at the average crack length of the interval is used to calculate the corresponding ΔK . It is not uncommon to collect data points more closely spaced than the 0.25 mm (0.010 in.) minimum crack extension for growth rate calculations. When more data are available, a straight line through the multiple data points can be fitted by regression analysis to calculate crack growth rates. A 50% overlap between data sets used for calculating successive crack growth rates can considerably reduce scatter in the processed data. This method is termed the modified secant method.

The polynomial method uses the derivative of a second-order polynomial fitted to a fixed number of data points (often five or seven). The growth rate and ΔK level are calculated for the average value of crack length in the interval. This method tends to provide data with less scatter than the secant method. In practice, there are no systematic differences in the da/dN versus ΔK trends if the same data are processed by these different techniques (Ref 38). In fact, little difference is observed between the data processed by the modified secant method and the polynomial method.

Variability. Although the apparent variability in the resulting da/dN value depends on the calculation method, none of the methods introduces a significant bias to an overall mean trend curve. Figure 19(b) plots da/dN versus ΔK , as calculated from the data of Fig. 19(a), using the secant, incremental polynomial, and five-point modified difference methods. Because methods of analyzing and interpreting the scatter in da/dN are not currently available, the simpler techniques—the secant and incremental polynomial methods—are often chosen.

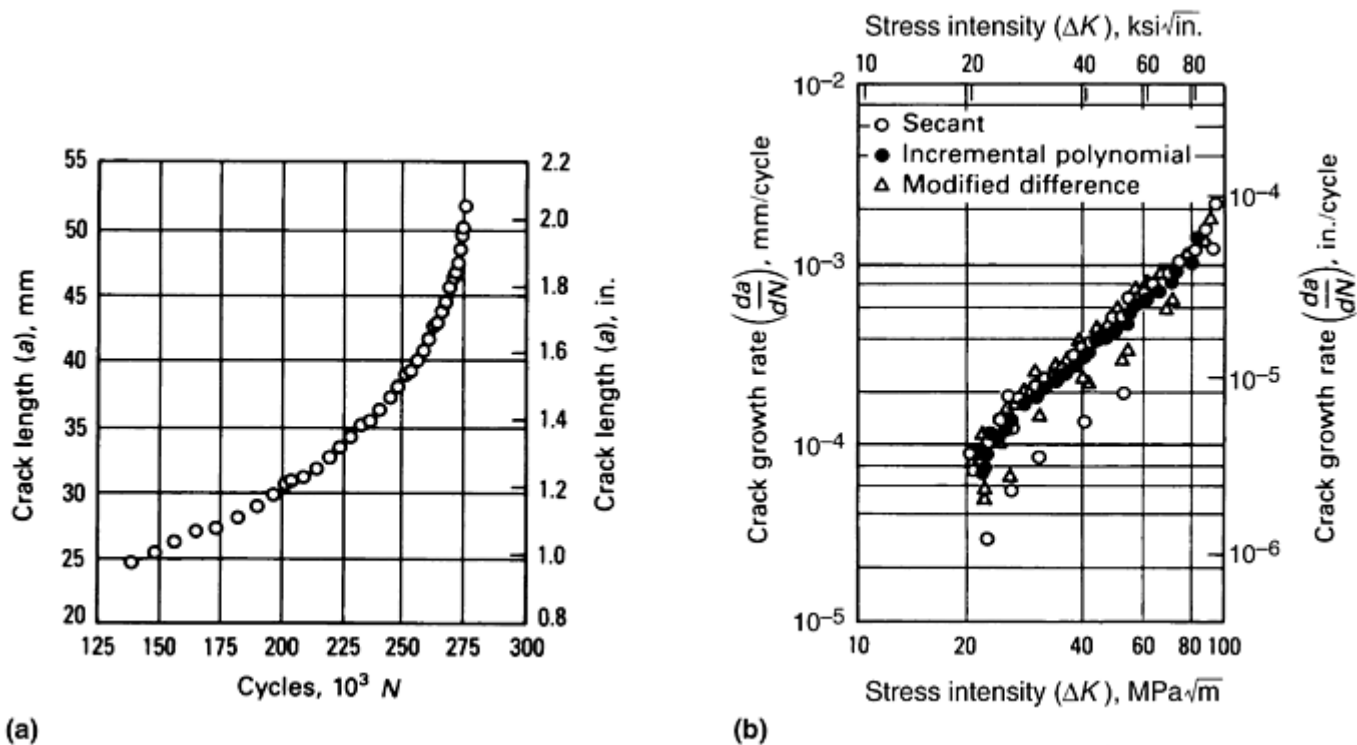

Fig. 19 Comparison of da/dN calculation methods. (a) Crack length test data. (b) Plot of calculated da/dN rates from the data in (a)

Crack Closure Analysis. The determination of the fatigue crack closure load is a subject of vigorous debate. Visual inspection of compliance curves can be used to estimate closure levels. However, the method is subjective and not well suited for large amounts of data. ASTM task groups have explored the use of the compliance offset and correlation method for closure analysis (Ref 39). In the compliance offset method, crack closure levels are determined by finding the point that deviates from the linear portion (i.e., is offset) by a set amount (usually 1, 2, 4, or 8%). The correlation method determines the closure level by mathematically representing the “strength” of the linear relationship between load and displacement/strain along the curve. To confirm that the methods are applied correctly, algorithms should be tested with hypothetical, bilinear compliance curves, for which both methods should yield identical results.

The compliance offset method is generally applied using a computer, because the calculations do not lend themselves to the use of spreadsheets. The procedure is as follows:

1. Collect digitized strain/displacement and load data for a complete load cycle. The data sampling rate should be high enough to ensure that at least one data pair (displacement and load) is taken in every 2% interval of the cyclic load range.
2. Starting with the first data sample below maximum load on the unloading curve, fit a least-squares straight line to a segment of the curve spanning approximately the uppermost 25% of the cyclic load range. The slope of this line is the compliance value that corresponds to the fully open crack configuration.
3. Starting with the first data sample below maximum load on the loading curve, fit least-squares straight lines to segments of the curve that span approximately 10% of the cyclic load range and that overlap each other by approximately 5% of the range. Store the compliance (slope) and the corresponding mean load for each segment in a vertical array with the highest load location at the top.
4. Replace the compliance stored in each location in the array with the corresponding compliance offset, which is computed as a percentage of the “open crack” compliance and is given by:

$$\text{Compliance offset} = \frac{(\text{"Open crack compliance"} - \text{compliance})(100)}{\text{"Open crack" compliance}} \quad (\text{Eq 16})$$

5. Identify the highest load location in the array that has a compliance offset greater than the selected offset criterion, and for which all array locations below have compliance offsets greater than the offset criterion.
6. Starting at the array location identified in step 5, identify the nearest, higher load location that has a compliance offset less than the selected offset criterion, and for which all array locations above it have compliance offsets less than the offset criterion.
7. Determine the opening load corresponding to the selected offset criterion by linear interpolation between the two (compliance offset, load) points identified in steps 5 and 6 (Ref 39).

An alternative to the offset method is the correlation coefficient method. The correlation coefficient, r , is defined as (Ref 39):

$$r = \frac{n\sum(x_i y_i) - \sum x_i \sum y_i}{[(n\sum x_i^2 - (\sum x_i)^2)(n\sum y_i^2 - (\sum y_i)^2)]^{1/2}} \quad (\text{Eq 17})$$

where n is the number of data pairs, Σ denotes the summation from $i = 1$ to n , x_i are individual load data samples, and y_i are individual displacement data samples. The closure level is defined as the load at which the correlation coefficient has the highest value. In contrast to the offset method, in which different levels of offset can be selected, there is only one criterion in this method. Both methods generate similar closure levels for the same data. However, issues of data quality are currently the biggest problem for consistent experimental closure analysis. Methods to characterize data quality are presently being explored.

Fracture Surface Characterizations. Cracked specimens are also useful for establishing modes of crack advance and other interactions of the crack with the microstructure. Scanning electron microscopy is used to characterize the fracture surface. Care should be taken to establish the level of ΔK associated with the image of the fracture surface. This relationship is especially important when working with brittle materials where inspection of the surface does not reveal an obvious difference in fracture surface morphology between the fatigued material and posttest fracture.

Portions are often removed from the interior of the specimen and mounted for metallographic preparation. "Crack profiles" can be useful for demonstrating the interaction of the crack with the microstructure. There can be marked differences in how cracks interact with microstructures, especially in instances where crack closure and distributed damage are important.

Appendix: High-Temperature Fatigue Crack Growth Testing

David C. Maxwell, University of Dayton; Theodore Nicholas, Wright-Patterson Air Force Base

Introduction

The concepts and procedures for fatigue crack growth testing at room or ambient temperature described in this article are generally applicable to elevated-temperature conditions. In this appendix, some of the features unique to testing and measurement at high temperatures are reviewed. In particular, methods for heating and controlling temperature are discussed briefly. Other aspects related to instrumentation, measurement, and test techniques are also highlighted. While there are no well-established standards for elevated-temperature crack growth testing, one standard testing procedure has been recommended recently based on a cooperative study using 304 stainless steel (Ref 40). While documentation on methods employed in elevated-temperature crack growth testing are scattered widely in the open literature, conferences devoted to this particular subject include many papers that provide details of individual investigations (e.g., Ref 41).

Specimen Design. In general, the specimens used in room-temperature testing are equally applicable for high-temperature testing. In fact, in making comparisons of crack growth rates as a function of temperature, it is considered good practice to retain the same test specimen geometry at all temperatures tested.

An exception to this practice is the specialized instance of testing under thermomechanical fatigue (TMF) crack growth conditions. Here, the temperature as well as the load is cycled. In order to control the cyclic temperature on the specimen, effective means of both heating and cooling the specimen must be employed. This procedure usually requires either a thin planar specimen or a thin-walled tube, both of which minimize the thermal mass and allow for more rapid heating or cooling and better control of temperature gradients. Information on some of the techniques that have been employed for TMF can be found in conference proceedings, such as those of ASTM (Ref 42, 43), American Society of Mechanical Engineers (ASME) (Ref 44), or the International Conferences on Fatigue and Fatigue Thresholds (Ref 45, 46).

Another aspect of TMF crack growth almost unique to this type of test is the use of strain control as the mode of load application, similar to that used in low-cycle fatigue. A brief discussion of the problems and limitations of the use of strain control in elevated-temperature or TMF crack growth testing can be found in Ref 47.

The final consideration in TMF crack growth testing is the ability to heat and cool the specimen, or the access of heat and cooling air to the specimen. For example, clevises used on CT specimens tend to shield the specimen from the heating or cooling source and make it difficult to control the temperature cycle. Therefore, other geometries, such as MT geometries, are generally used for this type of test.

Specimen Gripping. There are two main considerations in gripping specimens at high temperature. The first consideration is the possible introduction of friction at any type of pin joint. Whereas friction can be minimized at room temperature through lubrication or careful surface finishing, these methods are less effective at elevated temperatures. Special high-temperature lubricants or oxidation-resistant materials for pins and clevises are methods for minimizing the development of friction in pin joints. Rigid fixtures and grips, on the other hand, do not require such considerations.

The second aspect of gripping at high temperatures is the possible loss of friction due to mismatches in the coefficient of thermal expansion of grips and specimens. Calculations or experimental evaluations should be made to ensure that the load-carrying capacity of the gripping system does not degrade due to differential thermal expansions so that slippage might occur.

Further, it should be demonstrated that excessive clamping stresses do not develop such that the specimen is crushed or the grips fail. This aspect of high-temperature testing is only applicable to instances where “hot” grips are used, such as when the grips and specimens are both contained within a furnace. Cold grips, on the other hand, produce high-temperature gradients along the length of the specimen and make it more difficult to maintain a constant temperature over the gage length or the crack growth region of the specimen.

Heating Methods. There are several methods available for heating specimens and maintaining a constant and uniform temperature during elevated-temperature crack growth testing. One of the more common methods is to use a commercially available or homemade furnace and power controllers that produce one or more zones of uniform, controlled temperature. Temperature control is achieved from thermocouple feedback, either from within the chamber, where the air temperature is being controlled, or from thermocouples directly attached to the specimen at one or more locations. In either situation, temperature control with commercial units is generally accurate and reliable and can be considered a mature, state-of-the-art technology.

A second method of heating specimens is through the use of induction heaters, where the specimen is heated by alternating currents produced by an EMF generated by the inductance coil surrounding the test specimen. Shielding of the specimen by grips may cause nonuniform temperature distribution. Therefore, single-edge-tension specimen geometries are generally preferred. The number and spacing of the coils, though calculated from formulas provided with such apparatus, is determined most often from trial and error and usually requires a certain amount of experience for optimal performance. Feedback is provided from one or more thermocouples attached to the specimen, and uniformity of temperature must be checked with some type of temperature mapping system, such as multiple thermocouples on a dummy specimen.

Another method of heating used in several laboratories is the use of radiant energy from quartz lamps mounted in reflective and cooled housings. Each lamp focuses energy over a limited portion of the test specimen, so multiple lamps, multiple thermocouples, and good thermal conductivity across the specimen all lead to more uniform temperature fields. A description of the technique of quartz lamp heating can be found in Ref 48.

The last common method of specimen heating is direct resistance heating. Here, a current is passed directly through the specimen from one end to another. The test apparatus must be electrically insulated from the input and output leads. Uniform gage length specimens are better adapted to this method of heating than highly nonuniform ones; therefore, a MT specimen would be a much better candidate than a CT specimen. Because the high current passes through the specimen, no conducting leads can be attached to the specimen that would provide an alternative path for the current. Thus, temperature measurement from thermocouples attached directly to the specimen and electric potential crack growth measurements cannot be made with this type of heating. Similarly, extensometry that attaches directly to the specimen must use nonconducting elements.

Temperature Measurement. The science of the measurement of temperature, known as pyrometry, dates back before World War II. Books on the subject of pyrometry in general (Ref 49), or optical pyrometry in particular (Ref 50), were published in 1941 and provide detailed descriptions of the theory and the methods used in that era. The basic principles have not changed. The most common method for temperature measurement is through the use of thermocouples, or thermoelectric pyrometer, directly attached to the specimen. A thermocouple is made by welding two dissimilar wires together at one end. A change in temperature will generate an EMF that can be recorded on an instrument attached to the other end of the wires. These readings provide a real-time, continuous record of temperatures at a given point on a specimen, and they are commonly used for temperature control feedback as well as direct temperature measurement.

Another commonly used method of measuring temperature is through the use of commercially available infrared detectors, which sense the radiation emitted from a sample and convert the frequency of the radiation to temperature after appropriate calibration. The theory and methods of optical pyrometry are documented in numerous places (e.g., Ref 51, 52). The emissivity of the test material whose temperature is being measured is the quantity used as the basis of the measurement. Emissivity is the ratio between total radiant energy per square centimeter per second between the specimen being measured and a black body at the same temperature. Thus, as the emissivity of a material decreases from 1, the apparent temperature as measured by an optical pyrometer will deviate from the actual temperature by a greater amount.

The emissivity of a heated specimen will always be less than 1, and the apparent temperature will, therefore, be less than the desired test temperature. Emissivity can be influenced by surface roughness, the spectral transmission of any windows between the test specimen and the measuring instrument, and the chemical changes of the specimen surface due to oxidation or other environmental degradation. All these issues should

be addressed when using optical pyrometry. Commercial units are widely available for this type of measurement and usually come with detailed instructions.

Crack-Length Measurement. Electric potential drop is a common method of crack-length determination, both at room temperature and at elevated temperatures. The major consideration for elevated-temperature testing is to ensure that temperature fields are uniform and constant between the potential drop leads. Changes in temperature can result in a false indication of crack-length changes. The error is due to the resistivity change in the material caused by a change in temperature, and this change, in turn, is dependent on the resistivity characteristics of the material. For the direct current potential drop (DCPD) method, a 3 °C (5.5 °F) change in temperature in an aluminum alloy can result in a 1% change in the DCPD signal, whereas for the same change in resistivity, Inconel 718 requires a 100 °C (180 °F) change in temperature (Ref 53). The electric potential drop method of crack-length measurement, used commonly in both room- and elevated-temperature isothermal crack growth testing, has also been applied to TMF testing (Ref 54). As with any other technique, modifications and improvements are continually being developed and documented in the literature, as in the work of Shin et al. (Ref 55), where modification to the dc potential drop system is reported.

Compliance methods are equally valid at elevated temperatures as at room temperature, provided that some simple considerations are addressed. Nonconstant thermal gradients must be avoided, because any change in the dimensions of any part of a mechanical extensometer can result in a change in electrical output. The gage portion, which is normally attached to the specimen through special high-temperature extension arms or feed rods, is usually shielded from the specimen (Fig. 20) and cooled with either blowing air or circulating water. Whatever the setup, the gage should reach thermal equilibrium and stability before measurements are made, in order to avoid false indications due to thermal transients.

Fig. 20 Feed-rod attachment for high-temperature tests. Feed rods are made of quartz for tests up to 1000 °C or ceramics for tests at higher temperatures.

Optical methods are less widely used today than previously because of the availability of automated methods for crack-length measurement. Optical methods, such as use of a traveling microscope, are useful for reference measurements and are equally valid at room or elevated temperature. At elevated temperature, however, the resolution of crack length may be reduced because of deterioration of the specimen surface through oxidation. When specialized optical methods such as laser interferometry are used, the deterioration of the specimen surface over time should be considered so that the optical information is still available with sufficient resolution.

Special Methods. Other specialized techniques see occasional application in high-temperature crack growth testing. For example, crack growth over prolonged periods of time has been measured using real-time holographic interferometry (Ref 56). Compact-tension specimens were tested under sustained load at 120 °C (250 °F) for 860 h, and crack-opening displacement (COD) was monitored. The COD measurements had to be converted to crack lengths using an elastic-plastic finite-element analysis code and clip gage COD measurements on a reference sample.

Validity of K Solutions. The reduction of crack length versus N data to a $da/dN-\Delta K$ curve depends on having a K solution for the specimen geometry being used. Stress-intensity solutions are widely available, or can be easily generated, for almost any specimen geometry used in laboratory testing. These solutions, however, are based on the assumption of a homogeneous material and do not take into account any thermal gradients or

thermal stresses that may arise in elevated-temperature crack growth testing. For situations where the specimen and grips are at a uniformly high temperature, such as within a furnace, there is no problem. For situations where the temperature is nonuniform, such as with inductance or quartz lamp heating with cooled grips, temperature gradients are developed along the axis of the specimen. These gradients, in turn, may result in thermal stresses that produce thermal K -values that alter the isothermal K solution for a given specimen. These thermal K -values, therefore, must be taken into account in the K analysis of the particular crack geometry.

Ohta et al. (Ref 57) found that crack growth rate data at 300 °C (570 °F) in a MT specimen only matched room-temperature data in a low-alloy ferritic steel (SB46) when the parabolic temperature gradient that existed along the specimen was taken into account using finite element analysis, which was confirmed with experimental measurements. Coker et al. (Ref 58) conducted a finite element analysis of a single-edge-crack specimen with thermal gradients between the plane of the crack and the room-temperature grips. For the specific geometry and temperature profile, stress-intensity factors due to thermal stresses were below $2 \text{ MPa}\sqrt{m}$ for $a/W \leq 0.8$. While these values are small, near-threshold tests involving very small values of ΔK could be substantially influenced by thermal stresses. It is important, therefore, to have calculations or estimates of thermal-stress-induced values that have nonuniform temperature profiles. Unfortunately, there are very few papers in the literature where this particular problem is addressed. Nonetheless, this consideration can be important in high-temperature testing, particularly when testing in the near-threshold regime or when thermal gradients are severe.

Thermal gradients and effective K -values resulting from direct resistance heating are discussed by Cunningham and Griffin (Ref 59). The analysis shows when direct resistance heating becomes important during the cyclic conditions of thermal fatigue. The results indicate that stress intensities resulting from thermal gradients due to direct resistance heating are generally small except when thermal cycling frequencies are high. The thermal gradients and K -values resulting from thermal cycling are reported in a subsequent publication (Ref 60). There, for high thermal frequencies, significant magnitudes of K can be developed at the crack tip due to the thermal transients. For those involved in TMF crack growth testing, this information should be considered when determining the stress intensity at the crack tip.

Fatigue Testing and Behavior of Plastics

Lisa A. Pruitt, University of California at Berkeley

Introduction

FATIGUE FRACTURE OF ENGINEERING PLASTICS due to cyclic loading conditions is of critical concern when designing polymeric components for structural employment. Like all engineering materials, failure often ensues in the plastic as a consequence of accumulated irreversible damage or growth of a fatigue flaw to a critical dimension. The fatigue life of a polymeric component is controlled by a number of factors; in general, polymers are more sensitive to the testing environment than metal or ceramic counterparts. These variables include the stress or strain amplitude of the loading cycle; the mean stress of the cycle; the presence of stress concentrations or initial defects in the component; the frequency, temperature, and environment of the test; and the molecular properties of the polymer. These factors are of considerable interest and practicality for the safe design of structural polymeric components subjected to repetitive loading.

When designing for the fatigue life of an engineering plastic, one of two distinct philosophies is generally practiced. The total life approach is utilized with unnotched specimens that are assumed to be defect free, and this methodology is predicated on the notion that fatigue failure is a consequence of both crack nucleation and subsequent growth. Conversely, the defect tolerant approach bases the fatigue life of a component on the number of loading cycles needed to propagate a crack of an initial size to a critical dimension. Over the last few decades, numerous researchers have provided detailed reviews (Ref 1, 2, 3, 4, 5, 6, 7, and 8) of fatigue behavior in polymers based on both total life and fracture mechanics approaches.

This article provides a review of fatigue test methodologies and an overview of general fatigue behavior in engineering plastics. Many factors affect the fatigue performance of engineering materials, including molecular and mechanical variables as well as the design of the fatigue test. The appropriate test conditions should be used when evaluating the life of the polymer. If a structural component is likely to be free of defects and stress concentrations or if the component is likely to spend the majority of its lifetime in the initiation stage of crack growth, then the total life philosophy is preferred. On the other hand, fracture mechanics should be used for safety critical fatigue designs and in flawed structural components likely to sustain a high degree of stable crack growth prior to fracture.

Fatigue Testing and Behavior of Plastics

Lisa A. Pruitt, University of California at Berkeley

Fatigue Crack Initiation

Stress-Based Loading. The traditional total life philosophy for fatigue life prediction is based on an endurance limit established from stress-log cycle plots, also known as *S-N* curves. In these tests, uncracked specimens are subjected to a constant amplitude load cycle until failure occurs. Often fatigue tests are performed on closed-loop servohydraulic universal test machines, which enable fatigue tests to be performed under a variety of waveforms over a range of test frequencies (including spectrum loadings). The stress amplitude can be applied through torsion, rotation, beam bending, or axial loads. Specimens (Fig. 1) are chosen according to the loading method employed. For example, the standard fatigue test for plastics in ASTM D 671 specifies repeat flexural stress as a standard fatigue test. In this test, a triangulated specimen geometry (Fig. 1d) provides a uniform flexural stress across the entire gauge section.

Fig. 1 Schematic of specimens used for total life fatigue analysis. Tests can be done (a) in torsion, (b) with a rotating cantilever, (c) with a rotating beam, (d) with cantilever reverse bending, or (e) under axial loading

In fatigue testing, the applied stress, σ_a , is typically described by the stress amplitude of the loading cycle:

$$\sigma_a = \frac{\sigma_{\max} - \sigma_{\min}}{2} \quad (\text{Eq 1})$$

where σ_{\max} is the maximum stress and σ_{\min} is the minimum stress of the fatigue cycle. The stress amplitude, also denoted as S , is generally plotted against the number of cycles to failure, N , on a linear-log scale, which is called an $S-N$ plot. A general trait of these plots is that the number of cycles to failure increases as the stress amplitude is reduced. In some polymers, there is a critical stress level, often referred to as the *endurance limit* of the material, below which the specimen does not fail in less than 10^7 cycles.

Figure 2 shows the $S-N$ behavior of several commodity plastics. It should be noted that nylon and polyethylene terephthalate (PET) do not exhibit an endurance limit. Other plastics—including polyethylene (PE), polypropylene oxide (PPO), polystyrene (PS), polytetrafluoro-ethylene (PTFE), polypropylene (PP), polymethyl-methacrylate (PMMA), and epoxy (EP)—exhibit a stress limit below which failure does not occur in less than 10^7 cycles for these testing conditions. Because plastics are sensitive to many factors including frequency, temperature, mean stress, and molecular structure, the fatigue test conditions must closely mimic the service conditions of the polymeric component. Despite the simple nature of these experimental tests, the $S-N$ approach is widely accepted in the engineering plastics community for design applications where stress concentrations are expected to be minimal or where the fatigue life of the component is likely to be dominated by the nucleation of a crack.

Fig. 2 Stress amplitude versus cycles to failure, or $S-N$ behavior, of several commodity plastics

Displacement and Strain-Based Loading. While stress-based tests are appropriate for the evaluation of plastics chosen for load-controlled applications, these tests might not be suitable for circumstances where the structural component is likely to experience fluctuations in displacement or strain. In such instances, strain- or displacement-based tests might be more appropriate. In such tests, the configuration typically is based on a fixed cantilever subjected to repeated constant deflection. The initial stress range will typically decay under cyclic loading (much like a stress relaxation experiment) and is caused by plastic deformation or softening of the polymer. Hysteretic heating from deformation can further result in an inaccurate prediction of the cyclic stress amplitude (Ref 9). However, because stresses generally decay in this type of test, thermal failures are rarely encountered (Ref 5).

Strain-based tests are often utilized for components with accumulated strain or blunt notches (Ref 5). The majority of strain-based fatigue tests are performed using fully reversed loading conditions, generally accompanied by a cyclic softening phenomena in plastics (Ref 2, 9). Under cyclic strain conditions, the fatigue response is best characterized by the cyclic stress-strain curve. This curve is created by testing several specimens subjected to a range of controlled cyclic strain limits. Tests are continued for each specimen until the hysteresis loops become saturated. A curve is fit through the amplitude of these saturated hysteresis loops in

order to establish a cyclic stress-strain curve. Figure 3 shows a comparison of the cyclic and monotonic stress-strain curves for several polymers. An interesting feature of these polymers is that they all soften and exhibit lower yield points under cyclic strain than under monotonic conditions (as opposed to metals, which can exhibit either cyclic softening or cyclic hardening).

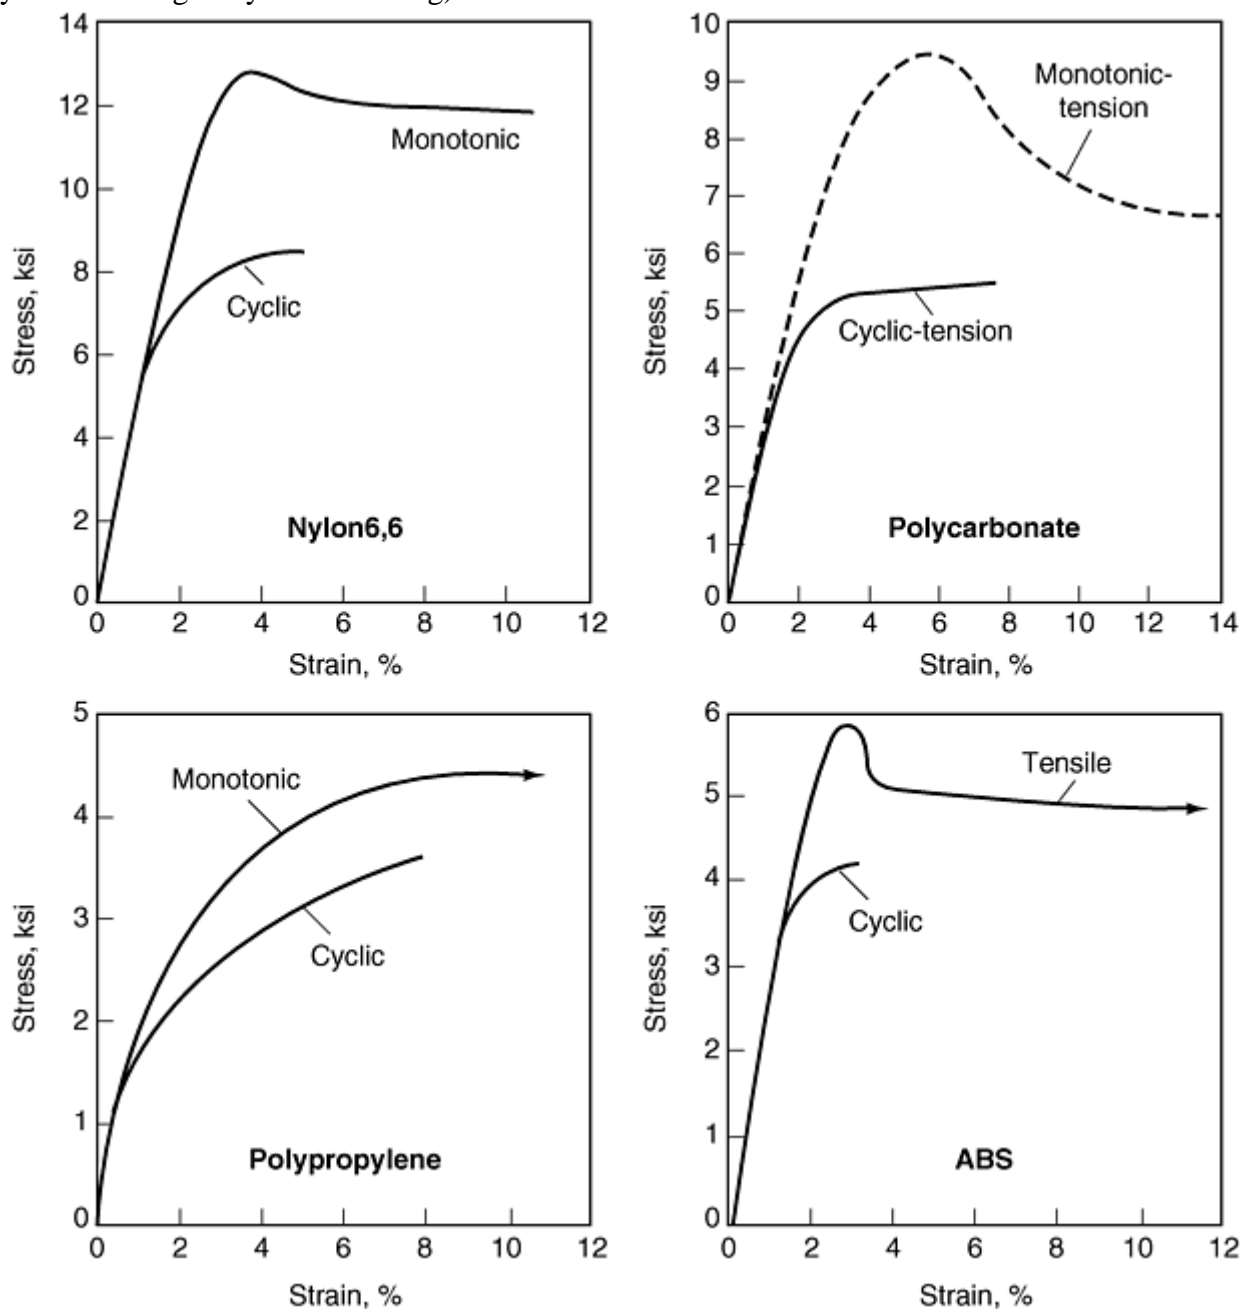

Fig. 3 Comparison of the cyclic and monotonic stress-strain curves for several polymers. Source: Ref 2

The cyclic strain life data can also be portrayed in a manner analogous to the $S-N$ approach. The total strain amplitude can be divided into elastic and plastic strain amplitude components. The strain amplitude of the fatigue cycle is plotted against the number of cycles or load reversals to failure, which provides an empirical relationship between the strain amplitude of the fatigue cycle and the number of cycles to specimen failure (Ref 6):

$$\epsilon_a = \frac{\sigma'_f}{E} (2N_f)^b + \epsilon'_f (2N_f)^c \quad (\text{Eq 2})$$

Here, ϵ_a is the strain amplitude, σ'_f is the strength coefficient, $2N_f$ is the number of load reversals to failure, ϵ'_f is the ductility coefficient, and b and c are material constants. The first term on the right side of Eq 2 is the elastic component of the strain amplitude, and the second term is the plastic component of the strain amplitude. Tests dominated by the elastic component of strain are considered high-cycle fatigue with little plastic strain. Low-

cycle fatigue tests are identified by the relatively small number of cycles or reversals to failure and the large degree of plastic strain.

An important concern in the testing of polymers is that the attributes of the fatigue test are crucial to the relative ranking of fatigue resistance among various polymers. For example, polymers with higher damping capacities can be less resistant to fatigue. These polymers experience thermal heating when tested under constant stress amplitude. Conversely, these same polymers can have enhanced fatigue resistance if tested under constant deflection conditions. Moreover, the relative placement of fatigue resistance in polymers correlates strongly to whether the tests are performed under adiabatic or isothermal conditions (Ref 5).

Thermal Fatigue and Hysteretic Heating. Due to the viscoelastic nature of polymeric solids, a portion of the strain energy dissipates under cyclic loading conditions. This heat generation results in an increase in specimen temperature until the heat generated per cycle is equal to the heat dissipated through conduction, convection, and radiation. The temperature of the specimen depends strongly on the frequency of the test, the amplitude of the applied stress or strain, and the damping properties of the polymer. In some instances, especially in unnotched specimens, the temperature of the polymer specimen can locally surpass the glass transition or flow temperature of the polymer. Ferry (Ref 9) has found that the energy dissipated per second, \dot{E} , is given by:

$$\dot{E} = \pi \nu J''(\nu, T, \sigma) \sigma^2 \quad (\text{Eq 3})$$

where ν is the frequency, J'' is the loss compliance, T is temperature, and σ is the peak stress of the fatigue cycle. The rate of change of temperature for adiabatic heating conditions in which the heat generated is transferred into temperature rise is given as:

$$\frac{dT}{dt} = \frac{\dot{E}}{\rho C_p} \quad (\text{Eq 4})$$

where ρ is the mass density and C_p is the heat capacity of the polymer. In general, the increase in temperature will scale with increase in frequency, stress amplitude, and internal friction of the polymer. Figure 4 shows the thermal fatigue behavior of polyacetal and its dependence on test frequency. The temperature rise in the specimen can be monitored with a thermal couple or an infrared sensor. In many polymer systems, the thermal work influenced by high damping and low thermal conductivity contributes to micromechanisms of permanent deformation including craze formation, shear bands, voids, or even microcracks (Ref 8).

Fig. 4 Plot showing the effect of increasing test frequency and stress amplitude on the fatigue failure of polyacetal

The hysteresis loops observed under cyclic loading conditions can provide useful insight into micromechanisms of fatigue damage. Figure 5 shows the hysteresis loops after various numbers of fatigue cycles in both high impact polystyrene (HIPS) and acrylonitrile butadiene-styrene (ABS). An interesting observation is that the hysteresis loops are symmetric for ABS, while the hysteresis loops become much larger for the tensile portion of the fatigue cycle in HIPS as the fatigue test progresses. These events are understandable considering ABS undergoes shear yielding mechanisms and the HIPS undergoes crazing that requires a tensile component of stress. Crazing results from fibrillation or polymeric drawing ahead of the fatigue flaw. The advancement of the craze zone is associated with damage accumulation in the leading fibrils; thus, the tensile portion of the hysteresis loop grows as damage accumulates in the specimen.

Fig. 5 Hysteresis loops after various numbers of fatigue cycles in both high impact polystyrene (HIPS) (bottom) and acrylonitrile butadiene styrene (ABS) (top). Note the lack of symmetry in the HIPS due to crazing mechanisms. See text for discussion.

Fatigue Testing and Behavior of Plastics

Lisa A. Pruitt, University of California at Berkeley

Fatigue Crack Propagation

Fracture Mechanics Concepts and the Defect-Tolerant Philosophy. The use of fracture mechanics for fatigue design is based on the tacit assumption that structural components are intrinsically flawed and capable of sustaining a considerable amount of stable crack growth before failure. The fatigue life of a component based on this defect-tolerant approach is dictated by the number of loading cycles needed to propagate a crack of an initial size to a critical dimension. Fracture mechanics is used widely in the characterization of fatigue crack propagation behavior of advanced engineering plastics capable of sustaining a substantial subcritical crack growth prior to fracture. Fracture mechanics is also used in safety-critical applications where defect-tolerant life estimates are essential. Characterizing crack growth behavior in polymers can be complicated by fatigue cracks known to propagate at different rates depending on the near-tip damage micromechanisms, mean stress, frequency, or test environment. These factors are of significant interest and practicality for the safe design of structural polymeric components subjected to repetitive loading.

The stress intensity factor, K , derived from linear elastic fracture mechanics, is the parameter used to describe the magnitude of the stresses, strains, and displacements in the region ahead of the crack tip. The linear elastic solution (Fig. 6) for the normal stress, σ_{yy} , in the opening mode of loading is written as a function of distance, r , and angle, θ , away from the crack tip (Ref 10):

$$\sigma_{yy} = \frac{K_I}{\sqrt{2\pi r}} \cdot \cos \frac{\theta}{2} \left(1 + \sin \frac{\theta}{2} \sin \frac{3\theta}{2} \right) \quad (\text{Eq 5})$$

where K_I is the mode I (opening mode) stress intensity factor. This parameter incorporates the boundary conditions of the cracked body and is a function of loading, crack length, and geometry. The stress intensity factor can be found for a wide range of specimen types and is used to scale the effect of the far-field load, crack length, and geometry of the flawed component. Standard specimens employed in fatigue crack propagation studies are the single-edge-notch specimen (Fig. 7a) and the compact-tension specimen (Fig. 7b). The form of the stress intensity factor for the compact-tension geometry is given as (Ref 10):

$$K_I = \frac{P}{B\sqrt{W}} \cdot f(\alpha) \quad (\text{Eq 6})$$

$$f(\alpha) = \frac{(2 + \alpha)}{(1 - \alpha)^{3/2}} [0.886 + 4.64\alpha - 13.32\alpha^2 + 14.72\alpha^3 - 5.6\alpha^4]$$

where P is the remote far-field load, B is the specimen thickness, W is the width, and α is the ratio a/W that increases as the fatigue crack, a , advances in length.

Fig. 6 Coordinate system for crack-tip stresses in mode I loading (see Eq 5)

Fig. 7 Specimens employed in fatigue crack propagation studies. (a) Single-edge-notch specimen. (b) Compact-tension specimen

Regimes of Fatigue Crack Propagation. Fracture mechanics provides a design approach for predicting the life of a cracked structural component under cyclic loading conditions. While the micromechanisms of deformation differ for metals, polymers, and ceramics, the fatigue crack propagation behavior of these materials share many macroscopic similarities. As with crystalline materials, there are three distinct regimes of crack propagation for polymers under constant amplitude cyclic loading conditions. These regimes include the slow crack growth or threshold regime, the intermediate crack growth or Paris regime, and the rapid crack growth or fast fracture regime (Fig. 8). The velocity of an advancing fatigue crack subjected to a constant stress amplitude loading is

determined from the change in crack length, a , as a function of the number of loading cycles, N . The fatigue crack propagation rate per cycle, da/dN , is found from experimentally generated curves, in which a is plotted as a function of N . For constant amplitude loading, the rate of crack growth increases as the crack grows longer. Paris et al. (Ref 11) suggested that the stress intensity factor range, $\Delta K = K_{\max} - K_{\min}$, which captures the far-field cyclic stress, crack length, and geometry, should be the characteristic driving parameter for fatigue crack propagation. This basis of the Paris relationship states that da/dN scales with ΔK through the power law relationship:

$$\frac{da}{dN} = C \cdot \Delta K^m \quad (\text{Eq 7})$$

where C and m are empirical constants. These constants can be strongly affected by polymer morphology, test frequency, stress ratio (the stress ratio, R , is defined as the ratio of the minimum stress to the maximum stress of the fatigue cycle) of the fatigue cycle, as well as by test temperature and environment. Figure 8 shows that the Paris equation is valid for intermediate ΔK levels spanning crack propagation rates from approximately 10^{-6} to 10^{-4} mm/cycle.

Fig. 8 Schematic illustration of the three distinct regimes of crack propagation rate observed in fatigue testing under constant amplitude loading conditions. For polymers, typical values of m range from 3 to 50 depending on the polymer system.

The Paris relationship is a useful tool for fatigue life prediction. It is implied in this defect-tolerant approach that all structural components are intrinsically flawed with an initial crack size, a_i . Assuming the fatigue loading is performed under constant stress amplitude conditions, the geometric factor, $f(a)$, does not change within the limits of integration. Fracture occurs when the crack reaches a critical value, a_c , the Paris equation can be integrated to predict the fatigue life of the component:

$$N_f = \frac{2}{(m-2)Cf(\alpha)^m(\Delta\sigma)^m \pi m/2} \cdot \left[\frac{1}{a_i^{(m-2)/2}} - \frac{1}{a_c^{(m-2)/2}} \right] \text{ for } m \neq 2 \quad (\text{Eq 8})$$

Crack Shielding Mechanisms in Polymers. The crack driving force near a fatigue crack tip, ΔK_{tip} , will be lower than the “applied” crack driving force, ΔK_a , when extrinsic toughening mechanisms are present. The presence of extrinsic toughening mechanisms shields the crack tip, thereby decreasing the crack driving force and the crack growth rate. Ritchie (Ref 12) has expressed the extrinsic crack-tip shielding effect:

$$\Delta K_{tip} = \Delta K_a - K_s \quad (\text{Eq 9})$$

where K_s is the stress intensity factor due to shielding. Under cyclic loading conditions, there are three general types of shielding mechanisms: crack deflection, process zone shielding, and contact shielding (Fig. 9). Shielding due to crack path deflection results in improvements in the fatigue crack propagation behavior over all ranges of ΔK . By contrast, process zone shielding mechanisms operate more effectively at high ΔK levels, whereas contact shielding mechanisms are more effective at low ΔK levels.

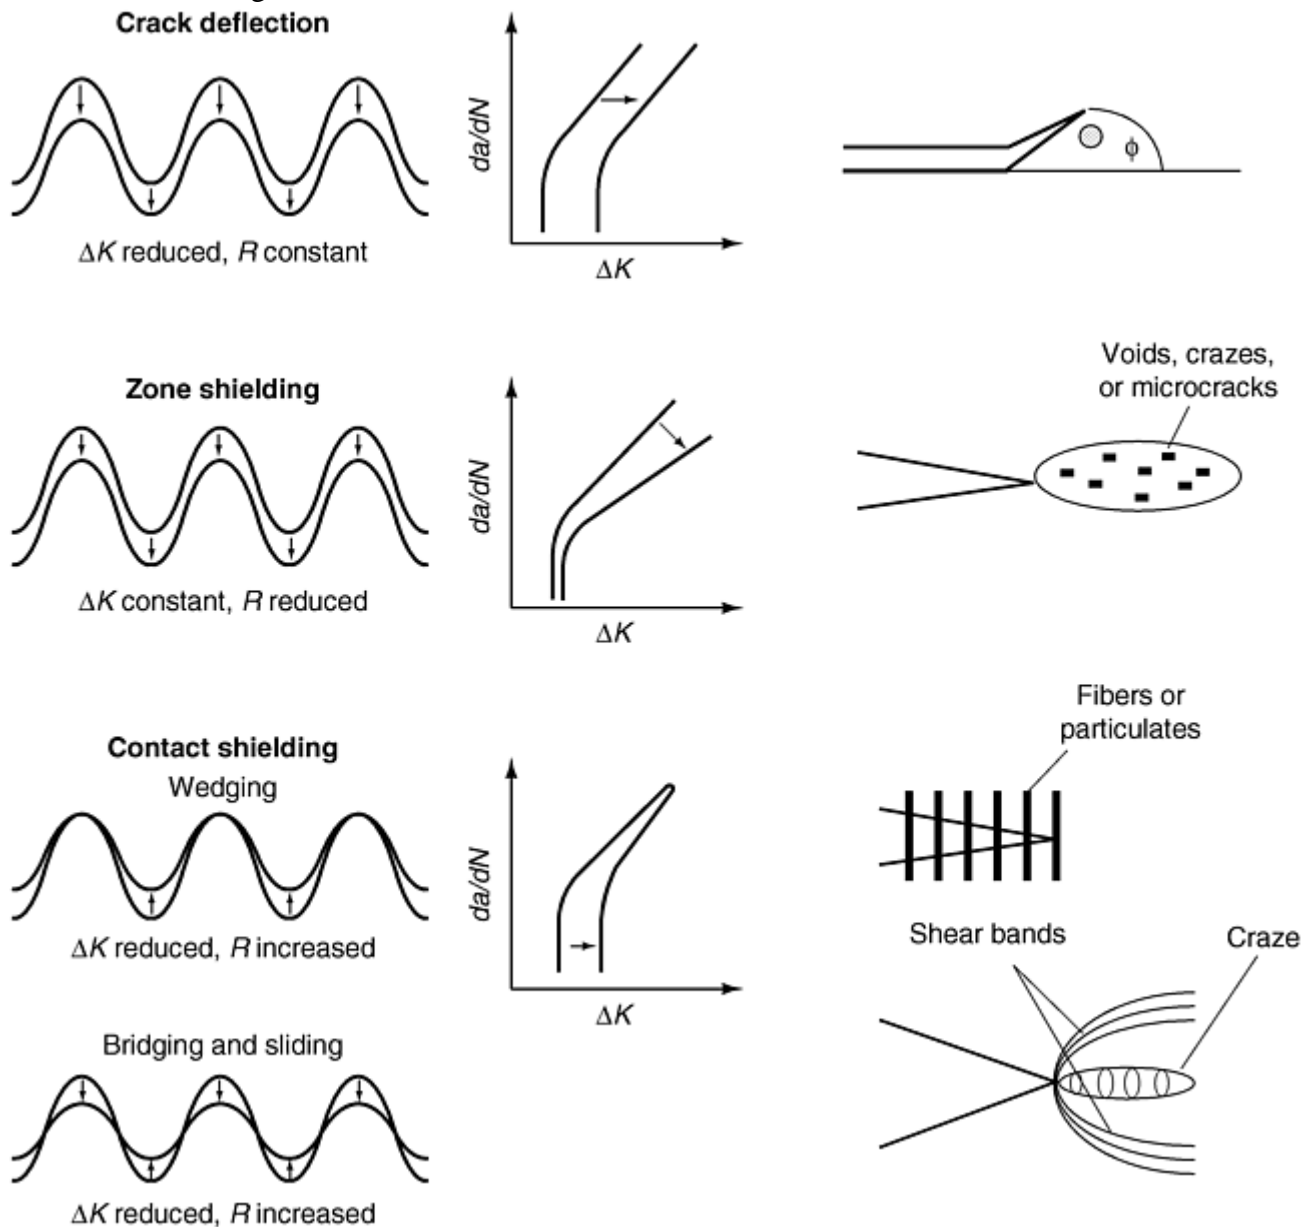

Fig. 9 Schematic illustration of the three types of shielding mechanisms: crack deflection, zone shielding, and contact shielding

The amount of shielding due to crack path deflection has been modeled by Suresh (Ref 13). Suresh derived the effective fatigue crack driving force and subsequent crack growth rates by analyzing a small segment of the crack with an out-of-plane deflection:

$$\Delta K_{tip} = \frac{b \cos^2(\theta/2) + c}{b + c} \Delta K_a \quad (\text{Eq 10})$$

$$\frac{da}{dN} = \frac{b \cos \theta + c}{b + c} \cdot \left(\frac{da}{dN} \right)_n \quad (\text{Eq 11})$$

where θ is the deflection angle, b is the deflected distance, and c is the undeflected distance.

The amount of shielding caused by process zone mechanisms depends on the nature of the plastic deformation of the crack tip, such as massive crazing or shear banding (Ref 14, 15, 16, 17, and 18). The yielding in front of the crack caused by far-field tensile loading results in the formation of a plastic or permanent deformation zone. For a crazeable polymer (Fig. 10), a Dugdale (Ref 13), or strip yield, approximation is used to estimate the size of this plastic zone, r_d :

$$r_d = \frac{\pi}{8} \left(\frac{K_I}{\sigma_y} \right)^2 \quad (\text{Eq 12})$$

where σ_y is the craze stress. For an elastic, perfectly plastic material behavior, the plane-stress plastic zone (Ref 13), r_p , can be estimated:

$$r_p \approx \frac{1}{\pi} \left(\frac{K_I}{\sigma_y} \right)^2 \quad (\text{Eq 13})$$

where σ_y is the yield stress.

Fig. 10 Crazing. (a) Schematic of a craze zone preceding the crack. Note the craze consists of load bearing fibrils and void space. (b) Transmission electron micrograph of a craze preceding a fatigue crack in polycarbonate

Under cyclic loading, a reversed cyclic plastic zone will be generated within the monotonic plastic zone. For an elastic, perfectly plastic material, this region of residual tensile stress is one fourth the size of the monotonic

plastic zone described in Eq 13. Cyclic plastic zones have been observed in several amorphous polymer systems and are important in the inception of cracks under cyclic compression loading (Ref 13). Qualitatively, it is easy to see that the size of the plastic zone increases with ΔK ; therefore, process zone shielding mechanisms are effective at high ΔK levels.

Contact shielding involves physical contact between mating crack surfaces because of the presence of asperities, second-phase particles, and/or fibers. Premature contact between the crack surfaces occurs during unloading at a stress intensity level known as K_{cl} , which is the closure stress intensity. The degree of shielding caused by closure effects can be calculated:

$$\Delta K_{tip} = K_{max} - K_{cl} \quad (\text{Eq 14})$$

where K_{max} is the maximum stress intensity of the fatigue cycle. It should be noted from Eq 14 that the ΔK_{tip} is less than ΔK_a , thus effectively lowering the stress intensity felt at the crack tip. Mechanisms such as contact shielding and fiber bridging can contribute to this phenomenon. Contact shielding can arise from contact between asperities or from fiber bridging in reinforced or blended polymers. Fiber bridging has been shown to be a viable shielding mechanism in short fiber composites by Lang and his coworkers (Ref 19). In summary, extrinsic shielding mechanisms can be utilized to improve resistance to fatigue crack propagation in engineering polymers.

Fatigue Testing and Behavior of Plastics

Lisa A. Pruitt, University of California at Berkeley

Factors Affecting Fatigue Performance of Polymers

Molecular Variables. Polymers are sensitive to a number of molecular variables including molecular weight, molecular weight distribution, crystallinity, chain entanglement density, and crosslinking (Ref 3, 5, 20, and 21). In general, as the molecular weight of the polymer is increased, the fatigue resistance of the polymer is

enhanced. Some polymers (as mentioned earlier) are susceptible to craze nucleation that leads to subsequent crack growth and fatigue failure. Figure 10(a) schematically illustrates the load bearing fibrils that comprise the craze zone. Figure 10(b) shows a transmission electron micrograph of a craze preceding a fatigue crack in polycarbonate (PC).

When a critical amount of damage has accumulated, the crack advances through the load bearing fibrils of the craze zone. This advancement can occur by a void growth mechanism potentially enhanced by temperature, chemical environment, or rupture of the highly stressed fibrils. The craze often advances in a discontinuous manner and results in discontinuous crack growth in certain stress regimes (Ref 5). Kramer (Ref 22) has shown that craze stability depends on numerous factors including the molecular weight and chain entanglement density of the polymer. The stability or strength of the craze can be improved by increasing the molecular weight of the polymer. Numerous studies indicate that increasing the molecular weight of the polymer increases craze strength, creep rupture strength, and endurance limit under cyclic loading conditions (Ref 3, 5, 18, and 22).

Semicrystalline polymers provide improved fatigue resistance over glassy amorphous polymers. One explanation is that the composite, two-phase structure, offers enhanced toughness. Improved strength is provided by the more rigid crystalline phase, and ductility is provided by the more compliant amorphous phase. Semicrystalline polymers provide higher fracture energies and can accommodate both amorphous and crystalline modes of plasticity.

The arrangement of the crystallites within the amorphous phase or the polymer morphology is also important to the resistance of fatigue. For example, branched versions of polyethylene offer decreased resistance, while very high molecular weight versions of polyethylene with an enhanced level of tie molecules provide superior resistance to fatigue crack propagation in comparison to generic linear polyethylene (Ref 3). In general, semicrystalline polymers, such as nylon, polyacetal, and polyethylene, offer excellent resistance to fatigue crack propagation and provide high *S-N* endurance limits (Ref 5). In comparison, amorphous glassy polymers often suffer inferior fatigue strength due to a lack of shielding or toughening modes, because many amorphous polymers are used below the glass transition temperature and are incapable of large amounts of ductile or viscous deformation. Figure 11 shows a comparison of fatigue crack propagation behavior in the Paris regime for several amorphous and semicrystalline polymers, and it is evident that the semicrystalline polymers offer improved fatigue crack growth resistance.

Fig. 11 Comparison of fatigue crack propagation behavior in the Paris regime for several amorphous and semicrystalline polymers. Note enhanced fatigue resistance of the semicrystalline polymers. Source: Ref 5

Effect of Reinforcements. The addition of rubber particles to a ductile or brittle polymer provides a process zone shielding mechanism involving massive shear banding of the matrix, which leads to improved fatigue crack propagation resistance. The role of crack-tip shielding mechanisms on the crack growth rate regime has been modeled by Ritchie (Ref 12). According to Ref 12, the occurrence of a process zone shielding mechanism should change the slope (m) in the Paris regime but should not change the crack growth behavior at low crack growth or near-threshold regime. Experimental support of this model has been given by Azimi et al. (Ref 23). Figure 12 shows that the addition of rubber decreases the slope, m , and retards crack growth at high crack growth rates due to toughening mechanisms. At low values of stress intensity range (ΔK), however, the crack growth rates for the rubber-toughened epoxies are nearly identical to those of the unmodified (neat) resin. At low ΔK levels, the process zone in front of the crack tip is small; the rubber reinforcements are not highly stressed; hence, the crack grows with minimal plasticity in this regime. Conversely, at high ΔK levels, the process zone is much larger than the size of the particles, and the rubber additions within this region are highly stressed. The subsequent rubber particle cavitation causes significant additional plasticity in the matrix, and the crack propagation rate is reduced.

Fig. 12 Fatigue crack propagation behavior for a rubber-toughened epoxy. The addition of rubber decreases the slope, m , at high crack growth rates due toughening mechanisms and retarded crack growth. CTBN, carboxy-terminated polybutadiene acrylonitrile rubber; MBS, methacrylate-butadiene-styrene

Blending rubber-toughened polymers with a small amount of inorganic filler can also improve fatigue crack propagation resistance. Azimi et al. (Ref 23) have studied several glass-filled, rubber-toughened blends, and they believe the improved fatigue crack propagation resistance is the result of a synergistic interaction between the hollow glass filler at the crack tip and the plastic zone triggered by the rubber particles. The synergistic effect occurs by crack bridging via the glass phase and enhanced plasticity due to the presence of the rubber particles.

An interesting distinction must be made between fatigue crack initiation and propagation studies. The addition of rubber particles or reinforcements results in an increased resistance to crack propagation. However, this same material often exhibits a *decreased resistance* to fatigue crack initiation or flaw inception. The second phase addition serves as a nucleation site for crazes, voids, or shear bands and results in a decreased threshold for crack inception. For example, high impact polystyrene studies (Ref 5) have shown an increased resistance to crack propagation but a degraded resistance to crack inception when compared to the neat polystyrene resin. Thus, designers need to have a clear understanding of the component design and loading environment when making their material selection.

Mean Stress Effects. The fatigue response of a polymeric material is highly sensitive to the mean stress, σ_m , of the fatigue cycle:

$$\sigma_m = \frac{\sigma_{\max} + \sigma_{\min}}{2} \quad (\text{Eq 15})$$

Depending on the structure of the polymer and the micromechanisms of deformation, there are two distinct responses to an increase in mean stress. For a nominal stress intensity range, some polymers exhibit an increase in crack propagation rate while others show a decrease in crack growth rate. The published research on the effects of mean stress and R -ratio covers a broad range of polymer classes including amorphous, semicrystalline, crosslinked, and rubber-modified polymers (Ref 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, and 34). Table 1 provides a summary of the effect of increased mean stress for several advanced polymer systems.

Table 1 Effect of increasing mean stress on polymer fatigue crack propagation

Polymer	Reference
Increasing crack propagation rate with increasing mean stress	
High density polyethylene	15
Nylon	5
High molecular weight PMMA	21, 25
Polystyrene	30, 35
Epoxy	24
Polyethylene copolymer	26
Decreasing crack propagation rate with increasing mean stress	
Low density polyethylene	5
Polyvinyl chloride	34
Low molecular weight PMMA	21
Rubber-toughened PMMA	15
High impact polystyrene	15, 35
Acrylonitrile-butadiene-styrene	15
Polycarbonate	24, 32, 33, 44
Toughened polycarbonate copolyester	27

Increasing crack growth rates associated with an increased stress ratio or mean stress are observed in epoxy resins, PMMA, HDPE copolymers, PS, PVC, and nylon. A number of different explanations and relationships have been proposed to rationalize the effect of mean stress on fatigue crack propagation. Arad et al. (Ref 28) suggested that the fatigue crack growth rates could be scaled to the stress intensity factor with the following relationship:

$$\frac{da}{dN} = \beta \cdot \lambda^n = \beta \cdot (K_{\max}^2 - K_{\min}^2)^n \quad (\text{Eq 16})$$

where β depends on the loading environment, frequency, and material properties, and n is a material constant. A micromechanistic explanation for this response to an increase in stress ratio or mean stress is also possible. Polymers that become more prone to fracture with increasing mean stress are most likely affected by the monotonic fracture process associated with the maximum portion of the loading cycle as it approaches a critical stress intensity level. In general, these polymers are susceptible to crazing, chain scission, or crosslink rupture. For these polymer types, an increase in mean stress results in faster crack propagation rates.

Remarkably, several polymer blends offer improved resistance to crack propagation as the mean stress is increased (Ref 5). These polymers include ABS, HIPS, PC, low density or branched polyethylene, low molecular weight PMMA, and rubber-toughened PMMA (Table 1). Hertzberg postulated that the strain energy normally available for crack extension is consumed through deformation or structural reorganization ahead of the crack tip. The use of strain energetics to describe fracture processes in polymers (Ref 1, 36) is formulated:

$$E = E_0 \cdot \left[\frac{C}{C - f(\psi)} \right] \quad (\text{Eq 17})$$

Here E is the total energy used by the solid to create a new unit area of surface through crack advance, E_0 is the energy expended for an ideal elastic solid, C is a material constant that depends on the strain state of the polymer, and ψ is the hysteresis ratio. The energy lost due to inelastic energy expenditure is captured by ψ . If the energy loss is large, the amount of energy needed to cause fracture increases; hence, it is expected that the crack growth rate will be reduced as ψ increases. Hertzberg and Manson (Ref 5) proposed that the effect of mean stress on the fatigue crack propagation resistance of polymeric materials is directly linked to the parameter, ψ . Thus, polymeric materials with a molecular structure susceptible to hysteretic losses or polymers capable of structural reorganization are likely to be more resistant to fatigue crack propagation as the mean stress is increased. These polymers have near tip processes that dissipate elastic energy ahead of the crack tip: rubber toughening, orientation hardening, chain slip, and shear banding.

Variable amplitude fatigue plays an important role in the design of polymeric components subjected to variations in the load cycle. Further, variable amplitude fatigue is a concern for components likely to experience periodic or unanticipated tensile or compressive overloads. It is conventional to model the effect of variable amplitude loading using the concept of cumulative damage (e.g., Palmgren-Miner mean accumulation rule).

While this concept has strength in crack initiation models, it does not capture the role of overload type or order in the loading sequence and the subsequent effect on a propagating crack.

Application of a single tensile overload can extend the life of a cracked component by retarding the rate of crack advance (Ref 13). This transient crack propagation behavior is often controlled by several mechanisms including crack closure (Ref 37), residual compressive stresses upon unloading (Ref 31, 38, and 39), and crack-tip blunting (Ref 40). The closure concept justifies the retardation of crack velocity in terms of residual compressive stresses left in the plastically deformed wake of the advancing crack. The result is premature contact between the crack faces while the specimen is still in the tensile portion of the fatigue cycle, and it effectively reduces the stress intensity range driving the crack advance. This crack closure mechanism has been proposed by Pitoniak et al. (Ref 41) to describe crack retardation in PMMA and by Murakami (Ref 42) for PC. Blunting has been proposed to describe the reduced crack velocity following tensile overloads (Ref 43). Although crack-tip blunting can temporarily affect the crack velocity subsequent to the overload, it does not explain a prolonged regime of crack retardation. Pruitt et al. (Ref 44) have shown that the zone of residual compressive stresses sustained at the crack tip upon unloading in amorphous polymers increases in size and magnitude as the far-field tensile load is increased. These residual compressive stresses sustained at the crack tip are believed to decrease the crack propagation rate following the tensile overload. The crack has to grow through this zone of residual compression before it can return to its initial crack propagation rate for the ΔK sustained prior to overload. This trend has been observed in numerous polymer systems (Ref 35, 44). Many current life prediction models are formulated on the basis of residual compressive stresses for the rationalization of crack retardation.

Compressive overloads can also be detrimental to the life of a structural component as the overload can result in an enhanced rate of crack propagation. The application of fully compressive cyclic loads results in the inception and growth of fatigue cracks ahead of stress concentrations and notches in polymers (Ref 39, 44). Figure 13 shows the nucleation and growth of a mode I fatigue crack in the plane of the notch as a result of cyclic compression loading in HIPS. The source of this crack growth is the generation of a zone of residual tensile stresses upon unloading from far-field compression. Permanent deformation ahead of the notch tip in polymers can be induced by crazing, shear flow, chain reorientation, or a combination thereof (Fig. 14). In summary, the application of compressive overloads to polymers with stress concentrations can result in the generation of residual tensile stresses and concomitant enhancement of crack velocity resulting in shortened component life.

Fig. 13 Optical micrographs showing the nucleation and growth of a mode I fatigue crack in the plane of the notch as a result of cyclic compression loading in HIPS. Waveform and Frequency Effects. Many polymers, due to the viscoelastic nature, are highly sensitive to the waveform or frequency of a fatigue test. Some crazeable polymers, such as PS, PMMA, and HIPS, exhibit decreased crack propagation as the test frequency is increased, while materials such as PC, nylon, and polysulfone exhibit no sensitivity (Ref 5). In crazeable polymers, the increased test frequency can diminish chain disentanglement effects at the crack tip and result in a decreased rate of crack propagation. Wnuk (Ref 45) proposed that the crack propagation in a polymer could be described as the sum of the elastic and viscoelastic contributions:

$$\frac{da}{dN} = C_1 \left(\frac{\Delta K}{K_{Ic}} \right)^{n_1} + C_2 \left(\frac{\Delta K}{K_{Ic}} \right)^{n_2} \cdot \frac{1}{\nu} \quad (\text{Eq 18})$$

where K_{Ic} is plane-strain fracture toughness, and the first term is the elastic contribution, which includes an elastic compliance term, C_1 . The second term is the time-dependent contribution, which includes a creep compliance term, C_2 , and the test frequency, ν .

Strain rate can also play a critical role in the fatigue response of time-dependent polymers. Hertzberg et al. (Ref 46) found strong sensitivity to waveform in PVC, PS, PMMA, and especially vinyl urethane. The square wave provides a high strain rate in ramp-up, then it subjects the specimen to a longer period of peak load than a triangular waveform with the same stress amplitude. This difference in load function can cause major differences in fatigue crack propagation. For example, in vinyl urethane (VUR), the fatigue crack propagation rate is reduced by a factor of 6 when switching from a triangular to a square wave loading function (Ref 47). This behavior is attributed to the higher strain rate that dominates for very flexible polymers, such as VUR. Another important factor is the amount of creep sustained at the peak load of the fatigue cycle. Polymers, such as PMMA, that are susceptible to creep damage will generally perform poorly when tested under the square waveform loading due to creep at peak load (Ref 46).

Environmental factors can play a critical role in the fatigue performance of engineering polymers. Many amorphous polymers are known to be susceptible to chemically induced crazing (Ref 5). In such instances, the crack inception values can be substantially reduced in the presence of aggressive media (Ref 5). For example, PC is known to nucleate surface crazes in the presence of acetone vapor. Many rubbers are susceptible to oxidation-induced embrittlement (Ref 48). Many medical polymers, such as orthopedic grade ultrahigh molecular weight polyethylene (UHMWPE) or bone cement (PMMA), degrade due to oxidation embrittlement and chain scission. These mechanisms are induced by ionizing modes of sterilization and subsequent aging (Ref 49, 50, 51, 52, 53, 54, 55, 56, 57, and 58). An example of the embrittling effect of gamma radiation sterilization on the fatigue crack propagation resistance of medical grade UHMWPE used for total joint replacements is provided in Fig. 15. While not all aggressive environments and effects on polymers are discussed here, it is clear that care should be taken to conduct fatigue tests that mimic not only the mechanical loads but also the chemical and aging environments that are most likely to be encountered in the lifetime of the device.

Fig. 15 Fatigue plot illustrating the devastating effect of gamma radiation sterilization on the fatigue resistance of orthopedic grade ultrahigh molecular weight polyethylene used for total joint replacements

Fatigue Testing and Behavior of Plastics

Lisa A. Pruitt, University of California at Berkeley

Fractography

One of the most useful tools in failure analysis is fractography, the study of fracture surfaces. Scanning electron microscopy (SEM) can provide vast insight into failure mechanisms of polymers subjected to cyclic loading. Analysis of the surface with SEM provides the site of crack inception. Discontinuous growth bands are often encountered with polymers that undergo crazing. In such instances, the damage must accumulate before the leading fiber can fail and the crack can advance. This results in discontinuous growth bands or markings that are observed in fractography (Ref 5). Fractographic examination can also provide information on the formation of discontinuous or continuous crack growth bands. Figure 16(a) shows the typical ductile mechanisms observed in pristine UHMWPE, while Fig. 16(b) shows a typical brittle failure in acrylic-based bone cement. Fractography can provide useful insight into the nature of fracture processes acting at the crack tip and is a valid supplement for thorough fatigue characterization of engineering polymers (Ref 59).

Fatigue Testing of Brittle Solids

J.A. Salem, Glenn Research Center at Lewis Field; M.G. Jenkins, University of Washington

Introduction

CERAMICS AND GLASSES subjected to static or cyclic loads exhibit time-dependent failure due to the growth in inherent and induced flaws to a critical size (Ref 1, 2, 3, 4, 5, 6, and 7). Cyclic loading is not required to generate crack extension. Hence, the phenomenon is referred to as “static fatigue.” The phenomenon is also referred to as subcritical crack growth, stress corrosion, delayed failure, slow crack growth, or environmentally induced fatigue.

This phenomenon depends on the chemical makeup and temperature of the environment and the applied stress-intensity factor. For relatively low stress-intensity factors, a fatigue limit below which crack growth arrests has been measured for static loading (Ref 8, 9, 10, and 11). However, the threshold occurs at low velocities, and the threshold is generally ignored in engineering applications.

Although slow crack growth is more severe for glass and glassy polycrystalline ceramics, single crystals such as sapphire and magnesium fluoride also exhibit time-dependent failure under static loads (Ref 12, 13, and 14). Thus, the structural application of glasses and ceramics requires consideration of static fatigue or slow crack growth behavior, and testing standards (Ref 15, 16, 17, 18, and 19) have been developed to generate data and determine fatigue parameters for materials screening and life prediction. Two types of flaws are generally used in the determination of the slow crack properties of ceramics: short, inherent flaws or long, induced cracks. Although machining processes such as surface grinding can introduce flaws, such flaws are generally short enough to be treated as inherent flaws. In some cases, the material can be heat treated (Ref 20) or etched (Ref 21) to minimize the presence of such populations. The testing standards focus on preexisting flaws within the material and allow those flaws to grow until catastrophic failure occurs. The fatigue parameters are inferred from strength data instead of by direct measurement of the crack growth.

In addition to the crack growth due to an environmentally induced stress corrosion mechanism, many ceramics materials exhibit enhanced fatigue crack growth during cyclic loading, and cyclically induced fatigue crack growth has been measured in vacuum (Ref 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, and 32). This behavior is somewhat akin to that exhibited by metals, and measurements with short cracks can be considerably different from those measured with long cracks. This sensitivity to crack length is a consequence of the mechanisms used to toughen ceramics (e.g., grain bridging in the crack wake), which are extrinsic in nature. Fatigue crack growth of long cracks in toughened ceramics results as the toughening mechanism breaks down during load reversals, whereas for short cracks or ceramics without the presence of a toughening mechanism, crack growth is dominated by environmental factors and intrinsic fatigue mechanisms. Factors such as grain size and grain boundary phase, which generally relate to the toughening or environmental sensitivity, influence the sensitivity to cyclic loading (Ref 29, 30, 31, 32, and 33).

The distinction between environmentally induced fatigue and cyclically induced fatigue is not always clear, and some ceramics will exhibit a combination of both mechanisms.

Structural components made from ceramics materials that are expected to have long lives will fail from small cracks developed over long times. Thus, the development of standardized cyclic fatigue test methods has also revolved around the use of small, inherent flaws.

Fatigue Testing of Brittle Solids

J.A. Salem, Glenn Research Center at Lewis Field; M.G. Jenkins, University of Washington

Fatigue Mechanism

Fatigue mechanisms in brittle solids can be classified as environmentally induced fatigue or as cyclic fatigue. Environmentally Induced Fatigue. Environmentally induced, or static, fatigue in ceramics and glasses is a chemically activated atomic reaction that is enhanced by stress and temperature. Crack growth occurs by breakage of the bonds at the crack tip. In particular, the introduction of water to the environment can have a severe effect on the fatigue parameters, and the moisture in air is sufficient to cause crack growth in ceramics and glasses subjected to stress.

For aqueous solutions, the rate of crack growth is increased with the increasing concentration of OH⁻ ions, which break the metal-oxygen-metal bonds in silicate glass and oxide ceramics. For nonoxide ceramics that do not contain a glassy phase (e.g., SiC), the presence of room temperature water vapor may have little effect on crack growth rates. Acid base pairs have the strongest influence on crack growth (Ref 14, 34). Michalske et al. (Ref 34) developed an atomistic model addressing the role of mechanical strain in accelerating chemical reactions between crack tip bonds in silica and environmental molecules. The strain field at the crack tip deforms the Si-O bond angle, thereby resulting in bond defects that increase the chemical activity of the bonds. Chemisorption of the attacking species results in bond breakage. The absolute rate of crack extension depends on the combined rates of active bond formation and chemical attack at strain-induced defects.

Additional studies on the {1012} of sapphire in water, ammonia, hydrazine, and acetonitrile indicated the same mechanism—dissociative chemisorption—but with different details that make the fatigue parameter more sensitive to the specific environment (Ref 14).

In contrast to the slow crack growth mechanism in sapphire, that in magnesium fluoride, which is ionically bonded, appeared to be ionic solvation of strained ions at the crack tip. The actively corrosive environments, in this case, water, methanol, and acetonitrile, reduced the electrostatic attraction between oppositely charged ion pairs at the crack tip.

For corrosive environments such as elevated temperature water or pressurized steam, silicon nitrides undergo severe pitting or grain loss, depending on the oxide additives and grain morphology (Ref 35, 36). For silicon nitride with amorphous silica at the grain boundaries, intergranular corrosion results in the Si₃N₄ grains falling out. However, for silicon nitrides with even small amounts of oxide additives, the leachability of the grain boundary is substantially changed. Depending on the additives, pits form under either a protective or nonprotective corrosion layer (Ref 35). The implication for environmentally induced crack growth is that harsh environments involving elevated temperature steam, such as turbines, will result in substantially accelerated crack growth.

Cyclic Fatigue. A variety of mechanisms have been proposed to result in cyclically induced fatigue in ceramics (Ref 26, 29, 30, 31, 32, 33, 37, 38, and 39). Generally, the fatigue mechanism is related to the crack growth resistance mechanism of the particular material. For example, the breakdown of bridging grains or transformation zones that produce *R*-curve effects in silicon nitrides and transformation-toughened zirconia. Also, mechanisms such as the coalescence of microcrack clusters at grain boundaries have been proposed (Ref 39). As the material is cycled, the toughening mechanism is broken down, thereby increasing the crack tip stress-intensity factor, allowing crack extension until the crack growth resistance redevelops.

One of the most critical aspects of cyclic fatigue testing is the size of the crack used. Results generated with long cracks can be substantially different from those generated with short cracks (Ref 28, 40).

Strength-Based Test Methods

Strength-based methods or “indirect” methods employ smooth test specimens, such as flexural beams or tensile specimens, and estimate fatigue properties from strengths measured over different time intervals. Strength-based methods directly sample the flaw distribution within or on the surface of the test specimens. The cracks thus develop from at least some of the same sources as in a component of the same material. However, the results are subject to the scatter inherent in the strength distribution of the material, and thus a relative large number of tests are required. Further, strength-based methods do not measure the actual crack size but infer it from the measured strength.

Three basic strength test methods and accompanying analytical relations have been developed for determining the fatigue parameters and behavior of ceramics and glasses: static loading, dynamic loading, and cyclic loading.

Static Loading. Typically, tensile specimens or flexure specimens (e.g., beams or plates) are subjected to a constant load in the environment of interest. The time-to-failure and the applied stress are recorded and used to determine the fatigue parameters according to any of the Eq 1, 2, 3, 4, and 5. The generalized slow crack growth behavior for static loading is shown in Fig. 2.

Fig. 2 Generalized failure stress as a function of time-to-failure on a logarithmic scale for ceramics and glasses exhibiting environmentally induced slow crack growth

One test method, Japanese Industrial Standard (JIS) 1632 “Test Methods for Static Bending Fatigue of Fine Ceramics,” has been standardized for the determination of fatigue strength by static loading (Ref 18) at room or elevated temperatures. The standard gives guidance on the test method but not in the calculation of fatigue parameters such as A and n .

Uniaxial flexural test specimens are manufactured and tested in three- or four-point loading in accordance with JIS R 1601, “Test Method for Flexural Strength (Modulus of Rupture) of Fine Ceramics” (Ref 56). The use of at least three stress levels is recommended, and the breaking times at one of the stress levels must be distributed between 0 and 100 h, minimum. No requirement on the number of test pieces is specified; however, three tests per stress level are recommended. Tests may be stopped after 100 h if failure has not occurred. An initial fatigue stress equal to 75% of the fracture strength is used. Subsequent stresses differing by 5 to 10% from the initial fatigue load are applied, depending on the initial time-to-failure and scatter in the data. An example of failure stress data as a function of the failure time is shown in Fig. 3 (Ref 18).

Fig. 3 Example of failure stress as a function of time-to-failure on a logarithmic scale for ceramics and glasses exhibiting environmentally induced slow crack growth. Adapted from Ref 18

The stress at fracture or fatigue strength σ_f , is related to the time-to-failure, t_f , by (Ref 43, 57, and 58):

$$t_f = \frac{B}{\sigma_f^2} \left[\left(\frac{\sigma_i}{\sigma_f} \right)^{n-2} - 1 \right] \quad (\text{Eq 7})$$

where B is a parameter associated with A , n , fracture toughness, crack geometry, and loading configuration, and σ_i is the “inert” strength or the strength under noncorrosive conditions for which no crack extension occurs. For most ceramics and glass, $n > 10$ so that Eq 7 can generally be simplified to:

$$t_f = B \sigma_i^n \sigma_f^{-n} \quad (\text{Eq 8})$$

The fatigue parameter n can be determined from the slope of a $\log t_f$ versus $\log \sigma_f$ plot by writing Eq 8 as:

$$\log t_f = -n \log \sigma_f + \log D \quad (\text{Eq 9})$$

where

$$\log D = \log(B \sigma_i^n) \quad (\text{Eq 10})$$

Once the slope and intercept of Eq 9 are estimated, the parameters n and D and the standard deviation SD_n and SD_D can be estimated by a Taylor series expansion of the random variable of interest (Ref 59):

$$n = -\alpha \quad (\text{Eq 11})$$

$$SD_n \approx SD_\alpha \quad (\text{Eq 12})$$

$$D = 10^\beta \quad (\text{Eq 13})$$

$$SD_D \approx (\ln 10)(SD_\beta)(10^\beta) \quad (\text{Eq 14})$$

where α is the slope and β is the intercept estimated by linear regression of Eq 9. For some design codes, the fatigue parameters B and A are necessary (Ref 60, 61, 62). The parameter B and the standard deviation can be estimated from:

$$B = 10^\beta \sigma_i^{\alpha+2} \quad (\text{Eq 15})$$

$$SD_B \approx 10^\beta \sigma_i^{\alpha+2} \sqrt{2 \ln(10) SD_\beta^2 - \frac{\alpha+2}{\sigma_i^2} SD_{\sigma_i}^2 + \ln(\sigma_i)^2 SD_\alpha^2} \quad (\text{Eq 16})$$

The parameter A in Eq 2 can be calculated from:

$$A = \frac{2 K_{lc}^2}{BY^2(n-2)} \quad (\text{Eq 17a})$$

or

$$A = \frac{-2 K_{lc}^2}{10^\beta \sigma_i^{\alpha+2} (\alpha+2) Y^2} \quad (\text{Eq 17b})$$

with

$$SD_A \approx A \sqrt{(\ln 10)^2 SD_\beta^2 + \frac{(\alpha+2)^2}{\sigma_i^2} SD_{\sigma_i}^2 + \left(\ln \sigma_i + \frac{1}{\alpha+2} \right)^2 SD_\alpha^2} \quad (\text{Eq 18})$$

where Y is the stress-intensity factor coefficient and treated as a constant.

Note that plots of static fatigue data (e.g., Fig. 3) are usually made with the applied stress appearing as the dependent variable; however, the dependent variable actually is the time-to-failure, and it must be minimized in the regression analysis.

Dynamic Loading. Typically, tensile or flexure test specimens (e.g., beams or plates) are subjected to a constant stress rate in the environment of interest. The failure stress and the applied stress rate are recorded and used to determine the fatigue parameters according to any of the Eq 1, 2, 3, 4, and 5. Figure 4 illustrates the observed strength as a function of stress rate for dynamic loading. A detailed error analysis has been conducted for dynamic loading (Ref 63).

Fig. 4 Generalized fracture strength as a function of stress rate on a logarithmic scale for ceramics and glasses exhibiting environmentally induced slow crack growth

Two test methods have been standardized for the determination of fatigue strength by dynamic loading (Ref 15, 17). One standard (Ref 17), ASTM C 1368 “Standard Test Method for Determination of Slow Crack Growth Parameters of Advanced Ceramics by Constant Stress-Rate Flexural Testing at Ambient Temperature” also

gives detailed guidance in the calculation of the fatigue parameter n , based on Eq 2. The standard uses uniaxial flexural test specimens that are manufactured in accordance with ASTM C 1161 “Standard Test Method for Flexural Strength of Advanced Ceramics at Ambient Temperature” (Ref 64) and tested in four-point flexure. A total of 40 test specimen loaded at four stress rates that cover at least three orders of magnitude are required, with a minimum of four tests at any of the rates. An example of failure stress data as a function of the stress rate is shown in Fig. 5. The stress at fracture or fatigue strength, σ_f , is related to the stress-rate, $\dot{\sigma}$, by (Ref 57, 58):

$$\sigma_f = [B(n+1)\sigma_i^n \dot{\sigma}]^{1/n+1} \quad (\text{Eq 19})$$

where B is a parameter associated with A , n , fracture toughness, crack geometry, and loading configuration, and σ_i is the inert strength. The fatigue parameter n can be determined from the slope of a $\log \sigma_f$ versus $\log \dot{\sigma}$ plot by writing Eq 19 as:

$$\log \sigma_f = \frac{1}{n+1} \log \dot{\sigma} + \log D \quad (\text{Eq 20})$$

where

$$\log D = \frac{1}{n+1} \log [B(n+1)\sigma_i^{n-2}] \quad (\text{Eq 21})$$

Fig. 5 Example of failure stress as a function of stress rate on a logarithmic scale for ceramics and glasses exhibiting environmentally induced slow crack growth. Adapted from Ref 17

The dependent variable is the fracture stress, and regression is performed to minimize fracture stress variation. Once the slope and intercept of Eq 20 are estimated, the parameters n and D and the standard deviation SD_n and SD_D are estimated from:

$$n = \frac{1}{\alpha} - 1 \quad (\text{Eq 22})$$

$$SD_n \approx \frac{SD_\alpha}{\alpha^2} \quad (\text{Eq 23})$$

$$D = 10^\beta \quad (\text{Eq 24})$$

$$SD_D \approx (\ln 10)(SD_\beta)(10^\beta) \quad (\text{Eq 25})$$

where α and β are the slope and the intercept, respectively, estimated by linear regression of Eq 20. These formulation follow a recently published standard (Ref 17) and provided values of n and D . For some design codes, however, the parameters B and A are necessary (Ref 60, 61, and 62). The parameter B and the standard deviation can be estimated from:

$$B = \frac{\alpha 10^{\beta/\alpha}}{\sigma_i^{-3+(1/\alpha)}} \quad (\text{Eq 26})$$

and

$$SD_B \approx \frac{10^{\beta/\alpha}}{\sigma_i^{-3+(1/\alpha)}} \left\{ \ln 10^2 SD_\beta^2 + (\alpha - \beta \ln 10 + \ln \sigma_i)^2 \times \frac{SD_\alpha^2}{\alpha^2} + \frac{(1 - 3\alpha)^2}{\sigma_i^2} \right\}^{-0.5} SD_{\sigma_i}^2 \quad (\text{Eq 27})$$

The parameter A corresponding to Eq 2 can be calculated from Eq 17aa or with the standard deviation of A from:

$$A = \frac{2K_{Ic}^2 (\hat{\sigma}_i)^{-3+(1/\alpha)}}{10^{\beta/\alpha} (1 - 3\alpha) Y^2} \quad (\text{Eq 28})$$

$$SD_A \approx A \left\{ 4 \frac{SD_{K_{Ic}}^2}{K_{Ic}^2} + \frac{(\ln 10)^2}{\alpha^2} SD_\beta^2 + \left(\frac{1}{\alpha} - 3 \right)^2 \times \frac{SD_{\sigma_i}^2}{\sigma_i^2} + \left[\alpha - \beta \ln 10 + \ln \sigma_i - \left(\frac{1}{\alpha} - 3 \right)^{-1} \right]^2 \times \frac{SD_\alpha^2}{\alpha^4} \right\}^{-0.5} \quad (\text{Eq 29})$$

In order to verify that the dynamic fatigue methodology is sufficiently robust for industrial use in the development of design data, several round-robin test programs have been performed (Ref 65, 66, 67, and 68). One round-robin involved dynamic fatigue testing of eight ceramic materials (Ref 65), with a given material being tested by only one research institute and one manufacturer. A total of 30 specimens were tested in distilled water at three to four stress rates ranging from 10^{-2} to 10 MPa/s. In addition, the inert strength and Weibull modulus were measured at 100 MPa/s. As Fig. 6 illustrates, good agreement occurred between the research and industrial laboratories for materials with a low fatigue parameter, n , but poor agreement for materials with a high fatigue parameter. It was believed that increasing the number of test specimens would improve the results, as a single data point tended to have an unduly large effect on the slope for materials with high n values.

Fig. 6 Round-robin results comparing fatigue parameters of various ceramics determined by using dynamic loading. SSN, sintered silicon nitride; RBSN, reaction-bonded silicon nitride; ZTA, zirconia-toughened alumina; HPSN, hot pressed silicon nitride. Source: Ref 66

A second round-robin tested alumina flexure specimens in distilled water (Ref 66, 67). The participants were instructed to test 15 specimens in the as-received condition and 15 specimens with a 5 kg indentation. Most participants covered less than two orders of magnitude in the stress rate, and the combined participant data covered nearly five orders of magnitude. Figure 7 summarizes the fatigue parameters generated by the participants for the as-received condition. Generally, the results improve as the number of specimens increases from 15 to 33. However, even 33 test specimens can be inadequate. Most troublesome is the fact that the fatigue parameter has been overestimated two out of three times. If the data points that appear to be outliers are removed, a slight improvement results, as shown in Fig. 8. Although the final recommendations from the round-robin were not published, the initial recommendations were that at least three orders of magnitude be covered. Also, for testing at rates greater than 100 MPa/s, a piezoelectric load cell was recommended.

Fig. 7 Round-robin results comparing estimated fatigue parameters measured by dynamic loading of an alumina in distilled water

Fig. 8 Round-robin results comparing estimated fatigue parameters for an alumina in distilled water. Outlying data were censored.

The effect of the range of the stress rate can be seen in Fig. 9. If three orders of magnitude are covered, the estimated value of n improves somewhat; however, more data are needed. It is not effective to increase the number of tests without increasing the stress range. For example, one data set consisting of 33 tests measured over 2.4 orders of magnitude still resulted in an estimated fatigue parameter three times greater than that for all the data. Based on these results, it appears that at least 30 specimens and three orders-of-magnitude separation

are required. Better results from a statistical viewpoint could be attained by testing $\frac{1}{2}$ of the specimens at the lowest rate and $\frac{1}{2}$ at the highest rate (Ref 63).

Fig. 9 Round-robin results comparing estimated fatigue parameters for an alumina tested in distilled water. Numbers in parentheses represent the number of specimens tested.

The round-robin results prompted the National Physical Laboratory to sponsor a follow-up, United Kingdom only, round-robin (Ref 68). This led to another testing standard, ENV 843-3 “Determination of Subcritical Crack Growth Parameters from Constant Stressing Rate Flexural Strength Tests” (Ref 15).

Cyclic Loading. Cyclic loading of ceramics and glasses has been performed for quite some time (e.g., Ref 1). Initial results on glasses and materials with glass boundaries indicated little synergy of cycling on the life. Thus, simpler test methods such as static and dynamic loading have generally been used, and the analysis adjusted to account for load variation (Ref 45). However, as ceramics materials have been made less glasslike by devitrification treatments and have been toughened by elongating the grain structure, transformation toughening, or adding second phase particles, cyclic loading has been recognized as a significant issue (Ref 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, and 32), and fatigue effects independent of the environment have been measured.

Two testing methods have been standardized for the determination of cyclic fatigue strength of ceramics (Ref 16, 19). The standards focus on the method of data generation and give no guidance on how the data are to be used. The two standards are somewhat complementary because one uses flexure of rectangular beam (Ref 16), while the other uses uniaxial tension (Ref 19).

Test method JIS R 1621 “Testing Method for Bending Fatigue of Fine Ceramics” (Ref 16) recommends applying a 20 Hz sinusoidal wave with an R -ratio of 0.1 to standard three- or four-point flexure configurations (Ref 56). Other waveforms and frequencies are allowed. Three tests at three different maximum stress levels that result in specimen fracture before 10^7 cycles are recommended. If three tests in a row result in lives greater than 10^7 cycles, the remaining tests are conducted at a higher stress. The initial stress level is based on the monotonic strength of the materials as measured with the same specimen and testing configuration. Testing can

be halted after 10^7 cycles. An example of failure stress data as a function of the applied cycles is shown in Fig. 10.

Fig. 10 Example of the cycles to fracture for a ceramic material subjected to cyclic loading. Adapted from Ref 16

Axial cyclic tensile fatigue testing can be performed with ASTM C 1361 “Standard Practice for Constant-Amplitude, Axial Tension-Tension Cyclic Fatigue of Advanced Ceramics at Ambient Temperatures” (Ref 19). Any of the tensile test specimens specified in ASTM C 1273 “Standard Test Method for Tensile Strength of Monolithic Advanced Ceramics at Ambient Temperatures” (Ref 69) are allowed. These include a variety of cylindrical button-head specimens, pin-loaded dog-bone specimens, and shoulder-loaded dog-bone specimens. The standard allows any frequency, waveform, and R ratio as needed for a particular application. A test may be terminated for any of four reasons: specimen fracture, reaching a predetermined number of run-out cycles, reaching a predetermined specimen compliance or material elastic modulus, or reaching a predetermined phase lag between control mode and response.

Tension-compression cyclic fatigue has been attained by use of the button-head tensile specimen and a clamping and alignment fixture (Ref 39). Fully reversed bending fatigue can also be attained with flexure specimens by use of two symmetric sets of load and support pins (Ref 70).

Another cyclic fatigue test method that has been applied to ceramics is rotary bending (Ref 71, 72). This approach is particularly relevant to applications involving shafts, such as ceramic turbocharger rotors. The method avoids problems associated with edge finish by using cylindrical specimens, and a wide range of frequencies is easily attained. Tests run on alumina and silicon nitride at 57 Hz indicate a linear $S-N$ curve to 10^7 cycles at which an indistinct knee occurs, implying a fatigue limit at $\sim 10^8$ cycles. The endurance stress corresponded to about $\frac{1}{4}$ of the strength of the alumina and about $\frac{1}{2}$ that of the silicon nitride. The fatigue parameter n was 13 for the alumina and 25 for the silicon nitride, respectively, which is lower than those typically determined for aluminas and silicon nitrides by static or dynamic techniques. The differences in the fatigue parameters were attributed to the effect of reversed bending.

Cyclic fatigue of ceramics has also been performed by using cantilever bending of rectangular, dog-bone, and tapered-beam test specimens at a variety of frequencies. Tapered beams and dog-bone specimens reduce the probability that failure will occur at the support where the stress is a maximum. Figure 11 illustrates a tapered-cantilever beam used to obtain 3000 Hz accelerated fatigue data on silicon nitride (Ref 39).

Fig. 11 Schematic of a high-frequency, tapered-cantilever beam test apparatus. Source: Ref 39

Testing of silicon nitride using tapered-cantilever beams at frequencies as high as 3000 Hz indicated a fatigue limit at 40% of the monotonic strength (Ref 39). Interestingly, the life depended on the number of cycles rather than the time and was well described by the modified Goodman diagram used to describe metallic fatigue. The probability of failure was well described by the Weibull model. Axial tension-compression testing of the same sintered silicon nitride indicated a fatigue limit around 10^7 cycles at a stress of 60% of the strength and an increase in fatigue strength with increasing R ratio. The implication for this particular silicon nitride is that a cyclic effect, rather than environmentally induced stress corrosion, dominated crack growth.

Tests using dog-bone specimens at 30 Hz (Ref 73) indicated no effect of cycling on the strength of two different silicon nitrides for less than 10^7 cycles; however, relatively few specimens were tested. At temperatures of 1200 and 1300 °C (2190 and 2370 °F), the effects of fatigue were more pronounced.

In contrast to the reversed fatigue results, tension-tension flexure fatigue of reaction-bonded, hot pressed, and sintered silicon nitrides indicated environmentally related crack growth to be the failure-controlling mechanism (Ref 74).

Fatigue testing of magnesia-partially-stabilized zirconia by using straight cantilever beams indicated a fatigue limit around 10^8 cycles at a stress of 50% of the tensile strength (Ref 40). Reversed loading significantly shortened the life of the material as compared with tension-tension loading.

Generally, servohydraulic actuators are used to generate cyclic fatigue loading of test specimens. However, piezoelectric actuators in the form of stacks and cantilever spring plates also have been used (Ref 75, 76). These systems allow relatively high frequencies (30 to 550 Hz) and compact test frames that do not require a hydraulic pressure source. Figure 12 illustrates the test apparatuses.

Fig. 12 Schematics of test apparatuses using piezo-electric ceramics to generate fatigue loading of ceramic beam specimens. Source: Ref 75, 76

Cyclic fatigue test results indicate substantial changes in the mechanism controlling crack growth (i.e., cyclically induced versus environmentally induced) for different materials. Fatigue behavior for a given ceramic (e.g., silicon nitride) depends on factors such as the grain boundary phase, grain size, and the fracture mode (transgranular versus intergranular). Thus, fatigue testing needs to consider both environmentally induced and cyclically induced crack growth.

Fatigue Testing of Brittle Solids

J.A. Salem, Glenn Research Center at Lewis Field; M.G. Jenkins, University of Washington

Fracture Mechanics Methods

Fracture mechanics methods or "direct" methods generally employ test specimens with relatively large, induced cracks. Crack growth data is typically determined directly by observation of the crack or by devices that monitor test specimen compliance, such as clip gages and strain gages (Ref 77, 78). One exception to this is the double torsion specimen, which has a relatively constant stress-intensity factor, K_I , over a wide range of crack length. Thus, the K_I can be calculated without observation of the crack length. When used in this fashion, the method is effectively an indirect, long crack method.

Two general types of fracture mechanics specimen are employed: line loaded or flexural specimens. Line-loaded specimens such as the double torsion (DT), double-cantilever beam (DCB), or compact tension (CT) allow cracks to be extended over large distances. Flexural specimens such as notched and precracked beams can be scaled so that crack length is comparatively small or large.

The main advantage of fracture mechanics specimens is that large amounts of data can be derived from a single test specimen, and the results are not subject to the scatter associated with the natural flaw distribution that is sampled by strength techniques. However, as the cracks are large in comparison with those developed naturally in smooth specimens, the fatigue behavior may be different. In particular, for materials that exhibit transformation toughening or for materials with a coarse or elongated grain structure, a strong effect of crack length on crack growth resistance is exhibited. Figure 13 shows the effect of crack growth resistance on the stress-intensity factor for both long and short crack lengths. Although the same range of stress-intensity factors is measured, the rates at which resistance develops, and possibly the rate at which fatigue damages the resistance, are very different. Thus, techniques that use different crack length scales may result in different fatigue parameters.

Fig. 13 Crack growth resistance as a function of crack extension for alumina

The Double Torsion Method. The double torsion method, which was developed by Outwater and Gerry (Ref 79, 80) and developed further by other researchers (Ref 81, 82, 83, 84, 85, 86, 87, 88, and 89) is illustrated in Fig. 14. Detailed experimental and analytical analyses of the specimen have been given by Fuller (Ref 88) and Pletka et al. (Ref 89). Tests can be performed with or without a guide groove on one or both sides of the specimen. However, the use of a guide groove can lead to errors (Ref 90, 91), and elimination of the groove can be achieved by using thin, carefully aligned specimens. If side grooves must be used, wide grooves and thinner specimens help to avoid interaction between the groove wall and the crack.

Fig. 14 Schematic of the double torsion test specimen. Source: Ref 88

A variety of complications associated with the test specimen have been discussed and analyzed to varying degrees. These include crack front curvature leading to a variation in the stress-intensity factor along the crack front; variation in the stress-intensity factor with crack length; and poor reproducibility of data for certain conditions, particularly for polycrystalline ceramics when multiple load relaxations are performed with the same specimens.

Most noteworthy is the last of the problems just noted, as opposite trends have been observed for different materials. It seems that the crack-microstructure interactions, which are more prevalent for long cracks, may be the source of discrepancy.

Despite the complication associated with the DT, it does provide a simple geometry that is easy to load and crack. Further, for testing of opaque materials or for hostile environments, the constant stress-intensity factor is advantageous.

The stress-intensity factor for the DT method is (Ref 89):

$$K_{I dt} = PW_m \sqrt{\frac{3}{Wd^3 d_n (1 - \nu) \xi}} \quad (\text{Eq 30})$$

with:

$$\xi = 1 - 0.6302t + 1.20t \exp(-\pi/t)$$

where P is the applied force, W_m is half the test specimen width minus half the notch width, d is the total thickness, d_n is the notch depth, W is the total width, ν is Poisson's ratio, and ξ is a correction factor for thick test specimens where $t = 2d/W$. It has been recommended that the crack length be maintained between $W < a < L - W$, where a is the crack length and L is the length, to ensure that the crack is in the constant K_I region (Ref 88).

Three methods of loading DT specimens have been developed: constant load, constant displacement (Ref 83, 84) and load relaxation. The load relaxation technique has the advantage that less crack extension is required to obtain an accurate measure of crack velocity and stress intensity factor (Ref 88).

In the load relaxation technique, a precracked specimen is loaded rapidly in a displacement control mode (~ 0.2 to 0.5 mm/min, or ~ 0.01 to 0.02 in./min) to nearly the load required to cause specimen fracture. If the crack begins to move rapidly, the displacement is halted and the load is recorded as a function of time. Once the crack has stopped apparent movement, the test specimen is removed and the final crack length measured. The stress-intensity factor at any load is calculated from Eq 30, and the crack velocity from the slope of the load-time curve and either the specimen displacement or the crack length and load before or after the test (Ref 91):

$$v = \frac{da}{dt} = - \frac{Wt^3 Ey}{6W_m P^2 (1 + \nu)} \left(\frac{dP}{dt} \right)_y \quad (\text{Eq 31})$$

$$v = \frac{da}{dt} = - \frac{P_{i,f} a_{i,f}}{P^2} \left(\frac{dP}{dt} \right)_y \quad (\text{Eq 32})$$

where E is Young's modulus, P_i and a_i are the initial load and crack length values, respectively, and P_f and a_f are the values at the end of the relaxation.

The DCB Method. The double-cantilever beam (DCB) specimen has been used to test glass, sapphire, magnesium fluoride, and various polycrystalline ceramics (Ref 8, 14, 91, 92, and 93). Also, a form of the DCB specimen referred to as the *compact tension* has been standardized for fracture toughness testing of metals (Ref 52). A variety of methods can be used to apply load to the DCB specimen. These include wedge loading and the application of a constant moment (Ref 94). If a constant K_I is desired, the specimen can be tapered (Ref 95). Often, side grooves are used to guide the crack longitudinally. For the geometry shown in Fig. 15, the stress-intensity factor and fracture toughness can be determined from:

$$K_I = \frac{Pa}{h^{3/2} \sqrt{Bb}} \left(3.47 + 2.32 \frac{h}{a} \right) \quad (\text{Eq 33})$$

where P is the applied force, h is half height of the test specimen, B is the thickness of the test specimen, b is the Web thickness, and a is the crack length. Some advantages of this geometry are the constant stress-intensity factor for some configurations (e.g., tapered DCB or applied moment DCB), simple test specimen preparation, efficient material usage, and the simple loading configuration. The primary disadvantages are effects associated with the side groove and the difficulty of introducing a sharp crack.

Fig. 15 Double-cantilever beam (DCB) test specimen (Ref 8). Slots on both sides of the specimen for restraining the crack to the midplane are not shown.

Generally, crack growth measurements are made by optical observation of the crack on the side of the specimens while a constant load is applied. For glass, good agreement between DCB and strength measurements (Ref 8, 91) and between DCB and DT measurements have been obtained (Ref 86, 96).

Cyclic Fatigue by Other Fracture Mechanics Methods. Cyclic fatigue measurement using the direct or fracture mechanics approach can be classified into two crack-length regimes: long cracks made by using large specimens that are typically applied in metals testing (e.g., compact tension) or shorter cracks generated by indentation with Knoop or Vickers hardness indenters (Fig. 16). Both the DT and DCB, however, can be loaded cyclically.

Fig. 16 Flexure test specimen with a precrack formed by Vickers indentation

Both crack-length regimes have advantages and disadvantages. The core issue for both approaches is whether the behavior in real applications is represented. For long cracks this is basically an issue of scale, while for the short, indentation cracks, the residual stress field about the indentation and its changes during fatigue are an issue.

Probably the simplest method of long crack testing is the use of the single-edge-precracked-beam (SEPB) specimen. A precrack is formed by bridge indentation (Ref 97) and loaded in three- or four-point flexure. The crack extension can be monitored directly on the specimen sides, or by compliance measurements via extensometers, clip gages, strain gages (Ref 77, 78), or electrical grids (Ref 98, 99).

This method has been used to generate long crack fatigue data for silicon nitride in vacuum and air (Ref 30). The results indicate lower threshold stress-intensity factors for cyclic loading or air as compared with static loading or vacuum. The threshold is also a function of crack length and thus related to the crack growth resistance mechanism. No dependence on frequency was found between 0.5 and 20 Hz, however, and an effect of R -ratio was found.

The compact tension specimen has been used frequently to test ceramics (Ref 25, 33, 100, and 101), and long-crack data have been generated for comparison with short-crack data for materials such as SiC-whisker-reinforced alumina, pyrolytic carbon, and magnesia-partially-stabilized zirconia.

For magnesia-partially-stabilized zirconia, fatigue measurements with long cracks indicate a threshold at ~50% of the fracture toughness and the slowest growth rates for the materials with the most transformation toughening. However, for short, naturally developing cracks, growth occurs below the long-crack threshold, and, as with metals, a negative dependency of growth rate on stress intensity is exhibited.

Short fatigue crack testing of many ceramics is complicated by the infrequent development of natural cracks and the difficulty of detecting such cracks. This difficulty can be circumvented by precracking the polished

surface of a beam with a Vickers or Knoop indenter. The crack size during static or cyclic loading in four-point or cantilever flexure is monitored optically or via electron microscopy (Ref 29, 100, and 101). Multiple cracks can be placed on a single specimen.

Ideally, short cracks without the residual stress should be used, as is done in standardized fracture toughness testing (Ref 102). This can be accomplished by polishing the specimen until a sufficient amount of the indentation and crack has been removed.

A number of more exotic methods, such as compressive cyclic fatigue of notched specimens, have also been used to demonstrate cyclically induced fatigue in ceramics (Ref 103, 104).

Fatigue Testing of Brittle Solids

J.A. Salem, Glenn Research Center at Lewis Field; M.G. Jenkins, University of Washington

Comparison of Indirect and Direct Methods

Several researchers (Ref 105, 106, and 107) have noted that indirect techniques, such as dynamic fatigue, can result in large errors in the estimated fatigue parameters of polycrystalline ceramics exhibiting environmentally induced crack growth when the failure times are relatively short. Further, such methods cannot be used to accurately predict the life of components unless some precautions are taken. For example, for a mullite with a region I fatigue parameter of $n = 41$ as measured with the double-torsion method, the use of stress rates greater than 1 MPa/s resulted in an estimated value of $n = 19$ (Ref 105). For a silicon nitride with a parameter of $n = 66$, the values estimated from dynamic fatigue was $n = 100$. Similar differences were shown to exist between flexural data and double torsion data for magnesium alumina silicate ($n = 51$ versus 84) (Ref 89, 107).

This is a result of the fact that indirect methods average all three regions of the fatigue curves into a single region, and for short duration tests, all the regions are significant. However, in a component with a long life, region I is dominant.

One exception to this is static fatigue tests, in which the failure times tend to be long and the crack growth dominated by region I. The dynamic fatigue test might be made more applicable to the generation of design data for long-term applications by using stress rates that are sufficiently slow.

Fatigue Testing of Brittle Solids

J.A. Salem, Glenn Research Center at Lewis Field; M.G. Jenkins, University of Washington

Summary

Fatigue testing of ceramics and glasses is performed by either indirect or direct methods. Indirect or strength methods employ smooth tensile or flexure specimens and infer the fatigue parameters from strength measurements without crack length measurements. Direct methods employ either long cracks or short cracks, and the crack length is measured by observation of the crack or by inference from devices such as strain gages and electrical resistance grids. Long crack test specimens include fracture mechanics specimens such as the DT, DCB, CT, and SEPB. Short crack methods employ surface cracks formed by indentation, or surface cracks that develop naturally on the surface of a smooth test specimen. Structural ceramic and glass components that are designed to have long lives will fail from small cracks developed over long periods of time. The cracks will develop from either inherent processing flaws or from damage generated in component machining and handling (e.g., machining cracks). Cyclic loading, though not required to induce growth in glasses and many ceramics, tends to accelerate fatigue crack growth. Thus the measurement of fatigue parameters should be done with tests employing realistic crack sizes, environments, and the applicable load histories. As a result, the development of standardized static and cyclic fatigue test methods has revolved around the use of small, inherent flaws.

Multiaxial Fatigue Testing

Yukitaka Murakami, Kyushu University, Japan

Introduction

TESTS for combined-stress fatigue and multiaxial fatigue have been conducted since the early stages in the history of fatigue testing. In particular, the combined-stress fatigue test for cylindrical specimens has been used by many researchers. The main objective for classical studies of combined-stress fatigue was to obtain fatigue data for axles and to find the criterion for the fatigue limit under combined stress. Although recent studies still use essentially the same testing method, the main objective is to elucidate the factors that control the fatigue mechanism and particularly the behavior of small fatigue cracks.

The influence of loading history and phases is also a topic of recent studies. Cylindrical specimens or tubular specimens are mostly used for these studies. Perhaps the most important recent topic in multiaxial fatigue studies is the behavior of cracks. The threshold condition of macrocracks and crack propagation paths in large structures have been investigated by many researchers.

Although cracks mostly propagate by mode I (the opening tension mode), even under mixed mode loading, the propagation behavior is affected by mixed mode loadings due to various factors such as the size of the yield zone at the crack tip, crack closure, and friction between crack surfaces.

On the other hand, a crack seldom grows by pure mode II (sliding or shear mode) or mode III (tearing mode) in real structures. Some examples of mode II fatigue are contact fatigue damage in rolls of steelmaking mills, contact fatigue of rails and bearings, and fretting fatigue. In these cases, the criteria for the threshold condition for mode II cracks and the resistance to mode II crack growth are needed. Crack growth by mode III is the form studied in the torsional fatigue test of circumferentially notched specimens. Thus, the fatigue testing method, specimen geometries, and stress intensity factors are all important factors in the study of multiaxial fatigue.

Many factors of multiaxiality make the testing method more complicated than mode I fatigue testing, and, accordingly, many researchers, working independently, have developed their own original methods. This article first explains stress states of combined stress and stress fields near crack tips and then describes various multiaxial fatigue testing methods.

Multiaxial Fatigue Testing

Yukitaka Murakami, Kyushu University, Japan

Stress States

Most engineering designs and/or failure analyses involve three-dimensional combinations of stress and strain (multiaxiality) in the vicinity of surfaces and notches, which can be limiting in fatigue applications. This section provides a brief review of these stress states. Additional information is provided in the article “Multiaxial Fatigue Strength” in *Fatigue and Fracture*, Volume 19 of *Asm Handbook*.

Two dimensional stress states without cracking are defined in Fig. 1, where the basic relations are:

$$\sigma_1, \sigma_2 = \frac{(\sigma_x + \sigma_y) \pm \sqrt{(\sigma_x - \sigma_y)^2 + 4\tau_{xy}^2}}{2} \quad (\text{Eq 1})$$

where σ_1, σ_2 are the principal stresses. $\sigma_x = \sigma_0$ and $\sigma_y = -\sigma_0$ in Fig. 1(d), and this is equivalent to the case shown in Fig. 1(b) if $\tau_{xy} = \sigma_0$.

Fig. 1 Two-dimensional stress states without cracking

The yield criterion or yield stress, σ_Y , is:

$$\text{Tresca: } \sigma_1 - \sigma_2 = \sigma_Y \quad (\text{Eq 2})$$

$$\text{Von Mises: } \sigma_x^2 - \sigma_x \sigma_y + \sigma_y^2 + 3\tau_{xy}^2 = \sigma_Y^2 \quad (\text{Eq 3})$$

Stress states at the tip of a crack in combined mode I and mode II are defined by stress-intensity factors. K_I is the mode I stress intensity factor, and K_{II} is the mode II stress intensity factor. Radial stress (σ_r), normal stress (σ_θ), and shear stress ($\tau_{r\theta}$) in polar coordinate (r, θ) in the vicinity of the crack tip are given as follows (Fig. 2):

$$\sigma_r = \frac{1}{\sqrt{2\pi r}} \cos \frac{\theta}{2} \left[K_I \left(1 + \sin^2 \frac{\theta}{2} \right) + \frac{3}{2} K_{II} \sin \theta - 2 K_{II} \tan \frac{\theta}{2} \right] \quad (\text{Eq 4})$$

$$\sigma_\theta = \frac{1}{\sqrt{2\pi r}} \cos \frac{\theta}{2} \left[K_I \cos^2 \frac{\theta}{2} - \frac{3}{2} K_{II} \sin \theta \right] \quad (\text{Eq 5})$$

$$\tau_{r\theta} = \frac{1}{2\sqrt{2\pi r}} \cos \frac{\theta}{2} [K_I \sin \theta + K_{II} (3 \cos \theta - 1)] \quad (\text{Eq 6})$$

Fig. 2 Stress state near a crack in a polar coordinate

The direction (θ_0) where σ_θ has the maximum value is given by:

$$K_I \sin\theta_0 + K_{II} (3 \cos\theta_0 - 1) = 0 \quad (\text{Eq 7})$$

$$\tan \frac{\theta_0}{2} = \frac{1 \pm \sqrt{1 + 8\gamma^2}}{4\gamma}, \quad \gamma = \frac{K_{II}}{K_I} \quad (\text{Eq 8})$$

This equation gives $\theta_0 = \pm 70.5^\circ$ for pure mode II ($K_I = 0$).

The stress intensity factor that prescribes σ_θ is defined by:

$$\begin{aligned} K_{\theta \max} &= \sigma_{\theta \max} \sqrt{2\pi r} \\ &= \cos \frac{\theta_0}{2} \left[K_I \cos^2 \frac{\theta_0}{2} - \frac{3}{2} K_{II} \sin \theta_0 \right] \end{aligned} \quad (\text{Eq 9})$$

The maximum value ($K_{\theta \max}$) of K_θ for pure mode II is derived, substituting $\theta_0 = \pm 70.5^\circ$ into Eq 9. Thus:

$$K_{\theta \max} = 1.155 K_{II} \quad (\text{Eq 10})$$

Stress State at the Tip of a Crack in Mode III. If there is a semielliptical surface crack and the crack is subjected to pure shear (Fig. 3), the condition at the deepest point of crack front, *A*, is pure mode III, and the condition at surface corner points, *B* and *C*, is pure mode II, which means the branching angle at *B* and *C* by mode I crack growth is 70.5° under reversed torsion (Ref 1). (There have been some discussions among researchers about the irregular singularity close to the corner point where a crack meets the free surface. It is known that a mode I stress component in tension has a singularity different from $-\frac{1}{2}$. If $K_{III} \neq 0$ at the surface point, it means that there exists a shear stress τ_{yz} on the free surface. Therefore, K_{III} must be zero at points *B* and *C*.)

Fig. 3 A semielliptical surface crack under shear. A, pure mode III; B, C, pure mode II

Multiaxial Fatigue Testing

Yukitaka Murakami, Kyushu University, Japan

Testing of Cylindrical Specimens

Torsion-Rotating Bending Fatigue. In a classical type of torsion-rotating bending fatigue test, cylindrical specimens similar to those for rotating bending fatigue are used (Ref 2). A static twisting moment is applied through the axis of the specimen. In this type of machine, the normal stress in the rotating test piece is continuously varied between positive and negative stress of equal magnitudes. Furthermore, the steady shearing stress is simultaneously induced in the specimen by connecting the testing machine with an electric absorption dynamometer, which consists of a small direct-current dynamo placed on an iron frame suspended by ball bearing. The specimen geometry for this type of fatigue testing is essentially similar to those for rotating bending except for the special grip shape. This type of testing machine has still been used in recent studies (Ref 3). In another classical test, bending moment is coupled with twisting moment, which is loaded by the reversed motion of a fly wheel. The specimen geometry for this test is shown in Fig. 4.

Fig. 4 Specimen for conventional reversed torsion test. Dimensions are in mm. Source: Ref 4

Torsion Coupled with Tension Compression. Biaxial fatigue testing machines of the closed-loop type in which torsion can be coupled with tension-compression are now commonly used. In the closed-loop type of testing machine, torsion and tension-compression can be loaded independently in phase or out of phase. Figure 5 shows a biaxial fatigue testing machine of this type. Figure 6 shows the extensometer used to measure axial and angular displacement. A cylindrical specimen (Fig. 7) is the standard geometry for this type of testing machine.

Multiaxial Fatigue Testing

Yukitaka Murakami, Kyushu University, Japan

Testing of Specimens Containing Notches or Cracks

Rectangular plate specimens containing an inclined central or edge crack are used for crack propagation tests in mixed-mode loading (Ref 6, 7, and 8). The axial load is applied through the pins attached to the holes at the grips. A notch or crack is introduced by a saw or razor. If a fatigue crack is introduced in a wide plate by preliminary tension-compression fatigue, a specimen such as that shown in Fig. 9 can be prepared by cutting the plate (Ref 6, 7, and 8).

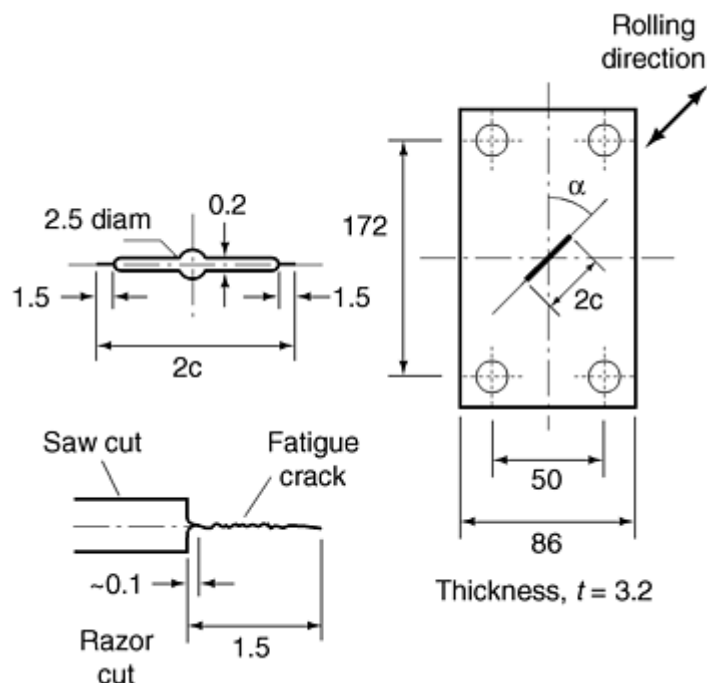

Fig. 9 Rectangular plate specimens containing an inclined center crack. Dimension are in mm. Source: Ref 7

Cruciform Specimen. The type of specimen shown in Fig. 10 is used to investigate the effect of plastic zone size or yielding at the tip of a crack. The stress intensity factor has the same value under the combination of an identical stress, σ_y , and a different stress, σ_x . However, the size of the yield zone at the crack tip is dependent on the value of the stress, σ_x , in the direction of the crack line.

Fig. 10 Cruciform specimen containing a central crack. Dimension are in mm. Source: Ref 9

Three-Point and Four-Point Bending Specimens with a Crack. In three-point bending (Fig. 11a), not only shear force but also bending moment is always induced at the crack and, accordingly, we have both K_I and K_{II} . On the other hand, in four-point bending, one can control the magnitude of bending moment at the crack by changing the location of loads. This can be done in such a way that there is only a K_{II} stress state at the crack tip (Ref 10).

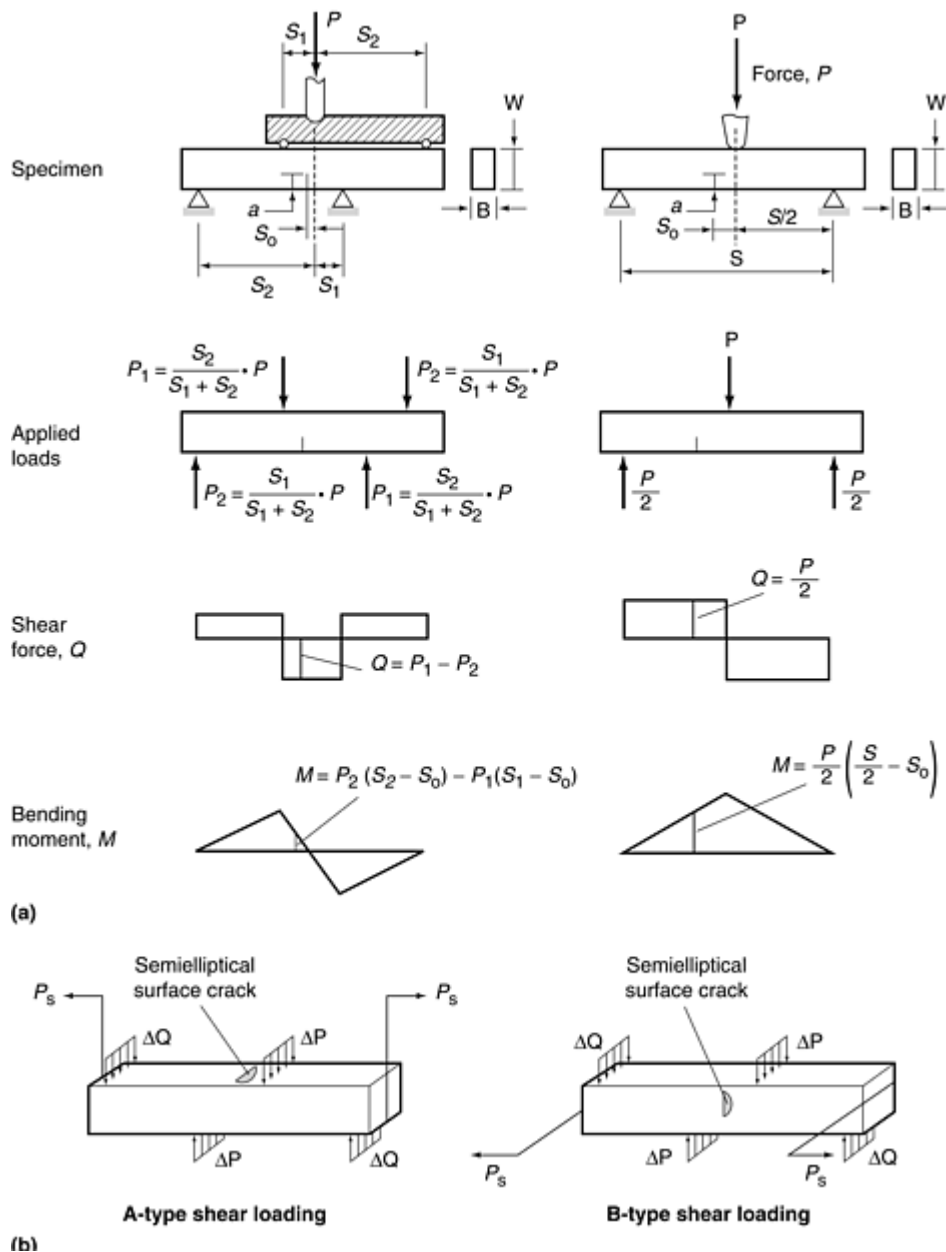

Fig. 11 Three-point and four-point bending specimens, (a) Three-point and four-point bending specimens with an offset crack. Source: Ref 10. (b) Four-point bending specimens with a semielliptical edge crack. Source: Ref 11

The specimens shown in Fig. 11(b) are variations of four-point bending specimens with edge cracks (Ref 11). However, it must be noted that the shear stress component is always zero at the free surface.

Compact Tension Shear Specimen. The compact tension specimen shown in Fig. 12 is used in combination with a jig that can control the direction of loadings and thus the combination of K_I and K_{II} (Fig. 13) (Ref 12).

Fig. 12 Shape and dimension of compact tension shear specimen. w , width; t , thickness; a , crack length. Source: Ref 12

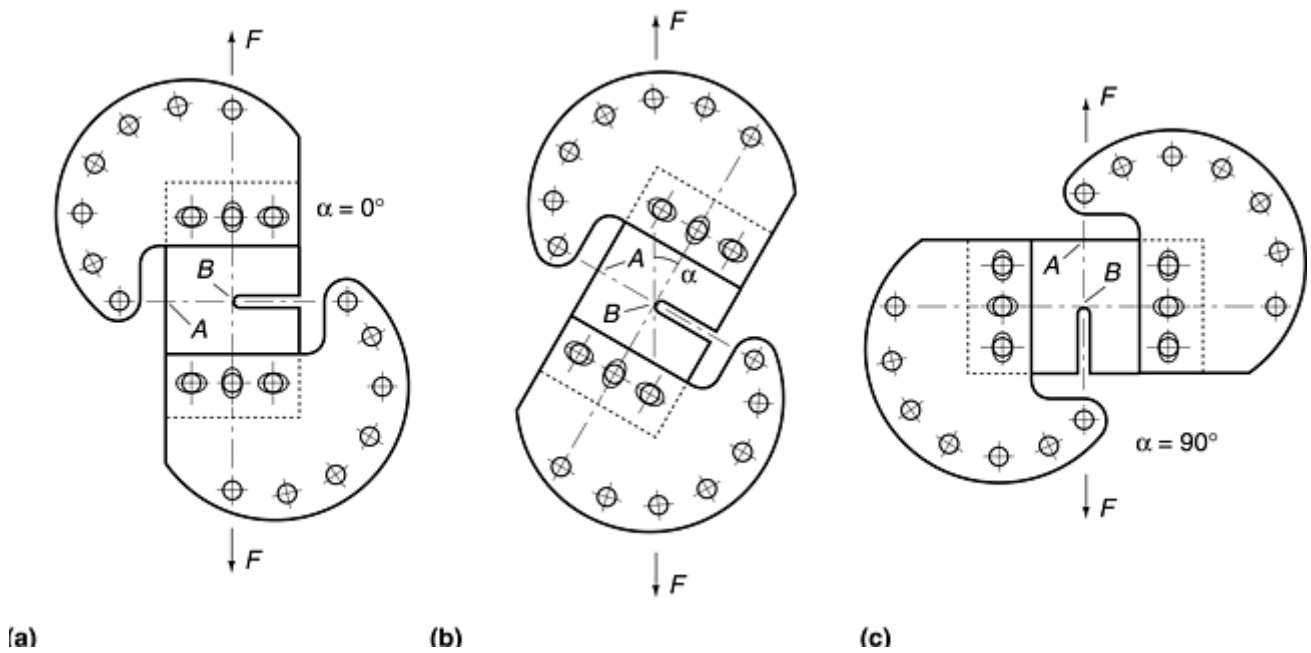

Fig. 13 Position of loading device. (a) Mode I ($\alpha = 0^\circ$), (b) Mixed mode ($0^\circ < \alpha < 90^\circ$), (c) Mode II ($\alpha = 90^\circ$). F , force. Source: Ref 12

Compact Shear Specimen. The compact shear specimen (Ref 13, 14) shown in Fig. 14 is used in the equilibrium loading system (Fig. 15a), though the mode is not pure mode II. If the distance between the pins of load application is small, the component of mode I is relatively small compared to the component of mode II. The specimen of the type in Fig. 15(b) is for the mode III test, but it also has a problem in that the mode I component is always induced in the system.

Fig. 14 Shape and dimension of compact shear specimen. Dimension are in mm. ρ , notch root radius. Source: Ref 14

Fig. 15 Loading apparatus. (a) Mode II type, (b) Mode III type. Source: Ref 14

Mode II Crack Growth Specimen (Ref 15, 16). The mode II threshold stress intensity factor range, ΔK_{IIth} , is an important material property with respect to rolling contact fatigue resistance. However, the measurement of ΔK_{IIth} in the laboratory is very difficult because a crack that has been growing in mode II can easily switch to mode I growth during the test. A method of measuring ΔK_{IIth} has been developed and applied to various steels (Ref 15, 16).

Figure 16 shows the basic model of measurement method in which a specially designed double-cantilever specimen is used. Figure 16 shows stress distributions and the normal and shear stress at the position without a slit. In principle, neither tensile nor compressive stress of σ_x exists on the neutral axis, and so a mode II fatigue crack is expected to grow along this section. The specimen (Fig. 17) has a chevron notch and side grooves.

Figure 18(a) shows the setup for the mode II fatigue crack growth test. In this test, two identical specimens are used as a pair so that a conventional closed-loop type tension-compression servomechanical fatigue machine can be used. Figure 18(b) shows the detail of attaching one specimen to the testing machine. Ceramic cylinders are inserted between cantilevers to share the applied load equally to each lever.

Fig. 17 Shape and dimension of mode II crack growth specimen. Dimensions are in mm

Fig. 18 Mode II crack growth testing machine, (a) Setup of mode II crack growth testing machine. (b) Detail of mode II crack growth testing machine with one specimen in place

Circumferentially Notched Cylindrical Specimen. This type of specimen is used to investigate the behavior of mode III crack growth under torsional loading (Fig. 19). Although the nominal stress intensity factor, K_{III} , is known, the exact value is difficult to estimate due to the friction between mating crack surfaces. A typical morphology of the fracture surface under these conditions is termed “factory roof” morphology (Ref 17).

Fig. 19 Circumferentially notched torsion specimen for mode III fatigue crack propagation. Dimensions are in mm. r_o , outer radius; r_N , radius of notch. Source: Ref 17

Tubular Specimen Containing a Slit. This type of specimen is used to investigate the fatigue crack growth behavior and approximately two-dimensional, mixed-mode stress condition under torsion coupled with tension-compression. A typical initial notch (Fig. 20) is usually introduced. The width of slit must be very small, because the initial geometry of the slit strongly influences the initial direction of crack growth.

Fig. 20 Tubular specimen containing a slit for combined torsion and tension-compression fatigue test. Dimensions are in mm. Source: Ref 18

Solid Cylindrical Specimen Containing a Small Hole or Initial Crack. The effects of artificial small defects on torsional fatigue strength can be studied by introducing an artificial small hole (Ref 4). Figure 21 shows the shape and dimension of a drilled hole.

Fig. 21 Shape and dimension of a small hole introduced on the surface of torsional fatigue test specimen. (Geometry of specimen is shown in Fig. 4.) d , diameter. Source: Ref 4

If a fatigue crack is introduced by a preliminary tension-compression fatigue test, crack growth behavior and threshold condition under mixed-mode loading can be studied. Initial small semielliptical cracks ranging from 200 to 1000 μm in length are introduced by preliminary tension-compression fatigue using a specimen containing holes of 40 μm diameter (Fig. 22). Crack growth behavior from the initial small crack, such as crack branching (Ref 1) and kinking (Ref 19), can be investigate. The threshold condition of a small crack can be studied based on the mixed-mode fracture mechanics analysis of a semielliptical crack (Fig. 3).

Fig. 22 Initial small surface crack introduced by tension-compression fatigue test using the specimens containing holes of 40 μm . (Geometry of specimen is shown in Fig. 7.) Source: Ref 1

Multiaxial Fatigue Testing

Yukitaka Murakami, Kyushu University, Japan

Summary

Since no standard testing method exists, it is important to choose a testing method suitable for a purpose of each testing. Various testing methods available for biaxial and multiaxial fatigue testing are summarized as follows. Biaxial fatigue testing machines, in which cyclic torsion is coupled with tension-compression loading, have been widely used because these testing machines can be applied to study the following:

- Mode III crack growth behaviors under cyclic torsion by using circumferentially notched cylindrical specimens
- Crack growth behaviors under approximately two-dimensional mode I and by using a tubular specimen with a slit
- Effects of small fatigue crack or defect under biaxial loading if an initial small crack is introduced by preliminary tension-compression fatigue testing

Triaxial Testing. In addition, biaxial fatigue testing (cyclic torsion with tension-compression) can be combined with the application of internal or external pressure for tubular specimens or cylindrical specimens. The influence of complex three-dimensional stress conditions can be investigated. However, these triaxial testing machines are very complicated and expensive.

Notched Plate and Precracked Bending Specimens. Rectangular plate specimens with an inclined notch or a crack and three-point or four-point bending specimens with a crack are used to investigate crack growth under mixed mode I and II. It must be noted that the stress intensity factors cannot be kept constant during the test, because crack growth mode shifts from mode II or III to mode I.

The cruciform specimen permits a wide variation of stress intensity factors, K_I and K_{II} . However, testing machines for this type of specimen are complex, and preparation of specimens is not easy. High compressive loads cannot be applied to the specimen because of the possibility of buckling.

Compact Specimen. The compact tension-shear (CTS) specimen is used to investigate the crack growth under mixed mode I and II, including pure mode II, loadings. The compact shear (CS) specimen is also used to investigate the crack growth under mode II and mode III. However, it is very difficult to achieve pure mode II crack growth by these specimens because crack growth mode easily switches from mode II to mode I. Thus, mode of loading is not necessarily the same as mode of crack growth.

Double Cantilever Specimen. Mode II crack growth plays an important role in crack growth under rolling contact fatigue. The values of ΔK_{Ith} for various steels can be measured using the specially designed double cantilever specimen. A conventional closed-loop tension-compression fatigue testing machine can be used in the system.

Multiaxial Fatigue Testing

Introduction to Mechanical Testing of Components

Introduction

TESTING OF COMPONENTS requires an understanding of service conditions and mechanical testing and design. While there are many types of components tests for a multitude of products, the articles in this Section focus primarily on the basic principles for some common types of engineering components. These articles provide an overview of the typical test methodology, developed by national organizations such as ASTM, as well as industry-specific organizations, test apparatus, procedures, test sample preparation, data collection, and interpretation. Using standard test methods provides for consistent test results.

The mechanical evaluation of components requires an engineer to use many sources of information. It also requires an understanding of service conditions, design, and manufacturing variables. All these variables can make it difficult to validate components. The following overviews briefly summarize some general factors in the design and manufacture of components. Additional information is also provided in the article "Overview of Mechanical Properties and Testing for Design" in this Volume. The remaining articles in this Section describe tests for common types of fabricated components and the modeling of metal deformation.

Introduction to Mechanical Testing of Components

Overview of Component Testing

Brian Klotz, Component Test Resources, General Motors Corporation

Testing of components involves a series of processes to validate the product for usage. Computer systems are playing a dominating role in the design of components and simulating how they react under different environments. Design engineers use three-dimensional modeling software to design components. This software allows the engineer to create a three-dimensional image of the component to scale. He or she can then manipulate the image to identify design concerns, match to models of mating parts to check for interference, and manufacture the component right from the model. This design model can also be used to generate a finite-element analysis (FEA) model. The FEA model can show an engineer how the design reacts under various loading conditions. If areas of the design are suspect, design changes can be made and reevaluated easily. While FEA models provide an engineer the ability to improve component designs without making a physical part, further test simulations to evaluate durability need to be developed to accurately predict the total capability of a component. The use of physical tests is required to develop these simulations.

An understanding of the operating environment in which the component must function establishes the basis for testing the component. The environment may include cyclic or static loading, vibration concerns, thermal variations, or many others. Duplicating or simulating this environment becomes a challenge at a component level. While elaborate test systems can be produced to incorporate multiple environments, in most instances the basic component design functionality is all that need be evaluated. Developing tests to perform the evaluations typically involves developing a set of fixtures to hold the component and impart the loading into the part on some type of test stand. Design of fixtures is critical to the repeatability of the overall testing. The loading characteristics the component experiences in its application must be understood in order for a test to be developed.

Once the test environment is understood, fixtures developed, and the component design manufactured, a test can be performed on the component. The testing is done either to correlate the output of the FEA model or validate the component design and manufacturing. Testing done to compare the results from math-based FEA models to real-life test results allows engineers the ability to further develop the capability of the models to predict design concerns. This type of testing typically requires less samples and can provide long-term cost

benefits to an organization. This iterative process of design analysis and testing ultimately leads to product designs that may require no component testing, only testing as part of an assembly to validate the system. Testing done to validate the component design and manufacturing requires knowledge of the duty cycle in which the component must operate. In order to develop component-level validation tests, test procedures and methods must be correlated to this duty cycle, and the test stand must be able to duplicate these load inputs. Validation tests require multiple samples to be subjected to duty-cycle loading. Results of these tests are then evaluated using statistical methods in order to determine whether they meet the product design requirements. This method of testing can be very costly if several redesigns must be done.

Introduction to Mechanical Testing of Components

Overview of Mechanical Properties for Component Design

Henry E. Fairman, MQS Inspection, Inc.

The ultimate result of performing mechanical tests is to provide information that may be used in the design and manufacture of components. Design of components requires an understanding of the materials properties and how they will be used by the component. The manufacturing process that is used to produce the part also must be considered during the design process because manufacturing methods influence materials properties and the selection of appropriate mechanical testing methods to ensure that the component will meet its required life cycle.

This overview briefly reviews the relationship of mechanical properties in the process of mechanical design. As previously noted, detailed materials properties and design methodologies are required for a wide variety of applications that encompass factors such as:

- Load-bearing capability to meet the desired service condition
- Capability of the design to meet the required lifetime
- Effect of service (environmental) conditions on the design
- Performance requirements such as minimum weight, stiffness, and life-cycle cost
- Size and shape factors

A significant part of the design process is also the experience based on the performance of similar components. The design process also uses predictive models, which may be a simple model or a more complex model developed by the FEA method.

Introduction to Mechanical Testing of Components

General Mechanical Behavior

One key aspect of product and process design is a basic understanding of fundamental mechanical behavior, which is described in the first two articles of this Volume (“Introduction to the Mechanical Behavior of Metals” and “Introduction to the Mechanical Behavior of Nonmetallic Materials”). In general, fine-grained materials have better mechanical and fatigue properties than coarse-grained materials. Components that have a mixture of fine- and coarse-grained materials will generally have properties similar to those of the coarse-grained material. Coarse-grained materials exhibit the lowest properties with the exception of creep and stress rupture, where single-grained materials have exhibited superior properties at elevated temperature.

Nonuniform microstructures will affect the mechanical properties of the material or component. For example, the center of 8 in. carbon or alloy bar produced by the strand casting process will exhibit different mechanical

properties than samples taken from the center, midradius, and outer diameter when tested in the longitudinal direction. Samples taken from the transverse direction will also have different properties than the longitudinal samples will have. Impact and fracture testing results are significantly impacted by the sample direction.

Mechanical working such as the rolling or drawing of materials can significantly improve the mechanical properties of the materials, raising the yield and ultimate strengths along with reducing the ductility values. Age hardening of metals generally raises the yield and ultimate strengths of materials. The fatigue properties are not generally significantly improved by age hardening.

Heat treating processes that result in transformation hardening, such as occurs with carbon and alloy steels, will raise the mechanical and fatigue properties of these alloys. It changes the creep properties by only a small degree because the principal effect is in the initial stage of creep deformation.

Introduction to Mechanical Testing of Components

Properties and Design for Static Loads

Tension and compression testing are common test methods as described in detail in the articles “Uniaxial Tension Testing” and “Uniaxial Compression Testing” in this Volume. Property data present in the literature are normally based on specimens machined from raw materials and represent ideal data for the materials. Typical stress-strain data for a variety of alloys are provided in Fig. 1. In the elastic region, stress and strain are proportional by Hooke's law ($\sigma = E\varepsilon$). In the plastic region, work hardening is described by a power law:

$$\sigma = Ke^n \quad (\text{Eq 1})$$

where K is the strength coefficient and n is the strain-hardening exponent. Typical stress-strain properties values are shown in Tables 1 and 2 (Ref 1) for selected steels and aluminum alloys, respectively, for monotonic loads. Tables 1 and 2 also list cyclic stress-strain properties, as described later. General properties related to monotonic stress-strain behavior are described briefly here.

Fig. 1 Typical stress-strain curves for selected metals

Ultimate strength refers to the maximum stress that a material can withstand before failure occurs. The ultimate strength is related to the materials composition, mechanical working, and heat treatment. The term *ultimate tensile strength* is synonymous with tensile strength, which is the accepted ASTM term for the maximum stress obtainable before fracture of the specimen.

Yield strength is commonly defined as the load at which a given amount of plastic strain has occurred. The yield strength is related to the materials composition, mechanical working, and heat treatment.

Elastic limit (or proportional limit) is the load at which plastic deformation begins to take place. Removal of the load allows the material to return to its initial shape. This property of materials is not commonly used in the design of components.

Modulus of elasticity is the ratio of stress to strain below the elastic limit. The modulus is a measure of material rigidity or stiffness for loading under tension, compression, or shear. The tensile modulus of elasticity (E), in principle, is roughly equivalent to the modulus in compressive. The shear modulus (or the modulus of rigidity, G) is related to the tensile modulus as follows:

$$G = \frac{E}{2}(1 + \mu) \quad (\text{Eq 2})$$

where μ is Poisson's ratio.

The moduli are usually characteristic for a given materials family such as aluminum, steel, and so on. Table 3 (Ref 2) provides data on the relative stiffness of a number of materials. Tensile moduli range from 45 to 207 GPa (6.5×10^6 to 30×10^6 psi) for common metallic materials.

Table 3 Comparison of the stiffness of selected engineering materials

Material	Modulus of elasticity (E), GPa	Density (ρ), mg/m ³	$E/\rho \times 10^{-5}$	$E1/2/\rho \times 10^{-2}$	$E1/3/\rho$
Steel (carbon and low alloy)	207	7.825	26.5	5.8	35.1
Aluminum alloys (average)	71	2.7	26.3	9.9	71.2

Dynamic Modulus. Modulus can also be determined from resonant vibrations with piezoelectric or electromagnetic transducers. ASTM standards C 1198 and C 1259 describe test method for determining the dynamic elastic module of advanced ceramics. These standards also form the basis for two recent additions to ASTM standards:

- ASTM E 1875-98; Standard Test Method for Dynamic Young's Modulus, Shear Modulus, and Poisson's Ratio by Sonic Resonance
- ASTM E 1876-98; Standard Test Method for Dynamic Young's Modulus, Shear Modulus, and Poisson's Ratio by Impulse Excitation

These two standards are almost verbatim versions of C 1198 and C 1259, which are generic and need not be confined to advanced ceramics, but are applicable to all elastic materials.

In resonant methods, Young's modulus, sheer modulus, and Poisson's ratio can all be computed from the resonant frequencies of prismatic bar, rods, or slabs. Dynamic methods of measuring elastic moduli are related to adiabatic conditions; whereas, static methods are isothermal. For ceramic materials (Ref 3), the adiabatic values can be of the order of 0.1% higher than isothermal values (Ref 4).

ASTM C 1198 is a clone of two earlier ASTM standards (C 848 and C 623) that are suitable for ceramic whitewares, and glass and glass-ceramics, respectively. Rather than using the tables and graphs in the earlier standards, the newer standard C 1198 uses the original equations for relating the elastic constants to the resonance frequencies. Although recommended sizes for flat and round specimens are given, the equations are sufficiently general that a wide size range can be used. The equations include the conventional polynomial correction factors to reflect the finite specimen thicknesses, but simplified equations are also provided for instances where the length-to-thickness ratio of the specimens is greater than 20. Specimen flatness and parallelism are critical; but, with proper care, accuracies and precisions of better than 1% are feasible. C 1198 is

primarily intended to be used with monolithic, or whisker-or particulate-reinforced ceramics. There is some potential for its use on continuous-fiber reinforced ceramics.

ASTM C 1259 describes a similar but more modern methodology for measuring the same properties as C 1198 except that impulse rather than continuous excitation is used to resonate the specimen. The fundamental resonant frequency of a rectangular-shaped specimen is measured following mechanical excitation by a singular elastic strike with an impulse tool. The resulting vibrations are monitored and transformed into electrical signals. The signals are analyzed and the properties calculated with a knowledge of the mass and dimensions of the specimen.

JIS Standard R 1602 also uses the resonance frequency method, but goes further by incorporating several alternate procedures. These include measurements of the static deflection of a beam in bending (with proper corrections for machine compliance), the strain in a strain-gauged specimen loaded in flexure, or the longitudinal-wave velocity in an ultrasonically pulsed specimen. The elevated temperature standard JIS R 1605 incorporates the resonance frequency or ultrasonic pulse methods to compute dynamic elastic moduli. Both Japanese standards prescribe specimen length to thickness ratios of 20 or greater. The same simplified formulas as given in ASTM C 1198 are used.

Elongation and reduction of area are ductility measurements determined during static mechanical testing and are related to the plastic deformation that takes place between the elastic limit and the ultimate strength of a material. These properties are useful when evaluating ductility during deformation such as extrusion, forging, or drawing.

Poisson's ratio, μ , is the ratio between axial strain to lateral strain during tensile loading. It usually has a value of approximately 0.3 for most metallic materials. For some materials with anisotropic crystal structures (such as the hcp structure of titanium α or α - β alloys with a preferred or textured crystal orientation), Poisson's ratio may depend on orientation.

Design of components for tensile loads normally uses the "fail-safe" concept of design in which a safety factor is applied to either the yield strength or the ultimate strength of the material. Design using cast materials typically uses the ultimate strength, whereas design using wrought materials uses the yield strength. Design that anticipates rapid loading often utilizes the ratio of yield strength to ultimate strength. A material having a ratio above 0.75 often will fail due to its inability to undergo plastic deformation under load.

Flexural Modulus and Strength. For ceramics and polymer materials, modulus and strength is often evaluated by flexural testing. In the case of ceramics, bend testing eliminates the gripping problems associated with the tension testing of ceramics.

Flexural testing by either three-point or four-point loading is the traditional method for evaluating the uniaxial strength ceramics. The method is applicable for purposes of material development, and sometimes design. However, for design purposes, tension testing is generally preferred (Ref 5).

Standards for the flexural testing of ceramics include:

- ASTM C 1161-90 Standard Test Method for Flexural Strength of Advanced Ceramics at Ambient Temperature
- ASTM C 1211-92 Standard Test Method for Flexural Strength of Advanced Ceramics at Elevated Temperature
- MIL STD 1942 Flexural Strength of Advanced Ceramics at Ambient Temperatures
- JIS R 1601 Testing Method for Flexural Strength (Modulus of Rupture) of High-Performance Ceramics
- JIS R 1604 Elevated Temperature Testing Method for Flexural Strength
- EN 843-1 Monolithic Ceramics, Mechanical Properties at Room Temperature, Part 1: Determination of Flexural Strength.

The latter standard has been adopted by the European Community and supercedes previous European Standards (DIN 51-110 Part 1 and AFNOR B41-104). There are many similarities between these standards. The specimen and fixture sizes are quite comparable and many tolerances and specifications are identical. Nevertheless, there are some differences that are of concern as discussed in Ref 5. For example, the U.S. and European standards require the load rollers to be free to rotate to eliminate friction error, but the JIS standard does not.

Although the flexure test is a simple method, significant errors (>5%) can occur from twisting, misalignment, and frictional constraints (Ref 3). Flexure testing of continuous-fiber, ceramic matrix composites must be

viewed with considerable caution because the failure mode could be tension fracture, shear fracture, compression failure, or buckling.

Hardness testing is a very common mechanical test applied to materials. Hardness testing is used extensively in quality control, where data can be collected that relate the mechanical properties of a given material, its microstructure, and processing methods.

Over the years, many researchers have endeavored to relate hardness values obtained from mechanical testing to the properties of the material. This has proved to be difficult because the shape of the indenters, loads, and rate of loading interact with each material in a different manner. For example, an annealed material will work harden during the test differently than the same material that has received various degrees of cold work. Materials such as carbon and alloy steels, which are strengthened by different processes (such as annealing, normalizing, and hardening), have different work-hardening behavior that influences indentation results. Likewise, cast aluminum alloys have similar hardness values to the wrought alloys yet possess significant different mechanical properties. Therefore, the correlation of strength and hardness (much like the conversion of hardness readings for different hardness scales) depends on the material, its condition, and the underlying strengthening mechanisms.

More information on the factors and variation of strength-hardness correlations are discussed in the article "Selection and Industrial Applications of Hardness Tests" in this Volume. In fact, Fig. 15(b) in that article illustrates an example of an inverse correlation of tensile strength and hardness for a line pipe steel. The explanation of this unexpected result is not clear, but it demonstrates the need for caution and empirically derived analysis when estimating mechanical strength from hardness.

Introduction to Mechanical Testing of Components

Properties and Design for Dynamic Loads

Mechanical design is commonly based on static loading of a component. However, there are many components that see an initial dynamic load followed by static or cyclic loading. Typical examples are explosive fasteners driven into concrete walls, the torsion spring used in overhead door mechanisms, dies for metal-forming operations, and aircraft landing gears. Impact tests and fracture toughness tests are the most common tests performed to demonstrate how materials behave under dynamic loads. These types of tests are performed to use standard test specimens and often bear no relationship to the complex shapes present in components. The rate of loading is also kept to standard conditions.

Impact testing of materials provides information on how a material will perform under dynamic loading. The data obtained from impact testing provide no values that can be used in the designing of components. The data do provide comparative information between different materials as well as the difference between lots of materials and/or heat treatment. The data are often plotted as a function of temperature because many materials exhibit a loss in impact strength as the temperature is lowered. This point is defined as the *transition* temperature (Fig. 2).

Fig. 2 Ductile-brittle temperature transition. bcc, body-centered cubic; fcc, face-centered cubic

The most common impact tests are the Charpy and Izod tests, in which the notched specimen is struck by a hammer. The notch concentrates the stresses so that plastic flow is minimized, and almost all of the energy is used to fracture the specimen. Other less-common impact tests are the tensile and torsional impact tests, which measure the performance of materials under these conditions.

The tensile impact test provides comparative information on the differences between various materials and lots of materials. It also can be used to predict the forming characteristics of materials being fabricated by high-energy forming methods. The torsional impact test provides information on how tubular cross sections of various materials will perform under load. The most common application of these data is for shafts that are rapidly brought up to an operating speed and supplement the torsional fatigue data on these sections. The test is rarely performed on solid specimens due to the more complex stress state that exists in this geometry.

Fracture toughness testing evaluates the ability of a material to withstand fracture in the presence of cracks. When fracture toughness is used as design criteria, the designer must be aware that the failure of the component will occur at nominal stresses below the design stresses for the given material. Cracks, discontinuities, and microscopic features such as inclusions and other anomalies are often present in components and should be accounted for in the design process.

The design philosophy for fracture toughness falls into four categories:

- *Infinite-life design*: This philosophy assumes that the component has no defects that will affect the life of the component. This philosophy incorporates the traditional design method that uses the fatigue (endurance) limit of the material.
- *Safe-life design*: This approach uses a design stress based on the number of cycles at the working stress that the component must carry to perform its task.
- *Fail-safe design*: This design philosophy assumes that the structure will continue to support its load after the failure of a single component of the structure. Fail-safe designs often include the presence of cracks.
- *Damage-tolerant design*: This approach was developed by the U.S. Air Force and incorporates the detection of cracks along with the crack growth rate of the material. Based on life histories, the remaining life of the component is determined.

Properties and Design for Cyclic Loads

In the real world, very few components are subject to static tensile, compression, and bending loads. The common approach for design of components in fatigue is the design-life approach, where data obtained from cyclic testing are presented as an $S-N$ curve. The data from $S-N$ testing are often combined in a constant-life fatigue diagram, which combines the alternating stress conditions with the cycles to failure. One of the advantages of such a diagram is that the effect of different loading conditions is easily seen in this type of diagram. Figure 3 (Ref 6) shows a typical constant-life diagram for alloy steel. This type of diagram can be used to construct $S-N$ diagrams for the expected loading of the component.

Fig. 3 Constant-life diagram for alloy steels. The data in this type of representation can be used to create an $S-N$ curve for any level of mean stress. Note the presence of safe-life, finite-life lines on this plot. This plot. This diagram is for average test data for axial loading of polished specimens of AISI 4340 steel (ultimate tensile strength, UTS, 125 to 180 ksi) and is applicable to other steel (e.g., AISI 2330, 4130, and 8630). Source: Ref 6

External and internal notches significantly reduce the fatigue properties of materials. For example, precipitation-hardened metals exhibit lower fatigue properties than would be expected from their yield/tensile properties. Ceramics and glasses contain internal defects, which reduce their expected fatigue strengths. The operating environment can produce external defects such as corrosion pits or stress corrosion cracks, which can serve as initiation sites for fatigue to occur.

Fatigue life data are also expressed in terms of a strain-based fatigue, which is divided into an elastic (high-cycle) component and a plastic (low-cycle) component as follows (Ref 1):

$$\frac{\Delta \epsilon}{2} = \underbrace{\frac{\sigma'_f}{E} (2N_f)^b}_{\text{Elastic}} + \underbrace{\epsilon'_f (2N_f)^c}_{\text{Plastic}} \quad (\text{Eq 3})$$

where N_f is the number of cycles to failure, σ'_f is the cyclic true fracture, ϵ'_f is the true fracture strain, and b and c are constants for a given material. Values for selected steels and aluminum alloys are listed in Tables 1 and 2, respectively.

Use of published fatigue data and stress concentrations combined with appropriate calculations and rate of loading provide only an approximation of the useful life of a component. If repeated failures of a component occur, a statistically designed, factorial test program should perform to validate the design assumptions. Data obtained from strain gage measurements are useful in the design of the experiment.

Tension-tension (axial) fatigue commonly occurs in press frames, bolted assemblies, and components subjected to thermal stresses. In the case of a press frame, it would be a zero to maximum tensile loading condition. The bolted joint normally has a preload applied so that the loading of the bolt is between a mean and maximum tensile stress. A bridge that undergoes thermal expansion will have both compressive and tensile loading, with the mean stress being that of the ambient temperature at time of construction. Many materials exhibit a good correlation of axial fatigue strength with their yield and/or ultimate strengths and typically have a ratio of 0.3 to 0.5 to these properties.

Bending fatigue results in the outer surface being subjected to alternating tensile and compressive stresses in varying ratios with the limiting strength being in the tensile direction. Common components subjected to bending fatigue include flapper-type valves and gear teeth. The stresses are given by:

$$\sigma = (Mc)/I \quad (\text{Eq 4})$$

where M is the bending moment, c is the distance from the center of the section to the outside surface, and I is the moment of inertia of the section.

Since the maximum stress is at the surface, processes such as shot peening and carburizing that produce compressive stresses are often used to improve the properties of the material.

Rotating bending fatigue tests have been performed for many years, and the bulk of fatigue data presented in the literature were produced by the R.R. Moore rotating bending fatigue machine. In this type of loading, a given point on the outside diameter of the specimens is subjected to alternating tensile or tensile-compressive stress each time it undergoes a 360° rotation. The effects of various stress concentrations on rotating bending endurance limits are also readily available. These data are widely used for shafts that are subjected to varying degrees of misalignment and are the predominate failure modes for these components.

Torsional fatigue data are less commonly reported in the literature. These are the predominate failure modes of compression springs and shafts that are connected to drive gears. For steels, the ratio between rotating bending and torsional endurance limits is typically 0.8.

Fatigue crack growth rates are directly related to the material's crystal structure, stress level, rate of loading, and stress concentrations present in the component. The field of fracture mechanics has provided significant data on the growth rate of fatigue cracks under axial loading where fracture toughness (K_{Ic}) has been determined for a wide variety of materials.

Introduction to Mechanical Testing of Components

Mechanical Properties and Design for High Temperature

Creep properties of materials are those in which a material continues to elongate under constant load at the working temperature of a component. Creep damage usually results in fracture, and creep properties of metallic materials are significant in such diverse applications as a toaster heating element, automobile exhaust system

components, high-temperature steam lines, furnaces and burners, and jet engine turbine components. It is of major importance for polymers, which exhibit creep at or just above room temperature.

Stress-rupture testing is also used to evaluate the creep resistance of materials. In this test, the sample is subjected to a constant load, and the time to fracture is measured as it varies with stress and temperature. It is often used as an acceptance test for high-temperature materials since it can be performed more rapidly than creep testing can. Creep fatigue results when cyclic loading occurs at elevated temperatures where creep damage can occur. It is directly related to the crack growth properties of the material, and is discussed in the article "Creep Crack Growth Testing" in this Volume. In general, materials are classed as being either creep-ductile materials (iron-base materials fall within this group) or creep-brittle materials (this group includes high-temperature aluminum alloys, titanium alloys, nickel-base high-temperature alloys, and ceramics).

Creep of Ceramics. Ceramics also exhibit creep behavior. Use of advanced ceramics for elevated temperature applications may involve the need for constitutive laws in order to predict deformation or strain up to a specified limit as established by design. Similarly creep-rupture models may also be required. Bending test data obtained at temperatures within the creep range are not suitable for establishing these laws because of difficulties in interpretation of specimen behavior (Ref 5). Therefore, to formulate these laws, data must be generated in both pure tension or compression in accordance with established standards.

ASTM C 1291 is a new standard that covers determination of the elevated-temperature time-dependent deformation tensile (creep) and stress-rupture properties of monolithic ceramics. Creep time-to-failure is also included in this test method. This method is only suitable for monolithic ceramics. This test is not suitable for continuous fiber-reinforced ceramic composites, which do not behave as isotropic, homogeneous materials. Specimens (dogbone flats or rounds) are subjected to uniform stress in the gage area, where creep deformation is measured by either optical or mechanical extensometers (Ref 7, 8, and 9). Optical extensometers provide good stability, while mechanical devices may have advantages in terms of accuracy and ease of use.

Introduction to Mechanical Testing of Components

Applications Factors in Mechanical Performance

Application of materials properties along with the operating stresses calculated from traditional mechanics yields only a best-case scenario for the performance of a component. Design shape, environmental effects and surface degradation, the manufacturing method, and the condition of the material all play significant roles in the design process.

Part Shape. In almost all cases, engineering components and machine elements have to incorporate design features that introduce changes in their cross section. For example, shafts must have shoulders to take thrust loads at the bearings and must have keyways or splines to transmit torques to or from pulleys and gears mounted on them. Under load, such changes cause localized stresses that are higher than those based on the

nominal cross section of the part. Figures 4 , 5 , 6 , and 7 (Ref 10) show the effects of notches on the stress field in tension, compression, torsion, and bending, respectively.

Fig. 4 Effect of stress concentrations in tension. (a) No stress concentration. (b) Surface stress concentrations. (c) Transverse hole stress concentration.

Fig. 5 Effect of stress concentrations in compression. (a) No stress concentration. (b) Surface stress concentrations. (c) Transverse hole stress concentration. Source: Ref 4

Fig. 7 Effect of stress concentrations in bending. (a) No stress concentration. (b) Transverse surface stress concentrations. Source: Ref 4

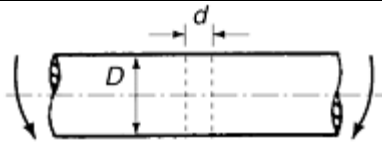

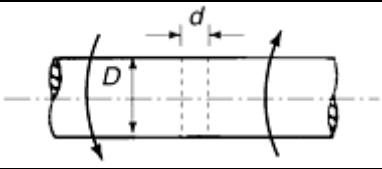

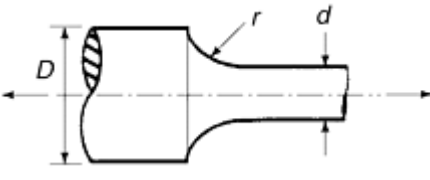

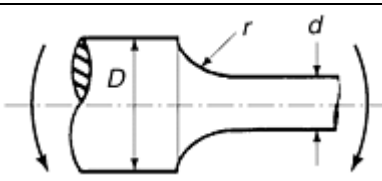

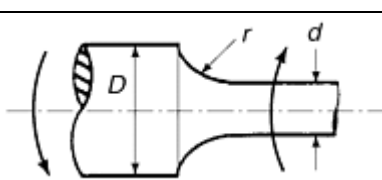

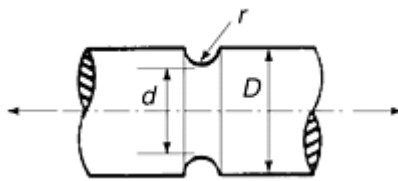

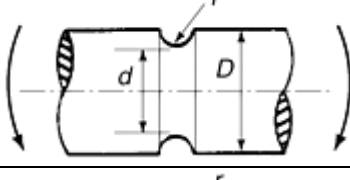

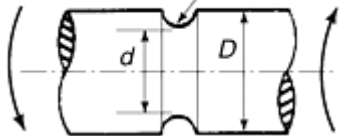

The severity of the stress concentration depends on the geometry of the discontinuity and the nature of the material. A geometric, or theoretical, stress concentration factor, K_t , is usually used to relate the maximum stress, σ_{max} , at the discontinuity to the nominal stress, σ_{av} , according to the relationship:

$$K_t = \sigma_{max} / \sigma_{av}$$

Stress concentration factors have been published for many years in references such as *Peterson's Stress Concentration Factors*, originally published in 1950 with a new edition recently published (Ref 11). The value of K_t depends on the geometry of the part and can be determined from stress concentration charts such as those given in Ref 11 and 12. Table 4 (Ref 2) also gives some typical values of K_t .

Table 4 Values of the stress concentration factor, K_t

Component shape		Value of critical parameter, K_t	
Round shaft with transverse hole			
Bending		$d/D = 0.025$	2.65

		= 0.05	2.50
		= 0.10	2.25
		= 0.20	2.00
Torsion		$d/D = 0.025$	3.7
		= 0.05	3.6
		= 0.10	3.3
		= 0.20	3.0
Round shaft with shoulder			
Tension		$d/D = 1.5, r/d = 0.05$	2.4
		$r/d = 0.10$	1.9
		$r/d = 0.20$	1.55
		$d/D = 1.1, r/d = 0.05$	1.9
		= 0.10	1.6
		= 0.20	1.35
Bending		$d/D = 1.5, r/d = 0.05$	2.05
		$r/d = 0.10$	1.7
		$r/d = 0.20$	1.4
		$d/D = 1.1, r/d = 0.05$	1.9
		$r/d = 0.10$	1.6
		$r/d = 0.20$	1.35
Torsion		$d/D = 1.5, r/d = 0.05$	1.7
		$r/d = 0.10$	1.45
		$r/d = 0.20$	1.25
		$d/D = 1.1, r/d = 0.05$	1.25
		$r/d = 0.10$	1.15
		$r/d = 0.20$	1.1
Grooved round bar			
Tension		$d/D = 1.1, r/d = 0.05$	2.35
		$r/d = 0.10$	2.0
		$r/d = 0.20$	1.6
Bending		$d/D = 1.1, r/d = 0.05$	2.35
		$r/d = 0.10$	1.9
		$r/d = 0.20$	1.5
Torsion		$d/D = 1.1, r/d = 0.05$	1.65
		$r/d = 0.10$	1.4
		$r/d = 0.20$	1.25

Source: Ref 2

Other methods of estimating K_t for a certain geometry include photoelasticity, brittle coatings, and finite-element techniques. Experience shows that under static loading, K_t gives an upper limit to the stress concentration value and applies it to high-strength, low-ductility materials. With more ductile materials, local yielding in the very small area of maximum stress causes some relief in the stress concentration. Generally, the following design guidelines should be observed if the deleterious effects of stress concentration are to be kept to a minimum (Ref 2):

- Abrupt changes in cross section should be avoided. If they are necessary, generous fillet radii or stress-relieving grooves should be provided.
- Slots and grooves should be provided with generous run-out radii and with fillet radii in all corners.
- Stress-relieving grooves or undercuts should be provided at the ends of threads and splines.
- Sharp internal corners and external edges should be avoided.
- Oil holes and similar features should be chamfered and the bore should be smooth.
- Weakening features such as bolt and oil holes, identification marks, and part numbers should not be located in highly stressed areas.
- Weakening features should be staggered to avoid the addition of their stress-concentration effects.

Pin Bearing Testing. Special geometric conditions or configurations may also have specially designed tests for strength evaluation. One example of this is the pin bearing test conducted on metal products that must sustain loads that are applied when the material is riveted, bolted, or similarly mechanically fastened. The purpose of the test is to determine the bearing strength properties and to indicate the bearing stress versus the deformation of the hole. The bearing load is applied to the specimen through a cylindrical pin, which is fitted into a hole normal to the surface of the specimen. The data obtained by this test procedure are used to calculate minimum properties that can be used in the design of structural members used in the aerospace industry.

The properties of primary concern in pin bearing tests are bearing yield strength and bearing ultimate strength. The bearing yield strength is the bearing stress at which a material exhibits a specified limiting deviation from the proportionality of bearing stress to bearing strain. The bearing ultimate strength is the maximum bearing stress a material is capable of sustaining. These values are normally determined at edge-distance ratios (e/D) of 1.5 and 2.0, where the edge-distance ratio is the ratio of the edge distance, e , to the pin diameter, D . Edge distance, e , is the distance from the edge of a bearing specimen to the center of the hole in the direction of the applied force. Bearing area is the product of the pin diameter and specimen thickness. The bearing loads are divided by the bearing area to yield the bearing stress or strength, which is the force per unit of bearing area.

Although a standard method for the pin-type bearing test is covered in ASTM E 238, "Standard Test Method for Pin-Type Bearing Test of Metallic Materials," it is oriented to testing aluminum and magnesium. Consequently, problems with pin distortion or failure may be encountered when testing higher-strength materials such as titanium and high-strength steel at ultimate strengths of 1860 to 2070 MPa (270 to 300 ksi). Much of ASTM E 238 is aimed toward obtaining consistent results among laboratories. Consequently, it must be recognized that values obtained under laboratory-type conditions will not be representative of those achieved under actual loading conditions of a part or structure.

Cleaning of the specimen and pin is also necessary to provide consistent, comparable results. However, cleaning produces test results that are higher than in actual service (where fasteners may have platings, sealants, or lubricants to facilitate installation). In aluminum and magnesium alloys, lubrication can cause reductions of up to 15% in bearing yield strength values obtained in tests with clean, dry bearing surfaces. This includes the unintentional application of oil from human fingers during handling of the specimens and test fixtures.

Pin bearing tests typically are conducted on sheet-type specimens, using the full thickness of the material when possible. If the specimen is too thick in relation to the pin diameter, the test pin may bend or break before the bearing strength can be achieved. Conversely, buckling may occur if the specimen is too thin in relation to the pin diameter. To avoid pin deformation or failure and specimen buckling, a pin diameter to specimen thickness ratio (D/t) of 2 to 4 is recommended in ASTM E 238. Most testing of aluminum is conducted using a D/t ratio of 2. To test high-strength steel, D/t ratios up to 4 may be necessary. Using a higher D/t ratio, however, increases the possibility of buckling.

Stress-Corrosion Cracking (SCC) occurs in a variety of materials as a result of internal and external stress conditions in the component in conjunction with the operating environment. After completion of stress analysis in the design process, a designer normally has a list of materials suitable for a given environment. However, SCC and other environmentally assisted cracking (EAC) are complex problems that warrant careful attention at the materials selection stage. Unexpected causes, such as the use of cleaning agents on high-strength or stainless steels, can be a factor. More details on the standards and tests associated with SCC and hydrogen embrittlement are described in the article "Evaluation of Environmentally Assisted Crack Growth" in this Volume.

Wear can occur by a variety of mechanisms depending on the properties of the material and the service condition. Wear resistance is, therefore, not a materials property as are strength, elastic modulus, endurance limit, or fracture toughness. Wear and its corollary, wear resistance, are systems properties or responses. A

summary of designing for wear resistance is provided in the article “Design for Wear Resistance” in *Materials Selection and Design*, Volume 20 of the *ASM Handbook*. Comprehensive information on the wear properties of materials is provided in *Friction, Lubrication, and Wear Technology*, Volume 18 of the *ASM Handbook*.

The properties of castings vary widely as a function of the section thickness due to the differences in the cooling rate and the specific characteristics of the alloy being cast. The reported properties of cast materials are normally obtained from test bars, which have solidified under ideal conditions. Properties can be specified at selected areas based on the expected design stress at these locations.

Forgings are often selected as the material form for components since the grain flow can be controlled to produce directional properties that improve the performance of the component. For example, if the grain flow is aligned with the direction of the maximum tensile stress, maximum properties can be realized. Gears are often forged with the grain flow normal to the applied load in order to improve the resistance to crack initiation and propagation.

Rolling and extrusion of metals also produce directional properties. For example, a strip of 1095 carbon steel having a hardness of 58-60 HRC will tear like a piece of paper when loaded parallel to the rolling direction and will be almost impossible to fracture in the transverse condition.

Powder metallurgy (P/M) parts must be carefully considered by designers. The mechanical properties and fatigue performance of press-and-sintered P/M parts generally do not match those obtained by cast or wrought materials of the same composition. Porosity is an integral part of castings and P/M materials. The net effect of porosity on mechanical properties is a combination reduced cross-sectional area along with internal notches, which reduces the ultimate strength and elongation of the component.

Testing for Deformation Modeling

Dan Zhao, Johnson Controls, Inc.

Introduction

COMPUTER MODELING OF DEFORMATION has become a popular engineering tool and is used with considerable success in the metal forming industry. The popularity of deformation modeling has increased with the rapid advancement of computer hardware and software technology. However, one of the key factors in successfully employing deformation modeling is accurate and adequate input of material properties. Various mechanical, thermal, and interfacial properties are required depending on the particular material and process being modeled.

The mechanical properties required for deformation modeling include flow stress, Young's modulus, Poisson's ratio, and anisotropic properties. The most important property is flow stress, and it is usually required as a function of strain, strain rate, and temperature.

Forming processes can be divided into three major categories: bulk forming, sheet-metal forming, and special forming processes. Bulk forming includes forging, extrusion, drawing, and rolling. Sheet-metal forming consists of stamping, deep drawing, blanking, punching, spinning, and superplastic forming. Semisolid forming and polymer extrusion are some of the special forming processes. In this article, each processing category is introduced with a brief description of the constitutive models. The required properties for process modeling are outlined, and the test methods for determining these properties are described. Special attention is given to the accuracy of data. Additional information on bulk workability testing and sheet formability is also contained in *ASM Handbook, Volume 14, Forming and Forging*.

Testing for Bulk Forming

As the name implies, bulk forming usually involves workpieces that are bulky compared with sheet metal. Because bulk forming usually involves large plastic deformation, the most important mechanical input for modeling is stress-strain data. For warm and hot forming processes, data may be needed over a range of temperatures and strain rates. Several efforts have been made to make such data available for a number of alloys (Ref 1, 2, and 3). In this section, both compression and tension tests are discussed in detail. In addition to stress-strain curves, other properties such as Young's modulus and workability data can also be obtained from these tests. Data reduction procedures, such as temperature correction and fitting to constitutive equations, are provided. Finally, testing for interfacial properties such as the friction coefficient and heat-transfer coefficient are described briefly.

Constitutive Equations

The general form of the constitutive equation for deformation processing is:

$$\bar{\sigma} = f(\bar{\epsilon}, \bar{\dot{\epsilon}}, T) \quad (\text{Eq 1})$$

where $\bar{\sigma}$ is equivalent true stress, $\bar{\epsilon}$ is equivalent true strain, $\bar{\dot{\epsilon}}$ is equivalent true strain rate, and T is processing temperature.

Most software packages for bulk forming modeling have options to input the testing data in a tabular form or as a constitutive equation. The tabular form is easy to use, but is not based on any fundamental metallurgical principles, as with some of the constitutive equations. The most frequently used constitutive equation is:

$$\bar{\sigma} = K\bar{\epsilon}^n\bar{\dot{\epsilon}}^m + Y \quad (\text{Eq 2})$$

where n is the strain-hardening exponent, m is the strain-rate sensitivity, and Y and K are constants.

Strain-rate sensitivity is important at elevated temperatures, while it has little influence at room temperature for most metallic materials. In contrast, the importance of the strain-hardening exponent increases with decreasing temperature. The values of m and n can be found in Ref 4 for a number of metals and alloys.

The equation above does not reflect the influence of temperature. For each temperature, there is a set of constants. A more fundamentally sound equation was proposed by Sellars and Tegart (Ref 5) by assuming material flow during deformation as a thermally activated process:

$$\dot{\epsilon} = A(\sinh \alpha\bar{\sigma})^{n'} \exp\left(-\frac{Q}{RT}\right) \quad (\text{Eq 3})$$

where A , α , and n' are constants determined by fitting the empirical data, and Q is the apparent activation energy. At low stresses ($\alpha\bar{\sigma} < 0.8$), Eq 3 reduces to a power law:

$$\dot{\epsilon} = A_1\bar{\sigma}^{n'} \exp\left(-\frac{Q}{RT}\right) \quad (\text{Eq 4})$$

At high stresses ($\alpha\bar{\sigma}$ is greater than 1.2), and Eq 3 reduces to an exponential relation:

$$\begin{aligned} \dot{\epsilon} &= A_2 \exp(\alpha n' \bar{\sigma}) \exp\left(-\frac{Q}{RT}\right) \\ &= A_2 \exp(\beta \bar{\sigma}) \exp\left(-\frac{Q}{RT}\right) \end{aligned} \quad (\text{Eq 5})$$

where β is a material parameter.

Other constitutive relations have been proposed to describe dynamic recovery and dynamic recrystallization, such as the Laasroui-Jonas model (Ref 6) and internal variable model (Ref 7). Those relationships have not

been implemented in commercially available software packages and can only be used as user-defined subroutines. The testing and data reduction procedures for these models were documented by Thirukkonda, Zhao, and Male (Ref 8).

Fracture Criteria

One of the most useful predictions that can be made from computer modeling is failure of parts during processing. To predict failure, ductile-fracture criteria must be incorporated in modeling. The most popular fracture criterion is the Cockcroft-Latham criterion, which states that fracture occurs when the integration of the maximum principal stress over equivalent strain exceeds a constant (Ref 9):

$$\bar{\epsilon}_f \int_0^{\bar{\epsilon}_f} \sigma_1 d\bar{\epsilon} \geq C_2 \quad (\text{Eq 6})$$

where σ_1 is the maximum principal stress, $\bar{\epsilon}_f$ is equivalent strain at fracture, and C_2 is a constant representing the workability of the workpiece material. If $\sigma_1 < 0$, there are only compressive stresses, and no fracture occurs. Zhao, Bandstra, and Kuhn (Ref 10) developed a new fracture criterion that can be directly related to the bulk workability test (Ref 11):

$$\sigma_{1f} \frac{\bar{\epsilon}}{\bar{\sigma}} \geq C' \quad (\text{Eq 7})$$

where σ_{1f} is the maximum principal stress at fracture, and C' is a workability constant. For incremental loading, Bandstra (Ref 12) proved the criterion can be expressed as:

$$\int_0^{\bar{\epsilon}_f} \frac{\sigma_1}{\bar{\sigma}} d\bar{\epsilon} \geq C' \quad (\text{Eq 8})$$

A review of fracture criteria can be found in Ref 10.

Testing for Deformation Processing

It must be understood that testing for deformation processing is very different from testing for static mechanical properties. Testing for static mechanical properties, such as tensile strength, yield strength, and elongation, needs to be conducted at a very low loading rate, and according to standards such as those published by ASTM (Ref 13, 14, 15, and 16). For example, the conventional strain rate specified in the standards for compression testing is $8.33 \times 10^{-5} \text{ s}^{-1}$, and the rapid strain rate is only $8.33 \times 10^{-3} \text{ s}^{-1}$ (Ref 14). Testing for deformation processing must be conducted to cover the range of strain rates experienced by the workpiece, which can reach 1000 s^{-1} . In addition, large strains, such as true strain of 120%, are common in metal forming processes. Such high strains may not be needed when testing for static properties.

Compression Test

Compression tests are normally used to determine stress-strain curves for bulk forming, because most bulk forming processes involve mainly compressive stresses. The test is also relatively easy to perform, and the specimen geometry is usually simple.

Testing Apparatus. The testing machine can be either a servohydraulic or mechanical screw-driven machine. A schematic of a testing apparatus is shown in Fig. 1. The capacity of the loading frame is rated in units of kilonewtons (kN) or kilopounds (kip). Selection of loading capacity depends on the material being tested. In general, a 300 kN servohydraulic machine is capable of testing most metallic materials over a wide range of temperatures and strain rates. High-speed testing machines can also be ordered with custom design from manufacturers.

Fig. 1 Schematic of a compression-testing system

Load cells are rated for load capacity. Several load cells may be needed to cover different load ranges and provide accurate readings. There are two kinds of load cells: static and dynamic. Hydraulic machines usually come with dynamic load cells. Dynamic load cells can be used for both static and dynamic loading.

For elevated-temperature testing, a furnace is mounted on the testing machine, usually on the loading frame. The furnace can also be mounted on a cart to be pushed in or out. Four types of furnaces are commonly used: resistance heating, radiant heating, induction heating, and vacuum. A resistance-heating furnace is slower compared to radiant and induction-heating furnaces, but usually has three heating zones and better temperature control. A radiant-heating furnace is fast and has good temperature control, but the life of the radiant bulbs is short, which increases maintenance cost. An induction-heating furnace is very rapid, but its temperature control is poor. In addition, specimens may not be heated uniformly in such a furnace. A vacuum furnace or environmental chamber is needed for specimens, such as titanium alloys, that can oxidize at elevated temperatures. Quenching may be performed to retain microstructures at testing temperatures. For the first three types of furnaces, quenching can be performed by opening the furnace and dropping the specimen in a quenching medium such as water. For a vacuum furnace, quenching has to be performed with an inert gas, such as helium, inside the furnace. The furnace door can only be opened after the furnace temperature is low enough (below 300 °C, or 570 °F, for a tungsten heating element) to prevent damage to the heating element.

Cooling blocks must be installed between the load cell and the top anvil, and between the bottom anvil and the actuator. Aluminum alloys can be used to construct cooling blocks. Several water channels are drilled through the cooling blocks and connected with copper tubing to circulate cold water through the blocks.

The top and bottom anvils can be made of stainless steel, superalloys, Ti-Zr-Mo alloy (TZM), or graphite. For temperatures below 1000 °C (1830 °F), stainless steel can be used. For temperatures below 1350 °C (2460 °F), TZM can be used. For temperatures above 1350 °C (2460 °F), graphite can be used. The diameter of the anvils should be at least three times that of the specimen. TZM and graphite are suitable in a vacuum furnace. In air, alternative materials for TZM would be Inconel 718, stainless steel 17-7PH, or Haynes 188. However, the temperature limits for these materials are not as high as for TZM.

The compression platens can be made of several materials. Table 1 shows the materials and their applicable temperatures and strain rates. In most cases, TZM anvils and platens are used for temperatures of 800–1350 °C (1470–2460 °F). For testing below 1000 °C (1830 °F), tungsten carbide (WC) platens can be used, especially when testing steel specimens. D2 steel is good enough to test nonferrous alloys, such as aluminum and copper. For testing above 1000 °C (1830 °F), silicon carbide (SiC), silicon nitride (SiN), and alumina can be used. However, if high-speed impact is encountered, such as when testing with strain rates higher than 1 s⁻¹, TZM or ceramic composite (Al₂O₃ + SiC) platens should be used. If the specimen is a high-strength heat-resistant alloy,

only the ceramic composite platens can sustain the impact. In general, when choosing tooling materials, one should consider the hardness of the material being tested and the impact strength and thermal conductivity of platens. For example, a high-strength heat-resistant alloy, such as Udimet 720, would damage TZM platens when tested at high strain rates and provide invalid testing data. In addition, high heating rates can explode the ceramic composite platens because the thermal conductivity of alumina is low.

Table 1 Platen materials for different temperatures and strain rates

Strain rate, s^{-1}	Temperature			
	RT-400 °C (RT-750 °F)	<1000 °C (<1830 °F)	1000–1350 °C (1830–2460 °F)	>1350 °C (>2460 °F)
<1	D2 Steel	WC	TZM, SiC, SiN, Al ₂ O ₃ + SiC	Graphite
1–60	D2 Steel	WC, TZM	TZM, Al ₂ O ₃ + SiC	Al ₂ O ₃ + SiC

The flat and parallel tolerance of platens should be within 0.0002 (Ref 13). To improve parallelism, adjustable platens (such as bearing blocks) may be used. A drawing of such blocks is shown in Ref 13. Using a subpress is suggested in the ASTM standards (Ref 13, 14), but it is very difficult with the limited space inside the furnace. Specimen Geometry. The simplest specimen geometry is a cylinder, as shown in Fig. 2. The height-diameter aspect ratio (H/d) is usually between 1 and 2. An aspect ratio that is too high can cause the specimen to buckle, while one that is too low can increase friction even if lubricant is applied. Excellent results have been obtained using $H/d = 1.25$ for high-strength steel specimens (Ref 8). Typical specimen diameter is 10 to 15 mm (0.4–0.6 in.), depending on microstructure. For a cast alloy with a coarse grain structure, larger specimens may be necessary. Subscale specimens can also be used for materials with a fine grain structure. In general, the specimen size must be representative of the material being tested.

Fig. 2 Cylindrical compression specimen geometry

The parallelism of the top and the bottom of specimens should be 0.0005 or better. The surface finish of specimens should be 1.6 μm (63 $\mu in.$) or better, which usually requires turning or grinding. A typical specimen with friction looks like Fig. 3 (Ref 17). The specimen shown in Fig. 3 exhibits bulging due to friction between the platens and the top and bottom surfaces of the specimen. Ideally, the test is frictionless, and the specimen is compressed homogeneously, as shown in Fig. 4. Shear banding may occur during compression testing, as shown in Fig. 5 (Ref 17). It can be caused by localized flow (Ref 18) or unparallel platens or specimens.

Fig. 3 Schematics of a regularly tested specimen

Fig. 4 Schematics of an ideally tested specimen

Fig. 5 Schematics of a tilted (sheared) tested specimen

Temperature Measurement. Temperature measurement using a thermocouple that just touches the specimen is not accurate until the specimen is soaked at the set testing temperature for a long time. To accurately measure the temperature of the specimen, thermocouples can be either welded to the specimen or inserted into a small hole drilled into the specimen. Hole drilling is not recommended for workability testing because the hole may induce premature cracking. To determine the uniformity of temperature within the specimen, three thermocouples may be used to measure the top, bottom, and center temperatures of a dummy specimen as a function of time. If the temperatures are identical, only one thermocouple is necessary during testing. If it takes some time for the entire specimen to reach the set temperature, this procedure can also be used to determine the necessary soaking time. To obtain the microstructure right before the compression testing begins, a specimen soaked at the testing temperature for the specified time should be quenched and examined. Some other detailed precautions for temperature measurement are specified in Ref 14.

It is essential that the platens be at the same temperature as the specimen. Temperature difference between the platens and the specimen results in a deformation gradient and, therefore, barreling of the deformed specimen (Ref 19).

Lubrication. When the specimen is compressed homogeneously, as shown in the ideal case (Fig. 4), the resulting stress calculations are accurate. For most tests, deformed specimens look like the one in Fig. 3 due to friction, even with lubrication. For testing at room temperature, TFE-fluorocarbon sheet and molybdenum disulfide can be used (Ref 13, 20). For testing at elevated temperatures, water-base graphite, graphite sheet, boron-nitride solution, glass-base lubricant, and molybdenum disulfide may be used (Ref 8, 21).

To retain lubricant on the ends of the specimens, various end designs have been developed (Ref 7, 21, and 22). One such design is shown in Fig. 6. The procedure for applying lubricant solutions on the ends of the specimens is also very important. The lubricant needs to be applied twice on each end. The second application can only be made after the first application dries.

Fig. 6 A typical groove design for the ends of compression test specimens

Machine Stiffness. Because the testing train consists of a number of components, as shown in Fig. 1, the stiffness of the system needs to be quantified. The easiest way to quantify is to bring the top and bottom platens together and record the displacement at a number of load levels. This procedure needs to be performed at each testing temperature. For high-strain compression tests, for instance, 60 to 80%, it is not possible to attach an extensometer to the specimen. The displacement data must be subtracted by the intrinsic displacement that resulted from the system. The subtraction can be incorporated into a data acquisition program.

Machine Control. The testing machine should be controlled to generate constant strain rates during testing. To do so, the motion of the crosshead must follow exponential curves. The true strain is expressed as a function of specimen height as follows:

$$\varepsilon = \ln \frac{h}{h_0} = \ln \left(1 - \frac{\Delta h}{h_0} \right) \quad (\text{Eq 9})$$

where ε is true strain (in the case of compression or tension, if the deformation is homogeneous, $\varepsilon = \bar{\varepsilon}$), and h_0 and h are the initial and instantaneous height of the specimen, respectively. $\Delta h = h_0 - h$ is the distance the crosshead has traveled since the compression test commenced.

For a constant strain-rate test, the instantaneous strain is simply the product of strain rate and time:

$$\varepsilon = \dot{\varepsilon}t \quad (\text{Eq 10})$$

Combining Eq 9 and 10 yields:

$$\Delta h = h_0[1 - \exp(-\dot{\varepsilon}t)] \quad (\text{Eq 11})$$

For hydraulic machines, the distance of crosshead travel is controlled by the voltage input as a function of time. For a mechanical machine, the crosshead is controlled by the motor speed. In general, Eq 11 is the governing equation for machine control for constant strain-rate compression tests. The equation for tension tests can be derived similarly with the exception of $\Delta h = h - h_0$. Software to control the machine for constant strain-rate tests has recently become commercially available (Ref 23).

Data Reduction and Temperature Correction. Load and stroke (displacement) data are acquired from testing. To reduce the data into true stress and true strain, deformation is assumed homogeneous. True strain is calculated using Eq 9. Of course, the correction for the elastic deflection of the machine needs to be considered (Ref 24). True stress is simply the load divided by instantaneous cross-sectional area, which can be calculated by assuming a constant volume of the specimen.

Deformation heating occurs inevitably during testing, especially at high strain rates. Because isothermal stress-strain curves are desired for analysis, correction for deformation heating is necessary. The commonly used equation for calculating temperature rise during deformation is (Ref 25):

$$\Delta T = \frac{\alpha \int_0^\epsilon \sigma d\epsilon}{\rho C} = \frac{\alpha \sigma_a \epsilon}{\rho C} \quad (\text{Eq 12})$$

where σ_a is the average stress value over the strain range of testing, ρ is density, C is mass heat capacity of the specimen, and α is the fraction of deformation energy transformed into heat. Usually α is equal to 0.98.

As shown in Eq 12, the temperature rises continuously as the test continues. A typical stress-strain curve obtained after testing and deformation heating correction would look like the curves in Fig. 7. Deformation heating is most severe at low temperatures and high strain rates, where the stress level is high. At high strain rates, higher than, for instance, 1 s^{-1} , there is not much time for heat to dissipate, and the specimen is basically under adiabatic conditions. Equation 12 applies under these conditions. In contrast, when strain rates are very slow, such as 10^{-3} s^{-1} , heat generated from deformation is transferred to tooling and the environment, and deformation heating is negligible. However, Eq 12 does not reflect the effect of strain rate, and still provides a finite temperature increase. In addition, the equation does not apply at even intermediate strain rates. To solve these problems, Zhao (Ref 26) developed an equation for calculating temperature increase due to deformation heating at all strain rates, which also includes the heat generated by friction at the platen/specimen interface:

$$\Delta T = \frac{h_a \sigma_a}{h_T} \left(\alpha \dot{\epsilon} + \frac{f v_a}{h_a} \right) \left[1 - \exp\left(-\frac{h_T t}{C \rho h_a} \right) \right] \quad (\text{Eq 13})$$

where h_a is the average height of the specimen, h_T is the heat-transfer coefficient between the platen and the specimen, f is the friction coefficient between the platen and the specimen, t is time, and v_a is the average velocity at the platen/specimen interface. If lubrication is excellent and friction is negligible, Eq 13 can be reduced to:

$$\Delta T = \frac{h_a \sigma_a \alpha \dot{\epsilon}}{h_T} \left[1 - \exp\left(-\frac{h_T t}{C \rho h_a} \right) \right] \quad (\text{Eq 14})$$

Fig. 7 A schematic of stress-strain curves before and after correction for deformation heating

The purpose of determining temperature increase is to obtain isothermal stress-strain curves. Strength loss of the specimen due to deformation heating can be expressed in terms of the derivative of stress by temperature (Ref 27):

$$\Delta \sigma = \Delta T \left. \frac{d\sigma}{dT} \right|_{\epsilon, \dot{\epsilon}} \quad (\text{Eq 15})$$

The way to determine the derivative is to plot stress data at constant strain and strain rate, and at corrected temperatures ($T = T_{\text{test}} - \Delta T$), as shown in Fig. 8. The derivative is usually a function of temperature.

Fig. 8 A schematic showing determination of derivative of stress in terms of temperature

The step-by-step procedure for reducing load-stroke data is:

1. Convert load-stroke data to true stress-versus-true strain data, including correction for machine elastic deflection.
2. Calculate ΔT for every data point using Eq 13 or 14.
3. Plot true stress-versus-corrected temperature at each strain rate and at a number of constant strains.
4. Obtain the slope of the plotted curves in step 3 using $d\sigma/dT$.
5. Calculate the stress increase when temperature is corrected to the nominal testing temperature.
6. Generate isothermal stress-strain curves by adding the stress increase to the true stress obtained in the first step.

Figure 9 shows both uncorrected and corrected stress-strain curves for HY-100 steel at 1000 °C (1830 °F) and at various strain rates.

Fig. 9 Stress-strain curves before and after temperature corrections for HY-100 steel at 1000 °C (1830 °F) and various strain rates. Source: Ref 8

Tension Test

When compression-testing equipment is not available, or the deformation process experiences more tension than compression, tensile testing can be used to obtain stress-strain curves. Tensile testing can be especially

useful for sheet-metal forming applications. Constant strain-rate tensile tests should follow an exponential curve, as shown in Fig. 10.

Fig. 10 Displacement as a function of time for tension and compression tests at constant strain rate

The setup of high-temperature tensile-testing equipment is similar to compression testing. The difference is that tensile testing does not need anvils and platens. Instead, it uses pulling bars and grips. Figure 11 shows a typical setup of high-temperature tensile loading train.

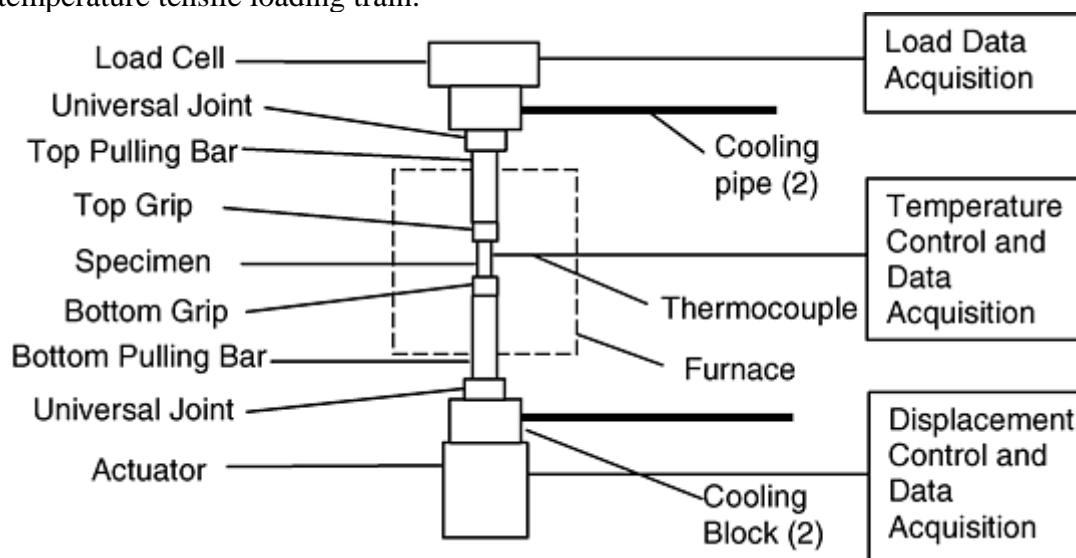

Fig. 11 Loading train for high-temperature tensile testing

The grips can be either of the screw type or the split-ring type; both are commercially available. Split-ring grips provide for a quick removal of the specimen if quenching immediately after testing is desirable and has to be performed outside the furnace.

Universal joints are necessary to align the loading train. In any case, the maximum bending strain should not exceed 10% of the axial strain. One way to check the bending strain is to use strain gages on a specimen at the middle of the gage length. If the maximum (or minimum) bending strain is within the limit at room temperature, the alignment should be fine at elevated temperatures. Care must be taken not to affect the alignment of the loading train with the furnace and its accessories. The alignment needs to be tested periodically.

Because tensile specimens usually have longer gage lengths than compression specimens, more than one thermocouple may be needed to monitor the temperature of the gage length. Thermocouples should very closely contact the reduced section. Shielding the thermocouple is necessary unless the difference in indicated

temperature from an unshielded bead and a bead inserted in a hole in the specimen has been shown to be less than one half the variation listed here (Ref 16):

Up to and including 1000 °C (1800 °F)	±3 °C (5 °F)
Above 1000 °C (1800 °F)	±6 °C (10 °F)

Thermocouples need to be calibrated as specified in Ref 16. Thermocouple wire exposed to a hot zone should be cut off after each test, and a new bead should be formed. During the entire test, temperature variation should not exceed the ranges indicated in the previous table for the entire gage length.

One of the advantages of a tensile test compared to a compression test is that the tensile test does not have a friction effect, and an extensometer can be used to measure true strain up to the maximum loading. The true stress would have to be corrected due to the reduction of cross-sectional area. Stress-strain data may not be useful beyond the maximum load point due to necking. Attachment of the extensometer should be carried out very carefully because it may affect alignment (Ref 28). Attaching extensometers on opposite sides and averaging the readings can reduce the error. When feasible, extensometers should be attached directly to the reduced section (Ref 16).

One important parameter that can be determined from tensile tests is the strain-hardening exponent, n , which is important for both bulk and sheet-metal forming. The procedure used to determine n -values is quite simple and is explained well in Ref 29.

Young's modulus can also be determined by tensile tests with accurate extensometers. Temperature control during the test is very important. The average temperature over the specimen gage length should not deviate from the indicated nominal test temperature by more than ±1.5 °C (2.5 °F) for test temperatures up to and including 900 °C (1650 °F), and ±3 °C (5.5 °F) for above 900 °C (1650 °F) (Ref 30). The loading rate should also be slow in order to avoid the thermal effect of adiabatic expansion or contraction. However, the test speed should not be so slow that creep effects are not negligible (Ref 30).

Data Reduction for Workability

Workability is an important issue in deformation modeling. For bulk workability, Kuhn developed the testing technique described in Ref 11. The workability constant C for a particular material at certain testing temperature and strain rate can be determined by a simple plane-strain bending test. The constant C is related to the constant C' in Eq 7 and 8 as follows:

$$C = 0.75C' \quad (\text{Eq 16})$$

It also relates to the constant C_2 in Eq 6 (Ref 31):

$$C_2 = \frac{2K}{3(n+1)} C^{n+1} \left(\frac{2}{\sqrt{3}} \right)^n \quad (\text{Eq 17})$$

assuming that the constitutive equation $\bar{\sigma} = K\bar{\epsilon}^n$ applies.

Fitting Testing Data to Constitutive Models

If one uses the tabular input form for modeling, the interpolation of data is left to the finite element modeling (FEM) software after stress-strain data have been obtained. Care must be taken to ensure that the temperature and strain-rate ranges in the data cover every possible case in the simulation for convergence.

If a constitutive model is being used, data needs to be fit to the equation. Equation 2 is not difficult to fit. However, Eq 3 has four constants: A , α , n' , and Q , and the procedure to fit it is somewhat complex. There are many ways to fit the data; some may lead to significant errors. A description of a general procedure to determine the constants follows.

Equation 3 can also be written as:

$$Z = A[\sinh(\alpha\sigma)]^{n'} \quad (\text{Eq 18})$$

where Z is the Zener-Hollomon parameter, defined as:

$$Z = \dot{\epsilon} \exp\left(\frac{Q}{RT}\right) \quad (\text{Eq 19})$$

To determine parameter α , we need to determine the strain-rate sensitivity, m , and another material parameter, β . At high stresses, the following relationship holds:

$$\alpha = m\beta \tag{Eq 20}$$

When n' is replaced approximately by $1/m$, the following equations result:

$$m = \left. \frac{\partial \log \sigma}{\partial \log \dot{\epsilon}} \right|_{T,\epsilon} \tag{Eq 21}$$

and

$$\beta = \left. \frac{\partial \ln \dot{\epsilon}}{\partial \sigma} \right|_{T,\epsilon} \tag{Eq 22}$$

Steady-state stresses are plotted for each temperature-versus-strain rate example on a log-log scale, as shown in Fig. 12. The slope of the straight lines is the strain-rate sensitivity, m . At high stresses, the lines are parallel. The parameter β can be determined from the slope of stress versus the natural log of strain rate, as shown in Fig. 13. From the m and β values, α can be determined using Eq 20.

Fig. 12 Steady-state stresses versus strain rate at different temperatures (°C) on a log-log scale for HY-100 steel

Fig. 13 Steady-state stresses versus natural log of strain rate at different temperatures (°C) for HY-100 steel

Equation 4 yields:

$$Q = \frac{R}{0.4343m} \left. \frac{\partial \log \sigma}{\partial (1/T)} \right|_{\dot{\epsilon}, \epsilon} \quad (\text{Eq 23})$$

Again, n' is approximately replaced by $1/m$. However, this time the m value is determined from the low stresses, as shown in Fig. 14. The apparent activation energy, Q , can be determined by plotting log stress versus $1/T$ at low stresses, as shown in Fig. 15. In Eq 23, R is the gas constant.

Fig. 14 Steady-state stresses versus strain rate at different temperatures (°C) on a log-log scale for HY-100 steel

Fig. 15 Log stress versus 1/T at different strain rates (in 1/s) for HY-100 steel

After obtaining the values of α and Q , the natural log of Z (Zener-Hollomon parameter) is plotted versus the natural log of $\sinh(\alpha\sigma)$ to determine the values of n' and A . If the deformation behavior is governed by Eq 18, the plot can be well fit by a linear equation, as shown in Fig. 16. The slope would be equal to n' , and the intercept would be $\ln A$. The final results for HY-100 steel are shown here:

m at high σ	0.1059
m at low σ	0.2089
β	0.0441
α , MPa ⁻¹ (ksi ⁻¹)	4.671×10^{-3} (6.775×10^{-4})
Q , kJ/mol	368.67
n'	5.8417
A , s ⁻¹	1.2519×10^{16}

See Eq 3

Fig. 16 Plot of $\ln(Z)$ versus $\ln[\sinh(\alpha\sigma)]$ to determine the values of n' and A

Testing for the Friction Coefficient

For bulk forming, the friction coefficient can be measured by a ring compression test (Ref 32). The principle of this test is that when a ring is compressed, the inner diameter of the ring either increases or decreases depending on the friction condition at the ring/platen interface. As shown in Fig. 17, measurements of the inside diameters of the ring specimens provide a sensitive means to determine the friction coefficient because the inside diameter increases if the friction is low and decreases if the friction is high.

Fig. 17 Variation in shape of ring specimen under different friction conditions. (a) Undeformed. (b) Low friction. (c) Medium friction. (d) High friction. 50% deformation for (b), (c), and (d). Source: Ref 32

The specimen, as shown in Fig. 18, is usually made with a specific geometry ratio. The ratio of outer diameter to inner diameter to thickness ($D_o:D_i:T$) is 6:3: x , where x can be 0.5, 1, or 2. The analysis of this test is based on homogeneous deformation. To avoid error introduced by bulging or for high friction, the x -value 0.5 should be used. For medium friction, the x -value 1 should be used, and for low friction, the x -value 2 should be used. Analytical treatment that takes into account bulging for the specimens 6:3:2 was provided by DePierre, Gurney,

and Male (Ref 33). Before testing, lubricant is applied to the surface of the ring specimen. The testing is conducted the same way as compression testing at a certain temperature and strain rate. After a certain amount of deformation (reflecting the forming operation reduction), the test is ended, and the inner diameter of the tested ring specimen is measured. The measured value and percent reduction are then compared to a set of calibration curves (Fig. 19) to determine the friction coefficient (Ref 4, 32, 34, and 35).

Testing for the Heat-Transfer Coefficient

Deformation processing often involves heat transfer. One of the difficulties in modeling is determining the input value of the heat-transfer coefficient. The most commonly used method of determining the heat-transfer coefficient is the inverse method. In this method, the temperatures of the workpiece and tooling are measured at different locations as a function of time. Subsequently, the process is modeled with trial values of the heat-transfer coefficient to match the temperature measured in the experiments. The trial-and-error method for determining the heat-transfer coefficient can be programmed to loop the simulations until an optimum value of the coefficient is determined.

Chen, Samarasekera, and Hawbolt (Ref 36) performed such work on the hot rolling of steels. Figure 20 shows the workpiece geometry and the position of thermal couples. Three thermocouples were used in this case to measure the temperatures at different locations. Figure 21 shows how the experimental equipment was

configured. The tube furnace was positioned right in front of the rolling mill to ensure an accurate starting temperature. During rolling, temperature data was acquired continuously by a computer. The thermal responses of the thermocouples are presented in Fig. 22. When the workpiece entered the roll gap, the temperature dropped immediately. As it came out of the roll gap, the temperature recovered to a level lower than the initial temperature. Figure 23 shows the detailed temperature reading for thermocouple 2 inside the roll gap.

Fig. 21 Experimental setup for temperature measurement during hot rolling. Source: Ref 36

Fig. 22 Thermal responses of two thermocouples (TC1 and TC2) in the workpiece during hot rolling. Source: Ref 36

Fig. 23 Detailed temperature reading for thermocouple 2 in the roll gap. Source: Ref 36

The rolling process was then modeled. The contact time of the workpiece in the roll gap is divided into a number of time steps. For each time step, the calculated temperature with the trial heat-transfer coefficient is compared to the measured temperature. When the two temperature values are close enough—for instance, within 1 to 2 °C (1.75–3.5 °F)—the assumed heat-transfer coefficient is accepted as the real heat-transfer coefficient. The calculation process is then repeated for the next time step. Results of the heat-transfer coefficient at two different rolling temperatures are shown in Fig. 24.

Testing for Deformation Modeling

Dan Zhao, Johnson Controls, Inc.

Testing for Sheet-Metal Forming

Sheet-metal forming comprises deep drawing, stamping, stretching, drape forming, spin forming, coining, ironing, bending, blanking, and superplastic forming. Sheet metals are usually produced by rolling, and so mechanical properties vary along different directions in relation to the rolling direction (RD). Figure 25 shows a schematic of a sheet-metal specimen and its directions relative to the rolling direction. In addition, spring-back is significant for sheet metals, and elastic properties are much more important than in bulk forming.

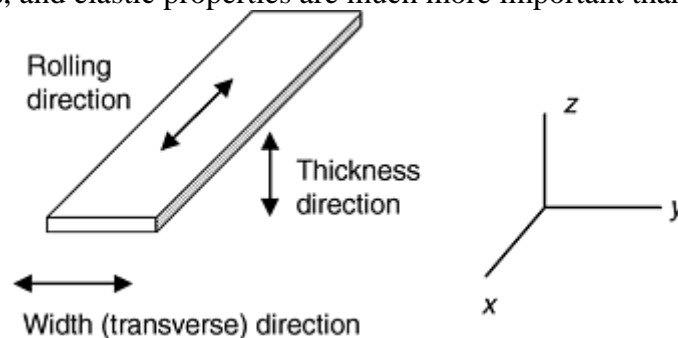

Fig. 25 Schematic of a sheet-metal specimen and its directions relative to the rolling direction

A very important parameter for sheet metal is the ratio (R) of plastic strains in width (transverse) and thickness directions:

$$R = \frac{\epsilon_w}{\epsilon_t} = \frac{\epsilon_y}{\epsilon_z} \quad (\text{Eq 24})$$

Because the strains in thickness direction are difficult to measure, they are usually calculated by using volume constancy:

$$\varepsilon_t = -(\varepsilon_l + \varepsilon_w) \quad (\text{Eq 25})$$

R -values vary in different directions on the plane of the sheet metal, and are usually denoted by the angle (in degrees) to rolling direction. In the rolling direction, R is denoted as R_0 , and in the transverse direction, as R_{90} . Most sheet-metal forming operations, such as deep drawing and stamping, are performed at room temperature. However, sheet forming in the aerospace industry with titanium alloys and superalloys almost always are done at elevated temperatures. Forming at elevated temperatures is also done to achieve the desirable benefits of superplastic behavior, which is described in more detail in the article “Superplastic Deformation at Elevated Temperatures” in this Volume.

Constitutive Equations

For elastic deformation, generalized Hooke's law holds (Ref 37):

$$\sigma_i = C_{ij}\varepsilon_j \quad i, j = 1, \dots, 6 \quad (\text{Eq 26})$$

where σ_i is the stress component, C_{ij} is the stiffness matrix, and ε_j is the strain component. Due to symmetry, C_{ij} has a maximum number of 21 independent constants. Table 2 lists the independent constants for different types of materials. For orthotropic material, there are nine independent constants; for transversely isotropic materials, there are five independent constants; and for isotropic materials, there are only two independent constants. The elastic constants can be measured using nondestructive testing techniques (Ref 38). Once these constants are determined, they can be directly input into modeling software.

Table 2 Independent constants in stiffness matrix for different types of materials

Material	Independent constants
Orthotropic	$C_{11}, C_{12}, C_{13}, C_{22}, C_{23}, C_{33}, C_{44}, C_{55}, C_{66}$
Transversely isotropic	$C_{11}, C_{12}, C_{13}, C_{33}, C_{44}$
Isotropic	C_{11}, C_{12}

For plastic deformation, Hill's anisotropic yield criterion (Ref 39) has wide recognition:

$$2f(\sigma_{ij}) = F(\sigma_y - \sigma_z)^2 + G(\sigma_z - \sigma_x)^2 + H(\sigma_x - \sigma_y)^2 + 2L\tau_{yz}^2 + 2M\tau_{zx}^2 + 2N\tau_{xy}^2 = 1 \quad (\text{Eq 27})$$

where $F, G, H, L, M,$ and N are constants that characterize the anisotropy. Tensile tests can be used to determine constants $F, G,$ and H , and shear tests can be used to evaluate constants $L, M,$ and N .

A tensile test in the x -direction provides the yield strength X . Similarly, tensile tests in the y - and z -directions provide yield strengths Y and Z . Inputting these yield strengths into Eq 27 solves $F, G,$ and H (Ref 26):

$$2F = \frac{1}{Y^2} + \frac{1}{Z^2} - \frac{1}{X^2}$$

$$2G = \frac{1}{Z^2} + \frac{1}{X^2} - \frac{1}{Y^2} \quad (\text{Eq 28})$$

$$2H = \frac{1}{X^2} + \frac{1}{Y^2} - \frac{1}{Z^2}$$

However, a tensile test in the thickness direction (z -direction) is very difficult. R -values in rolling and width directions can be used to obtain Z (Ref 26):

$$Z = Y \sqrt{\frac{R_0(1 + R_{90})}{(R_{90} + R_0)}} \quad (\text{Eq 29})$$

The plastic constitutive behavior for anisotropic material can also be described by Eq 2 for different directions. Tensile tests can be conducted in the rolling direction, width direction, and the direction 45° from the rolling direction. Yield strength, tensile strength, uniform elongation, total elongation, the strain-hardening exponent (n), K -values, R -values, and the strain-rate sensitivity (m) are recorded or calculated. The data can subsequently be input into commercial software for deformation modeling (Ref 40).

Failure of Sheet Metal

Failure of sheet metals can be caused by either fracture or plastic instability. A general way of describing the failure is a forming-limit diagram (FLD) (Ref 41). A typical FLD for a low carbon steel is shown in Fig. 26 (Ref 25, 42). If the combination of major and minor strains is above the solid line, failure is likely to occur. If this combination is under the line, the forming process is safe. Theoretical equations for calculating critical major strain (ϵ_1^*) have also been developed, including an equation for local necking (Ref 25):

$$\epsilon_1^* = \frac{n}{1 + \rho} \quad (\text{Eq 30})$$

where n is strain-hardening exponent, provided that $\sigma_1 = K \epsilon_1^n$ is followed; and ρ is the ratio of minor strain to major strain, ϵ_2/ϵ_1 . For diffuse necking, the critical major strain (ϵ_1^*) is (Ref 43):

$$\epsilon_1^* = \frac{2n(1 + \rho + \rho^2)}{(\rho + 1)(2\rho^2 - \rho + 2)} \quad (\text{Eq 31})$$

Fig. 26 Typical forming-limit diagram for steel

Tensile Test

Tensile tests for sheet metal are specified in ASTM standards (Ref 15, 16, 29, and 44). Several special issues for sheet metals are discussed in the following sections.

Specimen Preparation. Specimens can be rectangular with or without reduced section. The specimens can be either machined or sheared. Sawing is also permitted by the applicable ASTM standard (Ref 44), but may not provide good dimensional control. Shearing with a precise punch and die is the most efficient way of making specimens. Computer numerical control machining, though slower than punching, is very precise and introduces little deformation along the machined surfaces. Specimens should be made along different directions to reflect anisotropy. Figure 27 shows the orientation of specimens on a piece of sheet metal.

Fig. 27 Sheet-metal specimen orientations for tensile testing. RD, rolling direction; TD, transverse direction

Commercial extensometers are available for strain measurement. To measure local strains, grid patterns can be put on the specimen surface over the gage length, as shown in Fig. 28. The patterns can be inscribed on a layer of paint (Ref 45, 46), photoetched, or thermally transferred from printed transparencies. Thermally transferred patterns printed with a laser printer can stand testing temperatures up to 1200 °C (2190 °F). The size of the grid can be 1 to 2 mm (0.04–0.08 in.) to permit accurate local measurement.

Fig. 28 Grid pattern on the specimen gage length

Alignment of the Specimen. Special care should be taken to ensure the alignment of the specimen with a gripping apparatus. Improper gripping results in bending of the specimen, especially in the width direction. It is helpful to mark the specimen with gripping lines for reference.

Measurement of Strain. Displacement of the grid on the specimen can be recorded with a high-speed camera for calculation of instantaneous strains (Fig. 29). If a camera is not available, displacement can be measured manually. However, manual measurement is difficult at elevated temperatures. The fracture strains can always be measured manually with a microscope. Some specialized three-dimensional displacement-measurement systems, as shown in Fig. 30, are also available (Ref 45, 46).

Fig. 29 Strain recording with a camera during a tensile test of a sheet-metal specimen. Source: Ref 46

Fig. 30 Automatic noncontact 3-D surface-deformation measuring system. Source: Ref 46

Punch Testing

The punch test is used to obtain data for constructing FLDs of sheet metals. A schematic is shown in Fig. 31 for a punch-test apparatus. Punch testing can also be used to measure the workability for deep drawing. An

important parameter for drawability is the limiting dome height (LDH). In addition to the fracture data from punch testing, data from biaxial stretching and tensile tests can also be used for constructing FLDs.

Fig. 31 Schematic of a punch-test device

The specimen can be round or rectangular for the full-size punch test. The specimen is clamped around the edge. The punch moves at a specified speed (usually between 0.08 and 0.4 mm/s, or 0.003 and 0.015 in./s, unless simulating a specific operation at a different speed). When the specimen starts necking severely or fractures, a load drop stops the punch. A hydraulic sheet-metal testing machine has options to vary the clamping force and program the movement of the punch.

The punch should be lubricated with petroleum jelly. Clamping should be conducted carefully to ensure it does not cause the specimen to crack at the clamping site. Specimens with grids on them help determine fracture strains. Circular grids also help identify the directions of major and minor strains after deformation. However, if a three-dimensional digital measurement system is available, the strains can be calculated automatically, and square grids are as useful as circular grids.

Different widths of specimens are needed to cover the wide range of major and minor strain combinations. However, the width can change in the transverse direction or rolling direction, and FLDs constructed with the two different groups of specimens are different.

Testing for Deformation Modeling

Dan Zhao, Johnson Controls, Inc.

Testing for Sheet-Metal Forming

Sheet-metal forming comprises deep drawing, stamping, stretching, drape forming, spin forming, coining, ironing, bending, blanking, and superplastic forming. Sheet metals are usually produced by rolling, and so mechanical properties vary along different directions in relation to the rolling direction (RD). Figure 25 shows a schematic of a sheet-metal specimen and its directions relative to the rolling direction. In addition, spring-back is significant for sheet metals, and elastic properties are much more important than in bulk forming.

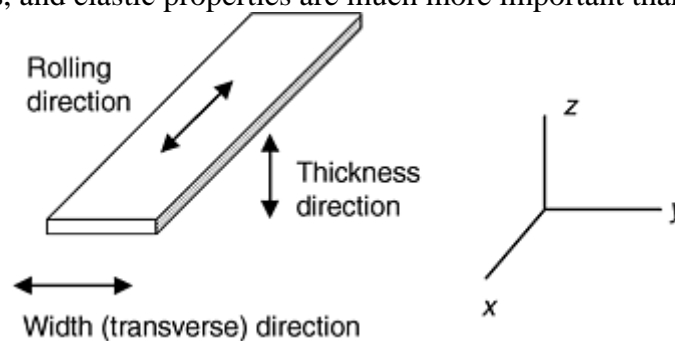

Fig. 25 Schematic of a sheet-metal specimen and its directions relative to the rolling direction

A very important parameter for sheet metal is the ratio (R) of plastic strains in width (transverse) and thickness directions:

$$R = \frac{\epsilon_w}{\epsilon_t} = \frac{\epsilon_y}{\epsilon_z} \quad (\text{Eq 24})$$

Because the strains in thickness direction are difficult to measure, they are usually calculated by using volume constancy:

$$\varepsilon_t = -(\varepsilon_l + \varepsilon_w) \quad (\text{Eq 25})$$

R -values vary in different directions on the plane of the sheet metal, and are usually denoted by the angle (in degrees) to rolling direction. In the rolling direction, R is denoted as R_0 , and in the transverse direction, as R_{90} . Most sheet-metal forming operations, such as deep drawing and stamping, are performed at room temperature. However, sheet forming in the aerospace industry with titanium alloys and superalloys almost always are done at elevated temperatures. Forming at elevated temperatures is also done to achieve the desirable benefits of superplastic behavior, which is described in more detail in the article “Superplastic Deformation at Elevated Temperatures” in this Volume.

Constitutive Equations

For elastic deformation, generalized Hooke's law holds (Ref 37):

$$\sigma_i = C_{ij}\varepsilon_j \quad i, j = 1, \dots, 6 \quad (\text{Eq 26})$$

where σ_i is the stress component, C_{ij} is the stiffness matrix, and ε_j is the strain component. Due to symmetry, C_{ij} has a maximum number of 21 independent constants. Table 2 lists the independent constants for different types of materials. For orthotropic material, there are nine independent constants; for transversely isotropic materials, there are five independent constants; and for isotropic materials, there are only two independent constants. The elastic constants can be measured using nondestructive testing techniques (Ref 38). Once these constants are determined, they can be directly input into modeling software.

Table 2 Independent constants in stiffness matrix for different types of materials

Material	Independent constants
Orthotropic	$C_{11}, C_{12}, C_{13}, C_{22}, C_{23}, C_{33}, C_{44}, C_{55}, C_{66}$
Transversely isotropic	$C_{11}, C_{12}, C_{13}, C_{33}, C_{44}$
Isotropic	C_{11}, C_{12}

For plastic deformation, Hill's anisotropic yield criterion (Ref 39) has wide recognition:

$$2f(\sigma_{ij}) = F(\sigma_y - \sigma_z)^2 + G(\sigma_z - \sigma_x)^2 + H(\sigma_x - \sigma_y)^2 + 2L\tau_{yz}^2 + 2M\tau_{zx}^2 + 2N\tau_{xy}^2 = 1 \quad (\text{Eq 27})$$

where $F, G, H, L, M,$ and N are constants that characterize the anisotropy. Tensile tests can be used to determine constants $F, G,$ and $H,$ and shear tests can be used to evaluate constants $L, M,$ and $N.$

A tensile test in the x -direction provides the yield strength $X.$ Similarly, tensile tests in the y - and z -directions provide yield strengths Y and $Z.$ Inputting these yield strengths into Eq 27 solves $F, G,$ and H (Ref 26):

$$2F = \frac{1}{Y^2} + \frac{1}{Z^2} - \frac{1}{X^2}$$

$$2G = \frac{1}{Z^2} + \frac{1}{X^2} - \frac{1}{Y^2} \quad (\text{Eq 28})$$

$$2H = \frac{1}{X^2} + \frac{1}{Y^2} - \frac{1}{Z^2}$$

However, a tensile test in the thickness direction (z -direction) is very difficult. R -values in rolling and width directions can be used to obtain Z (Ref 26):

$$Z = Y \sqrt{\frac{R_0(1 + R_{90})}{(R_{90} + R_0)}} \quad (\text{Eq 29})$$

The plastic constitutive behavior for anisotropic material can also be described by Eq 2 for different directions. Tensile tests can be conducted in the rolling direction, width direction, and the direction 45° from the rolling direction. Yield strength, tensile strength, uniform elongation, total elongation, the strain-hardening exponent (n), K -values, R -values, and the strain-rate sensitivity (m) are recorded or calculated. The data can subsequently be input into commercial software for deformation modeling (Ref 40).

Failure of Sheet Metal

Failure of sheet metals can be caused by either fracture or plastic instability. A general way of describing the failure is a forming-limit diagram (FLD) (Ref 41). A typical FLD for a low carbon steel is shown in Fig. 26 (Ref 25, 42). If the combination of major and minor strains is above the solid line, failure is likely to occur. If this combination is under the line, the forming process is safe. Theoretical equations for calculating critical major strain (ϵ_1^*) have also been developed, including an equation for local necking (Ref 25):

$$\epsilon_1^* = \frac{n}{1 + \rho} \quad (\text{Eq 30})$$

where n is strain-hardening exponent, provided that $\sigma_1 = K \epsilon_1^n$ is followed; and ρ is the ratio of minor strain to major strain, ϵ_2/ϵ_1 . For diffuse necking, the critical major strain (ϵ_1^*) is (Ref 43):

$$\epsilon_1^* = \frac{2n(1 + \rho + \rho^2)}{(\rho + 1)(2\rho^2 - \rho + 2)} \quad (\text{Eq 31})$$

Fig. 26 Typical forming-limit diagram for steel

Tensile Test

Tensile tests for sheet metal are specified in ASTM standards (Ref 15, 16, 29, and 44). Several special issues for sheet metals are discussed in the following sections.

Specimen Preparation. Specimens can be rectangular with or without reduced section. The specimens can be either machined or sheared. Sawing is also permitted by the applicable ASTM standard (Ref 44), but may not provide good dimensional control. Shearing with a precise punch and die is the most efficient way of making specimens. Computer numerical control machining, though slower than punching, is very precise and introduces little deformation along the machined surfaces. Specimens should be made along different directions to reflect anisotropy. Figure 27 shows the orientation of specimens on a piece of sheet metal.

Fig. 27 Sheet-metal specimen orientations for tensile testing. RD, rolling direction; TD, transverse direction

Commercial extensometers are available for strain measurement. To measure local strains, grid patterns can be put on the specimen surface over the gage length, as shown in Fig. 28. The patterns can be inscribed on a layer of paint (Ref 45, 46), photoetched, or thermally transferred from printed transparencies. Thermally transferred patterns printed with a laser printer can stand testing temperatures up to 1200 °C (2190 °F). The size of the grid can be 1 to 2 mm (0.04–0.08 in.) to permit accurate local measurement.

Fig. 28 Grid pattern on the specimen gage length

Alignment of the Specimen. Special care should be taken to ensure the alignment of the specimen with a gripping apparatus. Improper gripping results in bending of the specimen, especially in the width direction. It is helpful to mark the specimen with gripping lines for reference.

Measurement of Strain. Displacement of the grid on the specimen can be recorded with a high-speed camera for calculation of instantaneous strains (Fig. 29). If a camera is not available, displacement can be measured manually. However, manual measurement is difficult at elevated temperatures. The fracture strains can always be measured manually with a microscope. Some specialized three-dimensional displacement-measurement systems, as shown in Fig. 30, are also available (Ref 45, 46).

Fig. 30 Automatic noncontact 3-D surface-deformation measuring system. Source: Ref 46

Punch Testing

The punch test is used to obtain data for constructing FLDs of sheet metals. A schematic is shown in Fig. 31 for a punch-test apparatus. Punch testing can also be used to measure the workability for deep drawing. An

important parameter for drawability is the limiting dome height (LDH). In addition to the fracture data from punch testing, data from biaxial stretching and tensile tests can also be used for constructing FLDs.

Fig. 31 Schematic of a punch-test device

The specimen can be round or rectangular for the full-size punch test. The specimen is clamped around the edge. The punch moves at a specified speed (usually between 0.08 and 0.4 mm/s, or 0.003 and 0.015 in./s, unless simulating a specific operation at a different speed). When the specimen starts necking severely or fractures, a load drop stops the punch. A hydraulic sheet-metal testing machine has options to vary the clamping force and program the movement of the punch.

The punch should be lubricated with petroleum jelly. Clamping should be conducted carefully to ensure it does not cause the specimen to crack at the clamping site. Specimens with grids on them help determine fracture strains. Circular grids also help identify the directions of major and minor strains after deformation. However, if a three-dimensional digital measurement system is available, the strains can be calculated automatically, and square grids are as useful as circular grids.

Different widths of specimens are needed to cover the wide range of major and minor strain combinations. However, the width can change in the transverse direction or rolling direction, and FLDs constructed with the two different groups of specimens are different.

Testing for Deformation Modeling

Dan Zhao, Johnson Controls, Inc.

Testing for Semisolid Forming and Polymer Extrusion

Semisolid forming has become popular due to improved mechanical properties of the parts compared to those made by casting. Polymer extrusion has flow characteristics very similar to those of semisolid forming.

Constitutive Equations

The deformation of a semisolid is significantly affected by temperature and strain rate, as with a solid. The only difference is that the deformation of a semisolid is characterized by shear rate instead of strain rate.

Newton's law of viscosity states (Ref 47, 48):

$$\tau_{yx} = -\eta \frac{dv_x}{dy} = \eta \dot{\gamma} \quad (\text{Eq 32})$$

where τ_{yx} , is shear stress, η is viscosity, v_x is velocity, and $\dot{\gamma}$ is shear rate.

For Newtonian fluid, viscosity is only a function of temperature, and does not depend on shear rate. Most liquid metals and alloys are Newtonian. However, semisolid alloys, as well as polymeric materials, exhibit Non-Newtonian behavior. The viscosity of those materials varies with shear rate; in most cases, it decreases with increasing shear rate—so-called shear thinning. Figure 32 shows the viscosity behavior of Newtonian and Non-Newtonian fluids (Ref 47).

Fig. 32 Stress-strain rate curves for time-independent fluids. Source: Ref 47

For semisolid materials, viscosity is a function of temperature, shear rate, and fraction of solid. Figure 33 shows the viscosity of an Al-Si-Mg alloy with 0.45 and 0.55 solid fractions (Ref 49). Figure 34 shows viscosity variation as a function of temperature and shear rate for a polymer compound.

Fig. 33 Apparent viscosity of partially remelted Al-Si-Mg alloys with solid fraction 0.45 and 0.55.
 Source: Ref 49. (See also Ref 48.)

Fig. 34 Viscosity for a polymer material as a function of shear rate at several temperatures

The variation of viscosity as a function of shear rate can be described by a power law (Ref 50):

$$\eta = k \dot{\gamma}^{n-1} \quad (\text{Eq 33})$$

where k and n are empirically determined constants. More complicated equations have been suggested when viscosity data is not a straight line on a log-log scale, as shown in Fig. 33 and 34. One of the equations is the Carreau model (Ref 51):

$$\eta = \eta_0 [1 + (\lambda \dot{\gamma})^2]^{1/2n} \quad (\text{Eq 34})$$

where η_0 is the viscosity at zero shear rate, and λ and n are again empirical constants.

Viscosity is measured by various viscometers. Descriptions of three types of viscometers follow (Ref 50, 51).

Coaxial Cylinder Viscometer

The coaxial cylinder viscometer approximates the classic parallel-plate drag flow problem. As shown in Fig. 35, a cylinder is filled with the fluid with a viscosity to be measured. A coaxial cylinder rotates inside the cylinder with the fluid. The torque, T_0 , and the rotational speed, n , (in rpm) are recorded. The viscosity is given as:

$$\eta = \frac{15T_0 h}{\pi^2 r^3 n L} \quad (\text{Eq 35})$$

where h is the distance between the two cylinders, r is the radius of the inside cylinder, and L is the length of the inside cylinder.

Fig. 35 A schematic of the coaxial cylinder viscometer. Source: Ref 51

Cone-and-Plate Viscometer

The cone-and-plate viscometer, depicted in Fig. 36, is also called a Weissenberg rheogoniometer. It also approximates the parallel-plate drag flow with the flow in the gap between a plate and a cone at very small angles (a couple of degrees). This test also records the torque and the rotational speed. However, the rotational speed here is in rad/s, and it is denoted as Ω . The viscosity is calculated as:

$$\eta = \frac{3\alpha T_0}{2\pi R^3 \Omega} \quad (\text{Eq 36})$$

where α is the angle between the cone and the plate and R is the radius of the cone or plate.

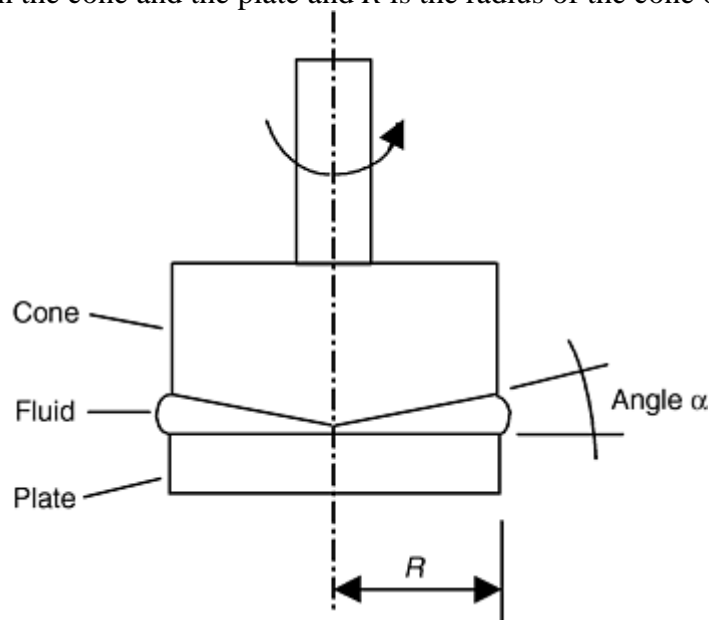

Fig. 36 Schematic of the cone-and-plate instrument. Source: Ref 51

This instrument works well for shear-rate ranges of 10^{-2} to 10^5 s^{-1} . At higher shear rates, flow in the radial direction develops, and the sample may fly out.

Capillary Viscometer

This instrument, depicted in Fig. 37, is good for shear rates of 10 to 1000 s⁻¹. In this test, the fluid is extruded through a tube by applying pressure. The shear stress is related to the pressure drop over the length of the tube:

$$\tau = -\frac{\Delta P R}{2L} \quad (\text{Eq 37})$$

where ΔP is the pressure drop. When the reservoir is large, the gradient of pressure in the reservoir is negligible, and, therefore, ΔP is negligible as well.

Fig. 37 Schematic of a capillary viscometer. Source: Ref 51

The apparent shear rate is:

$$\dot{\gamma}_a = \frac{4Q}{\pi R^3} \quad (\text{Eq 38})$$

where Q is the volume flow rate (mass flow rate over density).

There is a correction for the shear rate, which takes into account the resistance to stretching at the entrance of the tube. The resistance is small for Newtonian fluid, but large for polymer melts. With this correction (Rabinowitsch correction), shear rate becomes:

$$\dot{\gamma} = \frac{4Q}{\pi R^3} \left(\frac{3}{4} + \frac{d \ln Q}{4 d \ln \tau} \right) \quad (\text{Eq 39})$$

and the viscosity is:

$$\eta = \frac{\tau}{\dot{\gamma}} \quad (\text{Eq 40})$$

Figure 38 provides the ranges of viscosity suitable for different viscometers. In general, cone-and-plate viscometers are good for low shear rates, and capillary viscometers are good for medium to high shear rates.

Fig. 38 Viscosity ranges for different viscometers. Source: Ref 51

The control of temperature and structural changes of fluid being tested present difficulty in testing for viscosity. For semisolid materials, local segregation of solid fractions and interaction of particles can affect viscosity significantly. In the forming of semisolid parts, induction heating, which is difficult to control, is usually employed. A few degrees variation in temperature can cause a large difference in the solid fraction. For polymer materials, nonuniform heating and localized curing also greatly influence the data. In general, 10% error in viscosity data is not unusual.

Mechanical Testing of Threaded Fasteners and Bolted Joints

Ralph S. Shoberg, RS Technologies, Ltd.

Introduction

FASTENER ENGINEERING and the mechanical testing of threaded fasteners and bolted joints is an important specialty within the field of mechanical engineering. With the wide variety of fasteners and bolted joints available for use, no one set of tests can be specified to cover all applications. The guidelines and examples presented in this article are intended to introduce technical testing concepts and necessary theoretical background subjects. With this introduction as a guide, the interested reader can select and perform practical tests that can help confirm strength and reliability factors for fasteners and bolted-joint assemblies.

All testing and analysis efforts must begin with an understanding of the behavior of individual fasteners. A proper overview recognizes the complex interaction of the materials properties of the fastener, clamped components, and internally threaded components, as well as the influence of coatings, lubricants, and adhesives

on the performance of fasteners in bolted joints. The test methods and procedures that yield the most informative data will test the threaded fastener in the same manner in which it is actually installed.

Test methods for mechanical properties such as hardness, tensile strength, and torsional strength, as well as corrosion and hydrogen embrittlement, are covered in other articles of this Volume and in more detail in the various referenced SAE, ISO, DIN, and ASTM testing standards. These tests provide the baseline information necessary for proper interpretation of the torque-tension tests and testing methods for evaluation of bolted joints presented in this article.

This article outlines test procedures for obtaining useful data for understanding details critical to reliable threaded-fastener applications. Some tests described herein are based on versions of published testing standards. Users should study the referenced standards prior to beginning a testing program. For example, by following the standard test methods and procedures according to ASTM F 606M, the basic mechanical strength properties of threaded fasteners can be determined, and by following the procedures specified in DIN 946, thread and underhead friction coefficients for threaded fasteners can be determined.

Combining basic materials strength and friction coefficient information leads to the development of a powerful method called torque-angle signature analysis. This method provides valuable information on joint strength and performance when applied to testing fasteners in bolted joints. By careful review of an applied torque versus angle-of-turn plot, signature analysis can be used to evaluate bolted joints for loss of preload due to settling, creep, and relaxation, or vibration and dynamic loading. In addition, joint strength problems, such as thread strip and embedment of bearing surfaces and material yield within the bolted joint, are easily identified.

Mechanical Testing of Threaded Fasteners and Bolted Joints

Ralph S. Shoberg, RS Technologies, Ltd.

Torque, Angle, Tension, and Friction

A proper amount of tension, or clamping force, must be developed to ensure that a bolted assembly will function in a safe and reliable manner. The most common attempt to indirectly estimate fastener tension is to take torque measurements either dynamically as the fastener is tightened or with a breakaway audit after the fact. The torque that is required to produce the desired tension in a fastener is dependent on several factors, with frictional characteristics being the most important. Angle-of-turn measurements combined with torque measurements can help overcome the unknown friction-induced variability in the torque-tension relationship. This section provides a brief overview of the relationships between torque, angle-of-turn, tension, and friction and how they are measured and evaluated. This background information is the foundation of the testing methods described in subsequent sections of this article.

Tension

The tension that is created in a threaded fastener when it is tightened represents the clamping force that holds the assembly together. Once the assembly is brought together, the fastener responds like a tension spring, and the assembly acts like a compression spring. The interaction between the fastener and the assembly is illustrated in Fig. 1. As the fastener is turned and load is applied, the fastener is stretched, and the parts are compressed. This compression results in an elastic joint in which the fastener is normally the more flexible member, and the assembly is the more rigid member.

Fig. 1 Spring effect of fastener and assembly under load

The amount of clamping force that the fastener must provide to hold the assembly together must be sufficient to both maintain preloading and prevent slipping of the parts or opening of the joint when the service loads are applied. The factors that primarily establish the preload requirement are the stiffness of the materials in the joint and the loads that are placed on the assembly.

Fastener tension can be measured using different devices, such as strain-gaged bolts or fastener force washers, or by using special techniques, such as ultrasonic bolt measurement. Although these devices and methods are useful in research and engineering efforts, they are often impractical or costly for evaluating fastener tension in production quality-control efforts.

Torque

The most common way to estimate clamping force is to observe the amount of torque applied to the fastener, either as the fastener is tightened or with a breakaway audit of the tightened fastener. This procedure assumes that the relationship between torque and tension is known, such that, for example, the nut factor, or K , from the simple equation $T = KDF$ (where T is torque, D is diameter, and F is clamping force) is established and known to have acceptable variability. The truth of the matter is that if torque alone is measured, it can never be known with certainty whether the desired tension has been achieved. Thus, unfortunately, it must be concluded that torque is a highly unreliable, totally inaccurate measurement for evaluation of the preload on a threaded fastener. However, for many noncritical fasteners, where safety or the functional performance of an assembly is not compromised, it may be acceptable to specify and monitor torque alone. The most common measurement tools are hand torque wrenches that are used for installation and torque audit measurements and rotary torque sensors that are used to measure installation torque dynamically.

In order for tension to be developed, the torque applied to a fastener must overcome friction under the head of the fastener and in the threads, and the fastener or nut must turn. Because the friction may absorb as much as 90 to 95% of the energy applied to the fastener, as little as 5 to 10% of the energy is left for generating fastener tension as shown in Fig. 2. If the amount of friction varies greatly, wide variations in clamping force are produced, which can mean loose or broken bolts leading to assembly failures. To ensure proper assembly of critical fasteners, more than torque must be measured.

Fig. 2 Typical distribution of energy from torque applied to a bolted assembly

Angle

The amount of fastener tension can be correlated to fastener rotation once the parts of an assembly are drawn firmly together. The clamping force that is developed in this zone of the assembly process, called the elastic tightening region, has been proven to be proportional to the angle of turn. This proportional relationship is based on the helix of the threads and is not influenced by the frictional characteristics of the joint once sufficient clamping force has been produced to firmly align the components such that a linear torque-angle signature slope is attained. Many years ago, in one of his books on the fundamentals of threaded fasteners, John Bickford wrote, “If we knew where to start measuring angle, it would be easy to get uniform tension results.” For the benefit of all, that problem has been solved for many applications using the torque-angle analysis method described in detail in the section “Torque-Angle Signature Analysis” in this article. Practical application of this concept requires that the user learn how to locate what is called the elastic origin.

The basic procedure for locating the elastic origin involves the following steps:

1. A rotary torque sensor equipped with an angle encoder is used to measure the applied torque and fastener rotation.
2. After the tension-versus-angle signature is plotted, a line is drawn tangent to the straight-line elastic tightening section of the plot.
3. The tangent line is extended until it intersects the torque axis. The point where the tangent line intersects the torque axis locates the elastic origin (Fig. 3).
4. The amount of fastener rotation from the elastic origin to where the fastener stops turning can be used to estimate the clamp load that was developed in the joint.

A number of practical signature analysis techniques are presented in detail in the section “Torque-Angle Signature Analysis” in this article.

Fig. 3 Location of elastic origin using torque vs. angle signature

Thread and Underhead Friction Measurements

Whereas fastener engineering analysis of threaded fasteners must consider material strength, surface finishes, plating, and coatings to ensure reliable performance, for predictable and repeatable assemblies it is also necessary to understand, measure, and control the frictional characteristics in both the thread and underhead regions. This is particularly true when developing fastener-locking devices such as locknuts, serrated underheads, special thread forms, and thread-locking adhesives and friction patches. Achieving a specific clamp force during installation is always the desired result, and the roles of thread friction and underhead friction must be analyzed and understood to ensure joint integrity.

To determine both thread friction and underhead friction, measurements are taken using a torque-tension research head, as shown in Fig. 4. This device is a special load cell designed to simultaneously measure both thread torque and clamp load. When used with torque sensors that measure the input torque, it is possible to determine the underhead friction torque and the thread friction torque. With this measurement equipment, the fastener can then be tested to establish and maintain standards for friction performance.

Fig. 4 Torque-tension research head, 800 kN capacity

For example, in the test plot illustrated in Fig. 5, a locknut is initially driven onto a bolt. The thread friction torque is equal to the input torque until contact with the underhead-bearing surface is made. Once contact is made with the underhead area, the underhead friction torque is measured as the difference between the total input torque and the thread torque. As clamp force is developed, the pitch torque is calculated and subtracted from the thread torque to compute the thread-friction torque. Note that for prevailing torque locknuts, the elastic origin is located at the prevailing torque level as shown in Fig. 5, not at the zero torque level used for fasteners without prevailing torque characteristics.

Fig. 5 Determining friction forces for prevailing torque locknut

Considerations in Testing

There are a number of factors that can affect the tension created in a bolt when torque is applied. Depending on the fastener and joint configuration, direct measurement of tension is not always practical or even possible by any means. Fortunately, torque and angle measurements can be taken for most bolted joints and then analyzed to assist in determination of important characteristics and properties related to strength and reliability.

When tightening a threaded fastener, it is almost always important to know both how much torque is applied and how far the fastener is turned. Similarly, it is always important to fully understand how friction affects the relationship of torque, angle, and tension.

To ensure that critical joints are tightened properly, it must be kept in mind that it is the control of tension that is most important, not the control of torque. This fact must always be considered when choosing and setting up tools, when monitoring production, and when performing quality control audits. The fastener-tightening process is dependent upon the energy transfer from the tightening tool into the fastener and bolted joint. The integrated area under the torque-angle signature curve is a measure of the energy absorbed by the assembly.

The purpose of this chapter is to review basic methods and fundamental principles for mechanical testing of threaded fasteners and bolted joints. All fastener engineering applications must start with the assumption of the magnitude of the service loads to which a fastener or assembly will be subjected. Where the service load information is incomplete, the engineer responsible for the design or testing should always at least document assumed loading conditions for analysis and testing. Such assumptions can often be used to great advantage when, in the future, more precise service load information is obtained.

Standard Test Methods for Determining Materials Properties of Fasteners

The materials properties of the fastener must be known before a more detailed analysis of the bolted joint is possible. Many standards exist for the testing of fasteners. ASTM F 606M, a specification developed through the procedures of ASTM for metric fasteners, is considered to be one of the most complete. The corresponding standard for English threaded fasteners is ASTM F606. More complete descriptions of the methods can be found in the standard. The text following in this section is a summary of the basic test methods according to ASTM F 606M.

The test methods described in ASTM F 606M establish procedures for conducting mechanical tests to determine the materials properties of externally and internally threaded fasteners. For externally threaded fasteners, the following test methods are described:

- Product hardness
- Proof load by length measurement, yield strength, or uniform hardness
- Axial tension testing of full-sized products
- Wedge tension testing of full-sized products
- Tension testing of machined test specimens
- Total extension at fracture testing

For internally threaded fasteners, the following test methods are described:

- Product hardness
- Proof load
- Cone proof-load test

Test methods are also provided in the standard for washers and rivets. This article concentrates on the portions applicable to threaded fasteners.

Test Methods for Externally Threaded Fasteners

Product Hardness. The hardness of fasteners and studs can be determined on the ends, wrench flats, or unthreaded shanks after removal of any oxide, decarburization, plating, or other coating material. Rockwell or Vickers hardness standards may be used at the option of the manufacturer. Hardness is determined at midradius of a transverse section of the product taken at a distance of one diameter from the point end of the product. The reported hardness is the average of four hardness readings located at 90° to one another. Acceptable alternative methods of determining hardness for bolts are either at midradius, one diameter from the end, or on the side of the head of a hex-head or square-head product of all property classes after adequate preparation to remove any decarburization.

Tension Tests. Fasteners and studs should be tested at full-size and to a minimum ultimate load in kilonewtons (kN) or stress in megapascals (MPa). Such testing includes proof-load tests (by length measurement, yield strength, or uniform hardness), axial tension tests, wedge tension tests, and total extension-at-fracture tests.

Proof-Load Tests. The basic proof-load test consists of stressing the product with a specified load that the product must withstand without any measurable permanent set and evaluating the fastener in terms of any change in length. Alternative tests to determine the ability of a fastener to pass the proof-load test are the yield-strength test and the uniform hardness test. Although any of the alternative test methods described may be used, the proof-load test is the arbitration method used in case of any dispute.

Method 1, Length Measurement. The overall length of the specimen is measured at its true centerline with an instrument capable of measuring changes in length of 0.0025 mm with an accuracy of 0.0025 mm in any 0.025

mm range. Measuring the length between conical centers on the centerline of the fastener or stud with mating centers on the measuring anvils is preferred. The head or body of the fastener or stud should be marked so that it can be placed in the same position for all measurements.

The product is assembled in the fixture of the tension-testing machine so that six complete threads are exposed between the grips. Tests for heavy hex structural bolts are based on four threads. This is obtained by freely running the nut or fixture to the thread runout of the specimen and then unscrewing the specimen six full turns. For continuous threaded fasteners, at least six full threads should be exposed. The fastener should be loaded axially to the proof load specified in the product specification. The speed of testing, as determined with a free-running cross head, should not exceed 3 mm/min, and the proof load should be maintained for a period of 10 s before releasing the load. Upon release of this load, the length of the fastener or stud should be measured again to determine permanent elongation. A tolerance (for measurement error only) of ± 0.013 mm is allowed between the measurements made before loading and that made after loading.

Variables, such as straightness, thread alignment, or measurement error, could result in apparent elongation of the product when the specified proof load is initially applied. In such cases, the product may be retested using a 3% greater load and is considered acceptable if there is no difference in the length measurement after this loading within a 0.013 mm measurement tolerance as outlined.

Method 2, Yield Strength. The product is assembled in the testing equipment as described for method 1. As the load is applied, the total elongation of the product or any part of it that includes the exposed threads should be measured and recorded to produce a load-elongation diagram. The load or stress at an offset equal to 0.2% of the length of fastener occupied by six full threads is determined, as shown in Fig. 6.

Fig. 6 Tension testing of full-size fastener (typical set-up). Source: Ref 1

Method 2A, Yield Strength for Austenitic Stainless Steel and Nonferrous Materials. The product is assembled in the testing equipment as described in method 1. As the load is applied, the total elongation of the product should be measured and recorded in order to produce a load-elongation diagram. The load or stress at an offset equal to 0.2% strain should be determined based on the length of the bolt between the holders as shown in Fig. 6, which will be subject to elongation under load by using the yield-strength method described in the section “Tension Testing of Machined Test Specimens.”

Method 3, Uniform Hardness. The fasteners are tested for hardness as described previously, and in addition, the hardness is determined in the core. The difference between the midradius and core hardness should be not more than three points on a Rockwell C scale, and both readings must be within product specification.

Short Fasteners and Studs. Fasteners with lengths less than those shown in Table 1, or that do not have sufficient threads for proper engagement, are deemed too short for tension testing. Acceptance is then based on a hardness test. If tests other than product hardness are required, their requirements are referenced in the product specification.

Table 1 Required minimum length of fasteners for tension testing

Nominal product diam (<i>D</i>), mm	Min length, mm
5	12
6	14
8	20
10	25
12	30
14	35
16	40
20	45
Over 20	3D

Source: Ref 1

Axial Tension Testing of Full-Sized Products. Fasteners are tested in a holder with a load axially applied between the head and a nut or in a suitable fixture as shown in Fig. 6. Sufficient thread engagement must exist to develop the full strength of the product. The nut or fixture should be assembled on the product, leaving six complete fastener threads exposed between the grips. Studs are tested by assembling one end of the threaded fixture to the thread runout. If the stud has unlike threads, the end with the finer pitch thread, or with the larger minor diameter, is used. The other end of the stud is assembled in the threaded fixture, leaving six complete threads exposed between the grips. For continuous studs, at least six complete threads are exposed between the fixture ends.

The maximum speed of the free-running cross head should not exceed 25 mm/min. When reporting the tensile strength of the product, the thread stress area is calculated as follows:

$$A_s = 0.7854(D - 0.9382P)^2 \quad (\text{Eq 1})$$

where A_s is the thread stress area, mm²; D is the nominal diameter of the fasteners or stud, mm; and P is thread pitch, mm.

The product should support a load prior to fracture not less than the minimum tensile strength specified in the product specification for its size, property class, and thread series. In addition, failure should occur in the body or in the threaded section with no fracture at the juncture of the body and head.

Wedge Tension Testing. The wedge tensile strength of a hex or square-head fastener, socket-head cap screw, or stud is the tensile load that the product is capable of sustaining when stressed with a wedge under the head. The purpose of this test is to obtain the tensile strength and to demonstrate the head quality and ductility of the product.

Wedge Tension Testing of Fasteners. The ultimate load of the fastener is determined as described previously under “Axial Tension Testing of Full-Sized Products,” except to place a wedge under the fastener head. When both wedge and proof-load testing are required by the product specification, the proof-load-tested fastener for wedge testing should be used. The wedge must have a minimum hardness of 45 HRC for fasteners having an ultimate tensile strength of 1035 MPa or less, and a minimum of 55 HRC for fasteners having a tensile strength in excess of 1035 MPa. Additionally, the wedge should have the following:

- A thickness of one-half the nominal fastener diameter (measured at the thin side of the hole as shown in Fig. 7)
- A minimum outside dimension such that at no time during the test will any corner loading of the head of the product occur adjacent to the wedge
- An included angle as shown in Table 2 for the product type being tested

The hole in the wedge should have a clearance over the nominal size of the fastener and have its edges top and bottom rounded as specified in Table 3.

Table 2 Wedge angles for tension testing of fasteners

Nominal product diam, mm	Degrees	
	Fasteners ^(a)	Studs and flange fasteners
5–24	10	6
Over 24	6	4

(a) For heat-treated fasteners that are threaded one diam or closer to the underside of the head, a wedge angle of 6° for sizes 5 to 24 mm and 4° for sizes over 24 mm should be used.

Source: ASTM F 606M

Table 3 Requirements for wedge-hole clearance and radius for tension testing of fasteners

Nominal product diam, mm	Nominal clearance in hole, mm	Nominal radius on corners of hole, mm
To 6	0.50	0.70
Over 6–12	0.80	0.80
Over 12–20	1.60	1.30
Over 20–36	3.20	1.60
Over 36	3.20	3.20

Source: ASTM F 606M

Fig. 7 Wedge-test details for fasteners. D , diameter of bolt; C , clearance of wedge hole; R , radius; T , thickness of wedge at short side hole; W , wedge angle

The fastener is then tension tested to failure. The fastener must support a load prior to fracture not less than the minimum tensile strength specified in the product specification for the applicable size, property class, and thread series. In addition, the fracture should occur in the body or threaded portion with no fractures at the junction of the head and the shank.

Wedge-Tension Testing of Studs. When both wedge-tension and proof-load testing are required, one end of the same stud previously used for proof-load testing is assembled in a threaded fixture to the thread runout. For studs having unlike threads, the end with the finer-pitch thread or with the larger minor diameter is used. The other end of the stud should be assembled in a threaded wedge to the runout and then unscrewed six full turns, leaving six complete threads exposed between the grips as shown in Fig. 8. For continuous threaded studs, at least six full threads are exposed between the fixture ends. The angle of the wedge for the stud size and property class is as specified in Table 2.

Fig. 8 Wedge-test details for studs. D , diameter of stud; C , clearance of wedge hole; R , radius; T , thickness of wedge at short side hole; W , wedge angle

The stud should be assembled in the testing machine and tension tested to failure, as described previously under “Axial Tension Testing of Full-Sized Products.” The minimum hardness of the threaded wedge is 45 HRC for products having an ultimate tensile strength of less than 1035 MPa and 55 HRC for product lines having an ultimate tensile strength in excess of 1035 MPa. The length of the threaded section of the wedge must be equal to at least the diameter of the stud. To facilitate removal of the broken stud, the wedge can be counterbored. The thickness of the wedge at the thin side of the hole is equal to the diameter of the stud plus the depth of the counterbore. The thread in the wedge should have class 4H6H tolerance, except when testing studs having an interference fit thread, in which case the wedge will have to be threaded to provide a finger-free fit. The supporting fixture should have a hole clearance over the nominal size of the stud, and the top and bottom edges should be rounded or chamfered to the same limits specified for the hardened wedge in Table 3.

The stud must support a load prior to fracture of not less than the minimum tensile strength specified in the product specification or its size, property class, and thread series.

Tension Testing of Machined Test Specimens. Where fasteners and studs cannot be tested at full-size, tests are conducted using test specimens machined from the fastener or stud. Fasteners and studs should have their shanks machined to the dimensions shown in Fig. 9. The reduction of the shank diameter of heat-treated fasteners and studs with nominal diameters larger than 16 mm should not exceed 25% of the original diameter of the product. Alternatively, fasteners 16 mm in diameter or larger may have their shanks machined to a test specimen with the axis of the specimen located midway between the axis and outside surface of the fastener as

shown in Fig. 10. In either case, machined test specimens should exhibit tensile strength, yield strength (or yield point), elongation, and reduction of area equal to or greater than the values of these properties specified for the product size in the applicable product specification when tested in accordance with this section.

Tensile Properties: Yield Point. Yield point is the first stress in a material, less than the maximum obtainable stress, at which an increase in strain occurs without an increase in stress. Yield point is intended for application only for materials that may exhibit the unique characteristic of showing an increase in strain without an increase in stress. A sharp knee or discontinuity characterizes the stress-strain diagram. The yield point can be determined by one of the following methods:

- *Drop-of-the-beam or halt-of-the-pointer method:* In this method, an increasing load is applied to the specimen at a uniform rate. When a lever and poise machine is used, the beam is kept in balance by running out the poise at an approximately steady rate. When the yield point of the material is reached, the increase of the load will stop, but the poise should be run a small amount beyond the balance position, and the beam of the machine will drop for a brief interval of time. When a machine equipped with a load-indicating dial is used, there is a halt or hesitation of the load-indicating pointer, which

corresponds to the drop of the beam. The load is recorded at the drop of the beam or the halt of the pointer. This point is the yield point of the fastener or stud.

- *Autographic diagram method:* When a sharp-kneed stress-strain diagram is obtained by an autographic device, the yield point is taken as either the stress corresponding to the top of the knee, as shown in Fig. 11, or as the stress at which the curve drops, as shown in Fig. 12.
- *Total extension-under-load method:* When testing material for yield point, the test specimens may not exhibit the well-defined disproportionate deformation that characterizes a yield point as measured by the previous methods. In these cases, the following method can be used to determine a value equivalent to the yield point in its practical significance that may be recorded as the yield point. A class C or better extensometer is attached to the specimen. When the load producing a specified extension is reached, the stress corresponding to the load as the yield point is recorded and the extensometer removed (Fig. 13).

Fig. 11 Stress-strain diagram for determination of yield strength by the offset method. $o-m$ is the specified offset. To determine offset yield strength, draw line $m-n$ parallel to the line $o-A$. From the intersection point r , draw a horizontal line to determine the offset yield strength, R .

Fig. 12 Stress-strain diagram showing yield point corresponding with top of knee. $o-m$, offset to yield point. Source: Ref 1

Fig. 13 Stress-strain diagram showing yield point or yield strength by extension-under-load method. $o-m$, specified extension under load. Line $m-n$ is vertical, and the intersection point, r , determines yield strength value, R . Source: Ref 1

Yield Strength. Yield strength is the stress at which a material exhibits a specified limiting deviation from the proportionality of stress to strain. The deviation is expressed in terms of strain, percentage of offset, total

extension under load, and so on. Yield strength may be determined by the offset method or the extension-under-load method.

To determine the yield strength by the offset method, it is necessary to secure data (autographic or numerical) from which a stress-strain diagram may be drawn. Then, on the stress-strain diagram layoff, $o-m$, as shown in Fig. 11, equal to the specified value of the offset, $m-n$ should be drawn parallel to $o-A$ and thus locate r . The yield-strength load, R , is the load corresponding to the highest point of the stress-strain curve before or at the intersection of $m-n$ and r . In reporting values of yield strength obtained by this method, the specified value of the offset used should be stated in parenthesis after the term yield strength, thus:

$$\text{Yield strength (0.2\% offset)} = 360 \text{ MPa}$$

In using this method, a minimum extensometer magnification of 250 to 1× is required. A class B1 extensometer meets this requirement.

The extension-under-load method is used to determine the acceptance or rejection of materials whose stress-strain characteristics are well known from previous tests of similar materials in which stress-strain diagrams are plotted. For these tests, the total strain corresponding to the stress at which the specified offset occurs should be known as within satisfactory limits. The stress on the specimen, when total strength is reached, is the value of the yield strength. The total strain can be obtained satisfactorily by the use of a class B1 extensometer. The extension under load (mm/mm of gage length) can be determined as follows:

$$YS/E = R \tag{Eq 2}$$

where YS is the specified yield strength, MPa; E is the modulus of elasticity, MPa; and r is the limiting plastic strain, mm/mm.

Tensile strength is calculated by dividing the maximum load the specimen sustains during a tension test by the original cross-sectional area of the specimen.

Elongation. The ends of the fractured specimen are fitted together carefully and the distance between the gage marks measured to the nearest 0.25 mm for gage lengths of 50 mm or under, and to the nearest 0.5 mm of the gage length for gage lengths over 50 mm. A percentage scale reading to 0.5% of the gage length may be used. The elongation is the increase in length of the gage length, expressed as a percentage of the original gage length. In reporting elongation values, both the percentage increase and the original gage length should be given.

If any part of the fracture takes place outside the middle half of the gage length or in a punched or scribed mark with the reduced section, the elongation value obtained may not be representative of the material. If the elongation so measured meets the minimum requirements specified, no further testing is indicated, but if the elongation is less than the minimum requirements, the test should be discarded and performed again.

Reduction of Area. The ends of the fractured specimen are fitted together and the mean diameter or the width and thickness at the smallest cross section measured to the same accuracy as the original dimensions. The difference between the area thus found and the area of the original cross section expressed as a percentage of the original area is the reduction in area.

Total Extension at Fracture Test. The test to determine extension at fracture, A_L , is carried out on stainless steel and nonferrous products in the finished condition with the length equal to or in excess of those minimums listed in Table 1. The products to be tested are measured for total length, L_1 , described as follows and shown in Fig. 14.

Fig. 14 Determination of total extension at fracture (A_L) for a screw product. Source: Ref 1

Both ends of the fastener or stud are marked using a permanent marking substance, such as bluing, so that the measuring reference points for determining total lengths, L_1 and L_2 , are established. An open-end caliper and steel rule or other device capable of measuring to within 0.25 mm are used to determine the total length of the product (Fig. 14).

The product under test is screwed into the threaded adapter to a depth of one diameter (Fig. 6) and load applied axially until the product fractures. The maximum speed of the freerunning cross head should not exceed 25 mm/min.

After the product has been fractured, the two broken pieces are fitted closely together, and the overall length, L_2 , is measured. The total extension at fracture, A_L , is then calculated as follows:

$$A_L = L_2 - L_1 \quad (\text{Eq 3})$$

The value obtained should equal or exceed the minimum values shown in the applicable specification for the product and material type.

Test Methods for Internally Threaded Fasteners

Product Hardness. For routine inspection, hardness of nuts may be determined on the bearing face or wrench flats after removal of any plating or coating. Rockwell or Vickers hardness testing may be used at the option of the manufacturer, taking into account the size and property class of the nut. The reported hardness is a minimum of two hardness readings taken 180° apart, halfway between the major diameter of the thread and one corner or, if applicable, on a wrench face one-third of the distance from a corner to the center of the wrench face. In preparation of the surface, sufficient material is removed to ensure elimination of any oxide, decarburization, coating, or other surface irregularities. The preparation of test specimens and the performance of hardness tests for Rockwell or Vickers testing are in conformity with the requirements of ASTM E 18 and E 92, respectively. For the purpose of arbitration, hardness is taken on a longitudinal section through the nut axis with readings taken as closely as possible to the nominal major diameter of the nut thread.

Proof-Load Test. The nut to be tested is assembled on a hardened threaded mandrel or a test bolt using the tension method (Fig. 15a) or the compression method (Fig. 15b). The hardened test mandrel and the tension method shown in Fig. 15(a) is mandatory as a reference if arbitration is necessary. The specified proof load is applied for the nut against the nut. The nut should resist this load without stripping or rupture and should be removable from the test bolt or mandrel by the fingers after the load is released. Occasionally, it may be necessary to use a manual wrench or other means to start the nut in motion. Use of such means is permissible, provided the nut is removable by the fingers following the initial loosening of not more than one-half turn of the nut. If the threads of the mandrel or test bolt are damaged during the test, the test should be discarded.

Fig. 15 Proof-load testing of nuts. Source: Ref 1

The test fastener should be appropriate to the standard specified for the nut being tested and should have a yield strength in excess of the specified proof load of the nut being tested. Mandrels should have a hardness of 45 HRC minimum; the mandrel should have threads conforming to the same standards as those specified for the nut being tested, except that the maximum major diameter is the specified minimum major diameter for class 4H6H threads and the maximum major diameter plus 0.25 times the major diameter tolerance of class 4H6H threads.

The proof load is determined at a free-running cross head not exceeding 25 mm/min and is held at load for a minimum of 10 s.

Cone proof-load tests should be performed by the use of a conical washer and threaded mandrel (Fig. 16) to determine the influence of surface discontinuities (forging cracks and seams) on the load-carrying ability of hardened steel nuts through 36 mm in diameter by introducing a simultaneous dilation and stripping action of the nut. The conical washer should have a hardness of 57 HRC minimum and a hole diameter of the mandrel +0.05 mm and -0.00 mm. The contact point of the cone should be sharp for nut sizes 12 mm or less. For sizes greater than 12 mm, the point should be flat and 0.38 ± 0.03 mm in width. The nut and the conical washer are assembled on the mandrel and the cone proof load applied for the nut against the nut. The speed of testing as determined with a free-running cross head should be a maximum of 3 mm/min. Apply the proof load for 10 s. The proof load of the nut is computed as follows:

$$CPL = (1 - 0.012D)f \times A_s \times 0.001 \quad (\text{Eq 4})$$

where CPL is the cone proof load, kN; D is the nominal diameter of the nut, mm; f is the specified proof stress of the nut, MPa; A_s is the tensile stress area of the nut, mm^2 , equal to $0.7854 [D - (0.9382P)]^2$; and P is the thread pitch, mm.

Fig. 16 Cone-proof test. Source: Ref 1

To meet the requirements of the cone proof-load test, the nut should support its specified cone proof load without stripping or rupture.

Mechanical Testing of Threaded Fasteners and Bolted Joints

Ralph S. Shoberg, RS Technologies, Ltd.

Friction Coefficient Testing

This section describes the testing method for a tightening test to determine the coefficients of friction of assemblies using threaded fasteners under specified conditions. A standardized measurement and analysis procedure is presented for comparison of assemblies with different surface finishes or for cases where different coatings, plating processes, or lubricants are used.

The results of testing in accordance with this test specification can provide valuable insights as to the expected behavior of actual bolted-joint assemblies. Additional testing and analysis, including computer modeling, is necessary to confirm the influence of frictional components of torque in actual assemblies. Torque-angle signatures plotted from tests on actual assemblies can be best understood if accurate friction coefficient data are available for modeling the bolted-joint-tightening process.

The frictional coefficient data obtained are necessary for the design and testing of bolted assemblies. *In the final analysis, it is impossible to accurately model or calculate a bolted-joint design if correct friction coefficient information is not known.*

Principle

A tightening torque is steadily applied to a bolted-joint assembly at ambient temperature. In the range of elastic deformation, there is a linear relationship between torque and clamping load. This relationship is expressed by the following equation applicable to bolted-joint assemblies with ISO metric threads and to other screw threads

with triangular profiles and a 60° pitch angle as specified in ISO 68:1973 or ASME B1.13M-1995 (“Metric Screw Threads—M Profile”):

$$T_A = F_V \left(0.159 \cdot P + 0.578 \cdot d_2 \cdot \mu_G + \frac{D_{Km}}{2} \cdot \mu_K \right) \quad (\text{Eq 5})$$

where terms on the right side are defined in Eq 6, 7, 8, 9, 10, 11, and 12. The applied torque, T_A , is composed of a component acting in the thread and serving to both apply the proofing load and to overcome thread-friction torque, T_G . It also comprises a component acting at the bolt head or nut-bearing face, termed underhead friction torque, T_K .

$$T_A = T_G + T_K \quad (\text{Eq 6})$$

where

$$T_G = F_V (0.159 \cdot P + 0.578 \cdot d_2 \cdot \mu_G) \quad (\text{Eq 7})$$

where d_2 is the bolt thread pitch diameter, and where

$$T_K = F_V \frac{D_{Km}}{2} \cdot \mu_K \quad (\text{Eq 8})$$

The mean diameter required for measuring the coefficient of friction acting at the bearing face of the bolt head or nut is calculated from the following equation:

$$D_{Km} = \frac{d_w + d_h}{2} \quad (\text{Eq 9})$$

where d_w is the external diameter of the bearing face for frictional torque, and d_h is the clearance hole diameter. Equation 9 applies to plane-bearing surfaces located vertically to the bolt axis. In other cases, such as in the case of screws with a conical bearing face, D_{Km} is the nominal mean diameter of the conical contact area. Suitable allowance should be made for bearing faces that differ in form, such as countersunk heads or spherical faces.

Determination of the coefficients of friction are based on the relationships obtained when transforming Eq 7 and 8, such as the following thread friction coefficient:

$$\mu_G = \frac{T_G / F_V - 0.159 \cdot P}{0.578 \cdot d_2} \quad (\text{Eq 10})$$

and the following underhead friction coefficient:

$$\mu_K = \frac{2 \cdot T_K}{D_{Km} \cdot F_V} \quad (\text{Eq 11})$$

where the test apparatus does not permit a separate measurement of T_G and T_K , a reference coefficient of friction may be calculated from the following equation (reference friction coefficient):

$$\mu_{ges} = \frac{T_A / F_V - 0.159 \cdot P}{0.578 \cdot d_2 + (D_{Km} / 2)} \quad (\text{Eq 12})$$

This equation is derived from Eq 10 and 11 assuming $\mu_G = \mu_K$. The above coefficient can be used only for assessment of the overall friction behavior of bolted joint assemblies and is not suitable for the design of bolted connections in general. Because the test results are influenced by a variety of parameters, minimum requirements for the test procedure have been specified in the sections “Test Equipment” and “Procedure.”

The statement of this principle can be extended to cover determination of K , which is often referred to as the nut factor and is a function of thread and underhead friction coefficients as well as thread pitch and diameter. Basic threaded-fastener theory states that the torque required to tighten the joint is the product of the friction in the joint, K , the diameter of the fastener, D , and the applied force, F_V . This theory is represented by the following formula:

$$T = K \cdot D \cdot F_V \quad (\text{Eq 13})$$

Because the applied torque is the result of the torque required to overcome friction in the threads, T_G , and the torque required to overcome friction in the underhead area, T_K , the basic equation can be restated as

$$T_A = K \cdot d \cdot F_V = T_G + T_K \quad (\text{Eq 14})$$

By substituting the expressions for T_G and T_K from Eq 3 and 4, we obtain the following equation:

$$K \cdot d \cdot F_V = F_V(0.159 \cdot P + 0.578 \cdot d_2 \cdot \mu_G) + F_V \left(\frac{D_{Km}}{2} \right) \mu_K \quad (\text{Eq 15})$$

Placing the equation in terms of K , we obtain the following:

$$K = \frac{1}{d}(0.159 \cdot P) + \frac{1}{d}(0.578 \cdot d_2 \cdot \mu_G) + \frac{1}{d} \left(\frac{D_{Km}}{2} \cdot \mu_K \right) \quad (\text{Eq 16})$$

Simplifying terms results in the following equation:

$$K = \frac{1}{d} \left[(0.159 \cdot P) + (0.578 \cdot d_2 \cdot \mu_G) + \left(\frac{D_{Km}}{2} \cdot \mu_K \right) \right] \quad (\text{Eq 17})$$

The three elements in the above equation represent the components of K as related to pitch, thread, and underhead friction torque. When tightening nut and bolt assemblies, it should be understood that, depending on the frictional torque factors, the value of K could be different during tightening when either the nut or bolt is turned. For a given tension, the thread torque will always be the same, while the underhead torque depends on which element (nut or bolt) is turned. The value for K can be best understood and accurately represented only if the thread and underhead friction coefficients are determined. Simple torque-tension tests without friction coefficient determination capability do not provide enough information to precisely locate the source of variability in k -factors.

Test Equipment

The test equipment should be capable of fixturing the test bolt, nut, and washer. This equipment must also be capable of recording the torque- and force-related data. Care should be taken to ensure that whichever part (bolt or nut) is not moved during tightening of the assembly and the washer are both held firmly in place. Figure 17 shows an illustration of a typical test setup using a thread torque and fastener tension load cell.

Fig. 17 Cutaway of typical test setup using torque-tension research head. T_A , tightening torque for generating load F_V ; T_G , component of tightening torque acting in threads; T_K , frictional torque acting at bearing face of bolt head or nut; P , thread pitch

In cases of arbitration, only such coefficients of friction may be compared that have been determined using the same apparatus, the same washer, and a bolt and nut with the same thread. The measuring system should permit determination of T_A , T_G , T_K , and F_V with a limit of error of $\pm 3\%$ at the point of measurement (a discussion can be found in the section “Measurement Accuracy” in this article).

Procedure

Each test should be carried out with a set of new bolts, nuts, and washers with the property classes of bolt and nut being compatible.

When investigating the effect of lubricants on the tightening process, a special test setup may be specified, which then may be used for a series of tightening tests. In such cases, the bolt, nut, and washer all have the status of reference components.

Mounting of Bolt and Nut. The bolt and nut assembly to be tested should be clamped into the apparatus so that the bolt end projects beyond the surface of the nut when fitted for a maximum number of eight turns of thread. On the shank side of the nut, there should be at least two complete turns of thread not engaged.

The test washer should be constructed with material properties and finish representative of the bearing surface for which friction coefficient data are to be obtained. Where no particular agreements have been made as to the condition of the washer or type under that part of the assembly, which is rotated in the tightening process, steel washers can be used. The washers are required to have the following characteristics (DIN 946 contains further details):

- Polished lengthwise with surface roughness average, R_a , of 0.8 to 1.6 μm
- Flatness tolerance and parallelism tolerance, each of 0.04 mm
- Bright and degreased
- Minimum thickness of 0.5 d
- Hardness 38 to 42 HRC or 380 to 420 HV20
- Clearance hole diameter, $d_h = d_a$ (max), maximum internal bearing diameter (tolerance H 13), not countersunk

This list is intended as a sample specification that can be used as a model for definition of test washers in general. For simulation of production, component sections of actual parts can be made into washer coupons. Fixtures can often be fabricated to permit mounting unmodified components on the research head for efficient testing of as-manufactured surfaces.

Thread Tolerance for and Surface Finish of Reference Components. The surface finish and thread tolerance for reference components should comply with the following specifications appropriate to the parts to be evaluated. For example, DIN 946 suggests the following specifications for bolts and nuts used to evaluate lubricants and coatings:

- Where bolts are to be tested, nuts with a bright finish should be used as reference components, degreased and capable of being fully loaded with thread manufactured to a tolerance of 6 H. If the bolt cannot be easily screwed in by hand, nuts with thread manufactured to a larger tolerance should be used.
- Where nuts are to be tested, zinc-phosphated bolts should be used as reference components, degreased and with thread manufactured to a tolerance of 6 g. The coated bolt should permit the nut to be easily mounted by hand.
- When investigating the effects of lubricants, bolts and nuts that comply with the requirements specified under the preceding two items should be used.

In general, it is necessary that finishes and tolerances of test components be adequately defined to permit replication of test conditions.

Tightening Rate Specification (rpm). In order to standardize testing conditions, it is necessary to closely control tightening speed (rpm). Maintenance of a constant turning rate is essential to obtaining comparable results. The recommended tightening rate of the assembly is 30 rpm as specified by DIN 946. Certain locknut testing standards require 100 rpm. In general, larger fasteners must be run at slower speeds to achieve uniform, predictable results. Depending on the surface coatings, lubricants, and size of fasteners, testing speeds as low as 5 to 10 rpm may be necessary to ensure repeatable results. Because production tools are often selected improperly, based upon high speed capability, extreme caution must be taken to verify tension obtained on actual assemblies.

Evaluation

The coefficients of friction are determined from Eq 9, 10, 11, and 12, making allowance for the geometry of bolt, nut, and washer for the torque applied and the proofing load generated.

Using Eq 9, 10, 11, and 12, the following parameters are entered: nominal sizes of d_2 , P , and d_h , and the size of d_w in accordance with the relevant product standard.

Evaluation of the test results may best be made by reading the coefficients of friction from the diagrams plotted on the basis of Eq 7 and 8. Normally, the minimum value of d_w as specified in the relevant product standard is to be entered in these equations. The maximum hole size or chamfer diameter is used for d_h .

The test results should be plotted, where possible, in a single graph for ease of comparison. Where bolt and nut assemblies are to be subjected to repeated tightening and loosening cycles, the results for each assembly may be plotted separately to minimize confusion. Evaluation should be based on a proofing load obtained for an average value of μ_G , μ_K , or μ_{ges} as determined by testing as specified in VDI 2230, Part 1.

By way of simplification, for normal values of μ , from 0.10 to 0.16, evaluation may be based on a value of F_V equal to $0.7 \cdot F_{0.2}$ (nominally, 70% of yield load).

Outliers are ignored only if they can be definitely assigned to abnormal influences, such as a chip caught in a thread and so on. As a rule, the evaluation should be based on 12 tests. A different number of tests may be agreed upon between the concerned parties.

Test Report

It is recommended that test results reported include maximum, mean, and minimum values and the standard deviation based upon $n-1$ sample calculation, assuming a normal distribution. In the test report, the coefficients of friction, normally minimum and maximum values, should be given together with details of the test conditions as itemized in the section "Procedure," stating any deviations from these conditions. The test report

also should include any graphic data that the test equipment is capable of providing. For example, Fig. 18 shows the breakdown of the torque measurements. Figure 19 shows the calculated friction coefficients relating to thread and underhead torque. Figure 20 shows the k -factor as a function of the achieved force.

Mechanical Testing of Threaded Fasteners and Bolted Joints

Ralph S. Shoberg, RS Technologies, Ltd.

Torque Tension Testing

The amount of tension or clamping force exerted by a fastener when it is tightened is what actually holds the assembly together. Once the assembly is brought together, the fastener responds like a tension spring, and the assembly acts like a compression spring. As the fastener is turned and load is applied, the fastener is stretched, and the parts are compressed. The effect of this interaction between the fastener and the assembly is illustrated in Fig. 21. This response results in an elastic joint in which the fastener is the flexible member, and the assembly is the rigid member.

Fig. 21 Response of components in a bolted joint to applied load

The torque-tension testing procedure specifies a generic method for evaluating the effect of different surface finishes, coatings, or manufacturing processes on the torque versus tension characteristics of threaded fasteners. Test specifications published by standards organizations and engineering societies are identified in the section “Selected References.”

Test Equipment

Test Bolts, Nuts, and Washers. Test bolts should be of sufficient length so as to be easily fixtured into the adapters that are used with the test equipment. Test bolts should have a uniform application of finish, coatings, or both.

Test nuts should be plated, coated, and lubricated according to the test plan or experimental design.

Test washers should be square torque-tension test washers corresponding to the bolt size being tested. They should be appropriately hardened, finished, plated, or coated according to the test plan. The test washer provides the reference surface for contact with the underhead of the nut or bolt element to which torque is applied. The square shape provides means to prevent the washer from slipping on the test plate when the friction coefficient between the washer and plate is less than that between the bolt or nut and washer.

Test Equipment. A fixtured direct-current (dc) electric nutrunner or other drive system capable of maintaining the required constant test speed is used to tighten and remove the test bolt or nut. The nutrunner should have the capability of producing a torque output greater than the torque values specified for the size and grade of bolts to be tested and should be capable of reaching the continuous speed required by the test specification. Test specifications generally require 25 to 100 rpm for most fasteners. For tests that require torque application above 250 N · m, the continuous speed may be reduced to the range of 5 to 25 rpm. Speed should be held constant within 10% of the specified test rpm. For valid comparison to be made between results obtained by two or more laboratories, the testing speeds must be specified and controlled.

Torque Transducer. A strain-gage torque sensor is used to measure the torque required for the installation of the bolt being tested. The torque sensor should have an accuracy of $\pm 2\%$ at the point of measurement (more information can be found in the section “Measurement Accuracy”). A torque sensor equipped with an angle encoder is recommended in the event that additional analysis is desired.

Tension Load Cell. A tension load cell is used to hold the test bolt, nut, and washer in position and to measure the tension generated in the bolt as the test nut is tightened. The recommended accuracy of the tension load cell is $\pm 2\%$ at the point of measurement. A tension load cell with thread torque measurement capability is recommended in the event that additional analysis, such as frictional characteristics, is desired.

Data Acquisition and Control Equipment. A multiple channel recorder capable of recording the torque, tension, and angle and thread torque (if required) data during the entire test cycle should be used. Equipment that can control the dc electric nutrunner, calculate statistics, and provide graphic plots of the test is highly recommended.

Procedure

The following procedure can be used as a reference for conducting torque-tension testing. This procedure assumes that the bolt is secured and the nut is tightened. Some test evaluations of bolt underhead characteristics require that the nut be secured and the bolt rotated. In that case, the position of the nut and bolt should simply be reversed:

1. Determine the torque and tension loads that are appropriate for the size of the fastener to be tested. These are typically specified by the required test standard or special requirements of the customer.
2. Select an appropriately sized nut and test washer. A new nut and test washer should be used with each bolt that will be tightened.
3. Place the bolt being tested through the test fixture (load cell and adapters) and test washer so that the bolt extends beyond the test nut approximately six threads after bolt rundown. Make sure that the test washer is secured so that it does not rotate during testing (Fig. 17).
4. Assemble the nut onto the bolt approximately two threads.

5. Place the nutrunner tool on the bolt and tighten to the specified torque or tension value. Simultaneously record the torque that is applied and the tension that is achieved.
6. Loosen the nut, and return to the original starting position.
7. Repeat steps 5 and 6 for the specified number of bolts to obtain data that can be statistically analyzed to produce torque at tension to 3 sigma limits. A new nut and washer is to be used for each test bolt.

Note: In addition to obtaining torque-tension data for previously unused bolts and nuts as described, it is often desirable to tighten and loosen the same bolt-nut-washer combination multiple times to evaluate the effect of repeated tightening and loosening on the torque-tension relationship.

Test Report

The test report for torque-tension testing generally requires a multiple graphic plot of torque versus tension for the prescribed number of rundowns, as shown in Fig. 22. A statistical graphic plot of torque at tension also is desirable. This testing can be further documented by a report of the numerical data to which statistics can be added.

Fig. 22 Multiple rundown torque-tension plot

Locknut Testing

A locknut is a device that provides extra resistance to vibration loosening beyond that produced by proper preload, either by providing some form of prevailing torque or, in free-spinning locknuts, by deforming,

crimping, or biting into mating parts when fully tightened. A locknut counters the back-off torque created by the inclined planes of the thread. Locknuts and locking mechanisms take many forms. Such forms include thread interference locknuts, also known as prevailing torque locknuts, that use several different forms, such as nuts with out-of-round holes, a nylon locking collar in the nut, a nylon patch, or mechanically deformed dimples or crimps. Another form of locking devices are free-spinning locknuts, such as springhead nuts, beam-type nuts, and serrated nut bearing surfaces.

Because of the particular characteristics of prevailing torque locknuts, a unique testing process is required for them. In the past, there has been a wide range of equipment available for prevailing torque locknut testing from basic hand tool and indicator systems to various semiautomated systems. Test results for locknut prevailing torque are particularly sensitive to control of testing speed or a lack thereof. Automated testing systems have been developed with the capability to conduct multiple tightening cycles on production lots or research and development samples of locknuts, with tests preprogrammed according to Industrial Fasteners Institute (IFI) 100/107 for inch, ISO 2320 and ANSI B818.61.1 for metric, and other common test specifications. Precisely controlling test speeds, tension shut-off points, and cycle timing is necessary to ensure repeatability of test results.

The locknut testing procedure specifies a generic method for evaluating the effectiveness of prevailing torque-locking devices. Test specifications published by standards organizations and others that may apply to these types of fasteners are listed in the section “Selected References.”

Principle

There are several published standards for testing and evaluating prevailing torque locknut devices. The standards all generally attempt to determine how well the prevailing torque element works the first time it is used and how well it holds up when reused a specified number of times. The Industrial Fasteners Institute (IFI) publishes well-known and widely accepted test specifications. The IFI test is often referred to as a “first-on, fifth-off” test. In this test, the locknut is torqued on and off the bolt five times. Torque is measured and recorded the first time on and the fifth time off. On the first cycle, the locknut is tightened to a specified clamp load. The second through fifth cycles involve installation and removal without achieving clamp load.

Multiple locknut and bolt samples are tested to develop a summary report. On completion of the test batch, statistical data are generated for the breakthrough torque, where the locking device is first penetrated, the first-on maximum prevailing torque, the torque to reach the specified clamp load, and the fifth-off minimum prevailing torque.

Figure 23 shows a graph of a typical locknut test tightening cycle. The clamp-force-versus-angle curve is superimposed on the torque curve. The graph indicates the breakthrough torque, prevailing on-torque, prevailing off-torque, and the clamp force attained.

Fig. 23 Prevailing torque locknut testing cycle

Variations of the IFI test have been developed by other organizations and include the following differences (users may also specify their own variations):

- Tighten, but do not attain clamp-load cycle test, up to 30 cycles

- Tighten to clamp load each of three or five times on
- Standard torque versus tension cycles, from one time up to 30 cycles

When multiple tightening cycles are required, the user can specify dwell times after each tightening-and-loosening cycle to permit cooling of the test specimen. This procedure helps to ensure uniform testing conditions, which are particularly important when testing certain prevailing torque locknuts.

Test Equipment

Test Bolts. Test bolts should be specified to meet the strengths and finish characteristics of the fasteners intended to be used with the locking device being tested. Bolt length must be sufficient so that at least two threads are projecting past the nut after tightening. Test bolts should have a uniform application of finish, coatings, or both. If an applied adhesive is the locking device, its application must be uniform and consistent throughout the test sample. When production conditions are to be simulated, the maximum thread projection found in the production assembly must be replicated in the test assembly.

Test Nuts. The test nuts used in this type of testing generally contain the locking device described previously. However, if the locking device is an adhesive applied to the bolt, the bolt should have the same surface finish and be of the same size and grade as the bolt normally used in production.

Test Washers. Test washers should be hardened, finish-plated, or coated square torque-tension test washers corresponding to the surface conditions related to the application for which the locking device is being tested.

Nutrunner. A fixtured nutrunner is used to tighten and remove the test bolt or nut. The nutrunner should have a capability for producing a torque output greater than the torque values specified for the size and grade of nuts and bolts to be tested and should be capable of reaching and maintaining the continuous speed required by the test specification. Test specifications for prevailing torque testing are typically slower than those for torque-tension testing, around 25 rpm, ± 5 . However, a number of standards require tests to be run at 100 rpm.

Torque Transducer. A strain gage torque sensor is used to measure the torque required for the installation of the locknut being tested. The recommended accuracy of the torque sensor is $\pm 2\%$ at the point-of-measurement. A torque sensor equipped with an angle encoder is required so that the position of the locknut can be used to establish certain windows of measurement to obtain prevailing on- and off-torque values, as well as the breakthrough torque value, if required.

Tension Load Cell. A tension load cell is used to hold the test bolt, nut, and washer in position and to measure the tension generated in the bolt as the test nut is tightened. The recommended accuracy of the tension load cell is $\pm 2\%$ at the point of measurement.

A tension load cell with thread-torque measurement capability is recommended in the event that additional analysis, such as thread and underhead frictional characteristics, is desired. The use of a torque-tension research head is mandatory if the separation of underhead friction torque from thread friction torque is to be achieved for control of manufacturing tolerances for thread-loading friction.

Data Acquisition and Control Equipment. A multiple-channel recorder capable of recording the torque, tension, and angle and thread torque (if required) data during the entire test cycle should be used. Equipment that can control the dc electric nutrunner as well as calculate statistics and provide graphic plots of the test is highly recommended. Since achieving a specified clamping load is normally a part of the test, the test nutrunner drive should be capable of being stopped with no more than 2% overshoot once the target tension is achieved. Excessive overshoot of assembly torque can be a major source of variation in test results.

Procedure

The following procedure can be used as a reference for conducting prevailing torque locknut testing. This procedure assumes that the test bolt is secured, and the test nut is tightened:

1. Determine the torque and tension loads that are appropriate for the size of the fastener to be tested. These loads are typically specified by the required test standard or special requirements of the customer.
2. Select an appropriately sized bolt and test washer. A new bolt and test washer should be used with each locknut that will be tested.

3. Place the bolt being tested through the test fixture (load cell and adapters) and test washer so that the bolt will extend beyond the test nut approximately six threads after bolt rundown. Be sure the test washer is secured so that it does not rotate during testing (Fig. 17).
4. Assemble the nut onto the bolt approximately two threads so that the locking device will be ready to engage the threads.
5. Place the nutrunner tool on the bolt and tighten to the specified torque or tension value. Simultaneously record the torque that is applied and the tension that is achieved.
6. Loosen the nut and return it to the original position. Simultaneously record the removal torque that is required and the tension such that once the clamp load has been released, the prevailing off-torque can be measured in the specified window as the nut is loosened to the starting position.
7. Repeat steps 5 and 6 the indicated number of times to obtain the specified data.

Evaluation

The locknuts are inspected to determine conformance to the specific standard. Inspection procedures may be designated by the purchaser or may be agreed upon between the purchaser and the supplier prior to the acceptance of the order.

Test Report

As an example, the illustration in Fig. 24 shows a representative printed locknut analysis according to IFI specifications. The upper chart indicates the following:

- Measurements for five samples of breakthrough torque for the first cycle (initial angle window specified)
- Maximum on-torque for the first cycle (generally after the breakthrough is achieved and recorded in a 360° window before any clamp force is generated)
- Clamp load for the first cycle at a verified tension shut-off point
- Maximum off-torque for the first cycle (measured in a 360° window of turn after the clamp force has been released)
- Minimum off-torque for the first cycle (measured the same as maximum off-torque)
- Maximum off-torque for the fifth cycle (same window as first cycle)
- Minimum off-torque for the fifth cycle (same window as first cycle)

The lower chart provides statistics for the above values including high, mean, low, range, standard deviation, ± 3 sigma, and the process capability index, C_{pk} .

Fig. 24 Representative printed locknut analysis according to IFI specifications

Other test specifications may require that the on- and off-torque be reported for cycles other than those required by IFI. A common variation of the IFI 101/107 locknut test is to require that the specified clamp force be achieved on each of three or five loading cycles. The maximum and minimum off-torques are specified and checked on the last off cycle.

Mechanical Testing of Threaded Fasteners and Bolted Joints

Ralph S. Shoberg, RS Technologies, Ltd.

Angular Ductility and Rotational Capacity Tests

The ability of a fastener to provide additional clamping load after it has been taken into yield has been used to advantage in certain assemblies. The critical challenge has been to determine the point at which the fastener begins to yield. By measuring and recording torque and clamp load versus angle of turn as a fastener is taken to failure, the resulting signature can be analyzed to determine the angular ductility or rotational capacity of the fastener, which is an additional measurement indicative of the overall energy-absorbing capacity of the fastener. Angular ductility measurements are the torque-tension test equivalents to the reduction-in-area or elongation measurements made in stress-strain tensile testing.

This section describes a generic method for determining the clamp load at the torque-tension yield point and the angular ductility of threaded fasteners. Test specifications published by standards organizations and engineering societies are identified in the section "Selected References."

Principle

This testing quantifies the ductility of the fastener as it relates to rotational capacity. It locates the point of yield and determines the fastener rotation from yield to failure. This measurement can then be used to establish the relative toughness of the fastener.

The yield point may be located by offsetting the slope of the elastic tightening curve by an amount established by the following equation:

$$\alpha_{0.2} = \frac{L_e \cdot 0.002}{P} \cdot 360^\circ \quad (\text{Eq 18})$$

where L_e is the effective grip length of the fastener, and P is the pitch of the thread. The constant, 0.002, relates the angular yield point to the 0.2% offset often used in tensile testing to establish the yield point. For example, to calculate the offset angle for a $\frac{1}{2}$ -20 \times 1 English fastener, the effective grip length is 1 in., and the pitch of the fastener is $\frac{1}{20}$ or 0.050. Thus, the calculation would appear as follows:

$$\begin{aligned} \alpha_{0.2} &= \frac{1 \cdot 0.002}{0.050} \cdot 360^\circ = \frac{0.002}{0.050} \cdot 360^\circ \\ &= \frac{360^\circ}{25} = 14.4^\circ \end{aligned} \quad (\text{Eq 19})$$

Test Equipment

Test Bolts, Nuts, and Washers. Test bolts should be selected from a representative production lot with all dimensions, finishes, and coatings certified according to the appropriate manufacturing specification.

Test nuts or drilled and threaded test bars should be plated, coated, and lubricated according to the testing plan or experimental design.

Test washers should be square torque-tension test washers or suitably prepared test bars with holes prepared corresponding to the bolt size being tested. Test washers should be appropriately hardened, finished, plated, or coated according to the testing plan.

Nutrunner. A fixtured dc electric nutrunner or other drive system capable of predictable control of test speed and torque is used to tighten the test bolt or nut. The nutrunner should have a capability for producing a torque output sufficient to bring the test bolts to failure. Test specifications generally require 25 to 100 rpm, $\pm 10\%$, for most fasteners. For tests that require torque application above 250 N \cdot m, the continuous speed may be reduced to the range of 10 to 25 rpm, $\pm 10\%$.

Torque Transducer. A strain-gage torque sensor is used to measure the torque required to fail the bolt being tested. The torque sensor should have an accuracy of $\pm 2\%$ at the point of measurement (more information can be found in the section "Measurement Accuracy"). The measurement system must be equipped with an angle encoder with sufficient resolution for determining the yield point and plotting the torque and tension versus angle of turn.

Tension Load Cell. A tension load cell is used to hold the test bolt, nut, and washer in position and to measure the tension generated in the bolt as the test nut is tightened. The recommended accuracy of the tension load cell is $\pm 2\%$ at the point of measurement.

Data Acquisition and Control Equipment. A multiple-channel recorder capable of recording the torque, tension, and angle data during the test should be used. Equipment that can control the dc electric nutrunner and construct the required offset for yield determination in graphic form is highly recommended.

Procedure

The following procedure can be used as a reference for conducting angular ductility testing. This procedure assumes that the nut is secured and the bolt is tightened. Some test evaluations require that the bolt be secured and the nut rotated. In that case, the position of the nut and bolt are simply reversed:

1. Determine the torque and tension loads that are appropriate for the size of the fastener to be tested. These loads are typically specified by the required test standard or special requirements of the customer.
2. Select an appropriately sized nut and test washer.
3. Place the bolt being tested through the test fixture (load cell and adapters) and test washer so that the bolt extends beyond the test nut approximately six threads after bolt rundown. Be sure the test washer is secured so that it does not rotate during testing (Fig. 17).
4. Assemble the nut onto the bolt approximately two threads.
5. Place the dc nutrunner tool on the bolt and tighten to failure. Simultaneously record the torque that is applied, the angle of turn, and the tension that is achieved.
6. Repeat steps 3 to 5 for the statistically agreed-upon sample of fasteners.
7. Construct a plot of the data as torque or force versus angle of turn.
8. Using the test-reporting software or by hand, draw a straight-line tangent to the elastic tightening slope of the curve back to zero torque or force.
9. Draw a line parallel to the line drawn in step 8 at the offset calculated using Eq 18, extending the line upward so that it intersects the plotted curve. This intersection locates the point of yield in the fastener.
10. Calculate the angular ductility by determining the angle of turn from the yield point to the point of fracture (Fig. 25).

Fig. 25 Angular ductility calculation

Test Report

The test report for angular ductility generally requires a multiple graphic plot of torque or force versus angle of turn for the prescribed number of rundowns, as shown in Fig. 26. This testing can be further documented by a report of the numerical data to which statistics can be added.

Fig. 26 Angular ductility report

Mechanical Testing of Threaded Fasteners and Bolted Joints

Ralph S. Shoberg, RS Technologies, Ltd.

Torque-Angle Signature Analysis

The factors that must be considered when establishing a threaded-fastener, bolted-joint analysis program are described in this section. Included are methods for modeling the joint, experimental testing of components and assemblies, and procedures conducting postassembly audits.

The basic torque-angle signature is used as a starting point for all analysis. As a first example, it can be used to illustrate the influence of underhead and thread friction on the tightening process. An increase in friction, in either the thread or underhead regions, results in a proportional increase in the slope of the torque-angle signature. The study of the slope of the elastic tightening zone is an important element in analyzing the performance of threaded fasteners in bolted joints.

To apply torque-angle signature analysis, a torque-angle transient recorder is used for measurement and curve plotting. The transient recorder can provide curves onscreen for analysis as well as print them out for detailed study. Tightening, audit, and release-angle signatures for a given fastener can be simultaneously displayed and printed.

Classical Design Concepts: Modeling the Tightening Process

When developing a testing program to correlate the design of a bolted joint and the actual assembly, it is necessary to document the relationship between torque and turn in the development of tension. Before control of a tightening process can be gained, it is necessary to become familiar with what actually happens when the

fastener is tightened. The process of tightening a fastener involves turning, advancing the lead screw, and torque, or the turning moment, so that preload, or tension, is produced in the fastener. The desired result is a clamping force that holds the components together. A torque-versus-angle signature correlated to the clamp force-versus-angle plot offers the best model that can be used to explain this process. The most general model of the torque-turn signature for the fastener tightening process has four distinct zones, as illustrated in Fig. 27.

Fig. 27 Four zones of torque-angle tightening

Zone 1: Rundown. The first zone is the rundown, or prevailing torque, zone that occurs before the fastener or nut contacts the bearing surface. Prevailing torque, due to thread-locking features, such as nylon inserts or deformed threads, will show up in the rundown zone. Frictional drag on the shank or threads due to misalignment of parts, chips, or foreign material in the threads, as well as unintended interference due to out-of-tolerance threads, are additional causes of prevailing torque in the rundown zone.

Zone 2: Alignment. The second zone is the alignment, or snugging, zone wherein the fastener and joint mating surfaces are drawn into alignment, or a stable, clamped condition. The nonlinear alignment zone is a complex function of the process of drawing together the mating parts and bending of the fastener as a result of nonparallelism of the bearing surface to the fastener underhead surface. In addition to the macroeffects related to the alignment of parts, there are microeffects within the alignment zone. The microeffects include contact stress-induced deformations of plating and coatings as well as local surface roughness and thread deformations. These macroeffects and microeffects are illustrated in Fig. 28.

Fig. 28 Macroeffects and microeffects in the alignment zone

Zone 3: Elastic Clamping Range. In this zone, the slope of the torque-angle curve is essentially constant. The elastic-clamping-zone torque-angle slope is a very important characteristic of each bolted joint. This slope can be projected backward to zero torque to locate the elastic origin. For joints with prevailing torque in the rundown zone, the elastic origin is located at the intersection of the prevailing torque level and the backward projection of the tangent to the elastic clamping zone. If the angle of turn is measured from the elastic origin to the point where torquing was stopped in the elastic clamping zone, the tension in the fastener is directly proportional to that angle of turn. In this elastic zone, the compression of the parts and the stretching of the fastener are occurring in a linear fashion from the projected elastic origin. Even if friction between threads or in the underhead region of the fastener is varied, it still will be found that, within the elastic zone, the tension generated is always proportional to the angle of turn from the elastic origin. The angle of turn from the elastic origin to the point where the torque is removed can be multiplied by the angle-tension coefficient to estimate the tension that has been created by the tightening process.

To further illustrate the concept of the elastic origin, the torque-angle signatures in Fig. 29 show the increased slope, induced by increased friction, in the elastic tightening zone. It can be noted that as friction increases, the torque required to bring the bolt to yield is also increased. The curves in Fig. 30 show that, as friction increases, the clamp force at the yield point is reduced, while the torque that is required to reach the yield point increases. This illustrates the fact that for a given fastener size, the torque required to yield the bolt is a function of the material yield strength and the thread-friction coefficient.

Fig. 29 Friction effects on yield point

Fig. 30 Friction effects on applied torque and clamping force at yield for class 9.8 M12 × 1.75 bolts

Zone 4: Post Yield. The post-yield zone begins with an inflection point at the end of the elastic clamping range. Yielding can occur in the bolt or in the joint assembly as a result of underhead embedment or as thread strip in the bolt or mating threads. This fourth zone can be due to yielding in the joint or gasket or due to yield of the threads in the nut or clamped components or nut, rather than to yield of the fastener. The yield point of the bolt can be used to approximate the angle-tension coefficient for the tightening process.

The yield clamp load of a torqued fastener is less than the tensile yield due to the combined tension and thread torque. Because the thread friction coefficient is unknown, an initial assumption could be that the clamp load at yield torque is about 90% of the tensile-yield load. This calculation would be approximately correct for an average friction coefficient, μ_{ges} , of 0.1.

Torque-Angle (M -Alpha) Diagram

The torque-angle (M -alpha) diagram is a powerful tool for use in joint analysis. As shown in Fig. 31, it is a straight-line projection of the tangent to the torque-angle assembly curve projected backward from the predicted yield point through the elastic tightening point to zero torque. This tangent projection is used to locate the elastic origin. Because the M -alpha diagrams in this discussion were developed using SR1, a bolted-joint stress calculation software program based on the well-known German design standard, VDI 2230, terminology native to VDI is used in this discussion, such as M for torque, from the German word *Drehmoment* (torque moment).

Fig. 31 Torque-angle diagram

In addition to the applied torque, M_A , the torque-angle diagram has projections from the elastic origin for both the thread torque, M_G , and the pitch torque, M_{G0} (where $\mu = 0$). A very useful feature of the torque-angle diagram is the manner in which the diagram clearly illustrates the distribution of the torque in a tightening process. With M_A showing the total input torque, M_G represents the thread torque that is the thread friction plus the pitch torque, which creates the clamp force. The difference between the M_A and M_G curves represents the underhead-friction torque. The difference between the pitch torque curve, M_{G0} , and the M_G curve represents the thread-friction torque.

The torque-angle diagram is a straight line projected from the elastic origin to the yield point. By changing the coefficients for thread friction, μ_G , and underhead friction, μ_K , assumed for the VDI 2230 analysis, the effect of friction on the tightening process can be clearly seen. In the diagram shown in Fig. 32, the torque values required to reach the assembly preload and the yield point are lower because the assumed friction coefficients are lower.

Fig. 32 Torque-angle diagram with low friction coefficients

Strength Considerations

The clamp force and preload requirements for a bolted joint are determined by the static and dynamic loads that the assembly is expected to see in service. The bolted-joint design must be completely engineered with regard to the axial (concentric), eccentric, and shear loads to which the assembly will be subjected. This design is the first step in any fastener-engineering project.

After the external working loads have been defined, the necessary bolt preload can be calculated. Next, the safety factors against embedment and thread strip must be checked to ensure that yielding in the bearing areas or threads will not limit the preload to less than the required amount. Safety factors for shear slip, fatigue, loss of preload, and overelongation due to combined loads must also be evaluated.

The safety factors for embedment and thread strip are important both for the initial installation of the fastener and for long-term reliability with regard to both loosening and fatigue resistance. The illustration in Fig. 33 shows some of the strength factors that should be evaluated with regard to expected service loads and preload requirements.

Fig. 33 Basic clamping force and material strength considerations

Bolt Yield

Tightening a fastener beyond the yield point is a means of achieving the maximum preload possible for a given size and strength. This tightening method is commonly used in automotive engine assembly for connecting rod bolts, crankshaft bearing cap bolts, and engine head bolts. When bolts first replaced rivets in the construction of bridges and buildings, tightening beyond the yield point quickly proved to be a reliable method of assembly. The preload obtained by tightening beyond the yield point is proportional to the material yield strength and inversely proportional to the thread friction coefficient, μ_G . The thread friction coefficient is important because the yield point during tightening results from combined tensile loads plus the torsional load due to the thread friction and pitch torque.

After the yield load is reached, the clamping force will continue to increase in proportion to the increase in torque. In the elastic tightening zone, tension is proportional to the angle of turn from the elastic origin located on the torque-angle signature. When tightening beyond the yield point, the clamping force can be estimated by the procedure illustrated in Fig. 34.

Fig. 34 Bolt yield from initial tightening (Y_1) and from loosening and retightening (Y_2)

The tangent line to the elastic straight-line tightening section of the signature is projected beyond the yield point, and the final torque value is projected to the tangent line. The angle of turn from the elastic origin to the intercept of the backward projection from the final torque can be used to estimate the tension. This procedure can be seen as related to the strain-hardening phenomena observed when working materials beyond the yield point.

After the material is first loaded beyond yield, Y_1 , the yield point is found to be at a higher level, Y_2 , on the next tightening cycle. After yielding, when the load is released, the release curve is offset and parallel to the elastic tightening curve.

Thread Strip

In general, a properly designed bolted joint will not fail by stripping of the threads either during installation or if the assembly is overloaded in tension. As a matter of good design practice, failure should always be due to fracture of the bolt.

The thread-stripping areas for internal and external threads can be approximately calculated using the formulas expressed in Eq 20 and 21. The geometric configurations that define the formulas are shown in Fig. 35.

$$AS_B = \pi \left(\frac{d_3}{P} \right) \cdot L_e [0.5P + 0.577(d_2 - d_3)] \quad (\text{Eq 20})$$

where AS_B is the shear area of the bolt; L_e is the effective thread engagement; d_2 is the pitch diameter, external thread; d_3 is the minor diameter, internal thread; and D_3 is the maximum diameter, internal thread.

$$AS_N = \pi \left(\frac{D_3}{P} \right) \cdot L_e \cdot [0.5P + 0.577(D_3 - D_2)] \quad (\text{Eq 21})$$

where AS_N is the shear area of the nut thread; L_e is the effective thread engagement (grip length of the fastener); D_2 is the maximum pitch diameter, internal thread; D_3 is the major diameter, external thread; and d_3 is the minimum diameter, external thread.

Fig. 35 Thread-stripping areas in bolted assemblies. P , pitch; L_e , effective grip length of the fastener; d_2 , bolt pitch diameter; d_3 , bolt root diameter; D_2 , nut pitch diameter; D_3 , nut root diameter

Assuming that the maximum shear strength of the bolt material equals half of the tensile strength (ductile material, maximum shear stress failure mode), the bolt load to strip the threads can be estimated by multiplying the calculated shear area times the shear strength of the bolt or nut. This formula is a simplified calculation that assumes the loading is uniformly distributed on all engaged threads. In actual practice, due to the elastic coupling between threads, the first engaged thread carries a higher-than-average load, while remaining threads carry progressively lower loads as the load is transferred between the bolt and nut, or internally threaded hole.

When evaluating a bolted-joint, torque-angle assembly signature, the onset of thread stripping appears as a yield point, or a change of slope in the elastic portion of the tightening curve (Fig. 36). The thread-strip signature is similar to the signature for embedment of the fastener into the bearing surface. Both embedment (described in the following section) and thread strip lead to creep of materials within the loaded surface areas of the assembly. Over a period of time, embedment and excessive thread-stripping loads cause loss of preload as the high-stress regions relax and redistribute the loads.

Fig. 36 Test plot of fastener with stripped threads

In service, thread-strip failure can be progressive in nature, gradually transferring the load from thread to thread. Loss of preload due to thread strip can occur over many hours or days and is a cause of fastener loosening that is often difficult to diagnose.

Embedment or Loss of Preload

The release-angle method has been successfully used to study fastener-loosening problems. The basic procedure involves recording and analysis of the torque-angle signatures for tightening and then loosening the fasteners that are to be tested.

First, the torque-angle-tightening curve is plotted, the elastic origin is located, and the amount of angle of turn from the elastic origin is determined. After the assembly has been allowed to relax, for example, to sit overnight or run on a dynamic field test, the fastener is loosened and the loosening curve is analyzed. The release angle is determined, compared to the tightening angle, and if not equal, evaluated to see how much tension was lost by relaxation or loosening.

In one release-angle study, a fastener had a tightening angle of 120°. After 10 to 12 h, the release angle was 20°. The manufacturer was already aware there was a major problem because the parts were literally falling apart somewhere between the assembly factory and the automotive plant where they were delivered for final assembly in vehicles. The signature-analysis study showed that creep or relaxation in the threads was causing an approximately 80% loss in clamp force over a 12 h period. The release-angle method provided a quantitative answer as to the amount of clamp force lost and clearly showed that the parts needed to be redesigned.

The release angle method is particularly valuable for studying short-grip-length fasteners holding composite or plastic parts. These parts are generally too small to allow for use of strain gages or ultrasonic stretch measurements to confirm fastener preload.

For these applications, a torque-angle signature curve for tightening is recorded, and the parts are then put in an environmental chamber and load/temperature cycled.

Following the test-load cycle, the release-angle signature is recorded. Analysis of the release-angle signature in comparison to the tightening signature is used to directly estimate the percentage of initial clamp load lost due to embedment or creep of the plastic part in response to applied loads or temperature cycles. By changing geometric shapes and washer size, the effects can be quantitatively measured and compared. The section “Torque-Angle Tension Audits” describes an audit method that can be used along with the release-angle method to help audit relatively fastener tension values.

Estimating the Angle-Tension Coefficient

A number of different methods can be used to determine the angle-tension coefficient for the bolted joint. A basic assumption is that as the fastener is turned to develop preload in the joint, the fastener stretches, and the clamped parts compress elastically according to the effective spring rates of the fastener and the clamped parts. After the angle-tension coefficient is determined for elastic clamping through analysis of the torque-angle signature, it is relatively easy to estimate the tension achieved when tightening beyond the bolt-yield point.

The angle-tension coefficient for each bolted joint must be determined in order to establish the control parameters for torque-angle-tension control. By shutting off the assembly tool at a specified angle of turn after the threshold torque is attained, the scatter in achieved tension will be much less than the scatter observed for the same fasteners tightened with torque-only control. For this process to work reliably, it is necessary that the threshold torque level for starting angle counting be set at a level above the alignment zone of the tightening process.

The curves in Fig. 37 show how the process control limits are determined to achieve torque-turn-tension control for an application. Three examples are shown:

- With torque-angle control (110°) under normal friction, the clamping tension force achieved is 60 kN.
- With torque control of $60 \text{ N} \cdot \text{m}$ under high friction, the clamping tension achieved is 28.25 kN.
- With an angle count threshold of about $20 \text{ N} \cdot \text{m}$ and 110° torque-angle control, the clamping tension achieved is 56.15 kN.

Fig. 37 Torque-turn-tension control principles. Three examples are shown; see text for discussion.

After the installation process has been defined and implemented, methods must be specified to audit the results in order to verify that the process has achieved the desired fastener preload. Process audit procedures, including the release-angle measurement method and hand-torque breakaway audits, are presented later.

Release Angle Analysis

The complete analysis of a fastener involves looking at both the tightening and the loosening torque-angle curves as the fastener is first installed and then loosened. These curves are studied initially in the elastic tightening region where the fastener has not gone beyond yield, such as the assembly torque-angle signature shown in Fig. 38. When the fastener is loosened, a torque-angle-loosening signature, as shown in Fig. 39, can be recorded. The release signature shows the release of the fastener stretch as well as the release of the compression in the clamped parts. Analysis of this signature provides a direct method for verification of preload

or tightness. First, the line tangent to the elastic-release portion of the curve is projected to zero torque to locate the elastic origin. The release angle, measured from the point where loosening starts to the projected elastic origin, is a direct measure of the tension released from the bolted joint.

Fig. 38 Torque-angle assembly signature

Fig. 39 Torque-angle loosening signature

The tangent line must be drawn on the straight-line portion of the curve after the initial peak release torque due to static friction or thread-locking adhesive that has been broken free. The starting point is the angle where initial loosening motion begins. The total release angle is measured from the initial loosening point to the projected elastic origin. Note that if a significant prevailing torque is present after loosening the fastener, the elastic origin must be located at the prevailing level, not zero torque.

The torque-angle signature shown in Fig. 40 has been plotted as an *M*-alpha diagram with the tangent line, locating the elastic origin, drawn at 50% of the maximum torque to set the elastic tightening slope below the onset of embedment of the nut. The bolt is an M30 × 3.5 with a strength of class 11.9. The corresponding clamp force signature, plotted as an *F*-alpha (tension-angle) diagram confirms that the clamp force increases linearly

with the angle of turn from the projected elastic origin. In the example shown in Fig. 41, the elastic-tightening angle is approximately 125° .

Fig. 40 Torque-angle signature showing embedment

Fig. 41 Clamp force vs. angle of turn from elastic origin

The loosening torque-angle signature (Fig. 39) also has a projected release angle of approximately 125° . The tension-angle diagram (Fig. 41) confirms the fact that, even after embedment occurs, the clamp force increases in direct proportion to the angle of turn from the elastic origin. Similar to the analysis of added tension achieved after yield of the bolt, for embedment or thread strip, the backward projection to the extended tangent to the curve before thread strip or embedment is used to locate the effective tightening angle. Experiments with strain-

gage bolts or force washers, where the clamp force is measured along with the torque and angle during tightening, verify that this theory is correct for a given fastener.

Figure 42 shows a release-angle study performed on an automotive wheel nut. A tool with a torque and angle sensor connected to a transient recorder is used to loosen the nut, record the torque and angle values, and plot the data. The resulting printed curve shows an extremely high release torque. The high initial breakaway loosening peak torque region is disregarded because it is simply an indication of the static torque required to start loosening motion. The high value of release torque is significant from the point of view that it illustrates the high thread friction due to thread-pitch distortion on the wheel nut, a factor that helps prevent vibratory loosening on typical wheel nuts.

Fig. 42 Wheel nut-loosening signature

The elastic release angle for the wheel nut shown in Fig. 42 is approximately 40°. The nut had been tightened to a peak torque of 206 N · m (152 lbf · ft), which is 75 N · m (52 lbf · ft) greater than the vehicle manufacturer specification. The wheel nut was originally tightened to a torque of 160 N · m (118 lbf · ft), which did not appear to get past the tightening alignment zone as illustrated by the signature shown in Fig. 43. In this example, high underhead friction limited the tension on the stud, which for normal friction conditions, would have resulted in stud yield or fracture due to overelongation.

Fig. 43 Wheel nut-installation signature

The installation was followed by a hand-torque breakaway audit where the nut was advanced about 7 or 8° in the tightening direction, as shown in Fig. 44. The torque-angle diagram for the audit shows that the final torque was about 206 N · m (152 lbf · ft), with a projected elastic-tightening angle of 40°.

Fig. 44 Wheel nut-torque audit signature

Applying the release-angle method, a line is projected tangent to the elastic release portion of the curve to zero torque. This release angle, measured from the release-torque point to the point where the tangent line crosses the zero torque or prevailing torque level, is directly proportional to the tension or clamp force released. In comparing Fig. 44 with Fig. 42, a significant correlation is seen to exist between the release angle determined

by loosening the fastener and the torque-angle diagram as applied to the torque-angle signature for the breakaway audit. The loosening signature in Fig. 42 was recorded after the audit plotted in Fig. 44.

Torque-Angle Tension Audits

Torque-angle signature analysis is particularly useful for studying all critical fastener assemblies where, in terms of safety or reliability, it is important that proper preload is initially obtained and maintained throughout the operating life of an assembly. In addition to analyzing fastener problems, such as loosening and embedment, torque-angle signature analysis can also be used to evaluate the performance of tightening tools in applying the desired clamp force on fasteners. This technique is particularly applicable for evaluating processes that employ pulse tools and impact tools.

Due primarily to ergonomic considerations, pulse tools have recently been widely specified for use in high-volume assembly operations. Unfortunately, the limitations of these tools related to their energy transfer characteristics are not generally well understood. Pulse and impact tools are particularly sensitive to joint rate and friction variations. Because friction coefficients are a function of velocity as well as surface pressure, tightening results with pulse, and high-rpm tools must be carefully evaluated to ensure suitable tightening process capability.

For example, pulse and impact tools move fasteners at high speeds with a great deal of stick-slip, chatter, and unique frictional characteristics that are not seen with steady, continuous tightening processes. These factors can lead to a deceptively high torque reading but with minimal clamp force created. By checking the assembled joint with an audit method that can correlate angle of turn and clamp load, the user can ensure that the assembly is securely tightened.

The following series of tightening, breakaway-torque audits and release signatures illustrate the basic concepts of torque and tension audit using torque-angle signatures. Understanding of the engineering mechanics of threaded fasteners is greatly enhanced through the use of the concept of the elastic origin and the application of torque-angle (M - α) and tension-angle (F - α) diagrams to the audit process.

Tightening Curve Analysis. In the example illustrated in Fig. 45, an $M12 \times 1.75$ fastener was tightened to $80 \text{ N} \cdot \text{m}$ ($60 \text{ lbf} \cdot \text{ft}$). The signature was recorded with a recording threshold of $27 \text{ N} \cdot \text{m}$ ($20 \text{ lbf} \cdot \text{ft}$). The plot shows both torque and tension versus angle of turn, with zero angle located at the threshold.

Fig. 45 Torque and clamp load vs. angle

The signature analysis software used in this analysis can automatically locate the elastic origin on the torque-angle diagram by projecting a tangent line from the final point on the torque-angle curve to the zero torque level. The torque-angle diagram for the installation-tightening signature, shown in Fig. 46, illustrates that the

torque resulted in a projected elastic tightening angle of approximately 85° . The corresponding tension-angle curve, shown in Fig. 47, confirms the relationship between torque and angle with the concept of the elastic origin. Note that the 85° elastic tightening angle for the bolt results in a clamping force of approximately 33.4 kN (7500 lbf).

Fig. 46 Torque-angle diagram for installation tightening signature

Fig. 47 Clamp force vs. angle diagram corresponding to the torque-angle diagram in Fig. 46

Breakaway Analysis. The next signature is the breakaway torque audit (Fig. 48) on the bolted joint tightened for the example shown in Fig. 43 44 45. Breakaway hand-torque audits are often used in an attempt to correlate the dynamic installation torque with the measured breakaway point. In this example, the fastener was torqued in the tightening direction until an additional angle of turn of approximately 12 to 13° was attained. Note that the head of the fastener started to move at approximately $74.5 \text{ N} \cdot \text{m}$ ($55 \text{ lbf} \cdot \text{ft}$). The actual breakaway point and

continuation of the tightening process occurred at approximately 88 N · m (65 lbf · ft) of applied torque. These observations confirm the installation torque of 81 N · m (60 lbf · ft) as is normally done for a breakaway torque audit.

Fig. 48 Breakaway torque audit on the bolted joint tightened for the example shown in Fig. 43 44 45

The signature analysis diagram shown in Fig. 49 is one of the most significant analysis tools developed in the past 10 years. This diagram shows how it is possible to audit both the installation torque and correlate the signature of the audit curve directly with fastener tension. The projection of the tangent to the torque-angle signature curve that locates the elastic origin is the key to significant improvement of the hand-torque audit process. The torque-angle diagram for this audit signature clearly shows the torque breakaway point related to the installation torque, as well as the 85° initial tightening angle, which correlates with a preload of 33.4 kN (7500 lbf) clamping force. Note that the breakaway audit increased the tightening angle to approximately 95 to 100° projected from the elastic origin, with an expected proportionate increase in preload.

Fig. 49 Breakaway torque audit showing the torque breakaway point related to the installation torque

Release-Angle Audit. If the torque-angle signature is recorded when a fastener is loosened, as shown in Fig. 50, the resulting release-angle graph can be used to determine the elastic tightening angle and, thus, directly estimate the approximate fastener tension that was released, provided the tension-angle slope for the joint has been established.

Fig. 50 Release angle signature

Torque-angle plots and release-angle plots can be used to directly estimate bolt tension, or preload, which is the ultimate goal of the fastener-tightening process. The release angle of approximately 95° in the example shown in Fig. 50 confirms the tightening angle measured on the torque-angle diagram for the hand-torque audit. Clearly, the release-angle method of audit provides a direct measure of the capability of a given tool to develop tension in the tightened fastener.

Frictional Analysis Audits. To provide an example of how audit techniques can be used to the effect of differences in frictional characteristics, the fastener type used in the previous examples (Fig. 43, 44, 45, 46, 47, and 48) was stripped of all thread and underhead lubricants to create higher friction coefficients in the thread and underhead regions. The torque-angle diagram for tightening to $81 \text{ N} \cdot \text{m}$ ($60 \text{ lbf} \cdot \text{ft}$), shown in Fig. 51, indicates a tightening angle of only 25° projected from the elastic origin. Compared with the lubricated fastener, where the tightening angle was 85° , the predicted preload of 9786 N (2200 lbf) was confirmed by the clamp-force measurement. The breakaway audit for the dry-tightened fastener (Fig. 52), confirms that the installation torque was approximately $81 \text{ N} \cdot \text{m}$ ($60 \text{ lbf} \cdot \text{ft}$) and also reveals the expected very low angle of turn from the elastic origin.

Fig. 51 Torque-angle diagram for a fastener stripped of all thread and underhead lubricants, tightened dry

Fig. 52 Breakaway torque-angle audit for the dry-tightened fastener

Application of Torque-Angle Signature Analysis

The torque-angle signature method of analysis applied to tightening and loosening curves is plain, simple, and straightforward. It is a basic engineering analysis technique using fundamental stress, deflection, and material strength properties to model and measure the bolted-joint tightening process. Torque angle signatures can be analyzed to determine installation torque, thread strip, underhead embedment, bolt yield, and most importantly, fastener tension. While there are many factors that can alter the tightness of a given bolted joint, the torque-angle signature analysis method provides a practical method for direct verification of clamp force to assure a quality fastener assembly. The technique can be applied to fasteners of all sizes and all grip lengths.

The release-angle signature, when compared to the installation-torque angle, can be used to evaluate the clamp load retained after a dynamic test. Material creep and embedment phenomena, which lead to loss of preload, are readily analyzed and quantitatively evaluated through the use of release-angle analysis methods. The results of release-angle audits, being directly related to the achieved tension, are significantly more meaningful than the torque magnitudes obtained from breakaway torque audits. An improved version of the breakaway torque audit, which uses the torque-angle signature of the audit, can be used to directly estimate fastener tension. This analysis process correlates precisely with the release-angle-signature method. The only limitation is that the breakaway audit must be conducted in the elastic tightening region for the bolted joint where bolt yield or thread strip are not present.

Measurement Accuracy

It is important that all standards for fasteners be reviewed in regard to the specification for measurement accuracy. The specification of measurement accuracy for torque and clamp force should be in compliance with the ISO 25 methods used by the American Association for Laboratory Accreditation (A2LA) in the certification of laboratories. Both torque and clamp-force measurement specifications should refer to accuracy at the point of measurement. It is desirable to certify the accuracy and uncertainty of dynamic measurements at the real-time testing speeds (i.e., rpm) that are required by each test specification.

The following paragraphs of this section illustrate some examples of the accuracy specifications found in current standards that need to be reviewed and perhaps changed or revised. It is hoped that future revised editions of existing standards and all new standards will give proper attention to understanding the science of measurements and the capability of current state-of-the-art measurement equipment. From a practical point of view, it is also important to consider the true need of accuracy so that unnecessarily tight tolerances are not specified. This is especially true where broader tolerances that are capable of properly meeting the desired end result can be demonstrated as sufficient to qualify the measurement with regard to its intended purpose.

Defining the Measurement

All measurements are comparisons to standards, and practically no measurement is without a degree of uncertainty. To be valid, a measurement must have an unbroken chain of traceability to well-defined, established primary standards. Each step of the traceability chain introduces additional uncertainty, which has a cumulative effect on the accuracy and uncertainty of the final measurement.

It should be recognized that the accuracy of a measurement cannot be any better than the resolution of the measurement system. For most practical purposes, the measurement system resolution is defined as the smallest increment displayed on the measurement dial, such as the scale on a torque wrench or the pressure read on a hydraulic load-indicating gage. In digital electronic measurement systems, the smallest increment for the analog-to-digital (A/D) converter establishes the basic measurement resolution.

U.S. Standards

The American Society of Mechanical Engineers (ASME), the Society of Automotive Engineers (SAE), ASTM, the American National Standards Institute (ANSI), and the Industrial Fasteners Institute (IFI) all have established fastener standards in the United States. However, to meet the needs of a global economy where products manufactured in the United States can be marketed worldwide, it is important to recognize that a large amount of effort may be necessary to align U.S. testing standards with the international marketplace.

Significant progress has been made in the conversion of U.S. manufacturing to the metric (*Système International d'Unites*) (SI) system. Recognizing the United States' continued slow progress in this matter, the European commission has recently delayed the mandatory metric-only labeling requirement from 31 Dec 1999 to the year 2010.

International Standards

The European Committee for Standardization (CEN) centralizes the establishment of standards for the European Union (EU) member nations. By coordinating U.S. testing standards with those approved by CEN, it will then be possible to avoid or at least minimize any costly duplicate testing on products intended for sale to customers in EU member countries.

One area in which the United States needs to address serious deficiencies is in its method of definition of accuracy with regard to the test measurement procedures specified by U.S. standards. A number of U.S.

standards contain specifications that are obsolete, impractical, or not precise enough to be acceptable when subjected to the qualifying analysis applied to European testing methods.

For a number of years, many U.S. companies have been striving to become world class manufacturers with certification to ISO 9002. Fastener testing that meets the requirements of ISO/International Electrotechnical Commission (IEC) 25, titled “General Requirements for the Technical Competence of Calibration and Testing Laboratories,” would qualify to meet the requirements of ISO 9002. Failure to specify accuracy and uncertainty of measurements in a manner consistent with ISO 25 requirements will very likely make testing unacceptable for product sales to the European community.

Definitions of Accuracy

Accuracy can be defined only in terms of the entire measuring system and the environment, pertaining to both the instrumentation and the physical nature of the phenomena to be measured. Measurement accuracy is dependent on the capability of the measuring system to dynamically track the signal (frequency response) and provide sufficient resolution to permit comparison to be made between readings. Because a measurement reading is always an approximation of the true value, the uncertainty quantifies the limits of accuracy that can be expected. In the example illustrated in Fig. 53, the stated accuracy is 1% of the reading.

Fig. 53 Range of accuracy

Measurement Error

There are two general components of measurement error, bias and random. Bias is a constant value, such as a zero offset of a transducer or measuring amplifier, or a digital reference point. The random component is a complex function of system noise or the least-bit resolution in digital systems (Fig. 54).

Fig. 54 Nature-of-measurement error

Frequency response effects where the phenomena measured may occur dynamically in a region beyond the flat response of the measurement system are not random errors. Such errors are the result of poor measurement system performance resulting from improper understanding of the engineering physics of the process being measured.

Measurement Error Observations. Measurement errors of a random nature typically have a normal distribution as shown in Fig. 55. To evaluate a measurement system, it is necessary to input constant known values and determine the scatter in the measurements over a number of samples. Statistics, such as sample standard

deviation, can be used to quantify the probability function for the readings that define the uncertainty for the test conditions simulated.

Fig. 55 Measurement error observations

Allowable Uncertainty Versus Percent Full-Scale Reading

A number of currently used standards specify the accuracy of readings in terms of “percent full scale.” As shown in Fig. 56, the 2% full-scale accuracy specification results in a 4% error at a point of reading taken at 50% of the full scale of the measuring device range (in this case, a force transducer). Similarly, the error would extrapolate to 8% of the reading at 25% of measurement-transducer range. In an attempt to limit the error in measurement, this standard stipulates that “transducers cannot be used below 50% of their full-scale range.” If this stipulation is followed closely for locknut testing, the tester would need to use one set of transducers to obtain prevailing on-torque and clamp-load values, then stop the test and use a higher capacity set of sensors to obtain the torque at clamp load. This process would be followed by a return to the lower-range sensor to obtain the prevailing off-torque data to complete the test. This situation is impractical at the least and impossible in most cases. Fortunately, with properly calibrated and qualified modern testing systems and specifications based on accuracy at the point of measurement, the complicated process described is rendered totally unnecessary.

Fig. 56 Allowable uncertainty

It is far more practical and consistent with modern testing procedures according to ISO 25 that accuracy be specified at the point of measurement. In this example, it would be proposed that the accuracy specification be changed to “within 2% of reading.” Taking a modern approach in revising this standard, the totally impractical and unnecessary limitation on the use of the transducer below 50% of its full-scale range would be eliminated. There are a number of test procedures where accuracy specifications can be adjusted to different values at various points within the test, thus permitting a valid comparison of samples while using a single transducer over a broad measurement range. One possible example would be testing of prevailing torque locknuts where

the accuracy of torque measured for achieving clamp load could be 2% of the reading ($50 \text{ N} \cdot \text{m}$) and a fifth off-torque accuracy of 5% ($1.1 \text{ N} \cdot \text{m}$). In this case, testing could be done with a single transducer for all torque measurements.

Frequency Response Analysis

All test specifications should call for accuracy of measurements at the speeds at which the test is run rather than contain statements that specify reading rates or 3 dB points on filters, which can introduce errors as high as 30%.

A typical example is shown in Fig. 57, where a 30° hard joint is used to evaluate fastening tools according to ISO 5393. With a 100 rpm tool and the filter specified in the standard, an error of about 30% would be expected because the filter will have reduced the measured signal at least 30% for equivalent waveforms above 500 Hz. To properly capture the peak torque for a 1000 rpm tool, the system needs to be flat to 500 Hz, not down 3 dB in response at 500 Hz.

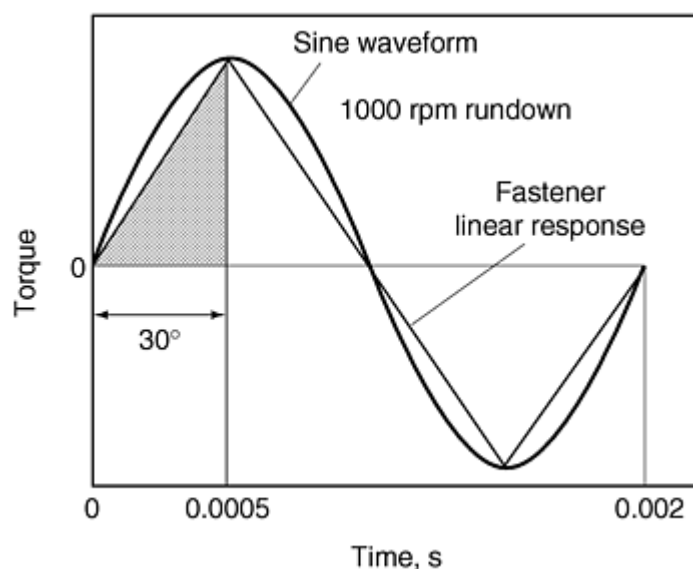

Fig. 57 Frequency response analysis

In this case, the intent of the standard was to minimize errors due to electrical noise and perhaps due to a perception that higher-frequency components did not contribute to the tightening process. The 3 dB point specified at 500 Hz in the standard clearly places a limitation on the upper rpm for the testing of tools.

Measurement Resolution

The measurement resolution and accuracy for a test should be verified at the specified testing speed. The example shown in Fig. 58 illustrates several important features verifying measurement capability. In the following test, two torque transducers in series are driving an M12 prevailing nut at 100 rpm. The initial position of the nut is such that the nylon patch is not engaged. The transducers have full-scale ranges of 68 and $9 \text{ N} \cdot \text{m}$.

Fig. 58 Measurement resolution using transducers with full-scale ranges of 68 and 9 N · m

The maximum applied torque is slightly less than 3 N · m, or about 2%, of full scale on the larger capacity unit and 30% of full scale on the smaller-capacity unit. It is clear from the recorded data plot that at 100 rpm, the transducers are reading precisely the same torque values.

This test verifies that the measurement system is capable of simultaneously capturing readings at the 100 rpm test speed. It also illustrates the possibility of the use of the high-capacity torque sensor to make valid measurements in the range of 2% of full-scale capacity when used with this measuring system.

ISO 9000 Registration Versus Laboratory Accreditation

There are significant differences between laboratory accreditation using ISO 25 and quality system registration. The key difference can be summarized in that the essence of ISO 25 is to ensure the validity of test data, whereas technical credibility is not addressed in ISO 9000.

ISO 9000 and QS 9000 registrations require that procedures are in place, well documented, and followed. ISO 25 goes further in that it requires the science of the laboratory measurements be understood and that the tester is capable of demonstrating that valid measurements are the product of his or her testing procedures.

All testing procedures should be evaluated to account for certain basic considerations. American testing standards for fasteners may not receive international recognition unless they can be shown to meet the basic requirements of ISO 25. The most important questions to answer when reviewing standards are the following:

- Will the procedure produce accurate results?
- How have the procedures been validated to ensure accuracy?
- Does the tester understand the science behind the test procedures?
- Are the limitations of the procedures known?

The science of measurement engineering is a critical area of technology needed to properly qualify both the specifications and the measurement systems used to verify the quality of threaded fasteners. The pure acquisition of data for its own sake is one of the greatest technical crimes of this era. All measurements must reflect a technical knowledge of the testing process, as well as a full understanding of the capability and limitations of the measuring system.

Testing of Adhesive Joints

K.L. DeVries and Paul Borgmeier, University of Utah

Introduction

MOST ENGINEERING DESIGNS require the connecting or joining of component parts. Means available to accomplish these goals can be broadly classified as mechanical connections, welding, and adhesives. Mechanical connections such as bolts, pins, and rivets have the advantages of being easy to install, they can be inspected often, and they can be repaired or replaced. On the other hand, such connections require making holes in the component members, which act as stress risers (with typical stress concentration factors of 3 or greater). Structures that experience dynamic loading, such as airframes, often fail from fatigue cracks originating at their stress concentrations. The heads of connections such as nuts and bolts can affect aesthetics, streamlining, and other parameters. Another type of mechanical connection that is becoming increasingly popular is the “snap” connector. These connections are wedge-like tabs and grooves that, when forced together, snap into place to hold containers or housings together. Snap connectors greatly facilitate assembly but have limited strength, are easily damaged in assembly (or even more likely during disassembly), and may deteriorate with time and wear. In welding, the joining segments of the component parts are locally melted, brought together, and fused (additional material may be supplied from a welding rod). Welded joints have the advantage of being relatively continuous, resulting in high strength. They have the disadvantage of requiring a relatively expensive process. The required heating can damage other parts of the structure or its contents. Not all combinations of materials can be welded. Most metals and plastics can be welded only to themselves or to a limited number of other similar materials. Some materials do not lend themselves to welding at all.

Adhesive joints involve joining parts by bonding component parts together with an adhesive. In some plastic applications, one of the parts may act as the adhesive, and in some cases, a solvent may be used to dissolve/soften the materials, which are then bonded by diffusion of the polymer chains into the respective parts, forming essentially one material. Examples of this type of bonding include the solvent bonding of polyvinyl chloride (PVC) pipe and acrylic materials. Very dissimilar materials can, in principle, be joined by

adhesives, for example, wood to plastic, metal to ceramics, and aluminum to steel. Likewise, it appears that the “load” could be distributed over a larger area compared with joining materials with, for example, bolts. This aspect can be even further enhanced by appropriate design as, for example, in the familiar finger-scarf joint used to increase the length of lumber. This type of joint design accomplishes several beneficial goals: it increases the bonded area, changes what for a butt joint would be largely tensile stresses to more shear stress, and produces a smooth, attractive (almost invisible) joint.

Along with their advantages, adhesive joints pose their own design problems. Prediction of load-carrying capacity is often neither straightforward nor reliable. Adhesive joints also have problems with inspection because the bonded surfaces are usually not visible after assembly. Stresses in an adhesive joint are generally not uniformly distributed on the bonded surfaces, and in fact, elastic stress analysis often exhibits singularities analogous to the stress risers associated with the other methods of joining already mentioned. Because adhesive joints usually involve very dissimilar materials in the adherends and adhesives, cure stresses, thermostresses, deformation mismatches, and so on may cause problems.

Despite these drawbacks, the advantages and positive features of adhesive joints are so attractive that the use of adhesives has enjoyed phenomenal growth over the last 50 years. One compilation of adhesives lists more than 5000 different commercial adhesives available to the U.S. designer (Ref 1). Adhesive selection, testing, use in design, and application is a very complex subject covered in a variety of large reference books (for example, Ref 2, 3, 4, 5, 6 and *Adhesives and Sealants*, Volume 3 of the *Engineered Materials Handbook* published by ASM International) and literally thousands of journal articles; dedicated journals include the *Journal of Adhesion* and the *International Journal of Adhesion Science and Technology*. Articles on adhesives and adhesion also appear in journals or publications of the following organizations: American Society for Testing and Materials, Society for Experimental Mechanics, American Society of Mechanical Engineers, Materials Research Society, and many others. The Society for Adhesion, the Gordon Research Conferences, and the American Chemical Society hold annual or periodic conferences dedicated to the subject of adhesives. Despite this extensive research and study, there is still much to be done, and adhesive joint design is still as much art as it is science.

Brazing and soldering are methods of joining that have similarities to adhesives and welding. These methods might be viewed as falling between welding and adhesive bonding. Brazing is closer to welding in that, while it uses a different material for “bonding” the “adherends,” its application typically involves extensive heating and perhaps some interpenetration of the brazing and host materials. The material used for brazing is melted in a puddle, in which there may be some alloying with the host material(s) on fusion. In soldering, on the other hand, usually only the solder material melts, and if it wets the host material(s), it attaches by adhering to the joined pieces. It might be viewed as a metallic form of hot-melt adhesive.

Adhesive science and technology remains an important area of active research. New adhesives continue to be developed, and work continues on the understanding of stresses; methods of analyzing stresses, strains, displacement, and load-carrying capacity; improved experimental techniques; and so on.

Purpose of Testing Adhesive Joints

In no area of materials is testing more important than it is for adhesives. In the United States, the largest organization devoted to standardizing test procedures is the American Society for Testing and Materials (ASTM). ASTM and its counterparts in other countries work through the International Organization of Standardization (ISO) in an effort to coordinate testing on an international scale. All these activities are very important and time consuming, entailing countless hours of volunteer efforts in the United States alone. Other organizations, besides ASTM, have established testing procedures that relate to the testing of adhesive joints. Such organizations include the military (MIL specs), other professional societies, such as the Society of Automotive Engineers (SAE), the American Society of Mechanical Engineers (ASME), and industrial organizations.

Many examples of the wide variety of standardized tests for adhesives can be found in the *Annual Book of ASTM Standards*, Volume 15.06, which is updated and republished annually (Ref 7). Except where specifically noted, the standards and practices listed in this treatise can be found in this volume. There are also many other less formalized tests used by various organizations and a few specialized tests for adhesives found in other ASTM volumes. ASTM practices, specifications, and test methods cover a wide variety of topics ranging from measurements of shelf life and pot life through resistance to mold or insect attack to determination of viscosity and various aspects of strength. This article concentrates on tests and methods used in the measurement of adhesive joint strength. A logical question in the discussion relative to the selection of the specific adhesive might be “How strong is it compared with the other available adhesives?” The answer to such a query is neither as simple nor as straight-forward as might be assumed. The reasons for this complexity are addressed in this article.

Testing of adhesive joint strength might be conducted for a number of reasons, including the following:

- *Quality control*: To ensure that changes such as adhesive age, mix method, and surface preparation that will affect bond quality have not been introduced
- *Comparative analyses*: To determine which of a series of adhesives, primers, surface preparations, cure methods, and so on is best suited for a given bond application
- *Generation of engineering design data*: To predict the load-carrying capability of a given bonded joint

The geometry of the test specimen selected is very important even for quality control tests. In fact, an adhesive that exhibits “high strength” in a tensile test may have poor peel strength and vice versa. In fact, many variables may affect bond strength. Each variable may affect the bond strength in a different manner, and the manner in which the bond strength is affected may be different for each test geometry. The amount of adhesive used in a mixing batch and the delay time between mixing and casting will likely affect strength and may affect peel strength differently than it affects tensile strength. As another example, bond thickness often affects lap shear strength in a different way than it affects tensile button strength. If a series of lap shear joint test are completed for various adhesive thickness is optimum for a given joint unless the geometry, adhesive, and loading are nearly identical to those of the lap shear joints tested. Thus, even for comparative analyses, a great deal of care must be used in applying laboratory test data to joints whose geometries differ in even subtle ways from that of the laboratory test specimens.

There are many standard adhesive tests available to the engineer for determining the strength of adhesive joints. In the example just discussed, reference was made to tensile and peel specimens. Indeed, most standard tests for adhesive joints fall within three general categories, namely, peel tests, lap shear tests, and tensile tests. It is important to recognize, however, that the stresses at the tip of the debond region are not necessarily of the character implied by the name. In fact, the stresses are usually of mixed character. For example, as discussed in the section “Lap Shear Tests”, the stress in the critical region of the so-called lap shear specimens are apt to be more crack opening (tensile) in nature than shear.

One purpose for obtaining adhesive joint engineering data is in an effort to ensure that a bonded joint will withstand the loads for which it was designed. This might be accomplished by “proof testing” every joint, that is, by loading every joint manufactured to its design load. However, this approach has its problems. First, such procedures are apt to be very costly. Furthermore, the joint may withstand such loading but be damaged by the loading such that it subsequently fails when subjected to aging, creep, and fatigue loading or the environment. In addition, when a joint is in place in a structure, it is often difficult to apply the actual or even a simulated load. The load may be prohibitively large and/or in an awkward location, making testing difficult, very expensive, or even impossible. There is also a danger that applying such proof loads might damage neighboring or adjoining parts of the structure.

For these reasons, an engineer is generally required to obtain data from laboratory size samples and use this data to infer the strength of a given “practical” joint. For many of the standard adhesive joint tests, the results are reported as the load at failure divided by bonded area. In one straightforward design approach, this stress is then compared with the average stress that exists in the joint being evaluated when its maximum load is applied. However, if the joint geometry, loading time, and other conditions are not identical to the laboratory test conditions, the direct comparison can lead to unsafe joint designs. This problem is discussed in subsequent sections (“Lap Shear Tests” and “Adhesive Fracture Mechanics Tests”).

Testing of Adhesive Joints

K.L. DeVries and Paul Borgmeier, University of Utah

Factors Influencing Mechanical Strength of Adhesive Joints

Before proceeding with a description of specific tests, a few general comments might be helpful. The strength of an adhesive joint should not be viewed as being essentially (or even largely) an inherent property of a given adhesive. Typically, strength depends on many factors. The nature of the adherends may have a dramatic effect on joint strength. A given adhesive may not even “adhere” to some potential substrates. Even where the inherent adhesion may be good, its quantitative value is typically highly dependent on proper cleaning, surface treatment, and details of curing. The presence of coupling agents and surface roughness can affect strength. Thickness of adhesive and adherends and other geometric factors also play strong roles in the strength of a joint. In short, it is safe to say that the strength of an adhesive joint is a system property that depends on many factors beyond the chemical and physical nature of the adhesive per se.

Some ASTM and other standards and practices address these other factors. For example, the following ASTM standards cover surface treatments for various materials:

- D 2093, “Standard Practice for Preparation of Surfaces of Plastics Prior to Adhesive Bonding”
- D 2651, “Standard Guide for Preparation of Metal Surfaces for Adhesive Bonding”
- D 2674, “Standard Test Method for Analysis of Sulfochromate Etch Solution Used in Surface Preparation of Aluminum”
- D 3933, “Standard Guide for Preparation of Aluminum Surfaces for Structural Adhesives Bonding (Phosphoric Acid Anodizing)”

Coupling agents such as silanes, titanates, zirconates, and chrominates are sometimes applied to the surface before application of the adhesive. The agents are also sometimes incorporated into the adhesive. In at least some cases, they are thought to form covalent bonds between the adhesive and the adherend surfaces (Ref 8).

As with most materials, aging can affect the properties of an adhesive and the strength of an adhesive joint. It is often not convenient (or possible) to simply wait to see how time and exposure to the elements might cause deterioration. Accelerated aging tests are an effort to infer from short-term tests, usually under very harsh conditions, how well materials might hold up under longer-term, more realistic service conditions. A comparison of how different adhesive joints in wood exposed to boiling water for several hours or days might, for example, be used to estimate their relative weatherability (ASTM D 3434, D 5572). While the comparisons might not be perfect, they are likely better than nothing. Several other standards that address accelerated testing of adhesives include ASTM D 1101, D 1183, D 2559, D 3632, and D 4502.

Testing of Adhesive Joints

K.L. DeVries and Paul Borgmeier, University of Utah

Qualitative Tests

Most “adhesive strength tests” are quantitative in nature. The test results are typically given as “average stress” at failure (tensile and lap joints) or force per unit width (peel tests). The preparation and testing of quantitative samples are expensive and time consuming. It would often be advantageous to have a means of making a qualitative determination of adherence to ascertain if the cost of conducting the quantitative tests would likely be justified. Such quick screening of candidate adhesive/adherend pairs might result in significant time and cost savings by eliminating unlikely candidates and assisting in selecting those worthy of further study.

The first effort along this line with which the authors are familiar is found in the patent literature (U.S. Patent 4,025,159, Cellular Retroreflective Sheeting). In this patent, Dr. J.M. McGrath of 3M Corporation explores means of increasing the bond strength between the cover sheet and the base sheet (polymer binder with embedded reflective glass spheres) in retroreflective sheeting. This sheeting is used in stop signs and other reflective signs. To accomplish this goal, McGrath proposes curing (cross linking or chain extension) the sheeting after the thermoforming operation. He points out that the proposed process does not work for all potential pairs of cover sheet and base materials. As an aid in selecting materials for further study, he suggests casting a small amount of candidate base materials on potential cover sheets and curing them in place. After curing, McGrath proposes a single-edged razor blade be used to lift, scrape, or otherwise separate the base material from the cover sheet. The relative effort required to facilitate this separation is assessed and used as guide in the selection of candidates for further study.

More recently, Committee D-14 of ASTM formalized and adopted ASTM D 3808 “Standard Test Method for Qualitative Determination of Adhesion of Adhesives to Substrates by Spot Adhesion.” The stated purpose of the document is to provide “a simple qualitative procedure for quickly screening whether an adhesive will, under recommended application conditions, bond to a given substrate without actually making bonded assemblies.” In this test method, spots of adhesive are placed onto a substrate using the application procedure and curing conditions acceptable to the user and supplier of the adhesive. To test adhesion, the document recommends the use of “a thin stainless steel spatula or similar probe” as a prying lever. It states “If the results are acceptable, then standard quantitative adhesive test procedures can be used to obtain quantitative measurement of the adhesive’s performance.” The authors believe such methods of preliminary screening are certainly worthy of consideration in many instances. They can often save time and testing costs.

Peel Tests

Peel tests are easy to visualize albeit their analysis and the interpretation of peel test results is neither so easy nor straightforward. When a strip of adhesive tape is placed partially on paper or on another substrate and then removed by pulling the free end (the portion of the tape that is not attached), in essence, a peel test is being conducted, as shown schematically in Fig. 1. Several quantitative observations might readily be made from such a test (it is important to note that the tape is a very flexible material). The force required to propagate the peel failure is a strong function of the angle at which the peel force is applied. If the angle is small (i.e., close to the direction of the substrate surface), large peel surfaces are required. As the angle increases to the point where the peel angle is 90° , perpendicular to the surface, the force is reduced significantly. As the angle is further increased, it reaches a limit at 180° (ASTM D 903 describes a 180° peel test for a “flexible” peel specimen). The force per unit width required to facilitate peel is called the peel force or the stripping strength. It can also be observed that the forces required to sustain peeling depend on the rate of peel. For tapes bonded with pressure-sensitive adhesives, very slow peel rates require relatively small peel forces, while at extremely high rates, the peel forces are much more substantial. It can also be noted in this simple peel test that the force required to initiate the peel may differ from that required to sustain the peel once it has started. It may also be observed that the force required to peel the tape from the substrate depends on the nature of the surface to which the tape is attached. For example, it may adhere very tightly to a clean glass surface but hardly at all to moist or oily glass.

Fig. 1 Schematic of the peel test

ASTM has formalized a variety of different peel tests in its *Annual Book of ASTM Standards*, Volume 15.06. Several of the standard peel test geometries (described in detail in ASTM D 903, D 3167, and D 1876) are illustrated in Fig. 2 (Ref 7). ASTM D 1781 describes the climbing drum peel test, which is used to determine the peel resistance of adhesive bonds between a relatively flexible adherend and a rigid adherend.

Fig. 2 Typical peel test specimens. (a) Stripping strength specimen (ASTM D 903). (b) Roller drum peel test specimen (ASTM D 3167). (c) T-peel test specimen (ASTM D 1876). Source: Ref 7

Several other peel tests are in common usage that have not been standardized by organizations such as ASTM. For example, the authors have found a test they have adopted from researchers at 3M Corporation to be very useful for measuring peel strength. This method makes use of a test jig incorporating a platform that uses rollers that allow the platform to move horizontally with extremely low friction. It is used to test the adhesion between two thin flexible sheets. For testing, one of the sheets is bonded to a thin aluminum sheet with a strong adhesive. A region of debond along the adhesive between the thin flexible sheets is initiated with a razor blade or by other means, leaving a loose tab. The aluminum sheet with the attached bilayer sheeting is inserted into slots on the jig platform, or otherwise held fixed to it. The jig is then attached to the lower crosshead of a universal-testing machine such that the platform is horizontal. The loose tab is then attached by a grip to the upper crosshead. During testing, motion between the two crossheads then peels the upper sheet from the lower. The peel angle is maintained at very nearly 90° as the platform moves horizontally (facilitated by the low friction rollers), keeping the peel region directly below the upper grip. In some cases where the adherence between the sheetings is high and the sheeting cohesive strength is relatively low, it has been helpful to reinforce the upper sheet by applying strapping tape that is gripped and peeled along with the upper sheet. It is important to note, however, that even though the peel failure may follow the same path, it would not be anticipated that the peel force would be the same as for the nonreinforced sheet. Adhesive joint strength is a “system property,” and the addition of another layer can modify the energy absorption during the peel process, thereby altering the associated peel forces. It is, therefore, important to compare the results from tests on reinforced materials with those of other materials that are similarly reinforced and vice versa.

All peel tests have the common characteristic that failure propagates from an initially debonded area. They also generally involve large displacements/deformations. For these and other reasons, linear elastic stress analysis is often not well suited to peel tests. The stresses and strains in the peel configuration are complex and seldom well understood. Test results are generally not given in terms of stress but rather as force per unit length required to peel the specimen. It is, therefore, generally difficult to compare the results from a peel test with those from other testing methods.

Because of the large deformations involved in peel tests, the analysis of such geometries is very difficult except under certain simplifying assumptions (Ref 3, 4, 6, 9, and 10). Some very interesting and informative observations can be made on the basis of simplifying assumptions and approximations. Indeed, considerable useful work has been completed using peel tests. The informative work of Gardon (Ref 10) and Kaelble (Ref 11) is noteworthy. The polymer research group at The University of Akron, under the direction of Professor A. Gent, has been particularly adroit in applying peel techniques and the concepts of fracture mechanics (see the section "Adhesive Fracture Mechanics Tests" in this article) to obtain critical information and insight into the behavior of adhesive joints (Ref 12, 13). The peel specimen is, in principle, a very versatile geometry for obtaining adhesive fracture energy because various combinations of mode I and mode II loadings can be applied by varying the peel angle (Ref 3). The stress analyses of Adams and Crocombe (Ref 14) have provided additional insight into the peeling mechanisms. They examined the stress distributions in peel specimens using elastic large-displacement, finite-element analysis techniques.

Testing of Adhesive Joints

K.L. DeVries and Paul Borgmeier, University of Utah

Lap Shear Tests

The most popular test geometry for testing adhesive joints is the lap shear specimen. Its appeal is probably based on the fact that it closely duplicates the geometry used in many practical joints. These lap joints are popular for several reasons:

- They facilitate use of larger contact areas than, for example, a butt joint.
- They are easier to make and align than butt joints.
- The adhesive is not exposed to “direct” tensile stresses. Direct tensile stresses are known to have deleterious effects on adhesives.

Typical lap shear test specimens for which ASTM standards have been written are presented in Fig. 3 (Ref 7). The specimens shown in this figure conform most closely to ASTM Standards D 1002, D 3163, D 3164, D 3165, and D 3528 for testing adhesives used to bond metals, plastics, and laminates. These represent only a small sampling of the more than two dozen standards in the *Annual Book of ASTM Standards*, Volume 15.06, that relate to shear testing. These other standards range from descriptions of block-type sample configurations for testing lumber and wood bonding in shear by compression loading, through descriptions of devices to simultaneously expose samples to lap shear stresses and extremes in temperature. Still others describe apparatus for exposing lap joints to sustained loads (using springs) to measure long-term creep or time to failure.

Fig. 3 Typical lap shear geometries. (a) ASTM D 1002, D 3163, and D 3164. (b) ASTM D 3165. (c) ASTM D 3528. Source: Ref 7

The results from lap shear tests are generally reported as the force at failure divided by the bonded area (overlap area). Such values are listed in a number of reference books and manufacturers' literature for a wide variety of adhesives. The reference book on types of adhesives (Ref 1) lists typical lap shear strength values for literally thousands of commercial adhesives. Such tables of “shear strength” values are without doubt of considerable utility for comparison and other purposes. However, their use also can lead to faulty expectations and

conceptions. Otherwise knowledgeable designers might logically assume from the tabulations that these average stress values could, in a straightforward manner, be used to design an adhesive joint.

For example, the tabulated shear stress value for a given adhesive from an ASTM D 1002 test might be given as 3000 psi. It might be assumed that this adhesive is to be used to bond two 25 mm (1 in.) wide by 3 mm (0.12 in.) thick 7075-T6 aluminum pieces together to carry a tensile load of 3200 lb with a safety factor of two. First, the designer must ascertain whether the aluminum pieces can carry such a load. Typically, 7075-T6 aluminum has a yield strength slightly in excess of 65 ksi for an allowable stress of 32.5 ksi. The pieces in question would have an allowable load of 4000 lb, which is more than the 3200 lb required in the design. The “straightforward” method to design the joint would be to assume that the allowable shear strength for the adhesive used in the joint would be $3000/2 = 1500$ psi, suggesting that an overlap of $3200/1500 = 2.13$ in. would be sufficient to support the load. This is, in fact, the approach taught by a variety of otherwise very good texts on material science and mechanical design. However, doubling the length of a lap joint almost never doubles its load-carrying capacity, and the increased joint strength is usually much less than doubled. The length of overlap recommended in ASTM D 1002 is 12.7 mm (0.50 in.). Typically, quadrupling the amount of overlap does not increase the load at failure by anywhere near a factor of four. For reasons given in the next few paragraphs, it is likely that it is not even the value of the maximum shear stress that determines the failure of the “lap shear joint.” As this article reveals, joint failure is more likely determined by the value of secondary induced cleavage stresses.

The stresses along the bond line of lap specimens are not constant. The bond stress distribution is highly dependent on the thickness of the adherends and the adhesive as well as the length of overlap. As a consequence, the load to initiate failure also varies markedly with both the adherend(s) and adhesive-bond thicknesses. The failure load increases very nearly linearly with width of the overlap but increases in a very nonlinear manner with length of the overlap. As the load is increased in a lap shear test, the debonding generally initiates at or near one of the bond terminations. Elastic stress analysis generally indicates that the stresses are singular at these termination points. Debond initiation in lap shear specimens can perhaps, therefore, be best characterized in terms of fracture mechanics parameters, which are discussed in the section “Adhesive Fracture Mechanics Tests” in this article. In addition, it has been demonstrated that for debonds after initiation, crack propagation is dominated by crack-opening mode displacements (mode I). For this reason and reasons given in the next couple of paragraphs, the word *shear* in the test titles and generally reported in test results may, therefore, be a misnomer.

It has been known for many years that the shear stresses in the bond line of lap specimens are accompanied by tensile stresses. Many analyses have been completed for lap shear geometries, almost all of which have clearly demonstrated the presence of induced tensile stresses in so-called lap shear specimens under load. In 1938, Volkersen (Ref 15) obtained expressions for the stresses in a lap shear joint by considering the differential displacements of the adherends and neglecting bending. This study was followed in 1944 by the now classical treatment of Goland and Reissner (Ref 16) who used standard beam theory and strength of materials concepts to obtain expressions for the joint stresses. Plantema (Ref 17) combined the results of these two earlier investigations to include shear effects in the system.

Because the stress state of the lap shear joint is so complex and does not lend itself to closed-form solutions, it is only logical that as numerical methods became available, researchers would apply them to analyze adhesive joints. Wooley and Carver (Ref 18), for example, used finite-element methods to calculate the joint stresses. They compared their results with the results obtained by Goland and Reissner and reported very good agreement. Adams and Peppiatt (Ref 19) used a two-dimensional finite-element code to analyze the stresses in a standard lap shear joint and also reported good agreement with Goland and Reissner. These authors also investigated the effect of a spew (triangular adhesive fillet) on the calculated stresses. A nonlinear finite-element analysis of the single lap joint was completed by Cooper and Sawyer (Ref 20) in 1979.

Anderson and DeVries conducted a linear elastic stress analysis of a typical single lap joint (Ref 21) making use of plane-strain finite-element computer programs using elements as small as 0.00025 cm (0.0001 in.). They considered steel (modulus of elasticity, 207 GPa; Poisson's ratio, 0.30) adherends of various thicknesses bonded with a 0.25 mm (0.01 in.) thick epoxy (modulus of elasticity, 2.76 GPa; Poisson's ratio, 0.34). The overlap region was taken as 13 mm (0.5 in.) long. The results of these analyses are shown in Fig. 4. Note that both the shear and tensile stresses are distributed very nonlinearly over the length of the bond region. Reference 21 reports stresses resulting from other adherend thicknesses. As the bond termini is approached, both shear and normal stresses appear to become singular. Careful analysis in this region suggests that the local mode I stresses

(tensile or crack opening) are significantly higher than mode II stresses (shear). Perhaps even more importantly, the mode I energy release rate is greater than that for mode II. From these results, it might be concluded that lap shear specimens fail by mode I crack growth. Therefore, the failure of lap shear specimens is usually governed by tensile stress rather than shear stresses. This is true for double lap joints as well as single lap joints (Ref 22, 23).

Fig. 4 Bond line tensile and shear stresses in lap shear specimen (adherend thickness = 1.6 mm, or 0.06 in.)

As noted, the end(s) of the overlap on bond termini on lap shear specimens are points of stress concentration and of large induced tensile stresses. While this closely simulates many practical situations, some have suggested that for determination of intrinsic adhesive properties, it would be useful if these termini could be eliminated. ASTM E 229 “Standard Test Method for Shear Strength and Shear Modulus of Structural Adhesives” is a test designed specifically for this purpose. In this test, the adhesive is applied in the form of a thin annulus ring bonded between two relatively rigid adherends in circular disc form. Torsion shear forces are applied to the adhesive through this circular specimen, which produces a peripherally uniform stress distribution. The maximum stress in the adhesive at failure is taken to represent the shear strength of the adhesive. By measuring the angle of twist experienced by the adhesive and having knowledge of sample geometry, it is possible to calculate the strain. A stress- strain curve can then be established from which the adhesive's effective shear modulus can be determined.

Testing of Adhesive Joints

K.L. DeVries and Paul Borgmeier, University of Utah

Tensile Tests

Generally, the idea of mechanical failure produces a vision of an object being pulled apart by tensile force. As noted previously, most practical adhesive joints are designed to avoid (or at least reduce) direct tensile forces across the bond line. Examples of such joints are lap joints and scarf joints. It was also pointed out that for many joints, where it appears that the primary loading is shear, failure might be initiated by the induced secondary tensile stresses. There are, therefore, reasons why an adhesive's or adhesive joint's tensile strength might be of interest. Accordingly, the third most common type of adhesive joint strength test is the tensile test. ASTM has also formalized this type of test.

The geometries of several tensile tests for which there are specific ASTM test procedures are shown in Fig. 5 (Ref 7). Some of these test geometries seem relatively simple; however, it has been demonstrated that the stresses along the bond line have a rather complex dependence on geometric factors and adhesive and adherent properties (adhesive thickness and its variation across the bonded surface, modulus, Poisson's ratio, and so on) (Ref 21).

Fig. 5 Typical specimen geometries for testing the tensile strength of adhesive joints. Source: Ref 7

It is almost always difficult to load tensile adhesion specimens in an axisymmetric manner, even if the sample itself is axisymmetric. Nonaxisymmetric loads have been shown to reduce the bond failure load capability and to cause large scatter in the resulting failure data. Superficially, the geometry for standard tensile adhesion tests is deceptively simple. The result of the tensile adhesion test, as normally reported by experimentalists, is simply the failure load divided by the cross-sectional area of the adhesive (Ref 22). Such average stress at failure can be very misleading. Because of the differences in mechanical properties of the adhesive and adherend, the stresses may become singular at the bond edges when analyzed using linear elastic analysis (Ref 21, 23). Even if the edge singularity is neglected, the stress field in the adhesive is very complex and nonuniform, with maximum values differing markedly from the average value (Ref 21, 23).

Some sense of the complex nature of the stresses can be obtained by visualizing a butt joint of a low modulus polymer (e.g., a rubber) between two steel cylinders. As these are pulled apart, the rubber elongates much more readily than the steel. Poisson's effect will cause a tendency for the rubber to contract laterally. However, if it is tightly bound to the metal, it is restrained from contracting, and shear stresses are induced at the bond line. Reference 9 provides the results of a finite element analysis that demonstrates how these stresses vary across the sample. As noted, for an elastic analysis, both the shear and tensile stresses are singular (tending to infinity) at the outer periphery.

For the tensile specimen configurations considered to this point, the applied loading is intended to be axisymmetric. There is another class of specimen in which the dominant stress is deliberately tensile but in which the loading is obviously "off center." At least four ASTM standards describe so-called cleavage specimens and tests. These tests are a logical preface to the next section in this article, "Adhesive Fracture Mechanics Tests". The reader familiar with cohesive fracture mechanics will see a similarity between the test specimen in ASTM D 1062 (Fig. 6) and the compact tensile specimen commonly used in fracture mechanics testing. ASTM D 1062 specifies reporting the test results as force required, per unit width, to initiate failure in the specimen, while in fracture mechanics, the results are given as G_c with units of J/m^2 , which might be interpreted as the energy required to create a unit surface. A knowledgeable and enterprising reader may want to adapt the D 1062 specimen for obtaining fracture mechanics parameters. ASTM D 3807, "Standard Test

Method for Strength Properties of Adhesives in Cleavage Peel by Tension Loading,” uses a different geometry to measure the cleavage strength. In this case, two 25.4 mm (1 in.) wide by 6.35 mm (0.25 in.) thick plastic strips 177 mm (7 in.) long are bonded over a length of 76 mm (3 in.) on one end, leaving the other ends free and separated by the thickness of the adhesive. Approximately 25 mm (1 in.) from the end of each of these free segments, a “gripping wire” is attached as shown in Fig. 7. During testing, these wires are clamped in the jaws of a universal testing machine and the sample pulled to failure. The results are reported as load per unit width (kg/m or lb/in.). Again, it would be possible to analyze this sample in terms of fracture mechanics, but it is unnecessary because, as the next section explains, this analysis is done in ASTM D 3433 for a very similar beam geometry.

Fig. 6 Specimen for testing the cleavage strength of metal-to-metal adhesive bonds (ASTM D 1062)

Fig. 7 Specimen for testing cleavage peel (by tension loading) (ASTM D 3807)

ASTM D 5041 also makes use of a sample composed of two thin sheets bonded together over part of their length. In this case, forcing a wedge (45° angle) between the unbonded portion of the sheets facilitates the separation. The results are typically given as “failure initiation energy” or “failure propagation energy” (i.e., areas under the load deformation curve).

This latter test is similar to another test, formalized as ASTM D 3762, that has been found very useful for studying time-environmental effects on adhesive bonds. This test is called by various names, but the authors prefer the name “Boeing Wedge Test” (Ref 24, 25). The test has been used by personnel at this and other aerospace companies to screen various adhesives, surface treatment, and so on for long-term loading at high temperatures and humidities. For testing, two long, slender strips of candidate structural materials are first treated with the prescribed surface treatment(s) and bonded over part of their length with a candidate adhesive (Fig. 8). As in the test described in the previous paragraph, the free ends are forced apart by a wedge. The amount of separation by the wedge (determined by wedge thickness and depth of insertion) determines the value of the stresses in the adhesive. These stresses can, of course, be adjusted and the values calculated from mechanics of material concepts. When the wedge is in place, the sample is placed in an environmental chamber. At periodic time intervals, the length of the crack is measured, and a plot of crack length versus time is constructed. The more satisfactory adhesives and/or surface treatments are those for which the crack is arrested or grows very slowly. While the environmental chamber typically contains hot, humid air, there is no reason why other environmental agents cannot be studied by the same method, including immersion in liquids.

Adhesive Fracture Mechanics Tests

Fracture mechanics originated with the pioneering efforts of A.A. Griffith in the early 1920s. The field remained relatively dormant until the late 1940s when it was developed into a very effective and valuable design tool to describe and predict “cohesive” crack growth. Interested readers are referred to a number of excellent texts on fracture mechanics (e.g., Ref 26 and *Fatigue and Fracture*, Volume 19 of the *ASM Handbook*).

In the 1960s and 1970s, researchers began exploring the use of the concepts of fracture mechanics in adhesive joint analysis as reviewed in Ref 3. These methods have the potential to use the results from a test joint to predict the strength of other joints with different geometries.

In a common fracture mechanics approach (including Griffith's papers), the conditions for failure are calculated by equating the energy lost from the strain field as a “crack” grows to the energy consumed in creating the new crack surface. This energy per unit area, G_c , determined from standard tests, is called by various names, including the Griffith fracture energy, the specific fracture energy, the fracture toughness, or the energy release rate.

In 1975, ASTM Committee D-14 adopted a test configuration and testing method with fracture mechanics ramifications based on the pioneering efforts of Mostovoy and Ripling (Ref 27, 28). The method is described in ASTM D 3433 “Standard Test Method for Fracture Strength in Cleavage of Adhesives in Bonded Joints.” Figure 9 shows the shape and dimensions for one specimen type recommended for use in this standard. The specimen is composed of two “beams” adhesively bonded over much of their length as shown. Testing is accomplished by pulling the specimen apart by means of pins passing through the holes shown near the sample's left end. This adhesive sample configuration and loading to failure gives rise to the sample's nickname, “split-cantilever beam.” Another recommended geometry in ASTM D 3433 is similar except the adherends are not tapered.

Fig. 9 Specimen for the contoured double-cantilever-beam test (ASTM D 3433)

It should now be clear that the stress distribution in adhesive joints is generally complex. Furthermore, the details of this distribution are highly dependent on specific details of the joint system. The maximum stresses in the bond almost always differ markedly from the average value, and elastic analyses often exhibit mathematical singularities at geometric or material discontinuities. From these observations, it should be clear that the use of the conventionally reported results from most tests (i.e., values of the average stress at failure) would be of little use in designing joints that differ in any significant detail from the sample test configuration.

For the resolution of this problem, the concepts of fracture mechanics have much to offer. One of the more popular and graphically appealing approaches to fracture mechanics views the joint as a system in which failure (often considered as the growth of a crack) of a material (or joint) requires the stresses at the crack tip to be sufficient to break bonds and an energy balance. It is hypothesized that even if the stresses are very large (often theoretically infinite), a crack can grow only if sufficient energy is released from the stress field to account for the energy required to create the new crack (or adhesive debond) surface as the fractured region enlarges. The specific value of this energy (J/m^2 , or $in. \cdot lbf/in.^2$, of crack area) for the adhesive bonding problem uses the same basic titles as given previously but prefaced with the term *adhesive*. Hence, *adhesive fracture toughness*

might be used to distinguish adhesive failure from tests of cohesive fracture. The word adhesion is dropped from the comparable term when cohesive failure is being considered. The cohesive and adhesive embodiments of fracture mechanics both involve a stress-strain analysis and an energy balance.

The analytical methods of fracture mechanics (both cohesive and adhesive) are described in Ref 3 and 25. These are not repeated here other than a few comments on the concepts and a brief outline of a numerical approach that can be applied where analytical solutions are tedious or impossible. Inherent in fracture mechanics is the concept that natural cracks or other stress risers exist in materials and that final failure of an object often initiates at such points. For a crack (or region of debond) situated in an adhesive layer, modern computation techniques are available (most notably, finite element methods) that facilitate the computation of stresses and strains throughout a body, even if analytical solutions may not be possible. The stresses and strains are calculated throughout the entire adhesive system (adhesive and all adherends), including the effects of a crack in the bond. These can then be used to calculate the strain energy, U_1 , stored in the body for the particular crack size, A_1 . Next, the hypothetical crack is allowed to grow to a slightly larger area, A_2 , and the preceding process is repeated to determine the strain energy, U_2 . This approach to fracture mechanics assumes that at critical crack growth conditions, the energy loss from the stress-strain field goes into the formation of the new fracture energy. The quantity $\Delta U/\Delta A$ is called the energy release rate, where $\Delta U = U_2 - U_1$ and $\Delta A = A_2 - A_1$. The so-called critical energy release rate $(\Delta U/\Delta A)_{crit}$ is that value of the energy release rate that will cause the crack to grow. Loads that result in energy release rates lower than this critical value will not cause failure to proceed from the given crack, while loads that produce energy release rates greater than this value will cause it to accelerate. This critical energy release rate value is equivalent to the adhesive fracture energy, or work of adhesion, previously noted. While the model just described is conceptually useful, computer engineers have devised other convenient ways of computing the energy required to “create” the new surface, such as the crack closure method (Ref 29, 30).

It is hoped that this simple model of fracture mechanics will help the reader who is unfamiliar with fracture mechanics to visualize the concepts of fracture mechanics. The molecular mechanisms responsible for the fracture energy or fracture toughness are not completely understood. They generally involve more than simply the energy required to rupture a plane of molecular bonds. In fact, for most practical adhesives, the energy to rupture these bonds is a small but essential fraction of the total energy. The total energy includes energy that is lost because of viscous, plastic, and other dissipation mechanisms at the tip of the crack. As a result, linear elastic stress analyses are inexact.

While fracture mechanics has found extensive use in cohesive failure considerations, its use for analyzing failure of adhesive systems is more recent. There has, however, been a significant amount of research and development in the adhesive fracture mechanics area. To review it all, even superficially, would take more space than is allocated for this article. A small sampling of publications in this extensive and rich area of research is listed as Ref 12, 13, 26, 27, 28, and 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58. Not only is this listing incomplete, but also many of the researchers listed have scores of other publications. It is hoped that the one or two listed for each investigator will provide the reader with a starting point from which more details can be found from reference cross listings, searching of citation indexes, abstracting services, and so on. These investigators have treated such subjects as theory; mode dependence, effects of shape, thickness, and other geometric dependence; plasticity and other nonlinearities; numerical methods; testing techniques; different adhesive types; rate and temperature effects; fatigue; and failure of composites, as well as a wide variety of other factors and considerations in adhesion.

Modern finite element or other numerical methods have no difficulty in treating nonlinear behavior. Physical understanding of material behavior at such levels is lacking, and effective use of the capabilities of such computer codes depends, to a large extent, on the experimental determination of these properties. For many problems, it has become conventional to lump all dissipative effects together into the fracture energy and not be overly concerned with separating this quantity into its individual energy-absorbing components. Another fracture mechanics approach, called the J -integral, has some advantages in treating nonlinear as well as elastic behavior (Ref 51, 52, 59, and 60).

It was noted previously that most adhesive systems are not linearly elastic up to the failure point. Nevertheless, researchers have shown that elastic analyses of many systems can be very informative and useful. Several adhesive systems are sufficiently linear so that it is possible to lump the plastic deformation and other energy dissipative mechanisms at the crack tip into the adhesive fracture energy (critical energy release rate) term. There has recently been some significant success in explaining many aspects of adhesive performance and

predicting the strength of a bond from tests on other, quite different, joints by using linear elastic fracture mechanics.

As noted, in principle, fracture mechanics lends itself to using test results from one test in the design of other joints that have significantly different geometries. A number of adhesive geometries have been proposed to measure fracture toughness in addition to the split-cantilever beam, but to date, it is the only one formalized by ASTM (Ref 3, 4, 6, 12, 36, 47, and 48). A recent paper by the authors (Ref 61) has demonstrated how such factors as end rotation (at the cantilever point assumed rigidly fixed in the original ASTM analysis) shear, and presence of the adhesive and its thickness (also neglected in the original analysis) affect the energy release rate. It is shown that inclusion of these effects can dramatically affect the results and greatly reduce test scatter. Furthermore, this paper demonstrates how fracture mechanics may be used to predict the locus of adhesive crack growth. To accomplish this, various crack paths were assumed, and using finite element methods, the energy release rate calculated for each path.

Testing of Adhesive Joints

K.L. DeVries and Paul Borgmeier, University of Utah

Conclusions

The adhesive researcher or technologist has many standard test methods from which to choose. These techniques are designed with various goals and objectives in mind. Many of these methods are useful for the purposes of comparing different adhesives and substrates, investigating the effects of different loading, investigating chemical or physical attacks on adhesives, exploring aging phenomena, determining the effects of radiation and moisture combined with sustained loading on adhesive properties, and so on. On the other hand, care should always be exercised not to use the test results for purposes for which they are not well suited. Results from many of the adhesive strength tests are conventionally reported as the failure force divided by the bond area. Such average stress at failure results cannot, in general, be consistently and reliably used to predict failure of other joints that differ even slightly from the test geometry. Fracture mechanics approaches, on the other hand, show promise and have been used to predict the strength of joints that differ considerably from the reference joint. ASTM D 3433 and Ref 27 and 28 describe a standard adhesive fracture mechanics joint in the form of a tapered double-cantilever beam. The specimen dimensions are shown in Fig. 9. It is important to note, however, that fracture mechanics is not limited to this or any other specific testing geometry. In principle, any geometry for which the described energy balance (or alternatively, calculation of the stress intensity factor, J -integral, and so on) can be accomplished might be used as an adhesive test.

Sometimes, circumstances dictate the use of a nonstandard test geometry. For example, a few years ago, the authors were given the problem of measuring the quality of natural barnacle adhesive. The barnacle dictated the exact form of the joint between the barnacle's shell and the plastic sheets that were placed in the ocean. This form did not lend itself to tensile, lap shear, or split-cantilever testing. It was, however, possible to predrill holes in the plate and to fill these holes with dental waxes that were solid and hard at the ocean temperatures near San Francisco, CA, where the barnacle growth experiments were conducted. The wax was later easily removed at a moderately elevated temperature. The base of the barnacle covering this hole was thereby exposed and could be tested by application of fluid pressure, thus forming a blister. Measurement of the pressurization at failure allowed the determination of the adhesive fracture energy (Ref 3, 62).

Once the adhesive fracture energy is determined by testing, fracture mechanics points the way that it, along with a knowledge of the flaw size and a stress-strain analysis of the joint, can be used to predict the performance of other joints. Modern computational techniques greatly facilitate the application of these methods.

Finally, it is noted that the stresses, strains, fracture energy, and other such parameters used in the adhesive analysis depend on loading rate, mode of stress at the crack tip, temperature, environment, and other factors. Development of means for incorporating these parameters into joint design has been, and continues to be, an area of active research. Such concepts and methodology can be found in the references cited previously in this section.

Mechanical Testing of Welded Joints

William Mohr, Edison Welding Institute

Introduction

IN WELDED STRUCTURES, the welds typically have a mechanical purpose. Loads must be carried across the weld joint. Standard mechanical tests have been devised to demonstrate that not only the base metals but also the entire welded joint can fulfill this mechanical purpose (Ref 1, 2). This article primarily discusses standard test methods that can be applied to many types of welds. These include tension, bending, impact, and toughness testing.

Residual stress measurement techniques and weldability testing also are discussed. Residual stress can be imposed by the welding itself, as well as by cutting and forming processes. The presence of high-tension or compression residual stresses can affect the ability of the welded structure to carry the mechanical loading. Cracking due to welding can also affect the load-carrying capacity of welded joints, and weldability testing techniques that combine welding and mechanical loading to test the resistance to cracking are available. Many other testing techniques can be applied to weld joints and welded structures. Fatigue and creep are both important areas where mechanical tests on welded joints have indicated properties different from those of the base metal. Testing of welded structure properties can also be done on structures that more closely model the service structure than the standard specimens described below.

Reasons to Measure Properties of Welds

The mechanical properties of welded joints, the properties related to stress and strain, are most often measured to show that such a weld and other similar welds will serve their purpose under loading. More rarely, several welds are compared to see which welding techniques, processes, or chemistries provide the best combination of mechanical properties.

Four stages in the qualification process for the weld joint can use standard mechanical test methods. The weld metal can be chosen based on the mechanical properties from standard tests. The base metal, in some situations, may also need to be qualified to demonstrate that its mechanical properties will not be substantially degraded by welding. Once base metal and weld metal are chosen, the other weld process parameters, such as weld shape or heat input, can be qualified by standard mechanical testing. Finally, after the weld is made, it may require qualification by mechanical testing.

Each of the four qualification stages requires different types of tests and different approaches. These approaches are described in the next four sections.

Weld Material Qualification

Weld metals are qualified by making welds that pass mechanical property tests on the weld metal itself. Such tests can be used to qualify filler materials, such as welding wire or electrodes. Mechanical tests for such qualification are described in the individual specifications of the filler metals, such as those in American Welding Society (AWS) Specification A5.1 (Ref 3) and others of the AWS A5 series.

Mechanical property tests applied to weld qualification are designed to determine a small number of standard values to check whether the weld metal passes or fails. This approach will not reveal the entire range of properties that the weld metal can achieve. For instance, weld metal toughness in AWS A5.1 is measured by a Charpy test specimen taken from the weld centerline. Other locations, which may have different toughnesses, are not checked.

Base Material Qualification for Welded Service

The heat of welding will modify the structure and properties of the region of the base metal adjacent to the weld in the heat-affected zone (HAZ). To prevent this modification in properties from causing service failures, some standards require that a sample of the base material be tested after undergoing a representative heat treatment.

American Petroleum Institute standard (API) RP2Z is an example of a standard that requires base-material qualification for welded service (Ref 4). Multipass welding provides the heat treatment. The welding parameters are chosen to represent the most severe heat treatment of the base material that may occur during fabrication. The parameter of interest is the fracture toughness, commonly measured by crack tip opening displacement (CTOD). Particular regions of the HAZ are the most likely to show low toughness (the local brittle zones, or LBZs), so there is also a requirement that the crack sample the required portion of that kind of microstructure.

Weld Procedure Qualification

Weldment properties are dependent not only on the materials used to make the joint but also on the other parameters of the welding process. Weld metal properties may be modified by the admixture of base material melted by the heat of welding. The region where the base metal was only partially melted, at the fusion line, may have local mechanical properties differing from those of the neighboring weld metal and HAZ regions. In addition, the welding processes and procedures may induce specific imperfections, such as slag inclusions, blowholes, or cracks.

Because the issues described cannot be resolved by either weld metal or base material tests alone, test procedures that use specimens containing weld metal, base metal, and HAZ are used to determine mechanical properties of welded joints in weldment procedure qualifications.

Weld procedure qualification tests may be less quantitative than weld metal qualification tests and often provide only a “yes-or-no” answer. They are often capable of being completed in a shop floor environment rather than a testing laboratory with calibrated equipment.

While many of the weld procedure qualification tests in wide use are discussed subsequently in this article, several are not, because they are not properly mechanical tests; that is, neither a loading parameter, such as stress, or a displacement parameter, such as strain, is measured. This group includes visual examination for surface flaws and the breaking of fillet welds to examine the weld root.

Weld Service Assessment

Assessment of existing welds to determine if they meet the needs of future service may require that material properties be obtained from representative weldments. In some cases, new weldments can be made with the same materials and process parameters, so that sections from these weldments can be tested to find representative properties for the existing welds. Generally, neither the original materials nor full information is available to allow replication of existing weldments. Instead, a sample must be taken from the existing weldments.

Taking a sample requires trading the advantage of obtaining mechanical property data for the disadvantage of damaging the existing structure. Choices often are made that limit the damage to the existing structure by limiting the amount of material to be tested. Tests such as macrohardness or microhardness, which damage a small surface volume, may be appropriate. Smaller-scale test specimens may also be used, for instance, subsize Charpy specimens. Alternatively, specimens can be taken from regions where subsequent repair is easiest or from an area that is being removed as part of a modification.

Mechanical Testing of Welded Joints

William Mohr, Edison Welding Institute

Mechanical Testing for Weldment Properties

Tensile Strength and Ductility of Weldments

Testing for mechanical properties of strength and ductility for welded joints is somewhat more complicated than it is for base metal, because these properties vary across the weld metal, the adjacent HAZ, and the base metal. Several different tests may be used or combined to assess the strength of the overall welded joints. Tensile testing is widely used to measure the strength and ductility of the weld metal alone. Tensile testing of welds in place, with weld metal, HAZ, and base metal, allows an overall strength to be determined but usually cannot provide the strengths of the individual parts of the weldment.

Tensile tests of welds can also measure elastic modulus. However, except in rare cases of dissimilar metal joining, the elastic modulus is not sensitive to the differences between weld, HAZ, and base metal. So,

measurement during weld tensile tests is not usually required. Also, most tensile testing procedures for weld joints cannot be relied upon to provide accurate values of elastic modulus. The specific procedures for testing of elastic modulus distributed by ASTM should be used if required (Ref 5).

Testing of Weld Material. Deposited weld metal can be tested for the mechanical properties of strength and ductility using the same test methods used for base metals (Ref 6, 7). However, a sufficient volume of deposited weld metal is required to remove a test specimen made entirely of weld metal. Often, arc welds are long only in one direction (the longitudinal direction), while the through-thickness and cross-weld directions are much smaller. This encourages all-weld-metal tensile test specimens to be removed with the long direction of the specimen corresponding to the longitudinal direction of the weld. Such longitudinal tensile test specimens are standard for all-weld-metal tests.

All-weld-metal tests are most commonly done on specimens with round cross section. The diameter of the specimen may need to be reduced from that used for base metal so that the specimen can be taken entirely from weld metal. Rectangular cross-section specimens also are used occasionally.

Ultimate tensile strength, yield strength (usually based either on yield point or a specified offset), elongation, and reduction of area are all commonly recorded.

While the specimen surface should be smooth, without deep machining marks, imperfections within the gage length due to welding should not be removed. This requirement may increase the variability of results within a group of similar specimens.

If the data required are for a class of weld material such as an electrode lot, the material can be taken from specimens that reduce the possibility of dilution of base metal into the weld, such as a built-up weld pad. If the data required are for a particular weldment, the geometry as well as the welding process and procedure should model those of the weldment as closely as possible. Some modifications of the weldment may be allowed, such as increasing the root opening by 6 mm ($\frac{1}{4}$ in.) or buttering the groove faces with the weld metal to be tested.

The surface of the tested section, in the gage length, is recommended to be 3 mm ($\frac{1}{8}$ in.) or more from the fusion line.

Testing of Welds in Place. When the weld metal extends over only part of the tested gage length, tensile tests can be performed similar to those performed on the round and rectangular specimen tests of weld metal. The nonuniformity of deformation or stresses of the weld, HAZ, and base metal combination limits the information normally recorded.

For transverse tests, ultimate strength and the location of fracture are the only commonly recorded parameters, because strength, elongation, and reduction in area will all be affected by the constraint of the adjacent differing materials. If the weld is undermatched, the yield strength tends to be higher than it is for an all-weld-metal specimen, while the elongation over the gage length and reduction in area are smaller. If the weld yield strength exceeds that of the base material, that is, it is overmatched, the failure tends to occur not in the adjacent HAZ, but in the base material closer to the end of the gage length, because of the constraint provided by the high-strength weld metal.

Local strain measurements, such as those made by strain gages, can add useful information to the results of transverse testing. The local strain information can be correlated to the load and displacement information to allow local strengths to be determined.

For longitudinal tests, the strain will be nearly uniform across the weld metal, HAZ, and base metal. Differences in response to the applied strain may result in stresses varying across the cross section. Only ultimate strength is commonly measured.

Testing standards may need to be varied for some specific geometries. For instance, girth welded tubes of less than 75 mm (3 in.) diameter are commonly tested in the form of tubes with central plugs at the grips. The weld is placed at the center of the gage length between the grips. The additional constraint induced by the hoop direction continuity tends to increase the measured strengths and decrease the measured ductilities for tube welds tested in this manner compared to a similar joint between flat sheets.

Shear Testing of Fillet Welds

Shear strength tests for fillet welds are described in AWS B4.0 for two orientations of fillet welds (transverse to the tension loading and longitudinal to the tension loading) (Ref 8, 9). The transverse specimen is a double lap specimen with loaded fillet welds, as shown in Fig. 1. The longitudinal specimen is a combination of two

lapped shear plates that are tack welded back to back, as shown in Fig. 2. These geometries are chosen to avoid rotation during loading. The longitudinal specimen requires machining of grooves after the fillet welds are made. The base plate is cut under the center of the lapped plate. The lapped plate is cut near each end so that each length of weld connecting the base plate to the lapped plate across the gap in the base plate is 38 mm ($1\frac{1}{2}$ in.).

Fig. 1 Transverse fillet weld shear test specimen. Source: Ref 9

Fig. 2 Longitudinal fillet weld shear test specimen. Source: Ref 8

Fillet-weld strength tests are sensitive to surface contour of the welds and to the condition of the weld root. Excessive gaps between the lapped plates should be avoided, because these tend to magnify stresses at the weld root. The specimens are also sensitive to underbead cracking and undercut. Fillet size is most accurately measured after failure in the test. The stress is calculated based on assuming uniform stress across the entire weld throat.

Bending Strength and Ductility

Bend tests are commonly used to evaluate the acceptability of weld procedures for providing sound welds (Ref 10). They allow rapid determination of strength and ductility on a specimen substantially simpler than the standard tensile specimen. Bend tests tend to provide vivid demonstrations of difference between welds with surface or near-surface flaws and welds without flaws adjacent to the convex surface of the bend. Bend tests are further described in the article “Bend Testing” in this Volume.

Bending ductility can be calculated by determining the radius of the outer surface of the bend specimen at the completion of the test. This ductility is usually smaller than that measured in a uniaxial tensile test. The bend ductility is localized at the outer surface of the specimen, and the constraint is more severe because of the shear stresses generated through the thickness of the bend specimen.

The thickness of the specimens and the size of the plunger or mandrel determine the outer surface ductility requirement. Table 1 provides a summary of the radii of plungers or mandrels and the maximum test specimen thicknesses for several groups of materials as required by the American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code (Ref 11).

Table 1 Bend test geometry for testing based on material thickness and material type

Radius of plunger or mandrel	Maximum test thickness	Materials
$2t$	$\frac{1}{8}$ in.	With >20% elongation
$(3 + \frac{1}{3})t$	$\frac{1}{8}$ in.	Alloy steels with <20% elongation High strength Al alloys
$4t$	$\frac{1}{8}$ in.	Ti or Ti alloy with strength <65 ksi
$5t$	$\frac{1}{8}$ in.	Ti or Ti alloy with strength ≥ 65 ksi Zr or Zr alloy
$(8 + \frac{1}{4})t$	$\frac{1}{8}$ in.	4000 series Al alloy Al alloy welded with 4000 series electrodes Cu base alloys with Al and <20% elongation
(a)	(a)	Other alloys with <20% elongation

t , material thickness.

(a) Radius of plunger or mandrel and maximum test thickness chosen to achieve the required minimum elongation from a base metal tensile test at the outer fiber of the convex surface of the bent specimen

Increasing specimen width can increase the constraint and reduce the likelihood of achieving the required bend test radius without cracking. Face bends for welds in plates of greater than 38 mm ($1\frac{1}{2}$ in.) thickness may require multiple specimens.

Root, Side, and Face Bends. The primary geometries for bend test specimens place the butt weld so that the bending stress is transverse to the weld axis. Different areas of the welds reach the highest bending stress in transverse root bends, transverse face bends, and transverse side bends. Root bends put the weld-root side of the tested butt weld on the convex side of the bend specimen. Face bends put the weld-cap side of the tested butt weld on the convex side of the bend specimen. Side bends put a cross section of the weld on the convex side of the bend specimen.

Longitudinal bend tests may sometimes be used to replace transverse tests, particularly when the strengths of the regions within the specimen differ greatly. However, longitudinal side bends are not possible since the weld cross section does not include the longitudinal direction. Longitudinal root bends, with the convex side of the bent specimen on the weld-root side, and longitudinal face bends, with the convex side of the bent specimen on the weld-cap side, can both be made and tested.

Longitudinal tests are less likely than transverse tests to fail from flaws that are long in the same direction as the weld.

Wrap-Around Bend Testing. While the plunger-type bend fixtures are by far the most widely used for guided bend testing, some circumstances require a fixture that creates a different distribution of strain. The most common is a wrap-around testing fixture. Both the plunger type and the wrap-around type force the material into a specified radius. However, the wrap-around fixture moves the points of bending load application around a mandrel rather than using a fixed location for the central force, as shown in Fig. 3.

Fig. 3 Wrap-around bend testing. Source: Ref 9

The wrap-around fixture is most commonly used for welds that have significant mismatch between base metal strengths, between base metal and weld metal strengths, or where the HAZ strength differs greatly from the weld or base metal. If such welds are tested in a plunger-type fixture, the strain can be concentrated into the lower-strength material, leaving a sharper bend in that material and much less bending in the higher-strength material. The wrap-around fixture forces a more uniform strain into the materials because the loading point in the center of the specimen moves across the weld.

Wrap-around test fixtures are commonly used for aluminum alloys where the strength of the weld metal and HAZ may be chosen to be lower than the base metal. For instance, 6061-T6 aluminum base metal that is welded with 4043 electrodes has a minimum yield strength of 240 MPa (35 ksi) in the base metal but only 100 MPa (15 ksi) for cross-weld tensile specimens (Ref 12). Wrap-around testing can limit the localization of the strain at the weld.

Hardness

Hardness testing of welded joints is widely used as a rapid measurement of mechanical properties across the varying microstructures of the welded region. It allows local regions and individual microstructures to be compared for strength, because strength is correlated to hardness. A further discussion of hardness testing can be found in the Section “Hardness Testing” in this Volume.

Hardness has been primarily related to the tensile strength rather than to the yield strength or the ductility. Standard conversion charts are available for conversion of one hardness measurement to another and from hardness to tensile strength measurement. Such converted information should be used with caution, because the

variation of weld microstructure may cause the average hardness to correspond to values that cannot be obtained in larger scale specimens.

Macrohardness testing of welds requires preparation of a small region of the surface. The major techniques are Brinell testing, which uses a spherical indenter, and Rockwell testing, which uses a diamond penetrator or a sphere. The Brinell indentation is typically 2 to 6 mm in diameter while the Rockwell indentation is much smaller but still is visible, unaided. Rockwell methods use several different loads for different hardness scales, so it is possible for a weld to require different hardness scales for different regions.

Macrohardness testing results can be limited by the microstructural gradients around the welds. A result of 240 HB may represent a hardness for one uniform microstructure or an average over the regions deformed by the indenter. Welds and HAZs often have gradients of microstructure and chemistry that can cause variations in hardness across the indentation. Interpretation of the hardness from the impression may be made more difficult if there is a large gradient in the hardness of the material under the indenter. This can result in noncircular Brinell impressions and Rockwell tests with the deepest point not under the deepest point of the indenter.

Microindentation hardness testing using an indenter requires an even smaller region of the surface to be used than macrohardness testing, but the surface preparation requirements are more stringent. Thus the Knoop and Vickers microindentation hardness tests are primarily applied to ground and polished cross sections or to ground, polished, and etched cross sections. Microindentation hardness traverses are often used to determine the variation of hardness within the weld, across the fusion line, and across the HAZ.

Impact Toughness

Several methods are available for measuring the material resistance to starting and growing cracks that can be applied to welded joints. This section discusses test methods that cause a crack to grow from a notch under the rapid load of an impact. Methods that use sharp crack tips and thus can apply the loading more slowly are discussed in the next section on fracture toughness.

Charpy. The Charpy V-notch impact test is the most common measurement method for fracture toughness of welded joints. Specifications for the test are given in ASTM E 23 (Ref 13) and AWS B4.0. The test uses a pendulum hammer to rapidly fracture a notched bar with dimensions of 55 mm by 10 mm by 10 mm (2.165 in. by 0.394 in. by 0.394 in.).

Several measures of toughness can be obtained from a Charpy test. Absorbed energy, measured in ft · lbf or joules, is the most commonly reported, but the percent shear fracture and the lateral expansion in inches or millimeters are also sometimes reported. Greater toughness material will have higher values of each of these three parameters. Occasionally, percent fibrous fracture, which is 100% minus the percent shear fracture, is reported.

Many metals, including carbon and alloy steels, have toughnesses that vary strongly with temperature. So tests on welded joints are often conducted at several temperatures, and the absorbed energy or other parameter is plotted as a function of temperature. Material specifications and weld qualifications that include Charpy V-notch testing normally require a minimum absorbed energy at a particular temperature. In this case, testing is routinely conducted only at the temperature of interest.

The choice of minimum absorbed energy and test temperature are often varied between standards or within a standard, based on service conditions. For instance, welded joints on bridges to be used in cold climates are qualified to lower temperatures than those used in warm climates.

The absorbed energy in a Charpy V-notch test includes both the energy to start the crack from the 0.25 mm (0.010 in.) radius notch and the energy to propagate the crack across the Charpy specimen. For many cases, including constructional steels, these two parts are of comparable magnitude. In fact, the popularity of the Charpy V-notch test was originally based on its ability to predict both crack initiation and crack arrest in ship steel plates. This means that both the metal microstructure at the notch tip and through the specimen thickness contribute to the reported toughness. For welded joints with heterogeneous microstructures, the position of the notch tip will be important in determining the measured absorbed energy. The absorbed energy, however, will also depend on the microstructures through which the fracture passes.

The dependence of Charpy impact test results on microstructure for many metals causes weld joints with heterogeneous microstructures to have a range of Charpy values depending on specimen orientation in the weld and notch position. Often weld centerline values are reported or compared with standards. Sometimes the HAZ is tested at a particular location, such as 1 mm from the fusion line. These tests cannot determine a toughness

appropriate to all microstructures in the weld or HAZ. Additional tests of a greater variety of specimens may reveal zones of lower toughness, such as unrefined columnar weld metal or coarse-grained HAZ, or zones of higher toughness, such as reheated weld metal or fine-grained HAZ.

Subsize Charpy specimens are sometimes taken from thin material or areas where the geometry prevents a full-size specimen. Only one dimension is reduced, the distance from the notched face to the unnotched surface opposite. Reductions of this dimension can be from 10 mm (0.394 in.) to 7.5 mm (0.296 in.), called three-quarter size; to 5 mm (0.197 in.), called half-size; and to 2.5 mm (0.099 in.), called quarter-size. These are the most common reductions. Reduced thickness Charpy tests can be used to test the toughness of the root or cap regions of fillet welds.

Charpy toughness test specimens can be taken from welded joints in several orientations. These orientations can be given two-letter designations to show the orientation. The first letter is the direction normal to the crack plane (the long direction of the Charpy specimen), while the second letter is the direction in which the crack will propagate. The letter designations are L, longitudinal direction; T, long transverse direction (the weld width direction); and S, short transverse direction (the through thickness direction). The letter designations are shown for compact tension specimens in Fig. 4. Care should be taken that the orientation letters describe the weld area, because different combinations of these letters may apply to the same orientation of specimen in base metal. For instance, in a girth weld in a pipe, the long direction of the weld is the hoop direction of the pipe, not the longitudinal or axial direction of the pipe.

Fig. 4 Orientations of toughness specimens in relation to welds. L, longitudinal direction; T, long transverse direction (weld width direction); S, short transverse direction (weld thickness direction). In the two-letter code for specimen designation, the first letter designates the direction normal to the crack plane, and the second letter designates the expected direction of the crack plane. Source: Ref 9

Nil-Ductility Temperature. Drop weight tests use a notched weld bead as the starting point for a crack. The test determines the ability of the base metal to arrest the crack running from an overlay of brittle weld metal. The test results do not describe the properties of the overlay weld metal, so the overlay weld metal is standardized. A brittle hard-facing alloy with good surface adhesion is used as the crack starter.

ASTM E 208 describes the test procedure (Ref 14). A standard weight is dropped onto test specimens at different temperatures. The lowest temperature without full-section fracture is determined as the nil-ductility temperature (NDT).

Weld metal can be tested for crack arrest by placing the notched weld overlay across a machined butt weld of the weld metal of interest. The notch is typically placed so its long direction is above the longitudinal direction of the butt weld.

Fracture Toughness

Fracture toughness testing of welded joints introduces several complications to standard fracture toughness measurement as described in the Section “Impact Toughness Testing and Fracture Mechanics” in this Volume. The weld and adjacent HAZ will have heterogeneous microstructures that can have widely varying strength and toughness. In addition, welding residual stresses may be retained.

Fracture initiation testing, using slow loading and a crack tip sharpened by precracking, allows determination of only the crack initiation portion of the fracture toughness. Charpy testing determines a combination of crack initiation and arrest properties. Fracture initiation testing of welded joints thus is even more sensitive to the local microstructure around the tip of the precrack than Charpy tests are to the microstructure at the notch.

Weld heterogeneity also causes welds to be particularly sensitive to the rules for data interpretation for fracture initiation tests. Fatigue precracks are less likely to be straight in a heterogeneous material. Tests may have multiple events of crack initiation and arrest in local areas (“pop-ins”). Varying strengths may cause validity criteria based on yield strength and specimen size to give ambiguous results. Each of these issues must be accounted for in a test protocol appropriate to welds.

Fracture toughness specimens can be taken from welded joints in several orientations. These orientations can be given two-letter designations to show the orientation. The first letter is the direction normal to the crack plane, while the second letter is the direction in which the crack will propagate. The letter choices are L, longitudinal direction; T, long transverse direction (the weld width direction); and S, short transverse direction (the through thickness direction). The letter designations are shown for compact tension specimens in Fig. 4, but the same designations can be used for other shapes of test specimen. Care should be taken that the orientation letters describe the weld area, because different combinations of these letters may apply to the same orientation of specimen in base metal. For instance, in a girth weld in a pipe, the long direction of the weld is the hoop direction of the pipe, not the longitudinal or axial direction of the pipe.

Fracture toughness testing to measure the fracture resistance of weld HAZs presents particular problems, because several different microstructures can cluster within the HAZ, based on the different histories of heating from the welding in different locations. A fracture toughness measured from the HAZ is likely to be affected both by the properties of the several HAZ microstructures that the crack tip passes through and by the properties of the adjacent weld metal and base material.

Fracture initiation toughness is measured most commonly using the stress intensity factor, K ; the J -integral, J ; or the crack tip opening displacement (CTOD). All of these are regularly applied to welded joints. CTOD measurements are somewhat more commonly specified in welded regions than in base metal, because the test was originally developed for welded joints. Conversions between K , J , and CTOD are routinely performed but should be noted, because the correlations have limited precision.

Test Modifications for Welds. Fracture toughness testing of welds may require precise positioning of the notch to test the microstructure of interest. Testing of welds may also require modification of the test specimen. Two methods of modification, local compression and gull-winging (Ref 15), are described in the following section. Local compression counteracts the effects of welding residual stress. Gull-winging allows a curved piece with a weld to be tested as a full-thickness specimen.

Local Compression. The sharp crack tip needed for a fracture toughness test to determine initiation toughness is commonly provided by fatigue precracking at low levels of stress. In welds, fatigue precracking may produce a crack front that is not straight across the specimen. This is particularly likely when the specimen is thick and was removed from a weld with as-welded residual stresses. The crack tip of the fatigue precrack can deviate from the average straight line so much that the fracture toughness test results are invalidated because the crack depth is poorly described by a single average value.

Determining valid or invalid precracks is part of the standard to which the testing is done, such as ASTM E 1290 for CTOD testing (Ref 16) or ASTM E 1737 for J -integral testing (Ref 17).

A local compression treatment can be applied before precracking to avoid excessive deviation of the precrack from a straight line. Compression is applied in circular regions around the points where the notch tip reaches the surface, as shown in Fig. 5. Local compression can be applied to the most common fracture test specimen shapes, including compact tension specimens and single-edge notched bend bars.

Fig. 5 Local compression of fracture specimens before fatigue precracking, P , load. Source: Ref 15

Gull-Winging. Some geometries of weld may be difficult to test for fracture toughness because the shape of the base metal around the weld limits the thickness or area of any standard geometry specimen, such as a compact tension specimen or a three-point bend bar. Welds in curved shapes, such as spheres and cylinders, can be particularly difficult.

As shown in Fig. 6(a), a flat specimen taken for fracture toughness testing from a curved part may be limited in dimension by both the inside surface and the outside surface of the curved part. This could force the use of small specimens preferentially determining the toughness near the inside or concave surface of the weld. Gull-winging is a mechanical bending process that allows the full thickness of the curved part to be used for fracture testing.

Fig. 6 Gull-winging of single-edge notched-bar weld fracture toughness specimen. (a) Small scale of specimen that can be obtained from a longitudinal weld in a cylinder compared to full thickness. (b) Gull-winged specimen at full cylinder thickness ready to be loaded. Source: Ref 15

Full-thickness transverse tests using a modified three-point bend bar geometry may be used for geometries where the weld is straight but the curvature is transverse to the weld by gull-winging. The gull wings are introduced by plastically bending the base material away from the weld. These bends must allow the three locations of loading to be the same as if the specimen were flat, as shown in Fig. 6(b). During gull-winging, the area adjacent to the weld must be supported to prevent plastic deformation of the weld or the area directly adjacent to it.

Gull-winged specimens should have limited deviation from the flat centerline of the equivalent flat specimen. Greater deviation may allow plastic deformation during testing at the point of greatest deviation.

Mechanical Testing of Welded Joints

William Mohr, Edison Welding Institute

Residual Stress Measurement

Residual stress measurement on welded joints must take account of the characteristics of the welded joint. Welds usually have gradients of residual stress through the weld area and have these residual stress gradients in the same regions as gradients in microstructure. These features may limit the amount of information that can be obtained from some techniques. Some residual stress measurement techniques, for instance, work by comparing the distances between atoms in the crystal structure from an unstressed area to the stressed area of interest. If no

unstressed area is available with the same crystal structure as the weld, the zero stress level for that weld region would be uncertain.

Two general types of measurements for residual stress in welds are most common: locally destructive techniques and nondestructive techniques. The locally destructive techniques include hole drilling, chip machining, groove machining, and block sectioning. These measure changes in strain as a new surface is created and determine residual stresses most sensitively around the area where the machining took place. The nondestructive techniques measure the local strain of the material by inputting a physical change, receiving a signal based upon that change and the residual stress, and then decoding the part of the signal induced by the residual stress. These techniques include x-ray diffraction, neutron diffraction, Barkhausen noise analysis, and ultrasonic propagation analysis.

Both groups of techniques do not measure stress directly. Both measure strain. Both groups have limitations for measuring rapidly varying residual stress fields because they need to sample a volume of material to get sufficient signal to determine the residual stresses with precision.

Sectioning Methods

One extreme way of imagining a residual stress measurement of a welded region is that many tiny pieces of the weldment could all be separated simultaneously from neighboring pieces and allowed to change shape to reach zero residual stress. The shape change in each tiny piece could be measured and that change correlated using the elastic properties of the material to the residual stress originally in each piece of the weldment.

Sectioning methods can come close to this extreme case, but each cut cannot happen simultaneously. So analysis techniques for determining residual stress by multiple cuts need to include calculations of the effects of previous cuts on the residual stress to find the original stress rather than the stress determined for an individual cut.

Block sectioning and block layering and sectioning are significantly more destructive than hole drilling. The part for which the residual stresses will be determined is cut into sections and layers while surface strain gages are monitored. These techniques can provide distributions of residual stress in multiple dimensions.

Hole Drilling and Similar Local Measurements

Hole drilling techniques, often called center-hole drilling or blind-hole drilling, measure the change in strain on the adjacent surface as the residual stress field is disturbed by the machining of a hole from that surface (Ref 18). The hole depth is generally between 1 and 2 mm (0.04 and 0.08 in.), although several organizations make residual stress measurements as a function of hole depth as the hole is drilled.

The drilling techniques should cause as little as possible additional stress around the hole, so techniques are commonly used that avoid contact of the walls of the hole as the bottom is drilled. Air turbine and air abrasion systems can provide holes with close dimensional tolerance and little machining-induced surface stress on the hole. Specialized strain gage rosettes are available for measurement, both with the hole placed in the center of the rosette and with the rosette on one side of the hole. The rosette on one side of the hole is used for cases where the surface is obstructed on one side of the measurement position, as may happen adjacent to a weld toe. The measured strain must be converted to a local residual stress in the area where the hole was drilled. This conversion can be done most simply by assuming a uniform residual stress distribution. Only components of the residual stress that are parallel to the surface are measured by this technique, giving two directions of axial stress and one of shear stress.

Chip machining has been used similarly to hole drilling to determine near-surface residual stresses. In this case, a small region of the surface is removed with the strain gage rosette on the surface of the chip rather than attached to the base material. The advantage is that the small chip can be assumed to reach essentially zero residual stress, so the change of strain measured on the chip can be directly correlated to the stress in the chip region. However, the chip must be larger than the most common size of drilled hole to carry the strain gage. The chip machining method will average the strains over a larger volume of material.

Other shapes of local machining can be used, including deep holes and partial thickness slits (Ref 19). These methods can measure residual strains either with surface strain gages or with measurements of post-cut displacement. As with hole drilling, only part of the residual stress tensor is obtained by these methods, but the direction of cutting can be oriented to find the residual stresses of most interest.

Nondestructive Techniques

Nondestructive techniques for measuring residual strains in welded joints use a variety of inputs, including x-rays, neutrons, magnetic signals, and ultrasonic waves. Each of these inputs can induce different outputs, depending on the residual strains in the welded joint area, but also depending on other parameters, such as the crystal structure or grain size. Nondestructive techniques thus are best applied where a standard for comparison without residual strains but with the same microstructure is available. The comparison of test material with an unstrained standard may be easiest in base metal outside the HAZ and much more difficult for HAZ or weld metal (Ref 20).

X-ray diffraction determines the residual strains by measuring the average distances between atoms. X-rays, being limited in surface penetration in metallic materials, can be used for detection of residual strains only within approximately 0.5 mm (0.02 in.) of the surface on which they impinge. The surfaces of welds may be more difficult locations than smooth surfaces of base material for measurement of residual strains. The rough surface of the weld cap and notches at weld toes may cause some of the area of interest for residual strain measurement to be hidden from residual stress detection by x-rays.

Neutron diffraction uses an input that is much more difficult and costly to generate than x-rays but has the advantage of penetrating much further into metallic materials. Neutrons can be used for detection of residual strains in steel thicknesses beyond 25 mm (1 in.). Average values of the residual strains are determined in a volume approximately 1 mm^3 ($6 \times 10^{-4} \text{ in.}^3$). The power of the source, the efficiency of the detector, and the time of exposure all influence the volume required for residual stress detection. Neutron diffraction is easiest when the grain size is significantly smaller than the detection volume and the grains are oriented randomly. Large grains and highly oriented microstructures can eliminate the diffracted neutron signal.

Barkhausen noise analysis uses an external varying magnetic field as input and monitors the magnetic response of the area of interest. The response comes from the jumps in magnetization as magnetic domain walls move within the metal. This response is a surface response, so the surface condition of the part is important.

Ultrasonic propagation analysis inputs ultrasonic waves and then monitors the response of the time taken for the waves to travel through the metal and reach the detector. Since the residual stress distribution can change the speed of propagation all along the path of the ultrasound, the resulting effect is summed over the entire path. Multiple path analysis can provide local results.

Barkhausen noise and ultrasonic propagation analysis both are limited by the microstructural variations around welds. The combination of welding induced changes cannot be easily deconvoluted, because both techniques are comparing unstressed areas to stressed areas and also are sensitive to microstructural variation.

Mechanical Testing of Welded Joints

William Mohr, Edison Welding Institute

Weldability Testing

Weldability, while sometimes defined in the general sense as the measure of the compatibility of base metal and any added filler metal with the heating cycles used for welding, is more commonly defined as the measure of the resistance of the materials to the formation of cracks during welding. Methods are available for assessing both hot cracking, at or near the solidification temperature, and cold cracking, at or near room temperature. Test methods do not check for all types of cracking at once, but, instead, each test checks for the susceptibility to a certain type of crack.

Weldability tests have been designed to allow small-scale specimens to mimic the cracking behavior of large, rigid welded structures. These tests either use specimen geometry to force the shrinkage of the weldment as it cools to be counteracted by plastic extension of the weld and HAZ, or they use additional loading to achieve plastic extension of weld and HAZ in addition to that caused by weld shrinkage. The bulk of this section will discuss the types of tests where additional loadings are required, because these are properly mechanical tests. A limited discussion of some test methods without additional loading is also provided for comparison.

The techniques that include welding and loading to measure weldability have been designed primarily for hot cracking at temperatures at or just below that for the last solidification of weld metal. The loading augments the shrinkage strains. Cracking when the weld has cooled, such as cracks due to hydrogen, is usually tested using welding without additional loading.

Varestraint Testing

Varestraint testing uses a cantilever beam specimen that is bent downward by a rapid application of force while a weld is being made on the top surface of the beam (Ref 21, 22). The weld is made parallel to the direction of tension once the force is applied with the welding torch moving toward the support point, as shown in Fig. 7. A die block 51 mm (4 in.) long is placed beneath the specimen to force it to a limiting value of augmented strain. The radius of the die block can be varied to examine the dependence of cracking on augmented strain, or a single radius can be used to examine the effect of other welding variables such as base metal chemistry or weld heat input. Common values of the augmented strain are between 0 and 4%. Standard varestraint testing methods are discussed in AWS B4.0.

Fig. 7 Varestraint test fixture and specimen. Source: Ref 9

The specimen size is usually 305 mm (12 in.) long and 51 mm (2 in.) wide with a thickness of either 6 or 12.5 mm ($\frac{1}{4}$ or $\frac{1}{2}$ in.), although minivarestraint specimens are sometimes tested, which reduce all dimensions by a factor of 2. To prevent local kinking of the specimen, auxiliary plates are bent along with the test plate. The auxiliary plates, rolled steel 305 mm by 51 mm by 12.5 or 6 mm (12 in. by 2 in. by $\frac{1}{2}$ or $\frac{1}{4}$ in.), are clamped to the edges of the test plate. A minimum of three specimens are tested for any experimental condition. The weld on the top surface is produced by gas tungsten arc welding (GTAW). Measurements are based on crack length of cracks found in the HAZ or fusion zone. Hot cracks typically form radially along the trailing edge of the weld pool and in the HAZ. Either the length of the longest crack or the total combined crack length of all cracks is the measured parameter. Cracks are counted and sized on the

surface under a low power microscope (40 to 80×). One parameter of interest is the maximum augmented strain without cracks. However, because only one augmented strain is measured per specimen, the value is most closely estimated by extrapolating to zero the crack length measured at higher augmented strains. Transvarestraint testing also uses welding on the top surface on a piece that is bent over a die block (Ref 23). However, the force is applied so that tension is rapidly applied across the direction of welding rather than along it. This method detects cracking sensitivity in weld metal more effectively than the original varestraint method. Cracks in weld metal are more likely to be subsurface, so weld cross sections or nondestructive methods, such as radiography, are required to observe the subsurface cracks. One problem with transvarestraint tests is that cracks formed during the rapid loading may continue to propagate after the specimen has been bent.

Spot Varestraint Testing

The spot varestraint test, or TIG-A-MA-JIG test, is a modification of the varestraint test. This test uses a stationary welding torch (Ref 24). The torch is shut off at the instant of bending of the specimen or a specified short time before.

The size of the weld pool should remain relatively constant between tests that are to be compared. This may require changes of welding current or arc time when materials of differing thicknesses are compared.

The die block for the spot varestraint test is curved in only one direction, that is, it is shaped like the surface of a cylinder. Cracking, thus, will be primarily found transverse to the tension above the highest part of the surface of the die block. Radii for the die block have ranged from 44.5 to 1270 mm (1.75 to 50 in.).

Like the varestraint test, cracks are measured visually on the surface using a low-power microscope. Because this test is primarily used to test for HAZ liquation cracks, crater cracks in the center of the weld metal are ignored.

A measure of the relative susceptibility to HAZ liquation cracks that is not available in the varestraint test is the shortest time from torch shut-off to bending that produces no cracks.

Weldability Testing without Augmented Strain

Weldability testing without augmented strain requires that the weld be made in a highly restrained specimen. Highly restrained geometries prevent weld shrinkage in more than one direction. Cracking is typically from the root of the weld, either at a fillet weld or a partial penetration butt weld. Specimen shapes sometimes surround the weld metal with base metal, as in the Lehigh restraint test. Other test geometries, such as the oblique Y-groove test, join two plates with welds at the ends and then put the test weld in the center.

Testing of Bearings

Charles A. Moyer, The Timken Company (Retired)

Introduction

BEARINGS can be divided into two major classes: rolling bearings, which include rolling elements (balls, rollers, or needle rollers) between the inner and outer raceways, and sliding, or plain, bearings, which have motion from one surface directly imposed on a stationary support.

Rolling bearings include radial, thrust, and angular contact designs. A review of the many versions of these bearings can be found in the article "Friction and Wear of Rolling-Element Bearings" in *Friction, Lubrication, and Wear Technology*, Volume 18 of the *ASM Handbook* (Ref 1). The primary requirement of rolling bearings is proper and adequate lubricant that provides separation of the moving surfaces under all conditions, maintains appropriate temperature, and provides an operating environment so that bearings will achieve their expected lives.

Sliding bearings include sleeve and thrust bearings of various designs. Based on designs and materials selection, plain bearings operate under dry or boundary lubrication conditions, partial film or mixed lubricant film conditions, or a full film, which means the "rubbing" surfaces are essentially separated. More details of sliding bearings can be found in the article "Friction and Wear of Sliding Bearings" in *Friction, Lubrication, and Wear Technology*, Volume 18 of the *ASM Handbook* (Ref 2) and in Ref 3.

Testing of Bearings

Charles A. Moyer, The Timken Company (Retired)

Rolling Element Bearings

Rolling bearings date back to the Neolithic period, or the new Stone Age (Ref 4). When heavy materials needed to be moved, or when primitive vehicles had wheels, someone devised bronze or wood “bearings,” with or without oils or fats. Archaeologists have found bronze balls, cylindrical rollers, and wooden tapered roller bearings dating back to 300 to 500 B.C.

Considering the different materials used, it is clear that finding the proper material, shapes, and sizes was then, and continues to be, important and is the core of testing to determine what performance can be expected from rolling element bearings. Advancements continued over the years, but bearings that resemble those in use today did not appear until the late 19th century. Modern rolling bearings developed gradually from 1850 to 1925 (Ref 4). One driving force was the need for bearings in bicycles.

While working in Berlin, Germany, Professor Richard Stribeck undertook early bearing tests, the results of which were published in 1901 and 1902 (Ref 5, 6). His goal was to determine safe ball loads statically and in complete bearings over different speed ranges. He made use of Hertz's work covering elastic bodies in contact (Ref 7) and started with a press arrangement with three hardened steel balls in contact, two steel balls with a steel plate between them, and finally, a single ball between two short cylinders set on end with cup shapes to fit the ball. He found the relation of load P on the ball diameter d to be:

$$P = Kd^2 \quad (\text{Eq 1})$$

K was a constant based on steel type and contact geometry. Based on the materials he used, Stribeck established that Eq 1 held to the elastic limit and somewhat beyond. He also ran tests on complete bearings and established the way balls shared loads under radial load conditions. Using bearings with 10 to 20 balls and no clearance between balls and rings, he determined that the most heavily loaded ball (P_0) was related to the total load P by:

$$P_0 = 4.37/Z \cdot P \quad (\text{Eq 2})$$

where Z is the number of balls in the bearing. To be conservative, Stribeck changed 4.37 to 5.0.

In 1912, Professor John Goodman published in England studies on rolling element bearings (Ref 8), covering life, friction, and wear. He knew of Stribeck's work and determined reductions in bearing load capacity based on bearing speed (N). Goodman's equation for this reduction was:

$$P = Kd^2/ND + Ad \quad (\text{Eq 3})$$

where D is the ball-race path diameter; A is a constant; and P, K , and d are the same as in Eq 1.

Studies of bearings and bearing materials (primarily steel) were followed by the emergence of the first manufacturing companies to patent and produce rolling element bearings. Bearing lubrication at this time was greatly influenced by the Reynold's equation (Ref 9) and the successes experienced in the hydrodynamic films generated in conformal bearings. It was assumed that the nonconformal contacts in “antifriction” bearings generated much thinner and, thus, less protective films for the contact region. The actual lubricating means for rolling bearings was thus a puzzle.

However, in 1949, Grubin (Ref 10) considered the elastic behavior of the contact materials and the pressure characteristics of the viscosity under the high stresses in the contact region in an equation that gave lubricant films one or two orders thicker than with the usual rigid cylinders assumption used for determining lubricant films as in hydrodynamic bearings. For rolling bearings, elastohydrodynamic lubrication came to be recognized as an important factor in determining life expectancy under a wide range of operating conditions. Tallian (Ref 11) described the stages of rolling element bearings as an empirical state until late 1920. A classical period then emerged that saw the engineering inclusion of Hertz's elasticity theory, the Weibull function, and statistics leading to worldwide bearing standards. Finally, the modern period began in the 1950s. The advancements in bearing technology allowed the new era to develop meaningful testing for rolling bearings.

Testing of Bearings

Charles A. Moyer, The Timken Company (Retired)

Sliding Bearings

There is evidence from potters' wheels and ancient vehicles that plain bearings date back more than 5,000 years (Ref 1). Materials were stone or primarily wood for wheels of vehicles. It is assumed that the axles were stationary and the wheels rotated. Changes of material and "design" brought plain bearings to the point that scientific studies were underway in the mid 1800s by people such as Gustov Hirn (Ref 12), who, by empirical means, provided information about fluid film lubrication.

Others, such as Robert Thurston (Ref 13), who studied journal bearing friction and lubrication; Nikolai Petrov, who explained the hydrodynamic characteristics of journal bearing friction (Ref 14); and Beauchamp Tower (Ref 15), who discovered the pressure that developed within an operating journal bearing and that a bearing with sufficient lubrication floated on a film of oil, followed Hirn's studies. Although the studies first

concentrated on understanding bearing friction, the important findings covering the mechanism of lubrication were profound.

These empirical findings, combined with the theory of fluid-film lubrication developed by Osborne Reynolds (Ref 9), have provided much of the understanding of what is required to successfully operate and test plain bearings working today. Unlike rolling bearings, sliding bearings went from simple journal bearings to a variety of designs of journal bearings and thrust bearings with various tilting pads, pivoted pads, and other thrust bearing designs made with a wide range of bearing materials, such as tin- or lead-based babbit, porous bronze, Teflon (E.I. DuPont de Nemours & Co., Inc., Wilmington, DE) fabric, and reinforced Teflon (i.e., a wide range of material aimed for specific applications and performance). In addition, the operating fluid for these bearings, depending on design, can be oil, grease, or gas, or the bearings can run when completely dry (Ref 16, 17).

Testing of Bearings

Charles A. Moyer, The Timken Company (Retired)

Role of Lubrication

One area of importance to both bearing types (fluid film and rolling contact) is the relationship of the operating oil film thickness between the contacting surfaces to bearing performance as this relates to the coefficient of friction or expected length of life. For plain bearings, the variation in operating conditions within the contact is often expressed by the Stribeck curve as illustrated in Fig. 1. As shown, the variation in coefficient of friction (μ) is related to the Sommerfeld number that ranges from 0.001 to over 1.0, going from left to right in Fig. 1. The lubricant condition goes from boundary (minimal film) to mixed- to full-film lubrication, also going left to right in Fig. 1, indicating how the actual oil film relates to μ .

Fig. 1 Stribeck curve of coefficient of friction versus Sommerfeld number, S , where $S = \eta N/P$. N , shaft speed; P , average pressure between shaft and bearing due to applied load; η , lubricant viscosity. Source: Ref 2

For rolling bearings, the variation in operating conditions is related to the minimum oil film thickness between the rolling surfaces by dividing the film thickness by the composite asperity height of the moving surfaces. This ratio, known as lambda, or η , gives an estimate of the actual operating conditions based on the lubricant condition of boundary, mixed- to full-film separation as shown in Fig. 1. Rather than Sommerfeld numbers, the curve for rolling bearings is expressed in η values. These are, going from right to left, above 1.0 (full lubricant film) to just under 1.0 (mixed film or intermittent contact) to η much less than 1.00, perhaps down to 0.05 (continuous contact of the two surfaces). The shape of the curve for η versus is somewhat the same as shown in Fig. 1, but for η versus rolling bearing relative life, the curve drops down toward the thinner film, boundary lubrication section, and the rise on the left of Fig. 1 does not occur (an example of η versus relative life can be found in Ref 4, p 558). Such curves appear in many tribology texts with considerable variation in shape.

Unfortunately, boundary lubrication can mean both minimal lubricating conditions and surface protection from films formed by chemical reaction (that is, adsorption, chemisorption, or chemical reaction, along with reaction with metal oxide films). Therefore, the appropriate η value that applies for contacting surfaces may need minimum reactivity and comparisons with topographies, microstructures, and lubricants that are known. Thus, η is very much used, but in reality, it may be only a general tool for estimating operating conditions for values between 3.0 to approximately 0.05 (Ref 18) unless one fully understands the specifics of the lubricant, related microstructures, and surface reactions that are part of a test.

Testing of Bearings

Charles A. Moyer, The Timken Company (Retired)

Testing of Rolling Bearings

From the 1910s to about 1945, bearing testing was primarily based on the use of test machines designed and built by the bearing manufacturer and in some universities. Enough information developed in this time period for a symposium on the testing of bearings (Ref 19). Thomas Barish covered fatigue test machines for ball and roller bearings (Ref 20). The rigs described were primarily large machines for testing full-sized bearings. Fafnir Bearing Company, The New Departure Division of General Motors, Marlin Rockwell Corporation, Timken Roller Bearing Company, and Tinius Olsen Testing Machine Company were represented.

It was stated that ball and roller bearings were fatigue tested primarily for product improvement but also for proposed changes in material, heat treatment, or mechanical limits. In the event of a field problem, specific tests might have been run but under conditions that would reproduce the failure or problem in the field. Loads were heavier than in service with the aim to reduce testing life to 100 to 500 h. Problems of increased deflection, misalignment, machine wear, and special lubrication system requirements, such as to handle excessive heat removal, were recognized. These considerations are still important and clearly more challenging than they were over 50 years ago when the early machines were operating. Figures 2 and 3 show typical roller and ball test machines from this era.

Fig. 2 Tapered roller bearing 24 in. radial and thrust load machine. Source: Ref 19

Fig. 3 Ball bearing combined load machine, A, $\frac{3}{32}$ in.; B, $\frac{9}{32}$ in.; C, $\frac{15}{16}$ in.; D, $\frac{3}{8}$ in.; E, $\frac{19}{32}$ in.; F, $\frac{7}{32}$ in.; G, $\frac{5}{16}$ in. Source: Ref 19

Because of these problems and the extreme scatter in life when rolling bearings are tested, there have been continuous attempts to find simpler test machines that can separately evaluate specific improvements. Such rigs might assess the merits of cleaner steels, closer tolerances, levels of surface roughness, and even special manufacturing processes or special design. Table 1 summarizes rolling contact fatigue (RCF) test methods that ASTM published in STP 771 (Ref 22). The table represents the variety of element testing machines in which balls only, balls against a flat washer, ball-rod combination, cylinder to ball, cylinder to cylinder, or ring against ring have been developed. Numerous variations of all these machines are available commercially or are specifically designed as one-of-a-kind units built for one purpose. Figures 4 5 6 7 8 9 10 11 12 13 14 illustrate test rigs described in Table 1.

Table 1 Summary of rolling contact test methods

Method	Description
NASA five-ball testing apparatus (Fig. 4)	Four lower balls, freely rotating 90° apart in a separator; simulates the kinematics of a thrust-loaded bearing; the contact angle can be varied; vibration sensor detects failure in unattended tests; low- (cryo) and high-temperature testing (to 1000 °C, or 1830 °F). (Ref 22, p 5–45)
Flat-washer testing apparatus (Fig. 5)	16 retained balls rolling in a circle on a flat washer with a 75 mm (3 in.) OD, 50 mm (2 in.) bore, and 6.4 mm ($\frac{1}{4}$ in.) thickness; 4.17 GPa (605 ksi) contact stress; 1500 rev/min; filtered lubricant delivery system; piezo sensor detects vibration. (Ref 22, p 46–66)
Unisteel testing apparatus (Fig. 6)	Flat washer on retained balls; hanging dead-weight load; contact stress approximately 4.5 GPa (650 ksi); 1500rev/min; drip feed of lubricant; vibration detection system; thermocouples monitor temperature (typically 50–60 °C, or 120–140 °F). (Ref 22, p 67–84)
Rolling contact testing apparatus	Two hemispherically ground, toroidal rollers loaded against a round bar; 40:1 ratio of roller diameter to bar diameter; 2.7–5.5 Gpa (390–880 ksi) contact stress; 12,500

(Fig. 7)	rev/min; drip-feed lubrication; velocity-vibration sensor. (Ref 22, p 85–106)
Ball-rod testing apparatus (Federal Mogul) (Fig. 8)	Three 12.5 mm ($\frac{1}{2}$ in.) balls loaded against a rotating 9.5 mm ($\frac{3}{8}$ in.) OD center rod; 3600 rev/min; spring load on opposing tapered retaining rings; accelerometer coupled with a shutdown device; drip-feed lubrication; stress per ball typically 6 GPa (870 ksi). (Ref 22, p 107–124)
Cylinder-to-ball testing apparatus (Fig. 9)	Symmetrical arrangement of two 19 mm ($\frac{3}{4}$ in.) balls rolling on a 12.5 mm ($\frac{1}{2}$ in.) OD captive cylinder; coiled-spring load through a multiplying lever; small cylinder rev/min = 22,677; splash lubrication; maximum contact stress, 5.8 GPa (840 ksi). (Ref 22, p 125–135)
Cylinder-to-cylinder testing apparatus (Fig. 10)	Symmetrical arrangement of two 12.5 mm ($\frac{1}{2}$ in.) cylinders on two 20 mm (0.8 in.) OD captive cylinders; coiled-spring load through a multiplying lever; small cylinder, cpm = 20,400; splash lubrication; maximum contact stress less than 4.4 GPa (640 ksi); vibration sensor terminates test. (Ref 22, p 136–149)
Ring-on-ring testing apparatus (Fig. 11)	Crowned rings rolling on their peripheries; ring diameters of 50 and 53 mm (2 and 2.1 in.) provide no-slip” condition, but various degrees of slip are possible by changing ring diameters; typically 2000 rev/min; contact ratio measured by electrical resistance; contact stress range typically 0.98–3.9 GPa (140–570 ksi). (Ref 22, p 150–165)
Various types	See review article of rolling contact fatigue and full-scale bearing testers. (Ref 22, p 169–189)
Multiple bearing testing apparatus (Fig. 12)	Deep-groove ball bearing design; typically 3000 rev/min; four bearings on a single center shaft; maximum contact stress, 2.9 GPa (420 ksi); accelerometers on the outer housing monitor failure. (Ref 22, p 206–218)
Rolling four-ball testing apparatus (Fig. 13)	Top ball drives three lower balls in a tetragonal arrangement; lower balls free to rotate in the cup; all balls 12.5 mm ($\frac{1}{2}$ in.) diam; upper ball spindle speed, 1500 rev/min; 5.9 kN (1325 lbf) load applied vertically. (Ref 22, p 219–236)
High-speed four-ball testing apparatus (Fig. 13)	Same arrangement as above, but speeds of 15,000–20,000 rev/min; operating temperatures often exceed 100 °C (210 °F) (Plint machine). (Ref 22, p 219–236)
“AOL” vertical testing apparatus (not shown)	11 retained balls clamped between two flat washers; thrust load; recirculating lubricant system. (Ref 22, p 219–236)
Inclined ball-on-disk testing apparatus (Fig. 14)	Spindle-held 20.5 mm (0.8 in.) ball rolling on a disk; up to 800 °C (1470 °F); ball speed up to 7200 rev/min; disk speed up to 3600 rev/min; variable slide/roll ratios; traction measurements; designed for ceramics. (Ref 26)

The chapter from STP 771 (Ref 23) that covered NASA John Glenn (Lewis) Research Center's over 20 years of rolling contact research spans early tests with the fatigue spin rig (Ref 24) developed by NASA to the NASA five-ball fatigue tester that provided over 500,000 test hours by 1981. Data developed included hardness effects, influence of compressive residual stress, lubricant types, elastohydrodynamic film thickness influence on life, along with traction fluids and many other factors with qualitative correlation between the fatigue tester and full-scale bearing tests (Ref 23).

Unfortunately, G.B. Johnston et al. (Ref 25) revealed different findings in their chapter in STP 771. They had run full-scale bearing tests (6,309 deep-groove ball bearings and then radial ball bearings with cylindrical inner rings) and flat washer tests somewhat like the Unisteel rig. Their results from the two last element test methods did not correlate well with full-scale bearing performance. Their experience does not rule out simpler, single-element rolling contact rigs but does indicate the need to verify element or simple rig machine data by also running full-sized related bearing tests. The newer specialized rigs, such as the ball-on-disk machine listed at the bottom of Table 1 (and shown in Fig. 12), has been able to simulate very specific contact, load/traction conditions and determine wear difference for rolling with incipient sliding using silicon nitride against different materials (Ref 26).

The very high contact stresses used in many rig tests can produce different modes of failure. Microstructures may be altered. Surface coatings and modifications may be destroyed. Failures may be initiated by internal and surface stress-raising features too small to be of consequence in normal bearing operation. In rigs, the volume tested may be too small to encounter statistically the macro flaws that often determine bearing life. Rig test results must be evaluated with careful examination of failures and attention to all tribological conditions.

At the end of this text there are 17 selected references that describe a wide range of rolling contact machines from recent work to those that started the modern era. These machines and others supply data to the goal of providing an accelerated test that could contribute to better defining the limits of material, manufacture, and the environment so that significantly longer life could occur in the real applications.

Testing of Bearings

Charles A. Moyer, The Timken Company (Retired)

Testing of Sliding Bearings

The 1946 American Society for Testing and Materials symposium also included testing of plain bearings for automotive engines under a range of operating conditions. These conditions included higher-than-service loads, constant loads or shock loads, shaft irregularities, and others aimed at shorter duration testing without the interference of other component failures that might happen in an actual engine. Figure 15 shows a diagram of the automotive plain bearing test machine. Results achieved included fatigue failure of linings (such as lead-based babbitt), seizure of the lining or corrosion damage, for example, corroded copper lead bearing (Ref 27). Duplicate bearing tests seemed to show closer agreement, especially for fatigue failures, so that mortality curves for groups of tests did not seem necessary. The difference between sleeve bearings and rolling bearings was thought to be primarily due to the ability of sleeve bearing flow under high local stress, thus providing some stress equalization for sleeve bearings (Ref 27).

Fig. 15 Schematic of sliding bearing test machine. Source: Ref 27

References 28 and 29 came from the same time period as the 1946 symposium and featured hydrodynamic journal bearings tested under cyclical loading or high-speed operation. The aim of these studies was to provide experimental data as a check to the theoretical Reynold's number of other theoretical curves. From the numerous discussions of these papers, it is obvious that the technical community sought worthwhile data to help explain the dynamic behavior of journal bearings.

In 1968, the Institution of Mechanical Engineers in England had a symposium on experimental methods in tribology that primarily considered testing methods and measurement techniques. Reference 30, *Basic Principles of Bearing Testing-Machine Design* includes simulation ideas for journal and thrust bearings.

References 31, 32, 33, and 34 contain designs and/or explanations of additional rigs for assessing loading systems, friction, local film pressure, and thickness measurement, stress distributions, merits of rig testing of materials, and fatigue strength assessment of plain bearings.

Measurement and testing of sliding bearing materials are reviewed in Ref 17. The article covers a wide range of materials and materials systems, both single metals, such as commercial bronze or porous metal bronze, and bimetal and trimetal bearing materials systems. Bearing alloy designations and nominal compositions are described in considerable detail. Because bearing testing aims to expose a specific bearing to similar but more rigorous conditions than are encountered in service, either speed, load, lubricant amount, or cleanliness and temperature, or several of these parameters, is degraded to cause failures in shorter time. Figure 16 shows two types of engine bearing test machines that are used to evaluate sliding bearings. As has been stated, in order to know how such accelerated tests match real world conditions, periodic full-scale bearing tests are still required.

Mechanical Testing of Gears

Douglas R. McPherson and Suren B. Rao, Applied Research Laboratory, The Pennsylvania State University

Introduction

MECHANICAL TESTS are performed to evaluate the durability of gears under load. One of the primary uses of gear testing is to generate performance data, which are used to develop design-allowable stresses. Design-allowable stresses are used as a guide for determining the size, geometry, material, manufacturing process, and process conditions for new designs during the design process. Gear testing is also used to compare the performance of a new attribute or characteristic introduced in the gear to a baseline, which defines the part

performance with the old or existing attribute or characteristics. These new attributes or characteristics may be related to tooth geometry, gear material, manufacturing processes, and even process parameters used to manufacture the gear. In the aerospace industry, gear testing forms the minimum basis for accepting a change in these characteristics and is usually termed “qualification” of a proposed or recommended change.

Mechanical testing of gears is conducted under different scenarios. The first scenario is termed *rig testing*, which is extensively discussed and defined in this article. In rig testing, the gear is subjected to simulated loading that exercises a distinct mode of gear failure. While this simulation may not always be successful for a variety of reasons, data on the resistance of the gear to a distinct mode of failure allow the analysis of the specific characteristics that need to be altered to change its performance.

After rig testing is complete, it is customary to incorporate the gear into a transmission and subject the transmission to *bench testing*. In bench testing, the input and output of the transmission under test are simulated using various devices for power input and absorption. After bench testing, it is not unusual to subject the transmission to *full-scale testing*, where the transmission is subjected to controlled but actual operating conditions to determine the performance of the specific gear. Both bench and full-scale testing represent very specific application-oriented testing and are usually carried out by the organization manufacturing a specific product. It is obvious that rig testing, bench testing, and full-scale testing represent increasing orders of cost. Consequently, in most situations, extensive rig testing is followed by limited bench testing and even more limited full-scale testing. While the testing methods described in this article are particularly applicable to carburized and hardened steel gears, the described techniques are applicable to through-hardened steel and gears fabricated from other materials, with modifications.

Mechanical Testing of Gears

Douglas R. McPherson and Suren B. Rao, Applied Research Laboratory, The Pennsylvania State University

Common Modes of Gear Failure

Gear tooth failures occur in two distinct regions, the tooth flank and the root fillet. The mechanisms of failure in these two regions are distinct and are discussed separately. While much more detailed information on the subject is available elsewhere (Ref 1, 2, 3, 4, 5, and 6), only the essentials are covered in this section.

Failure Modes on Tooth Flanks

In order to understand the common modes of failure on tooth flanks, it is important to study the kinematics of a gear mesh, illustrated in Fig. 1 for a pair of spur gears. For the direction of rotation shown, contact starts at the left side of the figure and progresses to the right. Initial contact occurs well below the pitch diameter of the driving tooth and well above the pitch diameter of the driven tooth. There is significant sliding along with rolling contact at this point. Sliding on the surface of the driving gear is in the same direction as rolling. As rotation continues, the point of contact moves toward the tip of the driving gear and toward the root of the driven gear. Sliding decreases as the point of contact moves toward the pitch diameter, reaching zero (pure rolling) at the pitch diameter. As the point of contact moves above the pitch diameter of the driving gear, the direction of sliding reverses. At the end of contact, significant sliding again occurs. Tests have shown that sliding in the same direction as rolling (as occurs below the pitch diameter of the driving gear) has a more severe effect on the surface durability of the material.

Fig. 1 Kinematics of a gear mesh

Failure modes on tooth flanks are caused by this combination of rolling and sliding. The more common failure modes are *scoring* (or *scuffing*), *wear*, and *pitting*. These modes are discussed briefly in this article. Additional information on these failure modes is provided in *Friction, Lubrication, and Wear Technology*, Volume 18 of the *ASM Handbook*.

Scoring (or Scuffing). This phenomenon is a lubrication failure, frequently brought on by an increase in the operating temperature. The lubricant film breaks down, allowing metal-to-metal contact at high spots (asperities) on the flank surfaces. Under sufficient conditions of load and temperature, this metal-to-metal contact causes asperities to weld together and then tear apart as the motion continues. The surface is characterized by torn or furrowed markings in the direction of sliding. Figure 2 shows a typical scored gear. The terms scoring and scuffing are used interchangeably in the literature, even though the term scoring is more prevalent in the aerospace industry, and the term scuffing is more commonly used in the automotive and other industries. Similar damage can occur without the instantaneous welding of the contact surfaces. This damage is sometimes caused by foreign material being carried through the mesh but is more frequently caused by high asperities on one contacting surface plowing through the other. This damage is termed *cold scoring* (or *scuffing*), or *burnishing*, and is differentiated from that described previously by the absence of tearing.

Fig. 2 Specimen gear with scoring (scuffing) failure

Wear generally describes the phenomenon that results in the gradual removal of material from the tooth flank. It can be accelerated by significant metal-to-metal contact, the presence of abrasive particles in the lubricant, or by chemical deterioration of the surface (corrosion) related to additives in the lubricant. A small amount of initial wear is sometimes desirable and is achieved by the process of “break-in” or “run-in.” This wear is generally accomplished by gradually loading the gears to their full load, thus allowing the individual tooth surfaces to interact and gently polish off the peaks of asperities. It is usually assumed that break-in enables the gears to last longer. Wear is hard to detect visually, frequently requiring measurement of tooth geometry to detect changes in profile or lead to confirm its occurrence. Wear will generally be more severe on portions of the tooth flank that experience greater sliding. This wear ultimately changes the shape of the tooth surface and increases dynamic loads. Thus, wear can be detected by an increase in noise or vibration. Obviously, the presence of metal particles in the lubrication oil is one sure sign of wear occurring, and this presence forms the basis of many diagnostic monitoring systems for gearbox applications.

Pitting is a fatigue failure brought on by the cyclical rolling contact load and aggravated by the surface traction forces due to sliding. Pitting failures are divided into three categories based on the location of the origin. *Surface origin pitting* is the result of interaction of asperities as tooth surfaces slide against each other. *Subsurface origin pitting* is the result of fatigue below the surface in the region of highest shear stress. The third category results from fatigue at the case/core interface, which should be well below the region of highest shear stress, and is termed *case crushing* or *spalling*. This third category represents parts that have been improperly manufactured and is not discussed here.

For most surface vehicle gearing and low-speed drives in general, surface origin pitting is the predominant flank failure mode. When tooth surfaces slide against each other, asperities on the opposing surfaces interact, resulting in very high, localized, shear stresses. This interaction produces a series of cracks at about 45° to the surface to a depth of up to 25 μm (0.001 in.). The cracks arrest at this point because the shear stresses produced in the bulk of the material by the contact load are not high enough to promote further propagation. When many such cracks occur on a localized area, the surface acquires a gray-etched appearance. This condition is termed *gray staining* or *microfissuring*. After continued cyclical loading, some of the surface material between the cracks may break away, leaving cavities up to 15 μm (0.0006 in.) deep. This condition is termed *exfoliation* or *frosting*. These conditions are not usually considered failure.

After continued running, some of the cracks may propagate further into the surface. The exact mechanism that allows some cracks to propagate, while most remain arrested, is probably related to nonmetallic inclusions providing stress risers, but it could also be related to more severe interaction of the surfaces in localized areas (scuffing) or the action of the lubricant. As cracks progress further into the surface, larger chunks of material can break away, leaving larger cavities. When cavities have grown from the size of exfoliation up to about 100 μm (0.004 in.) deep, the condition is termed *micropitting*. The term frosting sometimes is applied to this condition as well. For critical applications, the occurrence of micropitting over a significant area is considered failure. A gear in this condition is shown in Fig. 3.

Fig. 3 Specimen gear with micropitting (frosting) failure

As cracks progress further into the surface, the rate of propagation increases. This increase is related in part to lubricant (under contact pressure) being forced into the crack and wedging it further open, but it mostly is due to the higher shear stresses produced by the contact load. At some point below the surface, in the region of 100 to 500 μm (0.004 to 0.020 in.) or deeper, depending on contact geometry, shear stresses produced by the contact loading become high enough to promote rapid crack propagation. Progressively larger pieces break away from the surface, leaving yet larger cavities. This condition is termed *pitting* or *macropitting*. The material is torn away from the damaged area by the relative motion of the contacting part; thus, the cavity becomes wider and deeper in the direction opposite to sliding, leading to an arrow shape. Figure 4 illustrates a gear with an arrow-shaped surface origin pit at this stage. As pits become larger, they eventually cause a readily detectable increase in dynamic loads. A loss of material that reaches this level is frequently termed *spalling* and is considered failure.

Fig. 4 Specimen gear with arrow-shaped surface origin pit

Subsurface origin pitting typically occurs only in cases where the elastohydrodynamic lubricant film thickness is great enough to prevent significant asperity interaction. This pitting occurs in high-speed power gearing and in aerospace power drives. It is also typical in antifriction bearings (which operate with pure rolling as at the pitch diameter on spur gears). The origin is typically a nonmetallic inclusion or discontinuity in the structure, in the area of highest shear stress (about 100 to 500 μm , or 0.004 to 0.020 in.) below the surface. Crack propagation is initially quite slow, until a crack penetrates the surface, allowing lubricant to enter. It can be difficult to tell the difference between surface and subsurface origin pits, although subsurface origin pits often do not have the arrow shape typical of surface origin pits. As with surface origin pits, when the pit becomes large enough to cause a readily detectable increase in noise and vibration, it is considered a failure. Because most pits start small and progressively grow large, some critical high-speed drives incorporate a chip detector in the lubrication system to provide advance warning of imminent failure.

Failure Modes in Root Fillets

Failure of the gear tooth also can occur in the root fillet. This failure is primarily due to bending fatigue but can be precipitated by sudden overloading (impact). Sudden overloads can be caused by a large foreign object (e.g., a broken tooth) being drawn through the mesh, the driving or driven shafts suddenly stopping, or sudden loss of alignment (failure of an adjacent bearing).

Bending Fatigue. The origins of bending fatigue failures typically are imperfections in the surface of the root fillet (e.g., tooling “witness” marks) or nonmetallic inclusions near the surface. Cracks slowly propagate around the origin until they reach the critical size for the case material at the prevailing stress level. For hardened high-carbon material typically used for gears, when the crack reaches this critical size, it “pops” through the case (i.e., the entire case fractures). At this point, the rigidity of the tooth is reduced (compliance increases), and dynamic load increases significantly. This produces a readily detectable increase in noise and vibration and represents failure.

In many rig tests it is impossible to stop the rig quickly enough, once cracking is detected, to prevent complete fracture of the tooth and potential jamming of the test rig. This limitation causes some reluctance to conduct bending fatigue tests in high-speed power-circulating gear test rigs. However, with some transmission designs there is enough time between the onset of increased vibration and catastrophic failure for a vibration monitoring system to give sufficient warning to permit an orderly shutdown of the equipment. The mechanism that allows this shutdown is the reduced compliance of the cracked tooth, which transfers some of the load to adjacent teeth. The lower load and the lower hardness of the core results in slower crack propagation, allowing a brief

interval between the occurrence of detectable cracking and fracture of the tooth. This feature notwithstanding, tooth fracture is a potential catastrophic form of gear failure, and a substantial portion of gear test programs are dedicated to obtaining sufficient data to minimize its occurrence in service. In some gear designs (such as thin rims), cracks can propagate into the rim area. Rim fracture is the most catastrophic form of gear failure and should always be avoided.

Impact fracture of a gear tooth occurs in one loading cycle. The impetus for studying impact properties of gear steels is to ensure that steels used in gears have enough impact resistance to prevent failure when gears are subjected to normal spike loads.

Mechanical Testing of Gears

Douglas R. McPherson and Suren B. Rao, Applied Research Laboratory, The Pennsylvania State University

Stress Calculations for Test Parameters

Gear-rating standards, such as American National Standards Institute (ANSI)/American Gear Manufacturers Association (AGMA) 2001-C95 ("Fundamental Rating Factors and Calculation Methods for Involute Spur and Helical Gear Teeth") and International Organization for Standardization (ISO) 6336, base gear performance on contact and bending stresses. Nominal stresses are determined from first principles and are then modified to allow for the realities of manufactured gears running in actual gearboxes. This modification approximates a reasonable upper limit for the range of stress variation.

ANSI/AGMA 2001-C95 contains factors in the fundamental stress formulas for contact and bending to address overload, gear dynamics, size, load distribution, surface condition (contact only), and rim thickness (bending only). Design-allowable stress numbers are modified by further factors that address intended life, operating temperature, reliability, safety factor, and hardness ratio (contact only). It is normal practice in determining stresses to be reported with rig test results to take all of these factors as unity. The intent of rig testing is to compare the effect of various attributes or characteristics on performance. Thus, it is reasonable to determine the actual stress based on a value of unity for each factor, then determine suitable values for the factors based on test results.

The factors that are in essence being ignored by this approach represent real phenomena that occur as gears operate. It is critical to address this fact in the design of test rigs and in their day-to-day operation. For example,

it is important to conduct tests in a manner that precludes overloading; in a set of tests intended to evaluate the effect of overloading, only controlled overloads can be permitted. Most of the other factors can be handled in the same manner. However, gear dynamics and load distribution need to be addressed in a more direct fashion because they both can introduce uncontrolled variation in a set of test results.

Gear dynamics present a problem in determining the proper stress to be related to performance. Rating standards provide guidance on dynamic load variations in normal gearboxes. Gear test rigs, as described here, load one gearbox against another to keep power requirements to a minimum. Thus, there are two or more sets of dynamic variations, plus their interactions, to be considered. If the shafts connecting the gearboxes are quite rigid, the dynamic loading can be greater than the applied loading, even when precision gears are tested. Owing to the complexity of the situation, stresses for rig tests are computed making no allowance for dynamics. The fact that the dynamics of gear test rigs are not the same as real machines that use gears is a principal reason that bench testing and full-scale testing are required before a given gear design is adopted for critical applications.

The load distribution factor accounts for variations in alignment due to deflections of teeth, gearbox, and so on for variations in axial alignment of gear teeth, and for variations in load sharing between teeth. Much of the variation in load distribution can be minimized by straddle mounting test gears between bearings so their axes remain parallel under loading, modifying the profiles of test gears to optimize load sharing and so on. However, concentration of contact load at one end of a gear tooth (due to a small variation in axial alignment) produces a bending stress concentration. To avoid this condition, one or both test gears can be crowned to keep the load at the center of the face width. In this condition, the load-distribution factor is taken as unity for bending stress, and a suitable factor is estimated as shown in the following section for contact stress. However, crowning adds an additional variable that could affect test repeatability. It may be more expensive to accurately crown (and measure for verification) these test gears. Many times it may be more feasible to use high-accuracy standard test gears and very stiff (lateral) mounting to ensure uniform load distribution.

Contact Stress Computations for Gear Tooth Flank. Contact stresses on the surfaces of gear teeth are determined using Hertz's solution for the stress between contacting cylinders. The equation for contact stress taken from this solution, reduced to the simplest form applicable to spur gear teeth, is:

$$\text{Contact stress} = (P' \times B)^{1/2} \times EF \quad (\text{Eq 1})$$

where the contact force per unit width, P' , is:

$$\frac{\text{Pinion torque}}{\text{Pinion base radius} \times \text{effective face width}} \quad (\text{Eq 2})$$

and

$$B = \frac{R_1 + R_2}{R_1 \times R_2} \quad (\text{Eq 3})$$

where B is the geometry factor, R_1 is the radius of the pinion contact surface at the point of interest, and R_2 is the radius of the gear contact surface at the point of interest.

$$EF = \left[\pi \left(\frac{1 - \nu_1^2}{E_1} + \frac{1 - \nu_2^2}{E_2} \right) \right]^{-1/2} \quad (\text{Eq 4})$$

where EF is the elasticity factor, E_1 is the pinion modulus of elasticity, ν_1 is the pinion Poisson's ratio, E_2 is the gear modulus of elasticity, and ν_2 is the gear Poisson's ratio. For pinion and gear (both steel), the EF is 2290 in U.S. customary units (P' in lb/in., B in in.⁻¹, and stress in psi), and EF is 190.2 in Système International d'Unités (SI) units (P' in N/mm, B in mm⁻¹, and stress in MPa).

The most critical combination of contact load and sliding in spur gears occurs on the flank of the driving gear at the lowest point of contact with one pair of teeth in mesh (the location labeled "lowest single tooth contact" in Fig. 1). The radii of the contact surfaces at this point can be determined from the corresponding roll angles for the gear and pinion. The radius of curvature is the roll angle (in radians) times the base radius. The radii used in determining the geometry factor are thus:

$$R_1 = (OR_p^2 - BR_p^2)^{1/2} - \frac{2 \times \pi \times BR_p}{N_p} \quad (\text{Eq 5})$$

$$R_2 = \sin(OPA) \times OCD - (OR_p^2 - BR_p^2)^{1/2} + \frac{2 \times \pi \times BR_G}{N_G} \quad (\text{Eq 6})$$

where OR_p is the pinion outside the radius, BR_p is the pinion base radius, N_p is the number of pinion teeth, OCD is the operating center distance, BR_G is the gear base radius, N_G is the number of gear teeth, and OPA is the operating pressure angle, equal to $\cos^{-1} (BR_p + BR_G)/OCD$.

The contact stress returned by Eq 1 is a nominal stress and assumes uniform distribution of load. With crowned gears this uniform distribution will not be the case. The contact area becomes an ellipse, or in most cases, the center portion of an ellipse, with the highest contact stress at the center of the face width and progressively lower contact stress toward the ends. The proportions of the ellipse can be determined from a more complex form of Hertz's solution to the contact stress problem. A second geometry factor, A , related to the radius of curvature along the lead of the gears is needed:

$$A = \frac{R'_1 + R'_2}{R'_1 \times R'_2} \text{ or } A = \frac{1}{R'} \quad (\text{Eq 7})$$

where R'_1 is the radius of curvature along the pinion lead, R'_2 is the radius of curvature along the gear lead, and R' is the radius of curvature along the lead (only one gear crowned).

The amount of crown is usually a very small proportion of the face width; thus, the radius of curvature is large, and the section that can be measured represents an infinitesimal angular segment of the circle. This geometry makes it difficult for coordinate measuring machines (CMMs) to determine the crown radius. A useable crown radius can be determined from lead traces and Eq 8:

$$\frac{(\text{effective face width})^2}{8 \times (\text{average drop at ends of effective face})} \quad (\text{Eq 8})$$

The following equations regarding the contact ellipse are empirical in nature and assume that the ratio B/A is appreciably greater than 20, which will be the case with most crowned gears. If this is not the case, a thorough presentation of Hertz's contact solution, such as Ref 7, should be consulted.

$$k = \left(\frac{B}{A} \right)^{-0.62} \quad (\text{Eq 9})$$

where k is the ratio of ellipse minor to major axis.

$$\left[1 + \frac{B \times (\pi \times k \times EF \times \text{effective face width})^2}{48 \times (1 + k) \times P'} \right]^{1/2} \quad (\text{Eq 10})$$

If the crown radii are small enough in proportion to the contact load and effective face width, the contact area will be an ellipse narrower than the effective face width. The width of the elliptical contact area and the corresponding contact stress for this case can be determined from Eq 11, 12, and 13.

$$\text{contact force} = \frac{\text{pinion torque}}{\text{pinion base radius}} \quad (\text{Eq 11})$$

Width of contact ellipse, EW , is determined by:

$$2 \times \left[\frac{3 \times \text{contact force}}{B \times (\pi \times k \times EF)^2} \right]^{1/3} \quad (\text{Eq 12})$$

$$\text{contact stress (crowned)} = \frac{6 \times \text{contact force}}{\pi \times k \times EW^2} \quad (\text{Eq 13})$$

These formulas can compute contact stresses for rig test specimen gears far higher than would be predicted by the load distribution factors presented in gear-rating standards. The formulas are presented here to permit comparison of performance on a stress basis between gears with differing crown. Stresses determined in this manner should be reduced by a typical load distribution factor before being used to develop allowable design stresses.

In most cases, there will be variation in contact stress between specimen gears in the same lot (and from tooth to tooth on each gear) tested at the same load. The edge break at the ends of teeth is frequently applied in a manual operation; thus, the effective face width can vary. Crown can vary from tooth to tooth on each gear. Center distance can vary due to radial runout in shafts and bearings. The outside diameter of gears can vary (as required for manufacturing tolerance). It is important, therefore, to determine the mean contact stress and the probable range of variance.

Bending stress computations for root fillets are computed based on the assumption that the gear tooth is a cantilever beam with a stress concentration at its supported end. AGMA rating standards determine the form of the cantilever beam from the solution presented by Lewis and use a corresponding stress concentration factor. ISO and Deutsche Industrie-Normen (German Industrial Standards) (DIN) use different proportions for the beam and determine the stress concentration factor in a different manner. Only the AGMA approach is discussed here.

Figure 5 shows a spur gear tooth with a point load applied at the highest point of single-tooth contact. This point of loading corresponds to the highest bending stress when there is effective load sharing between gear teeth. Specimen gears used in rig tests should have effective load sharing, so this is the appropriate point of loading for determining bending stress in rig tests. For gears tested in single-tooth bending fatigue, the actual point of loading established by the test fixture should be used in calculating bending stresses.

Fig. 5 Layout of Lewis parabola for tooth-bending stress calculation

The Lewis parabola is drawn from the point at which the load line intersects the center of the gear tooth and is tangent to the root fillet. Methods used to lay out this parabola depend on how the root form is generated, the particulars of which are presented in detail elsewhere (Ref 8). The critical height and width are determined from the Lewis parabola as shown in Fig. 5. The angle between the load line and a normal-to-the-tooth center is termed the *load angle* (it differs from the pressure angle at the point of loading because of the thickness of the tooth). The bending stress is thus:

$$\frac{\text{load} \times \cos(\text{load angle})}{\text{face width}} \left[\frac{6 \times h}{s^2} - \frac{\tan(\text{load angle})}{s} \right] K_f \quad (\text{Eq 14})$$

where s is the critical width from the Lewis Parabola, h is the critical height from the Lewis Parabola, and K_f is the stress concentration factor:

$$H + \left(\frac{s}{r} \right)^L \left(\frac{s}{h} \right)^M \quad (\text{Eq 15})$$

where r is the minimum fillet radius, H is equal to $0.331 - 0.436 \times$ (nominal pressure angle, in radians), L is equal to $0.324 - 0.492 \times$ (nominal pressure angle, in radians), and M is equal to $0.261 + 0.545 \times$ (nominal pressure angle, in radians).

Equation 14 is derived from first principles but also can be derived from AGMA standards by taking the forms of relevant formulas pertinent to spur gears and setting all design factors at unity. While a similar formula could be developed for helical gears, testing them usually represents a step between rig testing and bench testing, and such tests are negotiated between the client and the testing laboratory.

Mechanical Testing of Gears

Douglas R. McPherson and Suren B. Rao, Applied Research Laboratory, The Pennsylvania State University

Specimen Characterization

Specimen characterization is a critical part of any fatigue test program because it enables meaningful interpretation of the results. It is important to know that the specimens to be tested meet specifications, where key parameters fall in the specified range, and what the variations are. Characterizations fall into four areas: dimensional, surface finish/texture, metallurgical, and residual stress.

Dimensional Characterization. Basic dimensional checks include size and alignment of mounting surfaces, size and alignment of test surfaces relative to mounting surfaces, and size and uniformity of edge breaks at the edges of test surfaces. These checks ensure that the specimens will fit into the test rig and either ensures that stresses will be consistent or provides data to determine variations.

The important dimensions to check on rolling contact fatigue (RCF) specimens are diameters of mounting trunnions and test surface, total indicator reading (TIR) test surface-to-mounting trunnions, and overall length. The important dimensions to check on the mating load rollers are inside and outside diameters, TIR inside to outside, crown radius and location of high point of crown, and thickness. In the case of nonstandard specimens where the entire width of the test surface is intended to make contact, the size and uniformity of the edge break needs to be checked.

The important dimensions to check on gear specimens fall into the areas of mounting surfaces, gear functional charts, and other specific features impacting stress. All of the gear specimens described in the following sections are mounted on their inside diameter. Thus, inside diameter, length between end faces, and perpendicularity of end faces to inside diameter need to be checked. For specimens with a splined bore, the pitch diameter, or inside diameter if so specified, counts as the inside diameter for alignment checks. The gear functional charts are developed with the gear mounted on the test mounting surfaces. Typical measurements include lead, profile, spacing, index, and runout. Other specific items to check include diameter over wires, root diameter, and size and uniformity of edge break at tooth ends and along the tip.

Surface Finish/Texture Characterization. It has been standard practice to specify surface finish and texture in terms of arithmetic average surface roughness (R_a). Because it is possible to manufacture surfaces with widely varying load capacity, all with the same R_a , more information than R_a is needed to interpret data. At a minimum, R_z (a measure of “average” peak roughness) should also be measured. A preferable method would be to examine surfaces with an optical interference system that maps the contour of an area rather than the traditional line contact. Test surfaces to be subject to contact fatigue should also be examined at 10× to ensure they are free of corrosion, dings, scratches, and so on.

Metallurgical Characterization. Both surface hardness and hardness gradients are to meet specification. For gear specimens, hardness should be checked at the tooth half height and at the root fillet. Details of the

microstructure should be characterized at the same locations as hardness. Typical practice has been to prepare and document photomicrographs of the etched structure at 400× to 600×.

Residual Stress Measurement. Residual stresses vary among a lot of parts; therefore, enough measurements should be made to permit a statistical analysis. Residual stress gradients provide more useful information than surface measurements but at a much higher price. A complete study should include some residual stress gradient data. Typical practice is to measure surface residual stress at six points per variant and measure the residual stress gradient at one or two of these points. Contact fatigue specimens should be measured at the center of the contact surface. Gear specimens should be measured at the tooth half height (or lowest point of single-tooth contact) for surface durability tests and at the midpoint of the root fillet for bending strength tests.

Mechanical Testing of Gears

Tests Simulating Gear Action

Tests that simulate gear action are the RCF test, the single-tooth fatigue test, the single-tooth single-overload test, and the single-tooth impact test.

Rolling Contact Fatigue (RCF) Test

The RCF test simulates the rolling/sliding action that occurs in a gear mesh, and depending on the test parameters employed, it can simulate the most severe condition in the mesh. Because the specimens are cylindrical, this test is the least expensive to run in both cost and time. Hence, it is frequently used as a screening test, and its results are used to plan further gear testing.

Test Equipment. Figure 6 shows a schematic of the rolling/sliding contact fatigue test. The specimen and load rollers are cylindrical. The outside diameter of the load roller is crowned to concentrate the load at the center of contact and eliminate the possibility of concentrated loading at the edge of contact due to misalignment. A normal load is applied by air pressure. Phasing gears, attached to the shafts on which the specimen and load rollers are mounted, control the extent of sliding at the specimen/load roller interface. The amount of sliding is determined by the gear ratio and can be fixed at any value (21 and 43% are commonly selected), simulating the rolling/sliding action at any desired location on gear teeth. This test is primarily intended to evaluate the resistance of candidate material systems to surface origin pitting, but other modes of surface failure can be studied. The surfaces of the specimen and load roller are sliding against each other, with lubrication, under high load. Therefore, some indication of the lubricated wear resistance of the material being tested can be obtained. In addition, the resistance of the material/surface finish/lubricant system to scuffing can be studied. Tests are conducted at very high overload to promote failure in real time; thus, it is possible to introduce plastic deformation (rippling) on the contact surface. With specially adapted equipment, these tests can be conducted at different temperatures up to 400 °F. Specimens and load rollers can be designed for a variety of testing requirements, depending on the exact material and objective of the test.

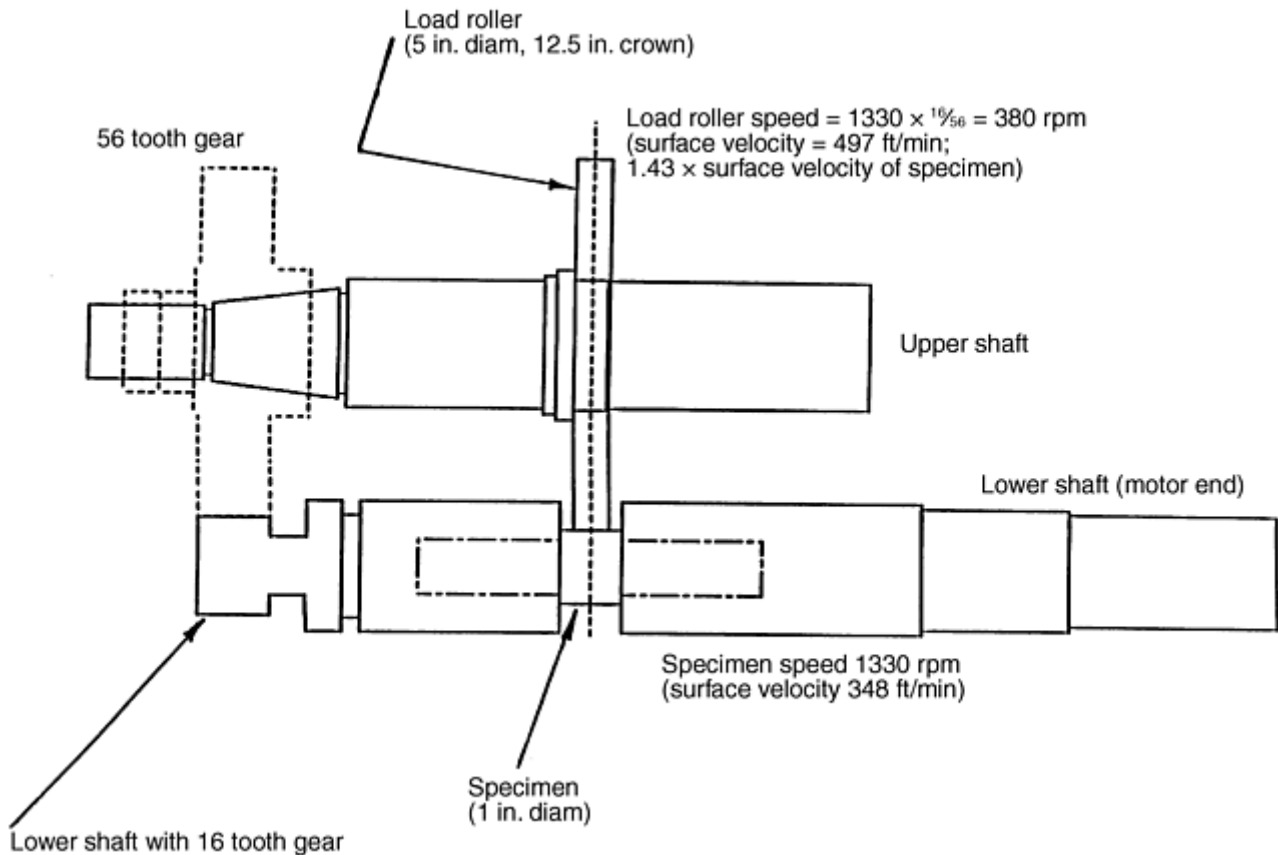

Fig. 6 Schematic of a rolling/sliding contact fatigue (RCF) test

Test Procedure. The lubricant stream to the specimen/load roller interface is aimed at the discharge side of the mesh (to cool the surfaces after contact). The lubricant flow rate is adjusted (typically to about 2 L/min, or as specified for the project), with the lubricant at test temperature.

Alignment of the specimen and load roller is checked as each test is set up. One method often used is to coat the surface of the load roller with a thin layer of layout blue and ensure that contact occurs uniformly at the center of the load roller. Before the start of testing at load, a break-in run is typically conducted. This procedure is accomplished by running the machine for 10 min at each of a series of increasing loads up to the full test load. The intent of the break-in run is to gently polish away asperities on the contacting surfaces that might cause scuffing (i.e., localized scoring), burnishing, or wear to occur under full load.

Tests are stopped periodically, and the contacting surfaces of the specimen and load roller are inspected for signs of surface distress. The diameter at the center of the specimen is also measured to provide an indication of wear. The formation of large, progressing pits produces a strong vibration signal, which, in turn, shuts down the test. Lubricant temperature, lubricant pressure, and air pressure (to apply the contact load) are also monitored, and the test is stopped if irregularities are detected.

The results of contact fatigue tests exhibit more scatter than is typical with other fatigue tests. One gage of scatter is the Weibull slope, a measure of the increase in rate of failure with increasing life. For many fatigue tests, a Weibull slope of six or more is typical. A Weibull slope of six can be roughly translated into practical terms as follows. If 20 samples were randomly selected from a large group of theoretically identical parts and tested to failure under identical conditions, the longest test would, on the average, last about twice as long as the shortest. For contact fatigue testing with current ultraclean steels, a Weibull slope of 1.5 is typical. In this example, if the Weibull slope were 1.5, the longest of the 20 tests would last approximately 20 times as long as the shortest. The impact on test programs is that many tests have to be conducted to develop enough data to make statistically meaningful comparisons. The minimum number of tests with each variant (at each load) to enable reasonable comparisons has typically been considered to be six. With six tests for each of two variants and Weibull slopes of 1.5, the G50 life of one variant would have to be twice that of the other to conclude that it is better. If the comparison were made on the basis of G10 life, the ratio would have to be 5 to 1.

Specimen Results. An example set of data, representative of the results of rolling/sliding contact fatigue testing, is shown in Table 1. In addition to specimen identification, load, and life to failure, other information is

reported to aid in the interpretation of results. Several test parameters can be varied as needed; thus, the actual values are reported with the results. These parameters include lubricant, lubricant bulk temperature, nominal filter size, test speed, and phasing gear set/slide ratio. Also reported for each test are data regarding surface roughness, ratio of elastohydrodynamic lubricant film thickness to composite roughness, wear, and wear rate. A Weibull statistical analysis of this set of results is shown graphically in Fig. 7. Comparisons between variants are made on either a G10 life or a G50 life basis.

Table 1 Example of rolling/sliding contact fatigue test data

Lubricant, automatic transmission fluid. Bulk temperature, 90 °C (194 °F). Filter, 10 µm (nominal). Test speed, 1330 rpm. Phasing gear set, 16 tooth/56 tooth. Slide/roll ratio, 43%. Contact stress, 400 ksi. Load, 3000 lb.

Test No.	Specimen No.	Test duration		$R_a^{(a)}$		$\lambda^{(b)}$	Wear ^(c) , in.	Wear rate ^(d)	Comments
		10 ⁶ cycles	h	Specimen	Load roller				
		1.173	14.7	13.5	3.8				
3	10-9/LR 1	1.603	20.2	8.5	...	0.58	0.0002	12	Surface origin pitting
8	10-11/LR 5	7.332	92.3	9.3	...	0.56	0.0001	1.4	Surface origin pitting
12	10-4/LR 13	7.565	95.3	...	5.0	0.57	0.0008	12	Surface origin pitting. Severe exfoliation and wear at center of wear track
18	10-2/LR 17	5.267	66.3	9.0	6.8	0.51	0.0002	3.8	Surface origin pitting
22	10-3/LR 22	6.322	79.7	...	5.0	0.56	0.0003	4.7	Surface origin pitting

(a) R_a , arithmetic average surface roughness measured in axial direction, µin.

(b) λ , ratio of elastohydrodynamic film thickness to composite surface roughness. In cases where surface roughness was not measured for a particular specimen or load roller, λ is based on average surface roughness for group.

(c) Diametral wear (i.e., change in diameter) on specimen.

(d) Change in diameter, in. $\times 10^{-5}$ /cycles $\times 10^6$

Fig. 7 Weibull analysis with RCF test data

Single-Tooth Fatigue (STF) Test

The STF test is used to generate a statistically significant quantity of bending fatigue data at a comparatively low price. Teeth are tested one at a time with a fixed loading point, allowing the generation of bending fatigue data at comparatively high cycles without risk of losing tests to other modes of failure. Another cost-saving measure is that four or more tests can be conducted with each gear specimen.

Test Equipment. A gear is placed in a fixture so that one tooth at a time can be loaded while another tooth supports the reaction. The test is usually done in an electrohydraulic, servocontrolled universal test machine. The primary object of this test is to determine fatigue properties in bending. However, the same setup can be used to determine single overload properties (ultimate bending strength) as well. Frequently, enough teeth are tested to develop a stress-cycles diagram to define the bending fatigue characteristics of the material system.

Several arrangements for loading can be considered. One fixture arrangement is shown in Fig. 8. This illustration shows the Boeing flexural design, which appears to have found favor with the aerospace sector. This

fixture is designed for a 32 tooth, 5.333 diametral pitch (DP), 8 mm ($\frac{3}{8}$ in.) face width spur gear with several teeth removed to provide access to test and reaction teeth. The gear is rigidly supported on a shaft. Load is applied through a carbide block contacting the test tooth at the highest point of single-tooth contact. The loading block is held in the specified orientation to the gear by a flexural loading arm. This flexural design ensures accurate loading of the gear tooth with minimal migration of the point of loading. Reaction is carried through a block contacting the reaction tooth at the lowest point of single-tooth contact. Load is cycled from the specified test load to a minimum load high enough to keep the slack in the system taken up (usually 10% of the test load). While most testing is conducted at 20 Hz, other frequencies also are possible. The fatigue test

machine is instrumented to monitor instantaneous loads and tooth deflections. Changes in compliance can be used for monitoring crack initiation and propagation in the root fillet region. In addition, a crack wire can be incorporated to monitor catastrophic tooth failure. Typical fatigue load capacity of such types of equipment is in the range of 10 to 20 kips, although higher loads, up to 110 kips, can be used for single overload tests.

Fig. 8 Flexure arm single-tooth fatigue (STF) test fixture

A second fixture arrangement (Fig. 9) appears to have found favor with many other industry segments. This fixture utilizes a 34 tooth, 6 DP, 25 mm (1 in.) face width spur gear and is derived directly from the Society of Automotive Engineers (SAE) Division 33 STF fixture. Fatigue test loads up to about 15 kips are feasible with this fixture, and single overload tests up to about 50 kips can be accommodated. These STF fixtures are compact enough to be immersed in heated fluid; thus, fatigue testing can be conducted at elevated temperatures (up to 400 °F).

Fig. 9 SAE division 33 single-tooth fatigue (STF) test fixture

Test Procedure. Special concern must be taken with regard to safety in conducting the STF test (in addition to general lab safety procedures). Setting up the test requires moving the hydraulic load ram while lining up the fixture, bypassing safety features, such as a light curtain to stop the machine, and so on, and considerable caution needs to be exercised during setup. Periodic calibration of the test fixture is important because there are many closely fitted parts that can wear and change the bending stress in specimen gears. A calibration gear is made from a standard specimen with strain gages fit at key points in the root fillets. This calibration gear is installed in the fixture and loaded to set loads periodically to ensure consistent loading. If specimens for a specific test program differ from the standard design established for the fixture, one of these specimens should also be fitted with strain gages, and calibrations should be conducted with both gears. Typical calibration intervals are from every six to every thirty tests, or any time the fixture is cleaned and repaired.

Other set-up items that can affect test results are mounting of the fixture on the universal test stand, tuning of the test-stand controller, and test frequency. If the SAE type fixture is used, it is important to ensure that the fixture floats freely on an oil film before starting each test. Other fixture designs can be bolted to the machine base, provided proper alignment between the load ram and loading point on the load arm is maintained. The feedback control should be tuned to suit test fixture and specimen compliance. Some systems do this automatically each time the machine is turned on; with others, this tuning may have to be done manually. At a minimum, tuning should be verified as often as fixture calibration. Some systems provide a feature to automatically adjust tuning as compliance changes. This feature should be turned off when running STF tests—a significant change in compliance is proof of failure. The maximum frequency for STF testing is limited by the capacity of the system to maintain a satisfactory load waveform. An inability to maintain peaks on the unload side of the wave at the specified value is a sign of testing at too high a frequency. All of the tests for a given project should be conducted at the same frequency, which is usually set at slightly less than the maximum for the highest anticipated load.

The other procedural item that can affect test results is the method used to detect failure and stop the test (and stop counting cycles). All systems can be set up to stop if the load goes out of the specified range. This deviation will happen when compliance changes, usually as a result of a crack in the root fillet. Many systems incorporate a linear variable differential transformer and can be set up to stop if the load ram moves beyond the specified range (also an indication of tooth failure). A limit switch can be set to trip when the load ram moves too far. Other failure detection devices, such as a crack wire bonded near the root fillet so that it will break when the tooth cracks, or an ultrasonic system to detect cracking, can be used to stop the test. At least two of these methods should be employed to ensure that the machine stops cycling load when the tooth breaks. If a computer is used to control loading during tests, one of the failure detection systems should be connected directly to the universal test-stand controller to guarantee that the machine stops if the computer crashes.

Specimen Results. Table 2 summarizes results from a typical set of STF tests. Testing was conducted in three phases. Initial searching tests were conducted to establish loads that would result in failure in reasonable time. A “modified staircase sequence” of tests was conducted to develop data at a series of loads representing zero to 100% failure. Further tests were conducted to fill in the stress cycles relationship. Searching tests are started at a high load to ensure starting with a failure, then stepped down until the tooth survives the specified number of cycles (here, 5 million cycles has been selected as a run-out limit). The modified staircase sequence is conducted by testing three specimen gears in sequence. If the tested tooth breaks before the specified limit, the next test is conducted one load step lower. If it does not break by the specified limit, the next test is conducted one load step higher. After the modified staircase sequence is completed, additional tests are conducted to ensure that all the specimen gears are tested at the lowest load. More tests are conducted to develop enough data for Weibull analysis at two loads resulting in 100% failure.

Table 2 Results from a typical set of gear single-tooth fatigue tests showing overall testing sequence, including modified staircase (“up and down”) tests

Legend: X, failure; O, runout. Specimen serial numbers 2, 4, and 6. Specimens cut from bar stock, hobbled roots. *R*, loading; *R* = 0.1. Frequency, 25 Hz

The load-cycles diagram shown in Fig. 10 was developed from the data in Table 2. Results at 9000 and 8500 lb were analyzed via Weibull statistical analyses (similar to that shown in Fig. 7) to determine lives to 10, 50, and 90% failure. The failure rates at 5 million cycles for loads from 6500 to 8500 lb were analyzed using normal probability concepts to determine 10, 50, and 90% failure loads. The curves labeled G10, G50, and G90 were then fit visually using the results of these analyses as a guide. Results are reported in terms of load versus cycles, and load can be converted to stress using the method discussed previously. Comparisons can be made between groups of gears with the same geometry on a load-cycles basis or between gears with differing geometry on a stress-cycles basis. When converting to stress for comparison with running gear data, consideration must be given to the different stress ranges applied to STF gears and running gears. Also, consideration must be given to the statistical difference between four, eight, or more data points from a single STF specimen gear compared with one data point from a running gear specimen set.

Fig. 10 Load cycles diagram constructed from STF data. See Table 2 for load-cycles relationship for data

Single-Tooth Single-Overload and Impact Testing

The single-tooth impact test is used to investigate impact strength of gear steels. Impact strength is an important property for steels to be used in high-speed gear drives or transmissions for off-highway equipment, which can be subjected to significant shock loading. It has been suggested that fatigue strength can be related to impact strength; however, results of tests to support this suggestion have been mixed.

Single overload tests are used to investigate the ultimate strength of gear materials. The results are useful in selecting loads for fatigue tests and in constructing allowable stress-range diagrams (e.g., for use in comparing STF results with bending fatigue data developed from running gear tests).

Test Equipment. Figure 11 shows a closeup of the test area of a 4.5 m (15 ft) drop tower for single-tooth impact testing. A single-tooth fatigue test fixture, without loading block, load arm, and so on, is placed on a load cell and arranged so that the striking surface of the drop weight hits the load point on the test gear tooth. Stops are provided to prevent the forces required to stop the drop weight after the test tooth fractures passing through the load cell. A high-speed digital oscilloscope captures the signal from the load cell.

Fig. 11 Test area of an impact test tower

Single-tooth, single-overload tests are accomplished with the same equipment used in STF testing. The only change is that a high-speed digital oscilloscope captures the signal from the single event.

Test Procedure. The single-tooth fatigue test fixture, without loading block, loading arm, and so on, is placed on a load cell and installed under the drop weight. The striking surface on the drop weight is adjusted to the correct angle to strike the test tooth at the load point. This point is verified by coating the tooth with a thin layer of layout blue and allowing the drop weight assembly to contact the tooth statically. The digital oscilloscope is set up to record a single event using a change in signal as a trigger. Usually three to six tests per variant are conducted.

For single-overload tests, the STF fixture is installed in the universal test stand as for fatigue testing, and a preload is applied. For the SAE fixture, 1800 kg (4000 lb) is used, and for other fixtures the load should be high enough to take the slack out of the system. The function generator is set up to ramp up the load to break the tooth in approximately 30 s for slow bend tests and in approximately 0.050 s for fast bend tests. One slow bend and three fast bend tests usually are conducted per variant.

Specimen Results. A load deflection trace for a single-tooth impact test is shown in Fig. 12. Results from fast and slow bend tests are similar. This trace shows load increasing linearly with deflection up to 5900 kg (13,000 lb), then increasing at a slower rate until tooth breakage at 9000 kg (20,000 lb). This result is typical for many materials and is possibly related to the onset of plastic flow prior to fracture. Based on this, the stress corresponding to the change in slope of the load deflection (or load time) trace corresponds to the ultimate bending strength of the material at the critical point in the case. Maximum load, or energy required to break the tooth, represents the strength of the core rather than the strength of the case.

Fig. 12 Load deflection trace from single-tooth impact test

Gear Power-Circulating (PC), or Four-Square, Tests

A gear failure map is shown in Fig. 13. This map indicates that by varying load and speed, failure by any of several different modes can be induced. Thus, PC gear tests can be used to evaluate bending fatigue strength, surface durability with regard to pitting, or scoring resistance. A limiting factor is that tests targeted at one of the failure modes may have to be terminated because of failure by another mode. For example, bending fatigue tests conducted at a comparatively low load, targeting failure in several million cycles, may have to be terminated due to pitting failure. Consequently, PC gear testing is more expensive than the tests simulating gear action previously discussed. It is, however, less expensive than bench testing, and several standard specimen designs are available to allow tests targeted at particular failure modes.

Fig. 13 Gear failure map

Test Equipment. A test and a torque-reversing gear set are mounted at opposite ends of the test bed. One shaft connects the test and torque-reversion pinions, and another connects the torque-reversing and test gears. One gearbox is loaded against the other by twisting the shafts to lock in torque. This rig is known as a power (re-) circulating, or four-square, test rig and is schematically illustrated in Fig. 14. The locked-in torque, which is fixed at various values to create the required tooth load, can be generated mechanically or hydraulically. The entire loaded arrangement is driven by an electric motor at the required speed, and the motor need only supply the friction losses. Significant transmitted power can be simulated in this system with comparatively little power input. Data from these tests can be directly translated for design use.

Fig. 14 Schematic of a power (re-) circulating (PC) test rig

In a four-square test rig, the tooth accuracy of the torque-reversing gears, and their transmission error, has a significant impact on the dynamic loads on the test-gear pair. These dynamic loads due to torque reversing gear inaccuracy can be further amplified or attenuated by the longitudinal and torsional frequency response characteristics of the four-square-test rig. This intensification is of particular significance in high-speed testing where operating frequencies will be close to or at torsional and/or longitudinal natural frequencies of the four-square system. However, high-accuracy torque-reversing gears are expensive. Consequently, the PC test rigs can be classified into two categories. The first category of PC test rigs have low power, operate at low speeds, and generally have AGMA quality class Q9 or Q10 gears in the torque-reversing gearbox that are quite adequate for many industry segments. The second category of PC test rigs operate at high power, high speed, and incorporate high-accuracy torque-reversing gears that are essential for gear testing in certain industry segments, such as the aerospace industry. Testing costs associated with each of the two categories of test rigs are significantly different.

The low-speed PC test rigs illustrated in Fig. 15 nominally operate at 900 rpm but can be adapted to operate at 1500 rpm. The standard center distance is 100 mm (4 in.), which can be modified if necessary, although there are some costs associated with doing so. These test rigs can simulate the transmission of up to 100 hp when driven with a 3 hp motor. Load is applied via a mechanical loading arm and locked in with a special coupling that can be set at any angle. Thus, load cannot be varied as the rig is running. Depending on specimen design, contact stresses of up to 450 ksi at the lowest point of single-tooth contact and bending stresses up to 160 ksi can be generated. Splash lubrication is standard, and spray lubrication to either side of the mesh can be provided. These rigs can be adapted to conduct scoring tests.

Fig. 15 Low-speed (4 in. center distance) PC test rig

Figure 16 shows a PC test rig with a 155 mm (6 in.) center distance that can operate up to 8000 rpm and simulate the transmission of up to 1400 hp. This test rig has two test gearboxes so that two pairs of gears can be tested simultaneously. In programs to evaluate materials for aerospace gearing, runout can be set as high as 400 million cycles for surface durability tests, making the project a lengthy exercise. In this case, obtaining two data points in one run can be a significant benefit. Figure 17 shows another PC test rig with a 90 mm (3.5 in.) center distance, capable of operating at 10,000 rpm and simulating transmission of up to 700 hp. Torque-reversing

gears in these high-power rigs are in AGMA quality class Q13 and Q14. Load is applied via a servocontrolled hydraulic system and can be varied as required during tests. Torque is monitored continuously by a noncontact torque cell. This monitoring permits interpretation of test results in light of the actual load signature. Based on input lubricating oil temperature and load, surface durability (pitting), bending, and scoring tests can be conducted on these PC test rigs. Spray lubrication, to either side of the mesh, is standard; oil-mist lubrication can be provided.

Fig. 16 High-speed (6 in. center distance) PC test rig

Fig. 17 High-speed (3.5 in. center distance) PC test rig

Test Procedures for Surface Durability (Pitting) and Root Strength (Bending) Testing. One or both gears in the specimen set are coated with a thin layer of layout blue prior to installation in the test machine. After the gears are installed, they are run briefly at low load with room-temperature lubricant to determine the contact pattern. The low-speed test rigs allow some alignment adjustment to optimize contact pattern. The specimen mountings in the high-speed test rigs are rigid, so the only remedy for nonuniform contact is to change specimen gear sets. A break-in run is generally conducted before the start of the test run. On the low-speed machines this run is

accomplished by applying one-half of the test load and running for $\frac{1}{2}$ h at test speed starting with room-temperature lubricant. The friction of the meshing gears warms the lubricant to near test temperature in this time. On the high-speed machines, load and speed are increased in a set pattern to accomplish break-in. As described previously, break-in is expected to increase the life of the gears. Thus, all specimens tested in a given project should be broken in using the same method. For root strength (bending fatigue) tests, break-in may not affect bending fatigue life but may delay the onset of pitting long enough to allow the gear to fail in bending.

In general, the main difference in surface durability (pitting) and root strength (bending) tests is the load. Most of the standard specimen gear sets are designed to allow surface durability testing at loads high enough to produce failure in less than 10 million cycles. Root strength tests, therefore, have to be conducted at loads high enough to produce failure in less than 1 million cycles to avoid surface durability failures. Thus, unless specially designed specimens are tested, the results of this test can only be compared to the lower-life portion of the stress-cycles relationship developed in the STF test.

Surface durability gear tests have similar problems with scatter as those previously described for RCF tests. However, each specimen gear has 18 or more teeth; therefore, the result of a single PC surface durability test represents the lowest performance of 18 or more items tested. This statistical difference causes the results of PC surface durability tests to exhibit less scatter than those of RCF tests, and Weibull slopes are generally three or higher. Six tests are still generally conducted with each variant at each load, the reduced scatter being used to allow more statistically reliable comparison of the results rather than to reduce the number of tests. A similar statistical difference exists between the results of STF tests and PC bending tests, and this difference must be considered when comparing STF and PC bending results.

Specimen Results. The end point of a surface-durability test may be somewhat ambiguous. The section regarding pitting in the discussion of failure modes indicates several points in the development of surface origin pitting that may be considered failure. Figures 3 and 4 show gear teeth with different stages of pitting, both of which were considered failures. Test gear teeth are also subject to wear and localized scoring, both of which can affect the appearance of the contact surface in ways similar to some of the stages of pitting development. A composite failure criterion has to be adopted that specifies the level of damage in each of these categories that

constitutes failure. A typical failure criterion for pitting is one pit 4 mm ($\frac{1}{16}$ in.) wide or several smaller pits with slightly greater total area. Typical failure criteria for micropitting is micropitting over half of the contact width of all the teeth and for wear, a loss of 12 μ m (0.0005 in.) at any point on the profile.

A test program evaluating bending and surface durability performance of candidate materials would include 24 tests with each material. Six tests would be conducted at each of two loads intended to result in bending failure; the balance of the tests would be conducted at two loads intended to result in pitting failure. The results of tests at each of the four loads are analyzed with Weibull statistical analysis (as illustrated in Fig. 7). A load-cycles diagram is then constructed showing loads corresponding to 10, 50, and 90% failures at various lives for both bending and surface durability. Comparisons are made on the basis of life to 50% (or 10%) failures at a given load, or the load corresponding to 50% failures at a given life. It is useful to construct a stress-cycles diagram (determining contact stress as described here) to compare surface durability results obtained from specimens having differing crown.

Test Procedures for Scoring (or Scuffing) Testing. Scoring is typically most severe in the dedendum of the driving gear (at the start of contact) and at the tip of the driven gear. Therefore, to facilitate observation of scoring, the gears and loading are set up so that the specimen is the driven gear. Scoring is more probable at high speed, high load, and/or high-lubricant temperature. Because of this probability, the test machine is set up to run at high speed and high-lubricant temperature. Resistance to scoring is then measured by the load that will precipitate scoring. Load is increased in comparatively small steps until scoring starts. Because small variations in lead or crown can produce as much variation in unit loading at the most heavily loaded area as one or more

load steps, specimens used for scoring should be those with the most consistent geometry that can be selected from the lot to minimize scatter. Gear alignment should be adjusted, if possible, to obtain the best contact pattern.

Break-in is a particularly critical part of this test. Therefore, all specimens should be broken in using an identical process, and control specimens should be included in the project test matrix to benchmark the results for comparison with prior tests. Typically, break-in is started at low load in room-temperature oil and run-in one to four load steps lasting 20,000 to 50,000 loading cycles each. The lubricant temperature is allowed to slowly rise due to the friction of the meshing gears during break-in. The condition of the lubricant also can affect the outcome of the test; thus, lubricant should be changed prior to the start of each test.

Specimen Results. After break-in, the surface roughness (R_a) is measured in the axial direction at the tips of several teeth on the specimen gear, and the surface condition is documented. The load is increased, and the lubricant temperature is raised to test temperature. The gear set is run 20,000 to 50,000 loading cycles for each load step. After each load step, surface roughness and surface condition are examined and recorded. The appearance of score marks, or an abrupt increase in surface roughness, indicates scoring failure. The gear shown in Fig. 2 illustrates a typical failure in this test. Typically, three tests are conducted per variant. Comparisons between variants are made on the basis of the load that precipitates scoring. Contact stress considered alone has little influence on scoring; consequently, comparisons made on the basis of contact stress may be misleading.

Testing of Pressure Vessels, Piping, and Tubing

E. Roos, K.-H. Herter, and F. Otremba, Staatliche Materialpruefungsanstalt (MPA), University of Stuttgart

Introduction

THE MECHANICAL EVALUATION OF PIPE FAILURES has evolved over time. An initial purpose of such analysis was to determine the causes of large breaks occurring in oil and gas pipelines. The development of commercial nuclear power plants initiated the need for additional tools to assess the reliability and the failure behavior of pressurized vessels and pipes under different loading and environmental conditions. The results of these efforts have been transferred to other relevant industrial branches as well.

The main effort in evaluating the mechanical and structural behavior of pressurized components started about 1950. Since that time, numerous investigations have been performed to assess the loading capacity and the failure behavior of pressure vessels, piping, and tubing. Investigations have also focused on determining failure loads and quantifying the margins of safety.

Testing of Pressure Vessels, Piping, and Tubing

Safety Aspects and Integrity Concepts

The license and operation of pressure vessels and piping in the different countries throughout the world are subject to national laws, special regulations, and safety criteria. Pressure vessels and piping are designed according to the relevant national technical codes and standards that contain detailed rules regarding materials, construction, design and calculation, manufacture, and quality assurance. These codes require that state-of-the-art technology is applied to the safe operation and maintenance of this equipment.

The relevant national technical codes and standards for pressure vessels and piping include the following:

- In the United States, the American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code—for example, Section III for nuclear power plant components (Ref 1) and Section VIII for the construction of pressure vessels (Ref 2)—and the ASME Code for Pressure Piping (B31) (Ref 3)
- In Germany, the Technical Rules for Steam Boilers (TRD) (Ref 4), the Technical Rules for Pressure Vessels (AD-Rules) (Ref 5), and the Safety Standards of the Nuclear Safety Standards Commission (e.g., KTA 3201 and KTA 3211) (Ref 6)
- In France, the code for the Construction of Pressure Vessels (CODAP) (Ref 7), the Industrial Piping Code (CODETI) (Ref 8), and the Design and Construction Rules for Mechanical Components of Nuclear Power Plants (RCC-M and RCC-MR) (Ref 9, 10)
- In the United Kingdom, the standards of the British Standards Institution related to Boilers and Pressure Vessels (BS 5500) (Ref 11)

For a general or a component-specific design of pressure vessels and piping according to the technical codes and standards, it has to be demonstrated that all stresses resulting from mechanical and/or thermal as well as environmental loadings are within the allowable stress limits, and the usage factor developed by a fatigue analysis is well below the limiting value.

This article describes general concepts related to the evaluation of pressurized components without or with defects. The reliability of these concepts is demonstrated by tests of full-scale components with and without

defects under internal pressure loading and, in some cases, with an external bending load superimposed at the relevant temperatures.

Integrity Concept

The integrity concept for pressure vessels, piping, and tubing is demonstrated in the following example for pressurized components of nuclear power plants. Requirements for nuclear power plants take into account not only the stresses resulting from operational loads, but also extreme loading conditions that could be caused by accidents (for example, water hammer, aircraft crash, earthquake, and postulated pipe rupture). For such loads it must be demonstrated that, on the one hand, catastrophic failures of the components can be excluded, or, on the other hand, sequential damages will not lead to critical sequences for the plant.

The engineering of high-performance steam-generating plants and chemical plants (including design and construction, selection of material, manufacture, and quality assurance of ductile steel components and systems) has evolved over decades. The ongoing advances in science and technology have increased the standards for the construction and operation of the plants, especially concerning the safety against catastrophic failure of pressurized components and systems (Ref 12).

Safety principles and approaches, especially for nuclear power plants, vary somewhat from country to country. However, a generally accepted standard requires that the possibility of catastrophic failure from double-ended guillotine breaks (DEGB) must be completely excluded for pressure vessels and piping. A leak-before-break (LBB) assessment is used to show the likelihood of detectable crack sizes, which allows countermeasures to be taken before a large break occurs (Ref 13, 14, 15, 16, and 17).

Analyses of the operational behavior of high-quality pressurized components and systems as well as flaw and damage analyses have shown that proven and well-defined principles exist to reliably attain and maintain high quality. In Germany, these principles have been codified as the basis safety concept (BSC) and break preclusion concept (Ref 12). These concepts require that the quality of components must be guaranteed during the production process. Furthermore, the BSC requires the existence of redundancies to ensure that any possible deviation from optimization is sufficiently unimportant and unlikely to cause catastrophic failure. One redundancy of considerable importance relies on verification and validation using calculation codes and fracture mechanics as well as nondestructive testing technologies. Testing and evaluation are indispensable to provide the knowledge basis for the validation of codes and standard. The validation work is done mainly based on the results of the uniquely large full-scale quasi-static and dynamic testing of components with and without degraded sections to demonstrate their load-bearing capacity and their failure behavior, for example, Ref 18, 19, 20, 21, 22, 23, 24, 25, and 26.

Testing of Pressure Vessels, Piping, and Tubing

E. Roos, K.-H. Herter, and F. Otremba, Staatliche Materialpruefungsanstalt (MPA), University of Stuttgart

Fracture Mechanics Analysis

Fracture mechanics approaches are used to validate components with longitudinal cracks and with circumferential cracks and to analyze crack growth behavior under cyclic loading.

Components with Longitudinal Cracks

The well-known methods for the validation of pressurized components with longitudinal part-through or through-wall cracks (slots) were developed on the basis of a huge number of experimental results, for example, Ref 14, 27, and 28, 29. These semiempirical engineering methods (Fig. 1) require major plastic deformation to occur in the region around the crack tip. In one of the methods, the behavior of a material is expressed solely by the flow stress, $\sigma_{fl} = (R_{p0.2} + R_m)/2$ (yield strength and tensile strength dependent method). In another method, the toughness values of the material, expressed by the Charpy energy impact toughness (C_v) in the upper shelf, are also considered (toughness-dependent approach). In Fig. 2, the influence of different toughness values of the material used is shown with respect to the critical length of through-wall cracks (for the same pipe dimension and corresponding material strength data). In the tensile load (σ_t) range of interest, $\sigma_t/\sigma_{fl} \leq 0.4$, the critical crack length for through-wall cracks increases with increasing Charpy energy.

Theory	Net section collapse concept					
Criterion	Toughness		Flow stress	Toughness		Flow stress
Formula burst pressure $P_B =$	$\frac{2t \sigma_{fl}}{d_i M_p}$	$\frac{2}{\pi} \arccos \left(\exp \left[\frac{-3.1 C_V E \pi}{k \sigma_{fl}^2} \right] \right)$	$\frac{2t \sigma_{fl}}{d_i M_p}$	$\frac{2t \sigma_{fl}}{d_i M_p}$	$\frac{2}{\pi} \arccos \frac{-3.1 C_V E \pi}{(e k \sigma_{fl}^2)}$	$\frac{2t \sigma_{fl}}{d_i M_t}$

Factors

$$\sigma_f = (R_{p0.2} + R_m)/2$$

Validity limit

$$\frac{l^2}{d_i t} < 40$$

Fig. 1 Methods for calculating maximum loads for piping with longitudinal cracks. Note: $\exp [A] = e^A$

Fig. 2 Toughness-dependent critical crack length for longitudinal crack in a pipe with an outer diameter of 800 mm (31.5 in.), wall thickness of 47.2 mm (1.86 in.), internal pressure of 20 MPa (2.9 ksi), and a ratio of crack depth to wall thickness of 1.0

Components with Circumferential Cracks

For pressurized cylindrical components with circumferential part-through or through-wall cracks, there are several methods available to determine the failure load for the degraded component. In piping systems, the relevant loads are external bending moments in addition to the internal pressure. Consequently, the methods for the validation of pressurized components with circumferential defects take into account not only the internal pressure, but also, in particular, the external bending moment.

Plastic Limit Load Concept. For pipes made of ductile materials, local yielding in the region of the crack tips can propagate until, under limit load conditions, the entire pipe cross section is subjected to plastic deformation. If linear-elastic/ideal-plastic material behavior is assumed, the stress distribution over the cracked cross section is as shown in Fig. 3 (Ref 30).

	Circumferential part-through crack	Circumferential through-wall crack
Criterion	Flow stress	Flow stress
Bending moment, $M_b =$	$2 \sigma_f R^2 t (2 \sin \beta - f \sin \alpha)$	$2 \sigma_f R^2 t (2 \sin \beta - \sin \alpha)$
Factors	$\beta = \frac{\pi - f\alpha}{2} - \frac{\pi p_i R_i^2}{4 \sigma_f R t}$	$\beta = \frac{\pi - \alpha}{2} - \frac{\pi p_i R_i^2}{4 \sigma_f R t}$
	$\sigma_f = \frac{1}{2} (R_m + R_{p0.2})$	$\sigma_f = \frac{1}{2} (R_m + R_{p0.2})$
	$f = \frac{a}{t}$	
Scope of application	Thin-walled vessels	Thin-walled vessels

	Circumferential part-through crack	Circumferential through-wall crack
Criterion	Flow stress	Flow stress
Bending moment, $M_b =$	$2 \sigma_f R^2 t (2 \sin \beta - f \sin \alpha)$	$2 \sigma_f R^2 t (2 \sin \beta - \sin \alpha)$
Factors	$\beta = \frac{\pi - f\alpha}{2} - \frac{\pi p_i R_i^2}{4 \sigma_f R t}$	$\beta = \frac{\pi - \alpha}{2} - \frac{\pi p_i R_i^2}{4 \sigma_f R t}$
	$\sigma_f = \frac{1}{2} (R_m + R_{p0.2})$	$\sigma_f = \frac{1}{2} (R_m + R_{p0.2})$
	$f = \frac{a}{t}$	
Scope of application	Thin-walled vessels	Thin-walled vessels

Fig. 3 Procedure and designations for failure moment of pipes with circumferential cracks according to the plastic limit load concept, p_i , internal pressure; NA, neutral axis

The shift of the neutral axis within the cracked-pipe cross section can be determined according to the balance of the forces in axial direction, with the flow stress σ_{fI} acting uniformly on the tension side of the cross section up to the neutral axis and the compressive flow stress $-\sigma_{fI}$ acting on the compression side. To allow for work hardening of the material, the assumption made in Ref 30 is, for example, $\sigma_{fI} = 0.5 (R_{p0.2} + R_m)$.

Compared with experimental results, the calculated failure loads for degraded pipes under internal pressure and superimposed external bending moment are conservative when using the flow stress as $\sigma_f = (R_{p0.2} + R_m)/2.4$. A more conservative assessment of the failure loads or the corresponding critical crack sizes is achieved by using flow stress of $\sigma_f = R_{p0.2}$.

Two-Criteria Approach (R_6 -Method). This section describes a calculation method for which the strength values determined by tensile testing are required as material characteristics as well as fracture toughness values. This is demonstrated using the R_6 -method and the R -curve method. It is indeed possible in fracture mechanics procedures to include not only the strength but also the fracture mechanics characteristics of the material in the failure analysis.

The *R6*-method is based on the idea that, depending on the material characteristics, failure of a component can occur from brittle fracture up to full plastic deformation with the transition between these two extreme conditions assumed to be continuous.

The limit curve is defined as:

$$K_r = (1 - 0.14 L_r^2) [0.3 + 0.7 \exp(-0.65 L_r^6)]$$

and

$$L_r(\max) = \sigma_{fl}/R_{p0.2}$$

where:

$$\sigma_{fl} = (R_{p0.2} + R_m)/2$$

The loading parameters of the components are given by:

$$L_r = F/F_K$$

as the ratio of the actual load F to the plastic limit load F_K and

$$K_r = K_I/K_{Ic} = \sqrt{J/J_i}$$

as the ratio of the actual stress-intensity factor K_I as a function of crack size and load, and the fracture mechanics material characteristic K_{Ic} for linear-elastic and J_i for elastic-plastic conditions (Ref 31).

In the above equation, the J_i values are derived from the linear-elastic K_{Ic} values. According to this concept, onset of stable crack extension occurs when the load point developed by L_r and K_r is on the limit curve. Instability is derived from the load path, which forms a tangent to the limit curve, taking into consideration the stable crack extension. A schematic of the application of this procedure is shown in Fig. 4. For this purpose, the constant load F acting in L_r is normalized to the crack-length-dependent limit load $F_K(a + \Delta a)$ and in K_I the applied K_I value, calculated with regard to the crack growth ($K_I = a + \Delta a$) is converted to J and normalized with the crack resistance curve of the material, which is usually represented by the J_R -curve ($J_R + (\Delta a)$), (a = crack depth).

Fig. 4 Application of the two-criteria approach (*R6*-method, Rev 3)

R-Curve Method. The *R*-curve method combines the crack driving force calculated for the component with the material characteristics (evaluated from the crack resistance curve), especially the fracture mechanics characteristics. The crack driving force is calculated in terms of the J -integral by superposition of the elastic and the plastic part, which is, according to Ref 32, 33, and 34:

$$J = J_{el} + J_{pl}$$

with

$$J_{el} = \frac{K_I^2}{E}$$

and

$$J_{pl} = \sigma_0 \varepsilon_0 \alpha h_1 \left(\frac{a}{W}, n \right) \left(\frac{F}{F_K} \right)^{n+1}$$

where K_I is the linear elastic stress-intensity factor, which is available for different geometries and loading conditions in the literature, and σ_0 , ε_0 , α , and n are parameters developed by the Ramberg-Osgood approximation of the true stress-strain curve of the material. The load, F_K , is the plastic limit load, and $h_1(a/W, n)$ is a calibration function evaluated from finite element analyses. Both are given for different geometries (e.g., Ref 33, 34).

Initiation occurs at the load at which the crack driving force curve intersects the J_R -curve of the material at the initiation value J_i . The instability load is given by the curve of the crack driving force that forms a tangent to the J_R -curve (Fig. 5).

Fig. 5 Application of the R-curve method

Crack Growth Behavior under Cyclic Loading

For components operating under alternating loads, the crack growth under these loading conditions should be known. The crack growth in a component under alternating loads can be calculated from the loading amplitude, the number of cycles, and the crack geometry. From the crack size and the loading amplitude, the range of the stress-intensity factor $\Delta K/2$ can be calculated as follows:

$$\Delta K = f(\Delta\sigma, a, f)$$

The crack propagation rate da/dN for ΔK -values greater than the threshold value ΔK_{th} can be calculated by the well-known Paris law (Ref 35), which has the general form:

$$da/dN = C (\Delta K)^m$$

A typical curve of fatigue crack propagation is shown in Fig. 6. There are three regions within the curve. Region I may be referred to as the near-threshold area. Table 1 lists threshold values for selected materials. If ΔK is smaller than ΔK_{th} then da/dN is assumed to be zero. If ΔK is greater than the threshold value ΔK_{th} , there is a crack growth under alternating loads (region II). The Paris law is a good approach, especially for this region II. In region III, the crack propagation is very progressive. With increasing crack size, the stress intensity increases and the crack growth rate accelerates until the remaining ligament fails due to instability. Forman's equation (Ref 36) could describe the fatigue propagation behavior in regions II and III (see Fig. 6) and also consider the stress ratio. Forman's empirical approach is:

$$\frac{da}{dN} = \frac{C(\Delta K)^m}{(1-R)K_{Ic} - \Delta K}$$

where C , m , ΔK_{th} , and ΔK_{Ic} are material characteristics determined with standardized test methods (Ref 37). Environmental conditions and the load range ratio R affect these values. For example, the ASME Boiler and Pressure Vessel Code (Ref 1) contains some C and m values for different R -ratios of typical steels of light water reactors.

Table 1 Threshold stress-intensity values for selected materials

Material	ASTM designation	German designation	Threshold stress-intensity value ($R = 0.1$)	
			MPa \sqrt{m}	ksi $\sqrt{in.}$
Carbon steel plate	A 573	St 52-3	11.5	10.5
High-strength low-alloy steel	A 633, grade C	StE 355	9.3	8.5
High-strength low-alloy niobium-vanadium structural steel	A 572	StE 47	9.1	8.3
Titanium alloy Ti-6Al-4V	B 265	TiAl6V4	8.3	7.6
High-strength manganese carbon steel pressure vessel plate	A 455	16 Mn	8.1	7.4
Chromium steel	...	30CrMnSiNi2A	3.3	3.0
Aluminum alloys	2.5	2.3

Transferability of Mechanical Properties

The generally used material characteristics in the design phase and in safety analysis are the strength properties (yield strength and tensile strength) of the material. Normally, requirements are given in standards and material specifications for the materials used. Additionally, toughness properties are used for characterizing the material. Toughness properties are reduction of area and maximum elongation derived from the tensile test and Charpy V-notch impact energy.

Besides these properties for the assessment of critical crack sizes, fracture mechanics characteristics also have to be evaluated. The fracture mechanics properties very much depend on the material behavior.

Unlike the calculation of the failure loads by the plastic limit load equations, which are based on the strength values evaluated from the tensile test, the calculations using fracture mechanics procedures are more distinguishing because the crack initiation as well as the maximum or instability load can be determined. The indispensable premise is the transferability of the fracture mechanics characteristics from small-scale

(laboratory) specimens to the components. This could be checked by the parameter that describes the event of the crack initiation with the same value for the specimen and for the component as well.

Numerous large-scale tests were conducted at MPA Stuttgart to investigate this issue of transferability (Ref 38, 39, and 40). The crack resistance curves were evaluated using large-scale specimens. Crack initiation values were consequently determined analogous to small-scale specimen tests. The results were verified for the effective crack initiation value J_i . The evaluation of this transferable fracture mechanics materials characteristic is only given in European standards ESIS P1-92 (Ref 41) and ESIS P2-92 (Ref 42).

The transferability, however, cannot be validated for all crack resistance curves (Ref 43). Figure 7 shows crack resistance curves determined from large specimens of different geometry and size made of the ferritic material 22NiMoCr-3-7 mod. The test temperature was 80 °C (175 °F); that is, the tests were performed at the onset of the upper-shelf regime of the C_v - T curve. The crack initiation values J_i of all specimens fall within a narrow scatterband, whereas the crack resistance curves demonstrate a significantly divergent behavior with increasing crack growth Δa . This is due to the distinct difference in the degree of multiaxiality of the stress state because of the different geometry and size of the specimens. The multiaxiality of the stress state could be quantified with coefficient of triaxiality (Ref 43):

$$q = \sigma_e / (\sqrt{3} \sigma_m)$$

where σ_e is the von Mises equivalent stress and $\sigma_m = (\sigma_1 + \sigma_2 + \sigma_3)/3$.

Fig. 7 Influence of stress triaxiality on J_R -curves above initiation J_I . Material: 22NiMoCr-3-7 mod; test temperature 80 °C (175 °F); ratio of crack length (a) to specimen width (W), 0.5

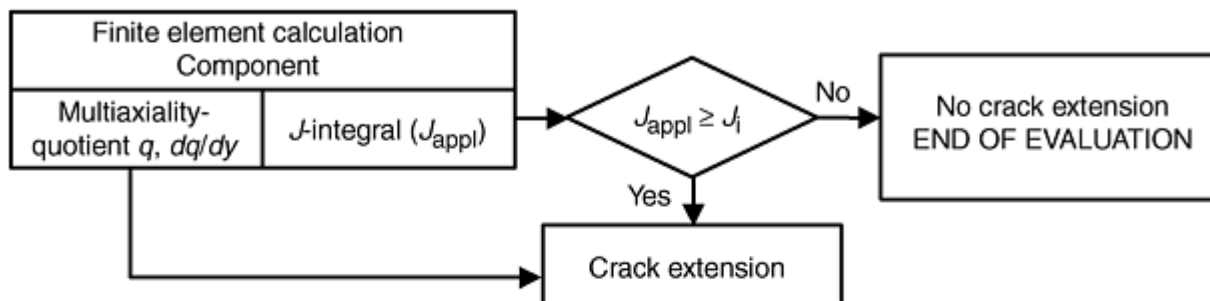

Therefore, crack resistance curves cannot be regarded as generally valid material characteristics, but instead are specimen- or component-specific characteristics. The failure process after crack initiation in terms of stable crack extension is very strongly dependent on and controlled by the stress state, especially by the multiaxiality of the stress state.

The transferability of the J_R -curve from a laboratory specimen to a component and the use of the J_R -curve within a fracture mechanics concept to calculate the failure behavior (e.g., instability load) is only possible if the distribution of q values across the ligament is comparable. The process of evaluating the initiation and instability load is represented in Fig. 8.

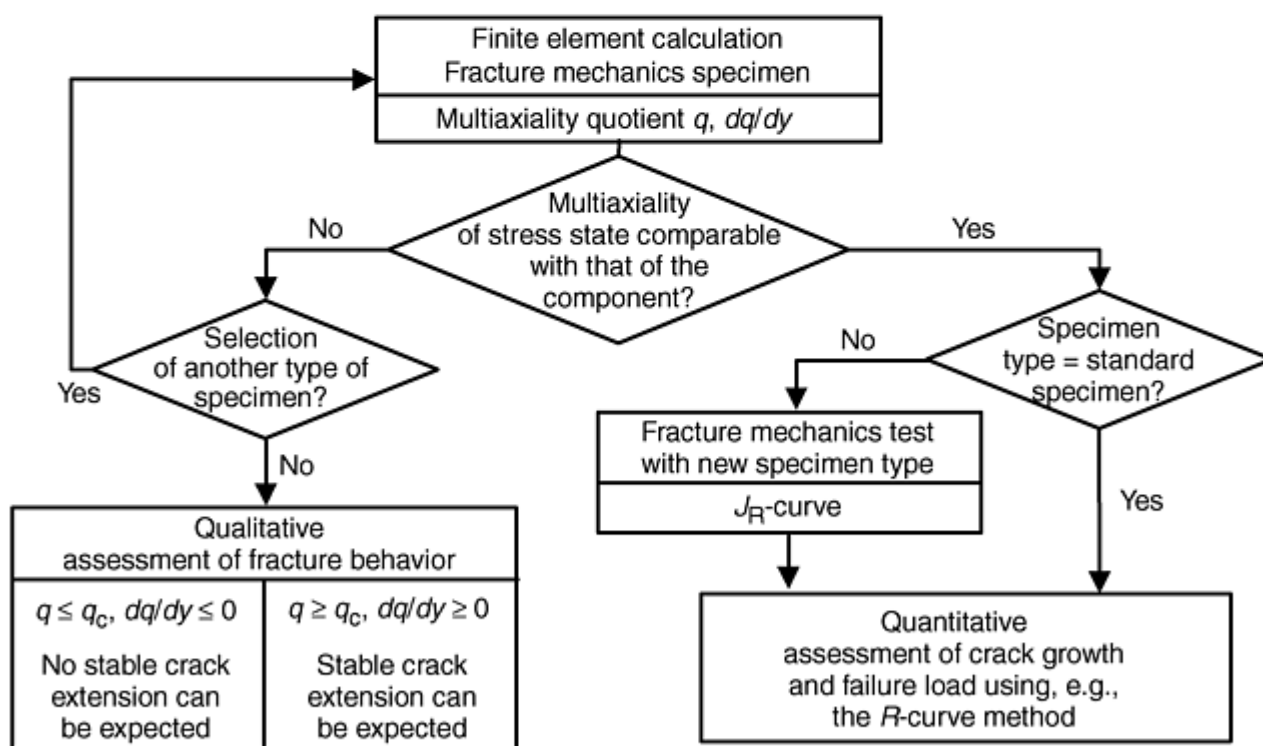

1 Material characterization

2 Evaluation of crack initiation $J_{appI} = J_I$

3 Evaluation of ductile crack growth $J_{appI} \geq J_I$

Multiaxiality quotient $q : q = f(\text{geometry, flaw depth, load, material})$
 Gradient of $q : dq/dy = f(\text{geometry, flaw depth, load, material})$
 Crack initiation value $J_I : J_I = f(\text{material})$
 Crack resistance curve : J_R -curve = $f(\text{geometry, flaw depth, load, material})$
 Critical q -value : $q_c \cong 0.3$ (for steel)

Fig. 8 Flow chart for the evaluation of degraded components

The quality of analytical and numerical approaches is highly dependent on the transferability of data developed by small-scale laboratory tests to the full-scale components. Within the scope of research programs performed by MPA Stuttgart, large-scale specimen and full-scale components with dimensions similar to the original components in power plants were investigated to demonstrate the transferability of material data. The following section describes some specific selected large-scale and full-scale tests and their results relevant to the topic of this article.

Testing of Pressure Vessels, Piping, and Tubing

E. Roos, K.-H. Herter, and F. Otremba, Staatliche Materialprüfungsanstalt (MPA), University of Stuttgart

Full-Scale Testing

The overall objective for full-scale testing of pressure vessels, piping, and tubing is the proof of integrity and the leak-before-break behavior. Full-scale testing also provides verification and validation of structural analyses and fracture mechanics calculations. In the following section, some full-scale testing facilities are described briefly as an introduction on general capabilities of the facilities. This is followed by a description of typical test results for various applications.

Requirements and Test Facilities

Quasi-Static (Monotonic Increase) Internal Pressure Loading (Burst Test). Straight pipe sections with an internal diameter of 700 mm (28 in.) and a wall thickness of 47.5 mm (1.87 in.) and closed on both ends were used as full-scale test components (Ref 44, 45, and 46). Regarding internal pressure and temperature, the test conditions were related to the operating conditions of pressurized water reactors. Water was mainly used as the pressurizing medium and had already been filled in the pipe during the heating process. The internal pressure was controlled in parallel with the heating temperature so that no steam could develop inside the pipes (for safety). After reaching the test temperature, the pressure was raised monotonically by further injection of water. In order to control the time-dependent decay of pressure during the fracture or failure process, the test could also be carried out under main steam line conditions or those similar to the conditions of boiling water reactors. Therefore, the test facility was additionally designed for the use of air as a compressible pressurizing medium in some tests.

Quasi-Static (Monotonic Increase) External Loading. In the case of straight pipes, different types of test equipment were used for static external bending moment loading:

- A four-point bending device with a capacity of 10 MN · m for pipe dimensions up to nominal diameter 800 mm (31.5 in.) and 50 mm (2 in.) wall thickness (Ref 47) and with a capacity of 3 MN · m for pipe

dimensions up to nominal diameter 400 mm (15.75 in.) and 15 mm (0.6 in.) wall thickness (Ref 48). To guarantee constant loading conditions in the phase of crack initiation and crack propagation, as well as to realize a testing system with high stored energy, air was used as a compressible pressurizing medium in the hydraulic actuators and as a reservoir in the test pipes.

- A constant-moment loading bending device with a capacity of 2 MN · m bending for pipe dimensions up to nominal diameter 300 mm (11.8 in.) and 35 mm (1.4 in.) wall thickness (Fig. 9), and with a capacity of 40 kN · m for pipe dimensions up to nominal diameter 80 mm (3.1 in.) and 10 mm (0.4 in.) wall thickness

The test temperature was ambient (room) temperature up to operational temperature (e.g., 300 °C, or 570 °F). The pipes were loaded under specified constant internal pressure and a superimposed monotonic increasing external bending moment.

Fig. 9 Constant moment loading bending device with capacity of 2 MN · m. Inset shows instrumented pipe after the test

In the case of elbows (pipe bends) depending on the loading mode (in-plane opening or closing, out-of-plane) different types of test equipment were used for quasi-static external bending moment loading:

- Moment loading for the elbows with nominal diameter 400 mm (15.75 in.) and 30 mm (1.2 in.) wall thickness was realized by transverse forces at the end of long pipe sections adjacent to the elbows (Ref 49). For the in-plane opening mode, the load was imposed by a 15 MN horizontal-testing device, which exerted a force combination of normal and lateral force on the pipe together with a bending moment; however, the long pipe leg meant that the bending moment imposed the dominant stress in the elbow

(Fig. 10). A similar test setup was used for the in-plane closing mode. Out-of-plane loading was realized by a combined torsional moment and a lateral force. The testing device was set up horizontally (Fig. 11). A hydraulic cylinder was imposed vertically at the long end of the two adjacent straight pipe sections of different length. A special fixpoint had to balance the forces resulting from the applied transverse forces of the loading point. In all the different loading cases, the elbow mid-sections were dominantly stressed by moment loading.

- Elbows with nominal diameter 800 mm (31.5 in.) and 50 mm (2 in.) wall thickness and degraded by longitudinal flaws on both bend flanks were loaded by constant internal pressure and superimposed bending moment with in-plane closing mode (Ref 50, 51, 52) (Fig. 12).

Dynamic Loading (High-Loading-Rate Tensile Testing). For high-loading-rate tensile testing, several concepts that differ mainly in the function of the testing equipment and especially in the attained load and maximum velocity as well as in the velocity history can be used for dynamic tensile tests. Hydraulic and hydropneumatic testing machines cover the range up to a maximum velocity of about 12 m/s (39 ft/s). Cable-loaded testing facilities or machines driven by a propellant charge attain 50 to 60 m/s (165–200 ft/s), whereas on rotary impact machines the velocity goes up to 80 m/s (260 ft/s) (Fig. 13). The velocity of hydropneumatic, cable-loaded testing machines and rotary impact machines is nearly constant during the test procedure, and full loading is applied instantaneously. The machines driven by a propellant charge attain the maximum velocity after a certain stroke, depending on the type and quantity of the propellant charge used, on the volume of the combustion chamber, and on the masses to be accelerated. This peculiarity allows a more realistic simulation of actual dynamic loading cases. The mode of operation of a propellant-driven 12 MN high-loading-rate tensile testing machine (Fig. 14) is shown schematically in Fig. 15 together with an idealized energy diagram. The energy that is released on combustion of the propellant divides into acceleration energy and deformation energy until fracture of the test specimen occurs. Subsequent to the fracture, the remaining energy of the accelerated components is absorbed by deformation of an aluminum damping element.

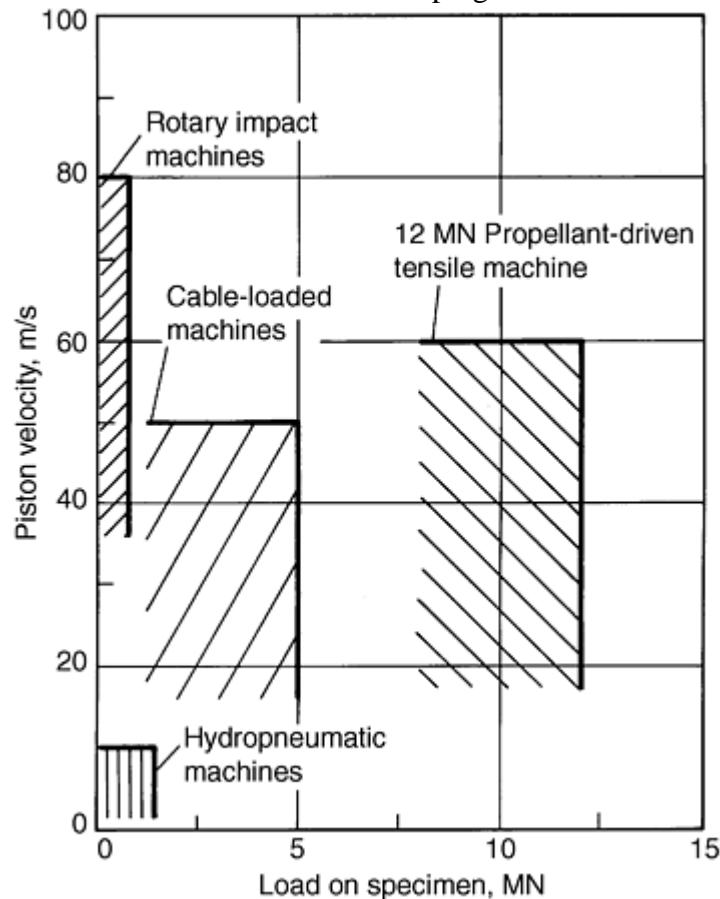

Fig. 13 Load capabilities of different high loading rate tensile testing equipment

Fig. 14 High-loading-rate tensile testing machine (12 MN capacity)

Fig. 15 Test configuration and energy diagram for high-loading-rate propellant-driven tensile testing machines

Tests were carried out on unwelded and welded wide plate specimens (e.g., 960 mm, or 37.8 in., long; 500 mm, or 19.7 in., wide; and 40 mm, or 1.6 in., thick) with and without different flaw positions as well as for pipe sections (e.g., 406 mm, or 16 in., outer diameter and 12.5 mm, or 0.5 in., wall thickness; 168 mm, or 6.6 in., outer diameter and 4.5 mm, or 0.18 in., wall thickness; or 220 mm, or 8.6 in., outer diameter and 16 mm, or 0.6 in., wall thickness) with and without circumferential cracks. Austenitic and ferritic materials were investigated (Ref 53, 54).

Cyclic/Repeated Loading. Different types of test equipment were used for cyclic/repeated external bending moment loading on straight pipes and elbows:

- Bending device for resonance excitation in which fast-alternating external bending loads with high acceleration can be generated (Ref 55) (Fig. 16).
- 12 MN · m bending device for low-cycle, load-controlled, bending loads for pipe dimensions up to 800 mm (31.5 in.) nominal diameter and 50 mm (2 in.) wall thickness (Ref 55).
- The deformation and failure behavior of thick-walled elbows made of austenitic material was investigated in Ref 56. The dimensions of the elbow were 108 mm (4.25 in.) outer diameter and 12 mm (0.47 in.) wall thickness. The bend angles were 60° and 90°.

Numerous piping experiments have also been performed at the German Heissdampfreaktor (HDR) Test Facility (Ref 57). It was built in the period 1965 to 1969 for a prototype superheated steam reactor, but was shut down in 1971 after only 2000 h of operation. After extensive decommissioning and conversion work, it was used from 1974 until 1991 by the HDR Safety Project of the Kernforschungszentrum Karlsruhe to perform vibrational/seismic, thermal hydraulic, blowdown, and other experiments related to the safety and design of nuclear power plants. The load-bearing capacity margins of a piping system with different pipe dimensions and degraded pipe sections under operating conditions were demonstrated for earthquake-type loads (Ref 58). Experiments were also performed to demonstrate the behavior of a full-size feedwater piping system under operational conditions (Ref 59) (Fig. 17).

Fig. 16 Resonance bending device. Dimensions are in millimeters.

Fig. 17 Reactor pressure vessel (RPV) piping system with degraded elbow

High-Temperature Loading. A pipe component test (700 mm, or 27.6 in., inside diameter and 47 mm, or 1.9 in., wall thickness) to verify the failure behavior postulated from small-specimen tests was carried out to simulate specific accident conditions (Ref 60). Under constant internal pressure of 16.3 MPa (2.4 ksi) using air as pressurizing medium, the pipe was heated up to about 700 °C (1300 °F) to determine the time to failure (Fig. 18).

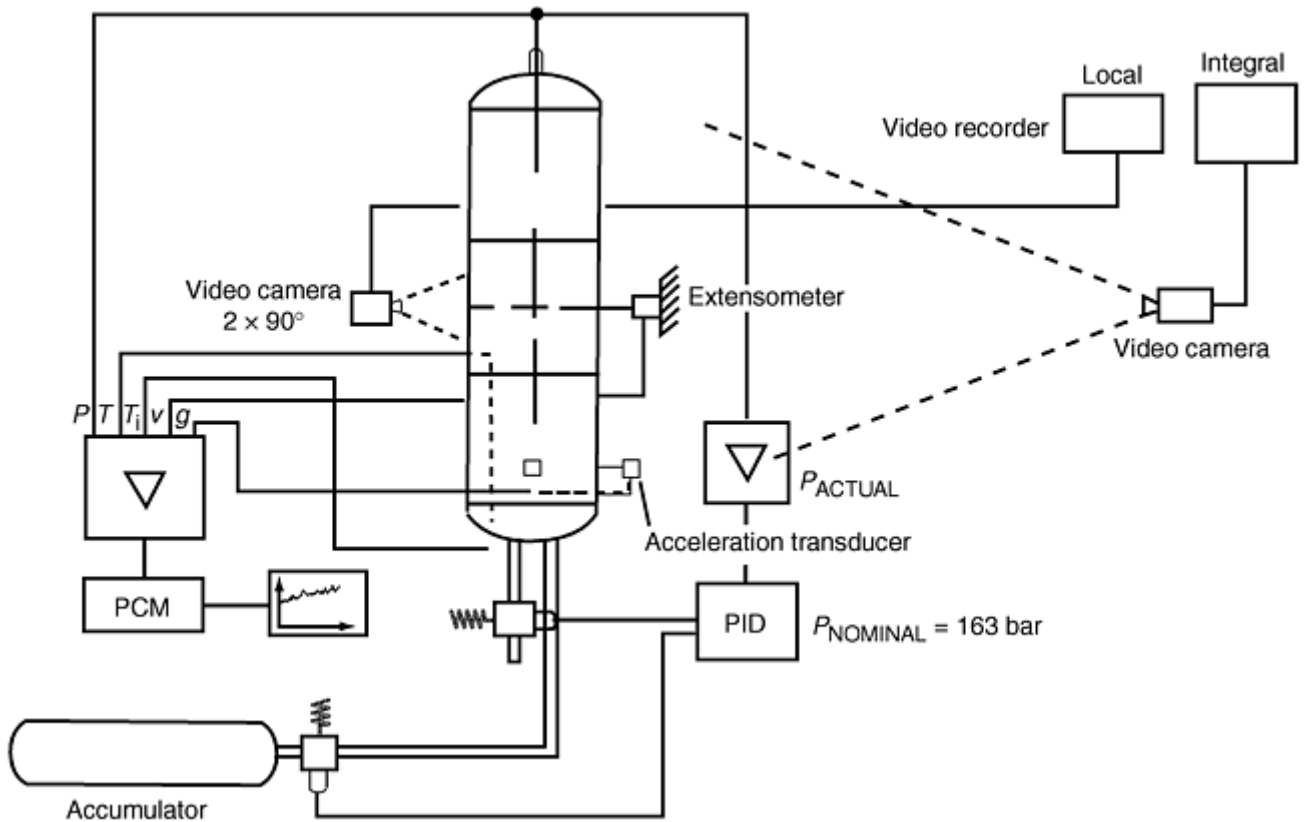

Fig. 18 Test assembly and measurement data collection for testing pipe components under high-temperature loading. PCM, pulse code modular (data acquisition unit); PID, pressure controller; p , pressure; T , outside temperature; v , displacement; g , acceleration; T_i , inside temperature

Creep damage had been observed in elbows (235 mm, or 9.3 in., outer diameter and 25 and 30 mm, or 1 and 1.2 in., wall thickness) in steam piping of fossil-fired power plants. It was assumed that the reasons for this damage were additional forces and moments and also geometrical effects (Ref 61). For that reason, the creep damage and failure behavior of a low-alloy 0.6% Mo steel elbow and a high-alloy 12% Cr steel elbow under internal pressure and a superimposed static bending moment at 550 °C (1000 °F) were investigated in experiments. The test configuration is shown in Fig. 19.

Fig. 19 Test configuration for evaluating long-term creep failure behavior of pipe elbows. F_0 , external static force; R , pipe elbow radius; L , length of the straight ends of the elbow

During all the tests, the variation with time of internal pressure, bending moment, crack opening displacement, crack extension, bending deflection (load-line displacement, strain measurement), and ovalization should be measured to monitor the loading conditions as well as the deformation behavior. Based on the results of the measurements, a comparison between experimental and numerical calculated data is possible. That is why a detailed plan of instrumentation before the tests was developed. In all of the tests mentioned above, the requirements on data acquisition systems and measuring parameters throughout the tests required high-performance data acquisition units.

Some of the specific and interesting test results achieved by running experiments with the above-mentioned test facilities are discussed in the following sections.

Examples of Test Results

Longitudinally Cracked Components. Figure 20 is an example of catastrophic failure from a full-scale internal pressure test (using air as the pressurizing medium) of a feedwater vessel. For crack initiation, a brittle disk was welded in the feedwater tank with a longitudinal notch to initiate the crack (Ref 45). The vessel was completely destroyed because of the compressibility of air. This test shows the influence of stored energy on the failure behavior.

Fig. 20 Catastrophic failure at internal pressure of a feedwater tank

Table 2 summarizes test results for straight pipe with longitudinal defects. The pipes are made of ferritic material having different toughness values, and the failure loads are calculated on the safe side by means of the toughness-dependent approximation technique (Ref 14, 45) (Fig. 21).

Table 2 Test results for longitudinally cracked piping under internal pressure loading

(a) Pipe outer diameter: 800 mm (31.5 in.), wall thickness: 47.2 mm (1.86 in.)

Fig. 21 Test results for longitudinally cracked straight pipes (outer diameter, 800 mm, or 31.5 in.; wall thickness, 47.2 mm, or 1.86 in.) under internal pressure (burst test). R_e , yield strength; R_m , tensile strength; a , crack depth; s , wall thickness

Tests were also performed on large-diameter pipe elbows and pipe T-joints under internal pressure and superimposed quasi-static external bending moment loading.

Circumferentially Cracked Components (Straight Pipes). The experimental results of more than 330 tests with circumferentially cracked pipes with both austenitic and ferritic material are shown in Fig. 22 as normalized experimental moment versus the normalized crack length. It has to be supposed by the test facilities that in the cracked cross section of the pipes the loading condition is constant, especially in moment loading (Fig. 23).

Fig. 22 Results of experimental moment versus crack length for tests for circumferentially cracked pipes (333 full-scale pipe tests)

Fig. 23 Constant-moment loading for straight pipes

With the engineering methods (plastic limit load calculation) used and an appropriate flow stress, the experimental maximum moment can be estimated with some accuracy if the expression to calculate the flow stress is adjusted to experimental results. This is demonstrated in Fig. 24 using plastic limit load calculations based on different flow stress assumptions in comparison with experimental results. More precise calculations of the failure course (for example, initiation and instability loads) are possible with the fracture mechanics approximation methods like the two criteria approach or the R -curve method. The results based on J_i demonstrate the transferability of this initiation value to components. The greater differences in the calculated results of the failure load depend on the J_R -curve that could be used only if the triaxiality of the stress state in the ligament in front of the crack tip is comparable to the specimen from which the J_R -curve is evaluated and the component. This is shown in Fig. 25 and 26.

Fig. 24 Comparison of experimental and calculated loads versus the crack length for pipe with outer diameter of 331 mm (13 in.) and wall thickness of 32 mm (1.3 in.)

Fig. 25 Comparison of experimental and calculated loads versus the crack length for pipe with outer diameter 800 mm (31.5 in.), wall thickness 50 mm (2 in.); ferritic material, through-wall crack, $\sigma_{fl} = (R_{p0.2} + R_m)/2.4$

Fig. 26 Comparison of experimental and calculated loads versus the crack length for pipe with outer diameter 800 mm (31.5 in.), wall thickness 50 mm (2 in.); ferritic material, part-through-wall crack, $\sigma_{II} = (R_{p0.2} + R_m)/2.4$

Figure 27 shows the distribution of the coefficient of triaxiality q across the ligament of a fracture mechanics compact tension (CT) specimen compared with q values calculated for a circumferentially cracked pipe. This comparison shows that the transferability of the crack resistance curve determined on a CT specimen to the pipe with circumferential crack is not direct. However, because of the much steeper q gradients and the higher q values in the investigated pipes, it is not surprising to be on the safe side when calculating the failure load of the pipes. In all cases, however, this has to be proven.

Fig. 27 Distribution of q value across the ligament at the plane of symmetry of a compact tension (CT) specimen and a circumferentially cracked pipe

Based on an extensive program of high-speed tensile tests with large-diameter pipes (406 mm, or 16 in., outer diameter; 12.5 mm, or 0.5 in., wall thickness; material with low upper-shelf Charpy impact energy), no indications of unfavorable material behavior resulting from the dynamic loading conditions up to transients of $\dot{\epsilon} = 6/s$ (Fig. 28, 29) were found. The tests show increasing loadability with increasing strain rate.

Fig. 28 Dependence of load-bearing capacity on strain rate for large-diameter pipes at room temperature

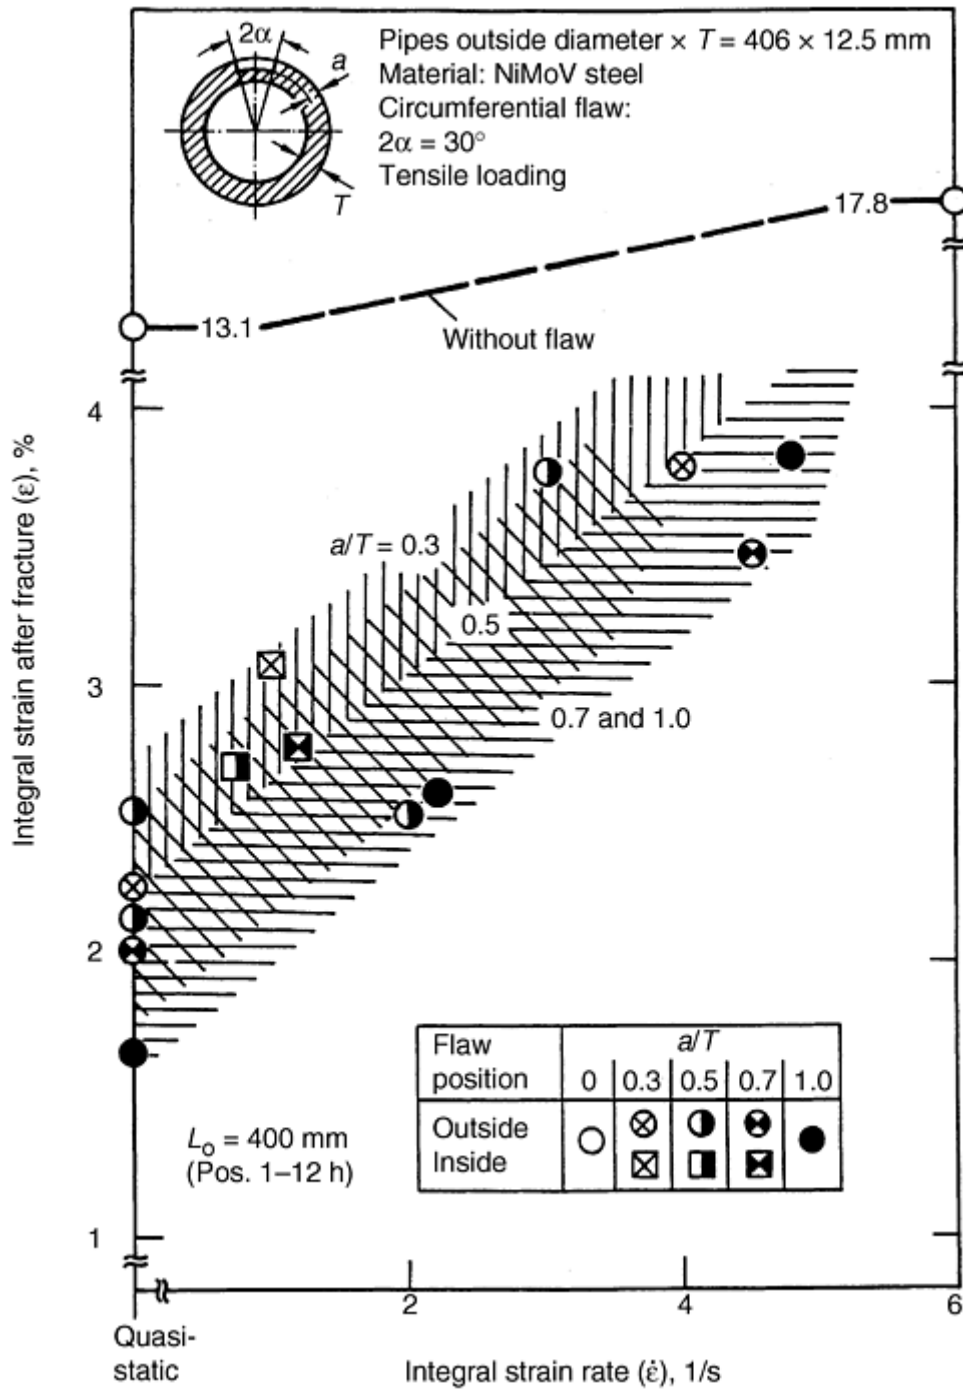

Fig. 29 Dependence of maximum elongation on strain rate for large-diameter pipes at room temperature

Test Results of Piping Systems. Incipient cracks were generated on the inner surface around the bend flanks by cyclic bending (Ref 59). In various phases of the test characterized by sinoidal and sawtooth modes of loading and different load frequencies, the cracks were further extended. At the end of the phases of cyclic testing a macrocrack was embedded in a crack field. In the final load test with monotonously rising bending moment, the pipe bend failed by leakage (Fig. 30).

Fig. 30 Multiple crack field pipe elbow

For a piping system (see Fig. 17) under real loading conditions and for a real loading history, the calculated number of load cycles up to failure based on the crack propagation law of ASME XI (wet conditions) was compared with the experimental values (Fig. 31). The actual number of cycles up to failure of the piping system was underestimated (estimated on the safe side) by all crack propagation analyses carried out.

Fig. 31 Measured and calculated number of load cycles to failure for a piping system under real loading conditions. FE, finite element

Test Results of High-Temperature Tests. The material behavior of components in the primary circuit of pressurized water reactors under conditions beyond design criteria (that is, temperature increases considerably and system pressure reaches a maximum level) was examined by means of a component test and small-scale specimen tests (Ref 60). A comparison of the heating test of small-scale specimens (without hold time) with the component test is shown in Fig. 32 as well as the relationship between temperature to failure and time to rupture.

Fig. 32 Failure temperature versus time to rupture for components in a pressurized water reactor. t_{BH} , time to failure of small specimen; t_B , time to failure of small specimen without heating time

For the long-term creep tests on elbows (Ref 61), the comparison of calculated and measured local creep deformation is shown in Fig. 33. It could be demonstrated that realistic stresses and strains can be expected if the constants of the creep law within the inelastic finite element calculation had been fitted using data from uniaxial creep specimen of the same material heat as the component under consideration.

Fig. 33 Comparison of calculated and experimental local creep deformation for pipe elbows. FE, finite element

Testing of Pressure Vessels, Piping, and Tubing

E. Roos, K.-H. Herter, and F. Otremba, Staatliche Materialprüfungsanstalt (MPA), University of Stuttgart

Summary

The safe and reliable operation of systems including pressure vessels, piping, and tubing with high stored energies has to be guaranteed under all loading conditions. The basis for this are design rules and material

requirements, given in applicable standards. However, the failure behavior of these components cannot be assessed on this basis; such assessment is only possible using fracture mechanics concepts. These concepts can be verified using numerous tests on straight pressurized pipes, elbows, T-branches, and nozzles with different dimensions and made of different materials. The tests have to be conducted with regard to the loading and environmental conditions and the measuring devices have to be adjusted to the expected damage mechanism. It can be demonstrated that the assessment of the failure behavior is in good agreement with the experimental results if the fracture mechanics procedures on the basis of the fracture toughness K_{Ic} in the linear-elastic regime and of the initiation value J_i in the elastic-plastic regime are used. The calculational procedures based on strength values of the material lead also to results to the safe side, if the procedure is fitted to the experiments that have to cover the boundary conditions under consideration.

Residual Stress Measurements

Clayton O. Ruud, The Pennsylvania State University

Introduction

MANY METHODS and techniques have been proposed for the measurement of residual stresses. A classification of techniques is provided in *Welding, Brazing, and Soldering*, Volume 6 of the *ASM Handbook* (Ref 1), and this list is shown in Table 1. However, only a few of these techniques may be applied generally in practice on items ranging from small components, such as bearing balls and rods, to very large structures, such as bridges and aircraft. For some of the methods described herein, the component in which residual stresses are to be measured must be brought to the measuring instrument. For others, the measurement devices are portable and may be brought to the component (Fig. 1). In some cases it may be feasible to remove a section from the component and bring that section to the residual stress measuring device. However, great caution must be observed in sectioning a component, because it will change the stress field by relieving and/or inducing stresses. The relieved stresses must be accounted for by the assumptions and reconstruction methods described in the section "Stress Field Condition Assumptions and Reconstruction" in this article.

Table 1 Classification of techniques for measuring residual stress

A-1 Stress relaxation techniques using electric and mechanical strain gages

- **Plate**
 - **Section technique using electric resistance strain gages**
 - **Gunnert technique**
 - **Mathar-Soete drilling technique**
 - **Stablein successive milling technique**
- **Solid cylinders and tubes**
 - **Heyn-Bauer successive machining technique**
 - **Mesnager-Sachs boring-out technique**
- **Three-dimensional solids**
 - **Gunnert drilling technique**
 - **Rosenthal-Norton sectioning technique**

A-2 Stress relaxation techniques using apparatus other than electric and mechanical strain gages

- **Grid system-dividing technique**
- **Brittle coating-drilling technique**
- **Photoelastic coating-drilling technique**

B X-ray diffraction technique

- **X-ray film technique**
- **X-ray diffractometer technique**

C Techniques using stress-sensitive properties

- **Ultrasonic techniques**
 - **Polarized ultrasonic wave technique**
 - **Ultrasonic attenuation technique**
 - **Hardness techniques**

D Cracking techniques

- **Hydrogen-induced cracking technique**
- **Stress-corrosion cracking technique**

Fig. 1 Measurement of residual stresses on a gas pipeline in the field using a portable x-ray diffraction instrument. (Courtesy of Proto Manufacturing)

Any manufacturing process that changes the shape of a solid, or where severe temperature gradients exist during the process, causes residual stresses. These processes include the preparation of a specimen for testing as might be performed for other tests described in this Volume. Fatigue testing is especially sensitive to surface residual stresses, and specimens must be prepared with known, consistent residual stress conditions.

By their very nature, processes that change the shape of a solid cause nonuniform plastic deformation in the solid, which leads to residual stresses. These processes include forging, rolling, drawing, machining, and so on. Also, processes that produce high thermal gradients in a solid often lead to residual stresses. These processes include quenching, casting, welding, and so forth. Further, processes that induce localized phase changes produce residual stresses. These processes include martensitic hardening.

The residual stresses caused by manufacturing processes usually show very steep residual stress to distance gradients as illustrated in Fig. 2. The steep gradients typical of residual stresses induced by manufacturing processes may be cited as the cause of disagreement between residual stress measurements made by stress relaxation techniques and those made by x-ray diffraction (XRD) techniques. The disagreement is nearly always because the volume of the component in which the stress is measured is not the same in the two

methods, and, thus, a different portion of the stress gradient is measured by each. Ruud et al. (Ref 2) showed that the hole drilling method resulted in measured stresses approaching those measured at the surface by XRD when the hole drilling results were extrapolated to the surface. Further, because of the steep gradients, stress measurements must be performed at many locations in the manufactured solid in order to establish the magnitude and distribution of the stress field of interest. Many researchers in XRD residual stress techniques have focused on enhancing the accuracy of residual stress measurement and have ignored the fact that from a practical standpoint, tens to hundreds of stress measurements are needed to define the stress field of interest. Thus, many of the residual stress measurement techniques require too much time to perform and, thus, are impractical. These include some of the techniques developed for XRD, strain gaging, and other methods. Measurement times on the order of a second are available with XRD and some other methods, and automated stress mapping has been performed with such techniques (Ref 3). Another concern in the measurement of residual stresses in manufactured components is that the area or volume over which the stresses are resolved must often be on the order of 1 mm (0.04 in.) or less. This is because the residual stress gradients are usually quite steep, and measurement resolution larger than this tends to average the stresses to such an extent that the high stresses are not detected.

$$\left(\frac{d\sigma}{dx} > \frac{200 \text{ MPa}}{\text{mm}} \right)$$

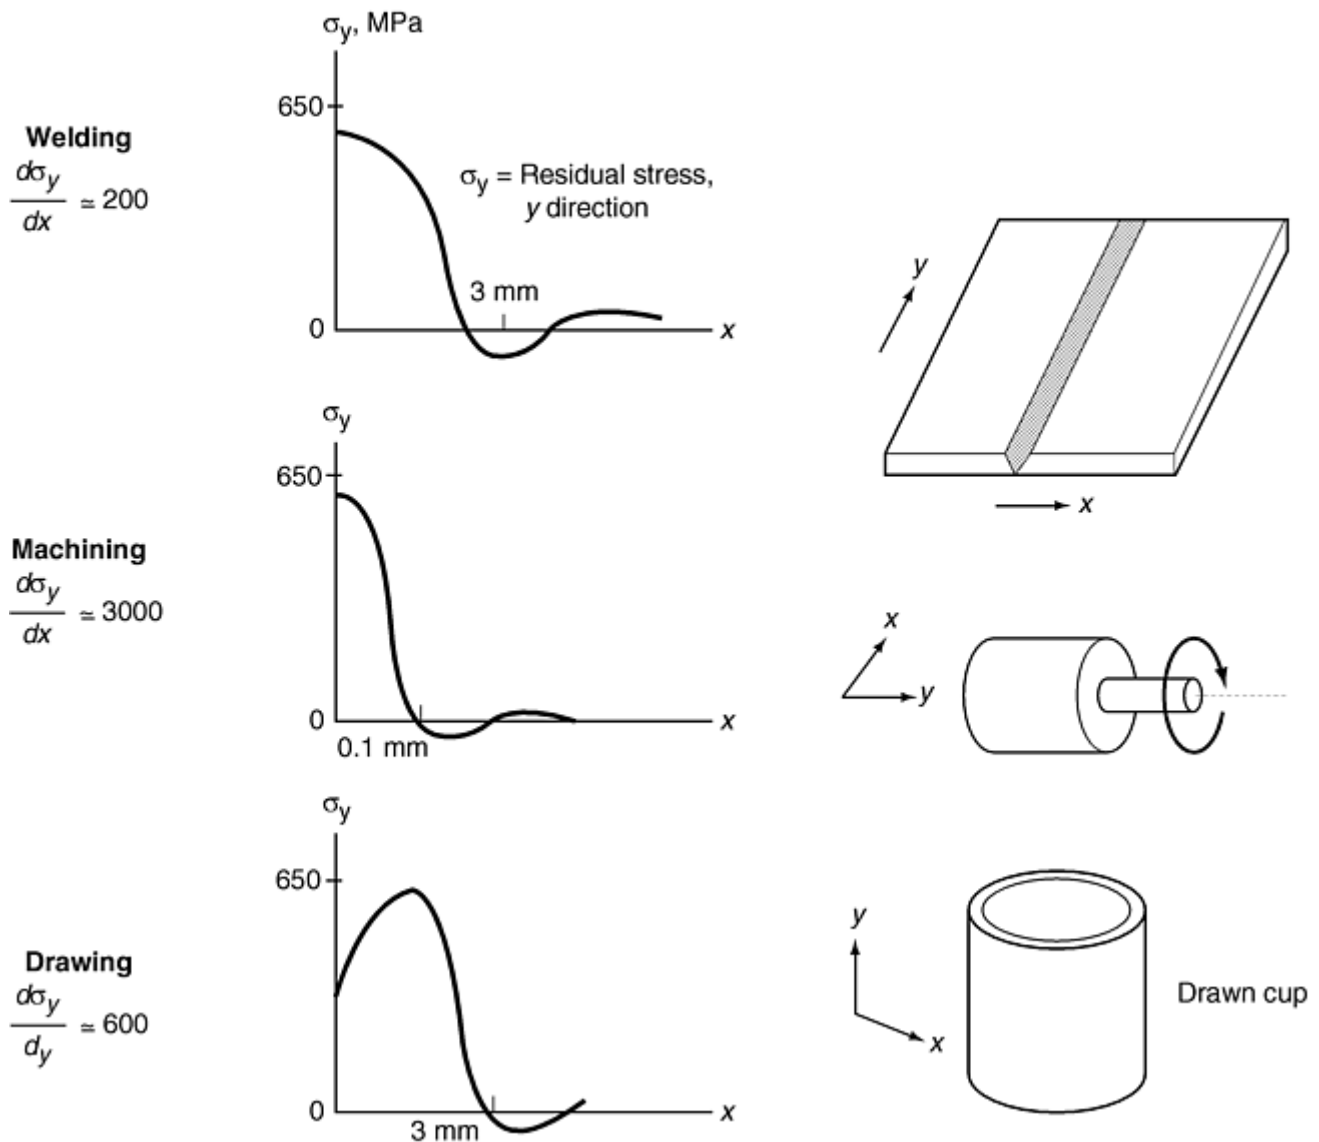

Fig. 2 The residual stress magnitudes and distributions typical of a 650 MPa yield strength metal. For example, in machining it is not unusual for the residual stress at the surface of the machined part to be near the yield strength of the cold worked material.

Some characteristics of metals that can cause error in residual stress measurement by the methods described herein include phase composition, plastic strain, grain size, crystallographic texture, and others. For example, in a mixed ferrite/austenitic structure, the residual stresses in the ferrite are invariably different than those in the austenite (Table 2). Also, Wimpory et al. (Ref 4) described the influence of varying amounts of cementite in a ferrite matrix. The possibility of one or more of these microstructural characteristics causing error in residual stress measurements performed by the methods described herein should be assessed by an expert in the method selected. Details of the errors and their causes are not discussed in this article.

Table 2 Sample of residual stress readings from a 316 stainless steel pipe weldment

Distance from the weld fusion line		Stress ^(a)			
		In austenite		In ferrite	
mm	in.	MPa	ksi	MPa	ksi
1.02	0.04	-145	-21	-315	-46
1.80	0.07	-130	-19	-460	-67
2.80	0.11	-110	-16	-425	-62
3.80	0.15	-115	-17	-450	-65

(a) The precision of these measurement was ± 3.0 ksi. Note that the ferrite places tensile stresses on the lattice of the austenite while the austenite tends to compress the ferrite. Therefore, the more compressive the stress in the ferrite, the less compressive the stress in the austenite.

The subsequent sections of this article discuss and describe the following:

- The need for measurement—the problem the engineer or metallurgist is trying to solve by obtaining information about the residual stress field
- The nature of the residual stress fields in metals—examples of the magnitudes and distributions
- The strain basis for residual stress measurements—elastic strain measured, not stresses
- The destructive methods of residual stress measurement. These procedures are all based on sectioning or removal of material to cause a redistribution of the residual stress, which is measured as a strain change. These include most of the techniques listed under A-1, A-2, and D in Table 1.
- The semidestructive methods of residual stress measurement. These procedures are based on the same principle as the destructive methods or on the perturbation of the residual stress field by other means, but the extent of deformation is very small and usually repairable with little or no degradation in the usefulness of the component. Semidestructive methods include some of the drilling and trepanning techniques under A-1 and A-2, as well as the hardness techniques under C in Table 1.
- The nondestructive methods of residual stress measurement. These procedures do not permanently disturb the residual stress field but directly measure the atomic lattice strain caused by the stress or measure some physical property perturbed by the lattice strain. The nondestructive methods include the techniques listed under B as well as ultrasonic methods, under C, and others to be described.

The purpose of this article is to provide an insight into the principles, practice, and limitations of residual stress measurement procedures for metals. The article is not meant to provide sufficient detail for the performance of the various methods described, but references are cited where such procedural details may be found, for example, Gunnert (Ref 5), Moore and Evans (Ref 6), Constantinescu and Ballard (Ref 7), the SAE Handbook Supplement (Ref 8), and Ref 9.

Residual Stress Measurements

Clayton O. Ruud, The Pennsylvania State University

Need for Residual Stress Measurements

Before committing to measuring residual stresses in some component or workpiece, the engineer or metallurgist must be sure that the reason for the need for measurement is clearly understood. The major reasons that residual stresses are of concern are these:

- Failures that are suspected to be due to fatigue, stress corrosion, corrosion fatigue, or hydrogen embrittlement
- Assessment for the continued serviceability of a component, for example, life assessment. This is usually focused on a concern for in-service failure.
- Inconsistent test results on a machined or otherwise manufactured test specimen, especially in fatigue testing
- Distortion occurring during processing of a component
- Distortion of components during storage or in-service

In the first three situations (where failure is of concern), surface stresses are usually of greatest interest, and surface measuring procedures and techniques that provide optimum spatial resolution are needed. These are required in order to identify the location and magnitude of the highest tensile residual stress, because those stresses and locations are likely to dominate the failure conditions. In the last two situations, where distortion is of concern, the stress field contour through the cross section of the component is usually most relevant and not

the location or magnitude of the maximum tensile residual stress. In these cases, procedures or methods that provide measurement of stresses through the cross section are more relevant than spatial resolution.

It is extremely important that the investigator understand the mechanism for the inducement of the residual stress field of concern. Most cases of suspected harmful residual stress fields are induced by manufacturing processing or repair procedures, although sometimes abusive service conditions or an accident may have caused them (Ref 10). When manufacturing processes or sometimes repair procedures are judged the most likely sources of the residual stresses, it is often possible to predict the magnitude and distribution of the residual stresses. Such information may be obtained through consulting the literature or applying computer modeling (Ref 11, 12, 13, 14, 15, 16, 17, 18, and 19). A preconceived model of the residual-stress field will aid the investigator in determining the best method for residual stress measurement and the location and number of measurements that need to be made.

Nevertheless, sometimes the source and cause of the residual stress field is not evident, and the investigator is compelled to perform measurements as a means to determine the cause. In such cases, measurement methods and location must be selected without the aid of a priori knowledge of the stress field, and it is prudent to consult the literature and experts in the field of residual stress measurement and manufacturing processes.

Residual Stress Measurements

Clayton O. Ruud, The Pennsylvania State University

Nature of Residual Stresses

Residual stresses are the inevitable consequence of thermal-mechanical processing of metals. The resulting stress fields usually are nonuniform and show high stress gradients. For example, Fig. 2 illustrates the residual stress magnitudes and distributions typical of a metal with a 650 MPa (94 ksi) yield strength. Because of the high stress gradients, tens to hundreds of residual stress measurements with resolution on the order of 1 mm (0.04 in.) may be required in order to precisely identify the maximum stress and its location.

The characteristically nonuniform, high stress gradient nature of residual stresses requires that either the induced stress field is well understood and predictable or many residual stress measurements are performed on one or more components in order to reveal the nature of the stress fields. Often scientists attempt to gain an understanding of a residual stress field by making a few measurements on one or two components, and, from this, they often derive erroneous conclusions regarding the nature of the stress field.

A few measurements may be useful if the scientist or engineer knows the distribution of the stresses a priori. However, this is seldom the case, and tens to hundreds of measurements are required on a single component or many samples to really understand the residual stresses induced by a given manufacturing process. This means that the method of measurement must be as rapid and as labor-efficient as possible. Some of the new, semidestructive hole drilling procedures, XRD, and ultrasonic instrumentation methods (for special cases) meet this criteria. Stress mapping is offered with some XRD instruments to map stresses over the surface of a component (Ref 3). Also, because the stress gradients are often very high, the method of measurement must be able to resolve the stresses in dimensions on the order of a millimeter or less. Here some of the hole drilling procedures and recently developed XRD instruments can offer the best resolution.

Finally, often the component in which residual stresses are to be determined is too large to be brought to a laboratory, and removing sections is not a rational solution. Note that sectioning often disturbs the existing stress field to the extent that it is not possible to reconstruct the original stress field from the residual stress measured in pieces removed from the original whole. Hole-drilling, XRD, and ultrasonic instrumentation are available as portable devices, which may be brought to the component in the field (Ref 10, 20, 21, 22).

Residual Stress Measurements

Clayton O. Ruud, The Pennsylvania State University

Stress Measurement

A number of procedures and methods have been applied to determining the residual stresses extant in a metallic component, usually as a result of manufacturing processing. However, stress is never the quantity measured, because stress is a quantity that is applied to a metal and can only be measured in the process of its application. What is invariably measured to determine residual stress is elastic strain—either the elastic strain resulting directly from the existing residual stress in the metal or the elastic strain change resulting from relief of some portion or all of the existing residual stress. The stress that is causing, or has caused, the strain is then calculated using the applicable elastic constants for the metal.

The methods described in the section “Nondestructive Procedures” in this article directly or indirectly measure the strain response of metals to the residual stress in situ, while the destructive and semidestructive methods described in the following sections measure the strain change caused in relieving some or all of the residual stress in the metal.

Residual Stress Measurements

Clayton O. Ruud, The Pennsylvania State University

Destructive Measurement Procedures (Stress-Relaxation Techniques)

The first concern in selecting a destructive residual stress measurement procedure is whether it is reasonable to destroy one or more components or samples in order to determine the residual stresses. Usually this implies that one or a few of the components are a small portion of the total number produced. Also coupled to this decision is whether the one or more components in which the residual stresses are to be measured are representative of all the others. In other words, how great is the expected variation of the residual stress field from part to part?

As mentioned at the beginning of this article, the need for the residual stress information on a component must be clearly understood. This includes whether the triaxial stress field must be established or if the uniaxial or biaxial condition of the stress field along specific directions is sufficient. Examples of these three situations are illustrated in this subsection. However, in any case, the fact that residual stresses are usually not uniform in any direction and show high stress gradients must be kept in mind when stress measurement criteria are selected.

Destructive methods of residual stress measurement are fundamentally stress-relaxation procedures (techniques A-1 and A-2 in Table 1). That is, the information is obtained by relaxing the residual stress in some finite volume element of the component and measuring the resulting strain change. The strain change is then used, along with applicable assumptions about the nature of the stress field, to reconstruct the original stress field. Assumptions about the nature of the stress field include the magnitudes and gradients in the stress field and whether it is sufficient to assume that the gradients are one-dimensional, two-dimensional, or three-dimensional. In particular, the gradients that exist will dictate the size of the element that is to be isolated and made stress-free, in that the higher the stress gradient, the smaller the finite element must be in the direction of

that gradient. It must be emphasized that the larger the element and the higher the stress gradient, the less quantitative and more qualitative are the measurement results. Electrical resistance strain gage technologies will be emphasized as the dominant method of strain change measurement for destructive and semidestructive stress relaxation methods due to their economic, procedural, and precision advantages over other methods. However, modern XRD stress measurement instrumentation (instruments designed specifically for stress measurement and not conventional XRD instruments modified with stress measurement accessories) has all of these advantages as well and can be used to measure the stresses existing before and after sectioning.

A generic destructive stress relief procedure will first be described along with the issues generally involved in each procedural step. A summary of destructive residual stress measurement procedures is provided in Table 3. This section on destructive methods concludes with discussion of qualitative chemical methods of residual stress measurement, which are listed in Table 1 under D.

Table 3 Summary of destructive residual stress measurement procedures

Component shape	Stress field condition assumptions	Stress direction measured	Method	Reference
Rods, cylinders, tubes	Uniaxial stresses; axial symmetry	Longitudinal	Bauer-Heyn	23
Rectangular cross section, bar	Uniaxial stresses varying through thickness	Longitudinal	Stablein	24
Rods, cylinders, tubes	Biaxial stresses; axial symmetry	Longitudinal, radial	Mesnager-Sachs	25, 26
Plate, sheet	Homogeneous planar; biaxial stresses varying through thickness	Biaxial in the plane of the component	Trenting and Read	27
Plate, sheet	Homogeneous planar; biaxial stresses uniform through thickness	Biaxial in the plane of the component	Gunnert	28
Plate, sheet	Homogeneous planar; biaxial stresses varying through thickness	Biaxial in the plane of the component	Gunnert	5, 29
Plate, sheet	Planar biaxial stresses varying through thickness	Biaxial in the plane of the component	Rosenthal and Norton	30
Plate, sheet	Planar biaxial stresses varying through thickness	Biaxial in the plane of the component	Moore and Evans	6
Plate, sheet	Triaxial	All	Chen	31
Cylinder, plate	Various	All	Moore and Evans	6
Plate, weldment	Triaxial	All	Johanssen	32

Generic Destructive Procedure

Once the decision to destructively measure the residual stresses is made, the following steps are usually applied in a typical stress-relief technique for residual stress measurement.

Stress Field Conditions. The engineering problem for which the residual stress information to be derived destructively is needed must be analyzed. This need is often generated by failures of the component in service, anticipated failures due to problems with similar components, or inconsistent mechanical test results, especially in fatigue testing. Distortion of a product in storage or during manufacturing can also be a concern. The shape of the component, that is, cylinder, disc, plate, and so on, or some irregular shape, must be considered. This consideration, along with the process or processes by which residual stresses were introduced, must be analyzed. From these considerations, the justification for assumptions regarding the condition of the residual stress field can be established. This may lead to simplifying assumptions about the stress field condition, such as axial symmetry for a cylinder in which the dominant residual stress field is due to quenching during heat treat processing or stress uniformity in the surface plane of a plate where stress gradient with depth is the major concern (see Fig. 3).

Fig. 3 Residual stresses in 7075-T6 plate specimens quenched in water at different temperatures

These assumptions and considerations lead to the methodology, that is, equations, to be used for computational reconstruction of the stress fields from the measured strains for the destructive methods.

Strain Measurement Technique. With the stress reconstruction approach established, the method of strain measurement and, consequently, the number and/or spatial frequency of measurements can be determined. The strain measurement technique selected will greatly affect the resolution of the stress measurement because of the spatial precision inherent in the technique.

There are a number of techniques that have been used to measure the strain induced by the relief of stresses due to sectioning or material removal in destructive residual stress measurement. These include mechanical gages, often dial gages, employed with specially made jigs and fixtures, reflected light schemes, photoelastic coatings, and electrical resistance strain gages. However, over the last few decades, the use of the latter has become dominant due to the variety, availability, and precision of these gages. They are available as uniaxial, biaxial, and rosette gages of many sizes. The section "Strain Measurement Methods" of this article provides some detail regarding these methods. Also, in the last several decades, extensive use of XRD to provide rapid and numerous stress measurements on sectioned components so as to provide information regarding the internal stress field has been applied (Ref 6, 32, 33, 34, and 35).

Preparation for Strain Measurement. With the strain measurement technique selected, the measurement location must be established and the component and/or element prepared for the measurement by, for example, attaching strain gages. A pre-stress-relaxation reading must be made before stress relaxation and isolation of the element is initiated.

Isolation of Gaged Element. With the measurement technique in place, material removal to isolate the gaged volume must be performed. The technique for material removal or sectioning must be carefully considered, because mechanical chip removal processes such as lathe turning, milling, sawing, grinding, and so forth introduce surface residual stresses that can be as great as the yield strength of the strain hardened material and tens of micrometers (several thousandths of an inch) in depth (Ref 36, 37). The section "Sectioning and Material Removal Methods" in this article discusses methods used to isolate the gaged element.

Post-Stress-Relaxation Measurement. After the residual stresses have been relaxed and, thus, the elements isolated, strain measurements are repeated, and the final reading is subtracted from the initial one to obtain the strain change resultant from the residual stress relaxation. The resultant quantities are then used in the residual stress reconstruction equations to obtain the original stress state of the component. The stress reconstruction equations were selected as a result of the assumptions made in the section "Stress Field Conditions" and described in detail in following sections.

Stress Field Condition Assumptions and Reconstruction

Engineers and research scientists have approached the measurement of residual stresses using destructive methods with the aid of assumptions about the stress field conditions, including that the stresses in only one axis are of interest, in order to simplify the measurement and reconstruction of the stress field. These have included certain uniaxial, biaxial, and triaxial stress field assumptions.

Uniaxial Conditions. A procedure applicable only to the measurement of residual stresses in rods, cylinders, and tubes, that is, components with axial symmetry, was reported by Heyn (Ref 23). In this work, it was assumed that the stresses were axially symmetric and that only the longitudinal stresses were of interest. Thus, the changes in length of the components (cylinders, rods, and tubes) were measured after removal of an axially symmetric layer from the outside radius or boring out from an inside radius. The length of the component was measured after each layer removal process, and this measurement was entered into various equations described in the article. This procedure is called the Bauer-Heyn or Heyn-Bauer method (Ref 23) and is applicable only to measuring longitudinal stresses in axially symmetric components. It does not measure radial or circumferential stresses.

A second procedure assuming a uniaxial stress field, or that only the stresses in one axis are of interest, was proposed by Stablein (Ref 24). Here the component was a bar with a rectangular cross section, and the residual stresses acting along its length and varying through its thickness (smallest dimension) were measured. The material from one face of the bar (one of the two faces with the largest area) was removed by milling. Equations used to reconstruct the original stress field are described in the article. The depth of the removed layer must be significantly greater than the depth of plastic deformation caused by the milling (see the section “Sectioning and Material Removal Methods” in this article) and sufficient to cause a measurable bend in the material. The length of the opposite face of the bar from where the material was removed is measured before and after layer removal to determine the effect of the removal of the stressed layer. Presently this is usually done using electrical resistance strain gages (see the section “Strain Measurement Methods”), but in the past it was done by sensitive mechanical gaging techniques. This measurement can also be accomplished by measuring the bend in the bar with suitable mechanical gages and fixtures; for example, a cantilever beam approach. This procedure is applicable only to components of rectangular cross section where the stresses parallel to the length are to be measured as they vary through the thickness.

Biaxial Conditions. A procedure applicable to axially symmetric components is the Mesnager-Sachs boring-out technique (Ref 25, 26). The technique is applicable to cylindrical components with an axially symmetric distribution of stresses. Here the change in length and diameter of the component is measured as material is removed by axially boring-out material from the inside to produce a hollow cylinder. Presently biaxial electrical resistance strain gages are usually attached to the outside of the component to measure the dimensional changes in the axial and tangential directions. The strain change results are entered into equations described in two articles (Ref 25, 26).

A procedure applicable to measuring biaxial residual stresses homogeneous over the planar surface of a flat metal plate or sheet was proposed by Trenting and Read (Ref 27). It was based on uniformly removing thin layers of the metal on one side of the sheet or plate and measuring the changes in curvature as the layers were removed. It was assumed that the stresses were constant over the plane of the sheet or plate and varied only through the thickness. Electrical resistance strain gages or mechanical gaging may be used to measure the change in curvature.

Another procedure for measuring biaxial stresses homogeneous over the planar surface of a metal plate was developed by Gunnert (Ref 28). This procedure assumes that a biaxial stress condition was uniform throughout the depth of a circular groove that was milled around an elemental volume of material (trepanning) to render it stress free. Thus, the strain change on only one surface was measured. The mechanical gaging technique involved measuring the distance between each of four sets of shallow holes drilled in the element before the groove was milled into the surface using a core drill. The distance between each set of holes was measured before and after the groove was produced and provided the information necessary to calculate the original, assumed biaxial residual stress condition parallel to the surface of the plate. Theoretically, only three sets of holes are required to measure the biaxial stresses, but Gunnert used a fourth set to improve the accuracy. A mechanical gage, termed an *extensometer*, was used to measure the distance between each set of holes. It should be noted that this technique could be used to measure the gradient in the biaxial stress condition by pausing in the milling operation at selected depths and measuring the distance between the holes at each groove

depth. Also, as with many of the older techniques, which originally applied mechanical strain gage apparatus, electrical resistance strain gages or modern XRD stress instrumentation (instruments designed specifically for stress measurement and not conventional XRD instruments modified with stress measurement accessories) could be used. A procedure involving the drilling of a blind hole and electrical resistance strain gage is somewhat similar to Gunnert's original technique and is described under semidestructive methods.

A more accurate procedure was later used to measure residual stresses in pipe weldments. Here the component (pipe) was divided into a network (grid) of squares, and biaxial electrical strain gages were placed in the center of each grid square on the outside diameter of the pipe (Ref 38). The pipe was then sectioned as shown in Fig. 4 into elements assumed to be stress-free, and the strain induced by the stress relief was read from the gages. In placing the gages only on the outside diameter, the biaxial stress field was assumed to be uniform with depth; however, had gages been placed on the inside and outside diameter, a more complete measurement of the stress field could have been obtained, albeit assuming a linear variation in the residual stress from the outside to the inside surface.

Fig. 4 Residual stress measurement of a girth welded pipe by strain gaging and sectioning. Note that strain gages shown in the final sectioning should be placed on the pipe prior to initial sectioning. For a more complete analysis, several of the layer sections detailed in the final sectioning step should be strain gaged and sectioned (Ref 38).

A variation on the Gunnert procedure described in a previous paragraph was later published (Ref 5, 29). This variation also was for application to plates and implied that the triaxial stress field could be measured by the technique. It assumed that a homogeneous residual biaxial stress field, which varied with depth through the plate thickness, existed. Four holes in a square pattern were drilled through the plate thickness. The distances between all of the holes were then measured at selected hole depths. Next, a circular groove is milled in steps

of, for example, 2 mm around the drilled holes using a core drill as in Gunnert's original procedure (Ref 28). The distance between the holes at the various depths was then measured at each core depth until the core was milled completely through the plate. The cored plug was then assumed to be completely free of residual stresses. The measured distances were then used to reconstruct the original biaxial stress condition of the plug at each cored depth. A similar mechanical measuring gage was used in this technique as was used in Gunnert's first technique (Ref 28).

Another approach to measuring residual stresses that has a broader application with respect to the shape of the component and the stress field distribution was proposed by Rosenthal and Norton (Ref 30). It is applicable to plates and plate-shaped weldments.

The procedure involved cutting two narrow blocks having the full thickness of the plate, each with its long axis parallel to one of the assumed biaxial, principal residual stress directions in the surface of the plate (see the near side of Fig. 5). Thus, the long axes of the blocks are perpendicular to each other and parallel to the face, the largest area surface of the plate. The smallest dimension of the block should be several times smaller than the thickness of the plate, and the largest dimension of the block should be at least twice the thickness. The block then can be further sectioned in order to determine the biaxial stress variation through the thickness of the component. This proceeds first by cutting the block at the location representing the midthickness of the component plate and then by removing thin slices parallel to the original surface and from the bisected block as shown in the upper part of Fig. 5.

Fig. 5 A welded steel plate, the near side of which shows the two narrow blocks suggested in Rosenthal and Norton's (Ref 30) procedure. The far side shows several blocks sectioned to reveal the stresses parallel to the weld with a gradient transverse to the weld.

The change in strain of the blocks is measured using shallow holes or dimples in the original surfaces of the component. These gage points are located along the long axis of the block on the original faces of the plate (see Fig. 5). The distance between these gage marks is measured before and after removal of the blocks from the plate and after each sectioning of the block (Ref 30).

This procedure assumes a constant biaxial stress field over the length of the blocks, which is not the case in welded plates in the direction transverse to the weld. The far side of the block in Fig. 5 shows a sectioning procedure that would reveal the stresses parallel to the weld along a gradient transverse to the weld. Also, electrical resistance strain gages could be used instead of measuring the distance between shallow holes or dimples.

Another approach to a constant biaxial stress field in a flat plate, varying only through thickness, was described by Moore and Evans (Ref 6). They relied on XRD for the measurement of the strains from which the stress was calculated, and the procedure consisted of removing layers from the surface of the plate and measuring the strains existing at each layer. The process assumed that the stress perpendicular to the surface was zero. It should be noted that in order for this procedure to be valid, the XRD-measured areas would have to be free of plastic deformation caused by layer removal (see the section "Sectioning and Material Removal Methods" in this article).

Triaxial Conditions. In reality, in most components in which residual stresses have been induced, usually due to manufacturing processes, the stress field is triaxial and varies from point to point (element to element) in all three directions. Thus, a number of destructive procedures and stress field condition assumptions have been applied in order to measure the three-dimensional residual stress field condition existing in most components of practical engineering interest. Two of these are described in this section as follows.

Chen (Ref 31) revised Rosenthal and Norton's (Ref 30) approach to deriving the triaxial residual stress condition. The typical method of residual stress measurement is by mechanically removing part of a body and measuring the change of stress in the rest of the body. The method of Rosenthal and Norton instead deals only with a small element that has been cut free from a plate. The sectioning procedure consists of removal of a narrow block from a plate with gages attached, followed by splitting the block in half with gages attached on the top and bottom surface of the block and successive slicing of both halves from the midsection to the outer surface as shown in Fig. 5.

When the half-block is sliced to a thickness of 2.5 mm (0.1 in.), gages are removed and stresses are measured (at at least two points) on the surface by XRD techniques. The basic assumptions of Rosenthal and Norton are these: (a) partial relief of stress occurs in the direction of the long axis of the block, and a total relief of stress occurs in the direction transverse to the long axis, (b) the small amount of stress relaxed in the remainder of the block follows a linear law through the thickness when a thin slice of metal is removed, and (c) variation of transverse stress along the axis of the weld is small in the middle portion of the plate weldment. The determination of residual stresses may be divided into the steps described in the following paragraphs.

Determination is made of ϵ'_1 and ϵ'_t , which represent the amount of strain relaxed in longitudinal and transverse directions respectively, by cutting one longitudinal and one transverse block free from the plate. This is done by determining the strain relief between two indentations on the top and bottom surface of each block using a mechanical gage (see Fig. 5) and subtracting the gage readings on the blocks from the initial reading from the plate. Note that this measurement also can be performed using electrical resistance strain gages or XRD (Ref 22, 33).

Determination is made of ϵ'_1 ϵ'_t the strain relaxed on the top and bottom surfaces by splitting each block in half and then successively slicing the blocks. Here again, measurements of the change are made by using mechanical or electrical resistance strain gages or XRD.

Determination is made of the strain relieved (using at least two points) on the top and bottom surface using sensitive mechanical gages to measure the distance between indentations and XRD after the thickness of the top and bottom halves of the blocks has been reduced to 2.5 mm (0.1 in.). Note that the strain mechanical gages were used because Rosenthal and Norton used conventional scanning x-ray instrumentation. With modern XRD stress instrumentation (designed specifically for stress measurement, and not conventional XRD instruments modified with stress measurement accessories), measurements can be made on any size of specimen (Ref 20, 22, 34, and 39).

Determination of the residual stress remaining in the top and bottom slices is made using XRD (an enhancement of the Rosenthal and Norton procedure as suggested by Chen) (Ref 31). Here, the lattice strain was measured in the remaining slices in at least two places near the gage points using XRD, and the absolute residual stress remaining in the transverse and longitudinal directions respectively, S^*_t and S^*_l , was calculated as described in the section "X-Ray Diffraction" in this article. These x-ray diffraction determined stresses measured for each block were averaged and designated S^*_t or S^*_l for that face. The original stress S'' , present before slicing was determined by the following equations:

$$S''_t = S^*_t + E\epsilon''_t \quad (\text{Eq 1})$$

$$S''_l = S^*_l + E\epsilon''_l$$

The total strain, ϵ'' , may be obtained by dividing S''_t or S''_l by the modulus of elasticity, E .

Computation of Stress Relaxed by Cutting the Blocks from the Plate. Using the values of ϵ' and ϵ'' obtained in previous steps, the amount of longitudinal and transverse stress, S'_1 and S'_t relaxed by cutting the blocks from the plate was computed by means of the following equations:

$$S'_1 = \frac{E}{1-\nu^2}(\epsilon'_1 + \nu\epsilon'_t) + \frac{\nu E}{1-\nu^2}(\epsilon''_1 + \nu\epsilon''_t) \quad (\text{Eq 2})$$

$$S'_t = \frac{E}{1-\nu^2}(\epsilon'_t + \nu\epsilon'_1) + \frac{\nu E}{1-\nu^2}(\epsilon''_t + \nu\epsilon''_1)$$

where ν is Poisson's ratio. Equation 2 is valid for the case where the length of the block is at least twice the thickness of the block. In case of shorter blocks, the following equations are used:

$$S'_1 = \frac{E}{1-\nu^2}(\epsilon'_1 + \nu\epsilon'_t) + \frac{E}{1-\nu^2} \times \left(\nu\epsilon''_t + \frac{\nu^2 - \beta^2}{1-\beta} \epsilon''_1 \right) \quad (\text{Eq 3})$$

$$S'_t = \frac{E}{1-\nu^2}(\epsilon'_t + \nu\epsilon'_1) + \frac{E}{1-\nu^2} \times \left(\nu\epsilon''_1 + \frac{\nu^2 - \beta^2}{1-\beta} \epsilon''_t \right)$$

where β is the correction factor for a shorter block.

These values, when plotted for the top and bottom faces of the block and joined by a straight line, give the stress, S' , relaxed by cutting the block from the plate.

Computation of Stress S'' Relieved by Splitting and Slicing the Blocks. This is done by means of the following equations:

$$(S''_\alpha)_t = E \left[\frac{1}{2} \frac{d\epsilon''_t}{d\alpha} (1-\alpha) - 2(\epsilon''_t - \epsilon''_t^0) + 3(1-\alpha) \int_{0.5}^{\alpha} \frac{\epsilon''_t - \epsilon''_t^0}{(1-\mu)^2} d\mu + (5\alpha - 4)\epsilon''_t^0 + (1-\alpha)\epsilon''_b^0 \right] \quad (\text{Eq 4})$$

$$(S''_\alpha)_b = E \left[\frac{1}{2} \frac{d\epsilon''_b}{d\alpha} (1-\alpha) - 2(\epsilon''_b - \epsilon''_b^0) + 3(1-\alpha) \int_{0.5}^{\alpha} \frac{\epsilon''_b - \epsilon''_b^0}{(1-\mu)^2} d\mu + (5\alpha - 4)\epsilon''_b^0 + (1-\alpha)\epsilon''_t^0 \right] \quad (\text{Eq 5})$$

where α = fraction of the total thickness removed; $\epsilon''_t, \epsilon''_b$ = relaxed strain measured on top and bottom surface for position; and $\epsilon''_t^0, \epsilon''_b^0$ = relaxed strain on the top and bottom surface when splitting the block in half.

Determination of total stresses relaxed across the thickness of the block in the longitudinal and transverse directions is made by the following equations:

$$S_l = S'_l + S''_l \quad (\text{Eq 6})$$

$$S_t = S'_t + S''_t$$

Determination of shearing stresses in the longitudinal and transverse directions is made by the use of the following equation:

$$\tau_{xy} = \tau_{yx} = \frac{S_w - S_v}{2} \quad (\text{Eq 7})$$

where S_w and S_v are the stresses measured in the direction w and v making angles $+45^\circ$ and -45° with the longitudinal axis. However, if the biaxial stress condition is assumed, only the strain relief in one 45° direction need be determined because the strain relief values would be equal. This requires that either a block at a 45° angle to the longitudinal block be removed or that electric residual strain gage rosettes or XRD measuring at the 45° angle be used.

Determination of Stress in the Thickness Direction. The equilibrium equations may be written as the following:

$$\frac{\partial S_x}{\partial x} + \frac{\partial \tau_{xy}}{\partial y} + \frac{\partial \tau_{xz}}{\partial z} + X = 0 \quad (\text{Eq 8})$$

$$\frac{\partial S_y}{\partial y} + \frac{\partial \tau_{xy}}{\partial x} + \frac{\partial \tau_{yz}}{\partial z} + Y = 0 \quad (\text{Eq 9})$$

$$\frac{\partial S_z}{\partial z} + \frac{\partial \tau_{xz}}{\partial x} + \frac{\partial \tau_{yz}}{\partial y} + Z = 0 \quad (\text{Eq 10})$$

Differentiation of Eq 8, 9, and 10 with respect to x , y , z , respectively, yields:

$$\frac{\partial^2 S_x}{\partial x^2} + \frac{\partial^2 \tau_{xy}}{\partial x \partial y} + \frac{\partial^2 \tau_{xz}}{\partial x \partial z} = 0 \quad (\text{Eq 11})$$

$$\frac{\partial^2 S_y}{\partial y^2} + \frac{\partial^2 \tau_{xy}}{\partial x \partial y} + \frac{\partial^2 \tau_{yz}}{\partial y \partial z} = 0 \quad (\text{Eq 12})$$

$$\frac{\partial^2 S_z}{\partial z^2} + \frac{\partial^2 \tau_{xz}}{\partial x \partial z} + \frac{\partial^2 \tau_{yz}}{\partial y \partial z} = 0 \quad (\text{Eq 13})$$

Subtracting the summation of Eq 11 and 12 from Eq 13, results in:

$$\frac{\partial^2 S_z}{\partial z^2} = \frac{\partial^2 S_x}{\partial x^2} + \frac{\partial^2 S_y}{\partial y^2} + 2 \frac{\partial^2 \tau_{xy}}{\partial x \partial y} \quad (\text{Eq 14})$$

Variation of S_x along the x -axis is small in the middle portion of the plate; therefore, the first term in Eq 14 can be neglected. Equation 14 can be approximated using the following:

$$\frac{\partial^2 S_z}{\partial z^2} = \frac{2}{\Delta y_1^2} (S_{y1} - S_{y0}) + \frac{2}{\Delta x_2 \Delta y_2} \tau_{x_2 y_2} \quad (\text{Eq 15})$$

where S_{y0} = value of S_y at the axis; S_{y1} = value of S_y at a distance Δy_1 on either side of the x axis; and $\tau_{x_2 y_2}$ = value of τ_{xy} at a distance Δx_2 and Δy_2 from the y axis and x axis respectively.

Therefore the stress in the thickness direction S_z can be obtained through double integration with the boundary condition that S_z vanishes at both the top and bottom surfaces. In this way the entire triaxial residual stress state was determined. Note that this procedure assumes that the residual stresses are uniform along the length of each block.

A variation on Rosenthal and Norton's (Ref 30) method using electrical resistance strain gages or a nondestructive technique such as XRD is as follows. The largest face of the blocks (described by the thickness of the component or plate and the longest dimension of the blocks, Fig. 5) is divided into a two-dimensional grid of elements. An electrical resistance strain gage is placed on each element, or a nondestructive measurement such as XRD is performed. The block is sectioned along the grid lines to produce elements that are assumed to be stress free. Note that if a nondestructive technique such as XRD is used, the plastically deformed surface created by removing the block from the original component must be removed. This is best done using electropolishing (see the section of this article "Sectioning and Material Removal Methods"). If electropolishing of these cut faces is done to remove the plastic deformation and resultant residual stress induced by a mechanical cutting procedure and XRD is applied, then the blocks need not be sectioned. The measured XRD stress will provide the absolute residual stress field condition in the block, and, coupled with the strain relieved by the original removal of the block from the plate, the entire triaxial residual stress condition of the plate may be obtained.

This variation on Rosenthal and Norton's (Ref 30) method provides the information necessary to derive the biaxial stress condition of each block, which can in turn be used to derive the triaxial condition of the original plate. The stresses on each of the measured faces of the blocks must be measured in three directions to provide the information necessary to obtain the principal stresses in the block faces in each element. Note that the strain change caused by the sectioning of the blocks must be added to the strains measured in each element.

This procedure may be applied to a weldment with a single weld through its center as described by Rosenthal and Norton (Ref 30), or to a more elaborate stress field, for example, where two orthogonal welds existed in the component (plate). With a single weld, only the block-intersecting weld needs to be sectioned into elements,

because the residual stress field in the block parallel to the weld is likely to be constant along the direction parallel to the weld.

Moore and Evans (Ref 6) proposed mathematical procedures for the reconstruction of the original three-dimensional residual stress fields in cylindrical and flat plate components, and Constantinescu and Ballard (Ref 7) recently proposed a modification of Moore and Evans's work. They proposed using XRD as the measurement technique and presented stress reconstruction equations for the following conditions: (a) solid cylinder bar with rotationally symmetric stresses; (b) solid cylinder bar without rotationally symmetric stresses; (c) hollow cylinder bar with rotationally symmetric stresses; and (d) flat plate with biaxial stresses.

The Moore and Evans procedures are described in the *Society of Automotive Engineers Handbook Supplement* (Ref 8) and summarized in the following paragraphs.

Solid Cylinder Bar with Rotationally Symmetric Stresses. It was presumed that the residual stress distribution had both rotational and longitudinal symmetry, except near the ends where measurements were avoided. Stresses were therefore functions of the radius, r , and did not depend on the angle, θ , measured around the cylinder, nor the distance, z , taken parallel to the axis. With repeated removal of thin concentric shells, the stresses on the exposed surface in depth were obtainable. The circumferential and longitudinal measures of stress, $\sigma_{\theta m}(r)$ and $\sigma_{zm}(r)$, respectively, were then used to calculate the original stresses, $\sigma_{\theta}(r)$ and $\sigma_z(r)$, as well as the radial stress, $\sigma_r(r)$.

The theory of elasticity provides nine partial differential equations—the three equations of equilibrium and the six equations of compatibility. Unique solutions are possible, depending on boundary conditions. For the case considered, the nine equations give the following working formulas:

$$\sigma_r(r_1) = \int_{r_1}^R \frac{\sigma_{\theta m}(r)}{r} dr \quad (\text{Eq 16})$$

$$\sigma_z(r_1) = \sigma_{zm}(r_1) - 2 \int_{r_1}^R \frac{\sigma_{zm}(r)}{r} dr \quad (\text{Eq 17})$$

$$\sigma_{\theta}(r_1) = \sigma_{\theta m}(r_1) + \sigma_r(r_1) \quad (\text{Eq 18})$$

where r is the original radius, and r_1 is the radius at the depth of interest.

Solid Cylinder Bar without Rotationally Symmetric Stresses. Stresses were again assumed independent of z but allowed to vary in the circumferential, θ , direction. Complex variable methods gave general solutions for stresses in the radial, $\sigma_r(r_1, \theta)$ circumferential, $\sigma_{\theta}(r_1, \theta)$; and axial, $\sigma_z(r_1, \theta)$, directions as well as the shear stress, $\tau_{r\theta}(r_1, \theta)$. Details of the equations used may be found in the references (Ref 6 or 8).

Hollow Cylinder Bar with Rotationally Symmetric Stresses. With the inside radius included in the equations used to calculate $\sigma_r(r_1)$, $\sigma_z(r_1)$, and $\sigma_{\theta}(r_1)$, the general solutions for these stresses are developed (Ref 6, 8).

Flat Plate with Biaxial Stresses. It was assumed that the residual stresses in a flat plate of uniform thickness depended only on the distance from one of the flat surfaces of the plate, except, of course, near the edges. It was also assumed that the principal stresses are σ_x and σ_y , lying in the plane of the flat surfaces, and that the stress normal to the flat surfaces, σ_z , was zero at all points sufficiently distant from the edges.

From the assumptions and conditions of equilibrium, the true stresses $\sigma_x(z_1)$ at depth z_1 could be expressed in terms of the measured stress $\sigma_{xm}(z_1)$ by the relation:

$$\sigma_x(z_1) = \sigma_{xm}(z_1) + 2 \int_{z_1}^H \frac{\sigma_{xm}(z)}{z} dz - 6z_1 \int_{z_1}^H \frac{\sigma_{xm}(z)}{z^2} dz \quad (\text{Eq 19})$$

where H = original thickness of the plate and z_1 = distance from lower surface to uncovered depth of interest.

A similar expression holds for the y direction. Equation 19 holds, even if σ_x and σ_y are not principal stresses, but in this case a shear stress also exists, expressed by:

$$\tau_{xy}(z_1) = \tau_{xy_m}(z_1) + 2 \int_{z_1}^H \frac{\tau_{xy_m}(z)}{z} dz - 6z_1 \int_{z_1}^H \frac{\tau_{xy_m}(z)}{z^2} dz \quad (\text{Eq 20})$$

$\tau_{xym}(z)$ is determined from:

$$\begin{aligned} \sigma_{\alpha m}(z_1) = & \sigma_{xm}(z_1) \cos^2 \alpha + \sigma_{ym}(z_1) \sin^2 \alpha \\ & + 2\tau_{xym}(z_1) \sin \alpha \cos \alpha \end{aligned} \quad (\text{Eq 21})$$

where α is the acute angle that the measured stress $\sigma_{\alpha m}(z_1)$ makes with the x axis. When measurements are taken 45° apart, $\tau_{xym}(z_1)$ becomes:

$$\begin{aligned} \tau_{xym}(z_1) = & \sigma_{45 \text{ deg}}(z_1) - \frac{1}{2}(\sigma_{xm}(z_1) \\ & + \sigma_{ym}(z_1)) \end{aligned} \quad (\text{Eq 22})$$

meaning that three x-ray stress measurements are required after each layer is removed.

Johanssen (Ref 32) proposed a procedure for the determination of the three-dimensional residual stress field in thick plate (plate weldments) components using XRD techniques to measure the strains on the surfaces of the plate and plate sections and on removal of layers of surfaces. The procedure included the measurement of the biaxial stress field existing on the top surface of the component (Fig. 6), assuming that the stress perpendicular to the surface is zero. Material was removed from this surface by, for example, milling and electropolishing or by electropolishing alone (see the section "Sectioning and Material Removal Methods"), and the biaxial stresses were remeasured at the new depth. Each time material was removed, the forces that the removed layer exerted on the remaining component had to be accounted for, and the subsequent measurements required correction for this change in the stress field. Johanssen based his method on the following assumptions:

- When a layer of material is removed, the resulting changes in the stress condition will be linear elastic; that is, Hooke's law is applicable.
- The residual stress distribution is constant in the z -direction, except at the surface, and σ_z is a principal stress in the z -direction (Fig. 6).
- On material removal, it is assumed that the strain, ϵ_z , remains unchanged. Together with the previous assumption, this implies that the change in stresses can be treated as a plane problem.
- It is assumed that the stresses are symmetrical with respect to the y - z plane. This assumption is, however, not necessary. The procedure can be developed to include asymmetrical stress states.

Fig. 6 A 2 ft by 2 ft by 4 ft weldment showing the layers proposed by Johanssen (Ref 32) where the thickness (T) of the layers are 12.70 mm (0.5 in.) and $\sigma_I = \sigma_y$, $\sigma_{II} = \sigma_x$, and $\sigma_{III} = \sigma_z$

Johanssen's (Ref 32) justification for his procedure to measure the three-dimensional stress field in the weldment shown in Fig. 6 is as follows.

Johanssen showed that the change in stresses resulting from the removal of material can be determined by $\Delta\sigma(x)$ and $v(x)$ shown in Fig. 7. These were to be measured at a number of positions x_i , $i = 1, \dots, N$, on the lower side of the plate. $\Delta\sigma_x(x)$ and $v(x)$ are the differences between the stress and deformation measured prior to

and following the removal of material. Changes in the internal stress conditions are thus calculated directly and need not be calculated as accumulated stress changes resulting from several layers of material being removed. The development of equations for the stress reconstruction may be found in Ref 32.

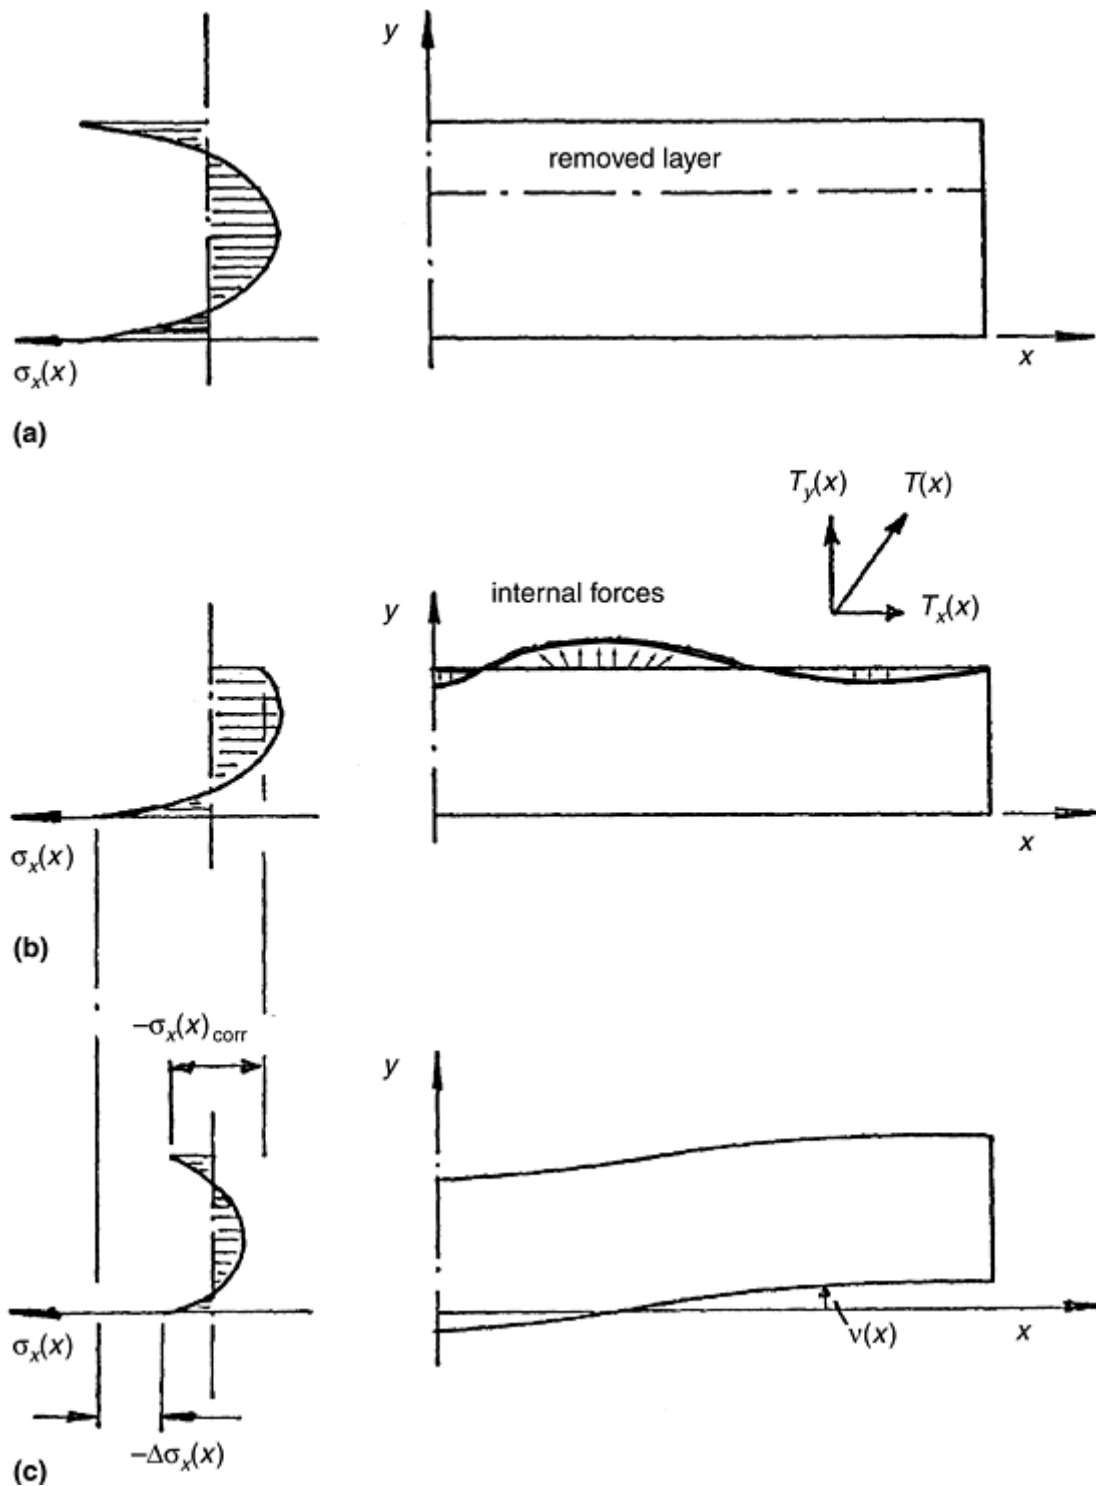

Fig. 7 Residual stress distributions, forces, and distortion of a plate before and after layer removal. (a) Residual stress distribution in the x -direction in the center of the plate in the x - z plane. (b) Same as (a) after removal of a layer with the forces $T_i(j)$ caused by the residual stresses tending to distort the plate. (c) Same as (b) with the distortion displacement shown (Ref 32)

Pickel (Ref 40) described a method for analytical solution of problems with similar boundary conditions to Johanssen's, using infinite, related series, but in this instance, an approximate method was used with trial solutions that were more convenient and numerically more stable than those used by Johanssen.

Sikarskie (Ref 41) proposed a stress reconstruction procedure (series method) when thin layers were removed from the surface of a component. He described procedures applicable to flat plates and solid cylinders. The procedure works well for shallow depths (a few percent of specimen diameter or thickness) or in instances where the stress gradient over the total depth removed does not change too rapidly and is of essentially one sign. The practicality of this method depends on the fit of the measured stresses in depth by a Taylor's series referred to the surface values of stress and successive derivatives at the surface. When the method is applicable, very convenient relations are obtained, which describe the stress correction in terms of the influencing factors; for example, layer depth, stress magnitude, stress gradient, and specimen size. Judgment is necessary, however, in using the series approximation, which does not arise when using the exact equations of the previous sections. The method is summarized for two of the previous cases as follows.

Flat Plate. (See the previous discussion "Flat Plate, Biaxial Stress" for the Moore and Evans procedures.) A generalized solution is written:

$$\begin{aligned} \sigma(z_1) = & \sigma_m(z_1) + 2 \int_{z_1}^H \frac{\sigma_m(z)}{z} dz \\ & - 6z_1 \int_{z_1}^H \frac{\sigma_m(z)}{z^2} dz \end{aligned} \quad (\text{Eq 23})$$

The subscripts x , y , or xy have been dropped, because the form of Eq 19 and 20 are exactly the same. $\sigma(z_1)$ represents the true stress in any direction at depth, z_1 , before a layer was removed, and $\sigma_m(z_1)$ represents the measured value at that depth.

The correction in stress, $c(z_1)$, at z_1 is the difference between the true and measured values, given by:

$$\begin{aligned} c(z_1) = & \sigma(z_1) - \sigma_m(z_1) = 2 \int_{z_1}^H \frac{\sigma_m(z)}{z} dz \\ & - 6z_1 \int_{z_1}^H \frac{\sigma_m(z)}{z^2} dz \end{aligned} \quad (\text{Eq 24})$$

The integrands are then expanded in a Taylor's series referred to the surface values, after which the integration is performed term by term. The final form for the correction is:

$$\begin{aligned} c(z_1) = & -4\sigma_m(H) \left(\frac{H-z_1}{H} \right) \\ & + [\sigma_m(H) + 2H\sigma'_m(H)] \left(\frac{H-z_1}{H} \right)^2 + \frac{1}{3} \\ & \times [2\sigma_m(H) + H\sigma'_m(H) - 2H^2\sigma''_m(H)] \\ & \times \left(\frac{H-z_1}{H} \right)^3 + \dots \end{aligned} \quad (\text{Eq 25})$$

where $\sigma_m(H)$, $\sigma'_m(H)$ are true surface stress and successive derivatives with respect to z at the surface. For shallow depths only, the first terms of the series may be used and:

$$c(z_1) = -4\sigma_m(H) \frac{\Delta z_1}{H} \quad (\text{Eq 26})$$

where $\Delta z_1 = H - z_1$. This correction is seen to be approximately proportional to the magnitude of the surface stress and thickness of the removed layer (Fig. 8). It is inversely proportional to the specimen thickness.

Fig. 8 Stresses in flat plate after layer removal

By solving for Δz_1 , the question of proper slice is given by:

$$\Delta z_1 = -\frac{1}{4} \frac{Hc(z_1)}{\sigma_m(H)} \quad (\text{Eq 27})$$

Thus, for example, if the measured stress is to be in error by less than 5%, $-c(z_1)/\sigma_m(H) = 0.05$, and the appropriate slice depth is:

$$\Delta z_1 = \frac{1}{4}(0.05)H \quad (\text{Eq 28})$$

For a plate 102 mm (4.0 in.) thick, for example, the slice depth is 1.3 mm (0.050 in.).

If the stress gradient is high, then the next term in the correction series should be included, and a quadratic in Δz_1 should be solved. This requires an estimate of $\sigma'_m(H)$ based on experience.

Solid Cylinder. (See the previous discussion "Solid Cylinder Bar with Rotationally Symmetric Stresses" for the Moore and Evans procedures.) A generalized solution from Eq 16 and 17 is written:

$$\sigma(r_1) = \sigma_m(r_1) - k \int_{r_1}^R \frac{\sigma_m(r)}{r} dr \quad (\text{Eq 29})$$

where, again, the subscripts r , θ , and z have been dropped because the form is the same.

When $\sigma_r(r_1)$ is desired:

$$\sigma(r_1) = \sigma_r(r_1)$$

$$\sigma_m(r_1) = 0$$

$$k = 1$$

$$\sigma_m(r) = \sigma_{\theta m}(r)$$

When $\sigma_z(r_1)$ is desired:

$$\sigma(r_1) = \sigma_z(r_1)$$

$$\sigma_m(r_1) = \sigma_{zm}(r_1)$$

$$k = 2$$

$$\sigma_m(r) = \sigma_{zm}(r)$$

$\sigma_{\theta}(r_1)$ is calculated from $\sigma_{\theta m}(r_1)$ using Eq 18.

The correction term in stress, $c(r_1)$, is written as before:

$$(\text{Eq 30})$$

$$(\text{Eq 31})$$

$$c(r_1) = \sigma(r_1) - \sigma_m(r_1) \quad (\text{Eq 32})$$

Again, expanding the integrand of Eq 29 in a Taylor's series and integrating term by term, a final form for the correction is obtained:

$$\begin{aligned} c(r_1) = & -k \left\{ \sigma_m(R) \left(\frac{R-r_1}{R} \right) \right. \\ & + \frac{1}{2} [\sigma_m(R) - R\sigma'_m(R)] \left(\frac{R-r_1}{R} \right)^2 \\ & + \frac{1}{6} [2\sigma_m(R) - 2R\sigma'_m(R) + R^2\sigma''_m(R)] \\ & \left. \times \left(\frac{R-r_1}{R} \right) + \dots \right\} \end{aligned} \quad (\text{Eq 33})$$

where $\sigma_m(R)$, $\sigma'_m(R)$ and so on, are the surface stress and successive derivatives with respect to z at the surface. Insights into the factors that influence the correction apply exactly as previously discussed, as do the limitations of the method.

Ruud et al. (Ref 33, 34) applied a modification of the Johanssen method to measure the triaxial stress condition of thick plate $\frac{1}{4}$ Cr-1 Mo plate weldments. They actually measured the strains in all directions and calculated the stresses but did not correct for layer removal due to the complex nature of the stress field.

Ruud et al. also measured the residual stress condition of expanded tubing including 304 stainless steel tubing (Ref 35) but focused on the residual stresses on the inside surface of the heat exchanger tube components. Table 3 summarizes the destructive residual stress measurement procedure described in this section of this article.

Sectioning and Material Removal Methods

As discussed in the previous sections on destructive measurement procedures, many procedures require that the component (sample or part) be sectioned and/or some material be removed from it to measure the residual stresses. This is especially true for the measurement of internal residual stress fields where the component nearly always must be sectioned to reveal the internal stress field. There are two exceptions to the necessity of sectioning and material removal, and these are neutron diffraction and ultrasonic methods, which will be described in the section "Nondestructive Procedures."

Sectioning or material removal may be required by a particular residual stress measurement procedure or method. Mechanical chip removal processes are usually applied because of their economy and speed. All chip removal processes, including lathe turning, drilling, milling, sawing, grinding, and so forth, introduce surface residual stresses that can be as high as the yield strength of the strain hardened metal and several thousandths of an inch (tens of microns) in depth (Ref 36, 42, 43, 44, and 45). Figures 9 10 11 show the residual stresses in steels caused by various machining processes. Further, some steels are especially prone to strain hardening, for example, austenitic stainless steels, and extra care must be used with these materials when selecting a material removal technique. Figure 12 shows plots of the residual stresses in 304 austenitic stainless steel caused by various grinding methods. Note that these plots are only samples and may not be typical. If the size of the element in which the strain change is measured is smaller, or thinner in the case of surface depth gradients, than about 2 to 3 mm ($\frac{1}{10}$ in.), then a chemical or electrochemical material removal technique must be used to remove the surface residual stresses caused by mechanical chip removal. These techniques may be used solely or in conjunction and after the chip removal method. It should be noted that material removal techniques such as electrical discharge machining (EDM) induce residual stresses (Ref 46) as do chip removal methods. Other methods, such as laser, flame, or plasma cutting, which cause heating of the element, must be applied with caution because they may reduce the stress field to be measured by annealing before measurement.

Fig. 9 Residual stresses at the surface and near the surface due to milling a medium carbon steel workpiece

Fig. 11 Residual stresses in an alloy steel workpiece induced by turning

Fig. 12 Samplings of residual stress distributions induced in 304 stainless steel workpieces by common grinding procedures

Thus, the only methods for material removal from a component surface that do not induce residual stresses are electrolytic or chemical polishing. Electropolishing is described in some detail in *Surface Cleaning, Finishing, and Coating*, Volume 5, 9th ed., of *Metals Handbook* (Ref 47), and guidelines are provided for application to various alloys on Table 1 of that publication. In electropolishing, the electrolyte and operating conditions depend on the alloy being polished as shown in the *Metals Handbook* (Ref 47) and the *SAE Handbook Supplement* (Ref 8). Electropolishing combined with XRD is used extensively to reveal residual stress gradients on machined, ground, and hardened surfaces.

However, application of these techniques requires that the subsurface stresses be corrected for the removal of prior surface layers (Ref 8).

Another concern when reducing components to a more convenient, smaller size when it is necessary in order to place them on or in a measurement device is that the stresses of interest are likely changed by the sectioning. Generally plates should be cut to a length and width of at least three times the thickness to avoid end effects. Cylinders, both thin-walled and solid, should be a minimum of three diameters in length.

Where the manufacturing process affects the entire thickness of a component, such as heat treatment or forging, it might not be advisable to section without means of measuring the stress change extensively over the entire component before sectioning. In other words, selection of the stress measurement procedure and methods should avoid sectioning unless techniques to measure the effects of sectioning are applied before sectioning is initiated.

On the other hand, when the processes that have induced the residual stress produce only shallow stress fields, then the three times rule suggested above is applicable.

Strain Measurement Methods

As discussed in the section “Stress Measurement” in this article, all residual stress determination methods measure elastic strain, not stress, and the residual stress is calculated from the strain values. Several methods for the measurement of strain have been applied in residual stress studies, and some have been mentioned previously. These methods include mechanical gages, electrical resistance gages, brittle coatings, optical gages, laser methods, birefringent methods, diffraction methods (x-ray and neutron), ultrasonic methods, and magnetic methods. The last three methods will be discussed in the section “Nondestructive Procedures” in this article.

Mechanical Gages. The application of mechanical gages such as those described by Heyn (Ref 23), Stablein (Ref 24), Gunnert (Ref 27), and others generally preceded the availability of electrical resistance strain gages and are not discussed here due to their general lack of precision, poor spatial resolution, and inefficiency.

Electrical Resistance Strain Gages. Most bonded electrical resistance strain gages are made from either metallic wire or foil materials. There are also the recently developed semiconductor gages. A variety of sizes, shapes, and configurations are available, including single-element gages and rosettes with two, three, or four elements. Electrical resistance strain gages are available in sizes as small as about 1 mm and thus provide a resolution of strain measurement on that order. Information on electrical strain gages is available in numerous sources, including the *Handbook of Experimental Stress Analysis* (Ref 48) and in reviews by Crites (Ref 49) and Masubuchi (Ref 15) as well as by suppliers.

Changes in temperature tend to cause an apparent strain. Some type of temperature compensation, therefore, is needed. Frequently, a dummy gage, which is not subjected to the strain, is exposed to the same temperature as the actual gage to provide a basis for comparison. A temperature-compensated gage can also be used.

Gages must be bonded securely to the specimen. Various types of cements have been developed. Sometimes gages must be protected from metal chips produced during machining as well as from the oil or water. A number of systems have been devised for protecting gages under various conditions.

Brittle Coatings. A simple inexpensive strain gage that will only provide qualitative indications of residual stress is used for brittle coatings. Here a brittle lacquer is applied to the area where the stresses are to be measured by a material removal method. After the lacquer has cured (dried), a change in the stress field is induced, and if the change is sufficient, strain will be produced in the lacquer, causing it to crack. If the material removal is in the form of a hole drilled in the lacquer, radial cracks indicate a tensile residual stress in the plane of the component surface, and circular cracks indicate compressive stress.

Optical Gages. In a well-fixtured component that is held securely in place during material removal to change the stress field and, therefore, induce strain change, light reflective methods can be used to magnify the movement of a reflective surface. Also, this method can be used if the component can be removed and replaced

precisely in a fixture and if the position of the reflected light can be measured before and after removal and replacement, during which a change in the residual stress field is induced.

Laser Methods. Other techniques applying laser light have been proposed as well. These have included shearography (Ref 50), interferometry (Ref 51), speckle-correlation interferometry (Ref 52), and others. Vikram et al. (Ref 52) suggested that a small volume of the material could be stress relieved by heating via a laser to induce a change in the stress field and the strain change measured by an optical technique to reveal the residual stresses existing in the volume before heating. However, it must be recognized that heating a volume of metal sufficiently to change the residual stress field will result in tensile residual stresses in the heated volume, as observed by Cullity (Ref 53, p 471–472), and this would likely be detrimental to the component in which stresses were being measured.

Birefringent Methods. Under the action of stresses, transparent materials become doubly refracting (birefringent), and if a beam of a polarized light is passed through a model (under stress) made of such a material, a colored image is obtained from which the stress distribution can be determined. This technique is called the photoelastic technique (Ref 48). A practical variation on this technique is to coat a metal component in which the residual stress is to be measured with a photoelastic polymer. When residual stress changes are induced in the component, strain changes are caused and transmitted to the polymer coating, which then becomes birefringent. This can be observed and measured using a reflection polariscope (Ref 15). Instructions for analyzing fringe patterns in this application (nearly the same as those obtained in ordinary photoelasticity) are provided by the manufacturer of the polariscope.

The photoelastic coating may be applied by brushing a liquid polymer on the surface of the specimen and polymerizing it by applying heat. Alternatively, a prefabricated flat or contoured sheet of polymer may be bonded to the part at room temperature (Ref 54). The maximum strain that can be measured ranges between 3 and 50%, depending on the type of polymer used; the strain sensitivity usually decreases with the increase in the maximum measurable strain.

Chemical Methods

A number of qualitative methods to detect residual stresses that may lead to stress corrosion or hydrogen-induced cracking (HIC) in metals have been applied to specimens representing components to be manufactured. Magnesium chloride solutions have been applied extensively to the study of stress corrosion in nickel alloys and austenitic stainless steels, including some recent work by Bouzina et al. (Ref 55).

Masabuchi and Martin (Ref 56) studied the susceptibility of SAE 4340 steel weldments to hydrogen-induced stress cracking. The test procedure was to immerse the weldment specimens in a 4% H₂SO₄ (sulfuric acid) aqueous solution charged with H₂ and to which two drops of a 5% phosphorus (P) solution of CS₂ was dissolved. A direct current (dc) was applied between a specimen and a lead anode to provide a current density of 0.5 to 1.2 mA/mm² (0.35 to 0.8 A/in.²). The crack patterns that developed were related to the surface tensile residual stress distribution in each specimen.

Stress corrosion cracking (SCC) induced by residual stresses in carbon and low-alloy high-strength steels have been investigated by several researchers (Ref 56, 57, and 58). One procedure consisted of immersing the specimens in a boiling aqueous solution of 60% Ca(NO₃)₂ and 4% NH₄NO₃ for 31 h. The crack patterns that developed were related to the surface tensile residual stress distributions in the specimen.

A number of standard practices for testing the susceptibility of metals to SCC have been published by ASTM, including the following:

ASTM No.	Title
G 38	Standard Recommended Practice for Making and Using C-Ring Stress Corrosion Test Specimens
G 58	Standard Practice for the Preparation of Stress Corrosion Test Specimens for Weldments
G 39	Standard Practice for the Preparation and Use of the Bent-Beam Stress Corrosion Test Specimens
G 30	Standard Recommended Practice for Making and Using U-Bend Stress Corrosion Test Specimens
STP 425	Stress Corrosion Testing

However, these tests for the most part do not reveal the residual stress but the susceptibility of the metal to cracking under known stresses in the specified corrosion medium—not residual stress.

Residual Stress Measurements

Clayton O. Ruud, The Pennsylvania State University

Semidestructive Procedures

Nondestructive methods of residual stress measurement are characterized as methods that in no way affect the serviceability or reduce the mechanical strength or other properties of the component in which stresses are

measured. Between the nondestructive and destructive methods, which have a severe effect on the serviceability, strength, and properties, are the semidestructive methods. These are methods that have a small to negligible effect on the components in which stresses are measured or methods for which the component may be repaired after the measurement.

The methods that are considered semidestructive are those that require small holes to be drilled, rings to be trepanned in the component, or indentations to be made in the surface. The first two methods provide quantitative data, and the third produces only qualitative data.

Blind Hole Drilling and Ring Coring. The hole-drilling method was proposed nearly seven decades ago (Ref 59) and is based on measurement of the change in surface strain caused by stresses relieved by machining a shallow hole in the test piece. The principle is that stressed material, on being removed, results in the surrounding material readjusting its stress state to attain equilibrium. The method has been standardized in ASTM E 837 (Ref 60). The ring core method (Ref 61) is also based on the strain caused by redistributing the stress field, but in this case a relatively stress-free island of material is isolated by making a shallow ring around a strain gage. This method is also called trepanning. These two methods are the least destructive mechanical stress relief techniques and are relatively simple and economical. They, as by and large all stress relief techniques do, rely on electrical resistance strain gages to measure the strain change due to metal removal. Rosettes of strain gages are available especially for hole drilling. The size of the rosettes has been progressively reduced over the last few decades, and rosettes are now available in sizes less than about 10 mm from a number of manufacturers.

As with most residual stress techniques, hole drilling and ring coring have been applied mostly to steels. Most applications have been done on flat plate or cylindrically round parts (Ref 9, 62, 63). Stresses can be determined at various depths into the surface of the material, down to a depth equal to the diameter of the hole or core (Ref 64, 65). Kelsey (Ref 66), however, observed that stresses with depth cannot be measured accurately to greater than half the hole diameter. The thickness of the layers in which stresses may be resolved is about 10 to 20% of the hole or core diameter.

The equipment necessary to perform the measurement is reasonably inexpensive, portable, and can be used in a manufacturing shop environment. However, experienced technologists are necessary to perform many tasks in taking the readings—from selecting the area in which stresses are to be measured to preparing the surface, applying the strain gages, and reading and interpreting the data. Due to the possibility of residual stresses being induced by the hole drilling or coring technique, prior calibration of the application is recommended in all cases, with the possible exception of certain applications where holes are produced by abrasive jet machining (Ref 67).

Rendler and Vigness (Ref 68) developed calibration constants for cold-rolled steel, which they proposed as generally applicable to all metals, provided that the elastic constants were known. However, they seem to have overlooked variations in the strain hardening coefficients and the accompanying residual stress, which exist between alloys and even between tempers of the same alloy. Dini et al. (Ref 69) showed that direct experimental determination of the necessary constants for any isotropic material with known elastic constants can be eliminated by using data available for cold-rolled steel and calculating these constants using a formula presented. Despite the success that some researchers have claimed in circumventing the development of calibration constants, experimental calibration is strongly recommended. This is best done by applying strain gages and drilling the holes in test pieces prior to stressing them known amounts (Ref 67, 68). The abrasive jet machining (AJM) technique should be applied to any material with high propensity to work hardening during machining, for example, austenitic stainless steel (Ref 70).

The following are general limitations and/or concerns of hole drilling and ring coring:

- Areas of high stress gradients should be avoided because the stress gradient must be assumed to be constant across the hole or ring diameter.
- Areas where stresses are greater than one-third the yield strength of the material are likely to produce erroneous results due to local plastic yielding during metal removal.
- The thickness of the part or specimen must be at least four times the hole or core diameter.
- Strain hardening of the metal in the vicinity of the hole may result during metal removal, which can result in tens of ksi (69 MPa) error.
- Heating may result during the metal removal.
- Holes or cores must be spaced at least eight times their diameter apart.

- The area in which stresses are to be measured must be accessible to a rather bulky drilling or coring alignment device.
- Preparation of the surface for strain gage adherence may induce residual stresses that introduce substantial error to the subsequent measurement (Ref 71).

In conclusion, the drilling and ring coring methods are nearly nondestructive variations of the destructive mechanical stress relief techniques and require only rather simple equipment and instrumentation. The state-of-the-art is relatively well developed compared to many nondestructive methods, some of which require considerable research and development work before they will ever be suitable to general application in terms of alloys and stress field conditions. Technological advancements in hole drilling and ring coring have largely been due to advancements in the more general areas of mechanical stress relief methods and research in new metal removal techniques for metal fabrication.

Indentation Methods. For more than six decades, engineers and scientists have proposed the use of indentors, such as those used to perform hardness measurements, as a means to measure or detect surface residual stresses. Kokubo in 1932 reported that stresses applied under bending load changed the apparent Vickers hardness values in carbon steel rolled sheets, both as rolled and annealed. He showed that tensile stresses tended to decrease the apparent hardness, and compressive stresses tended to increase the hardness. The stresses applied in tension and compression were sufficient to cause 0.3% strain.

Two decades later Sines and Carlson (Ref 72) proposed a method that required various amounts of external loads to be applied to the component in which residual stresses were to be measured while hardness measurements were made. The loads were made to cause both tensile and compressive applied stresses. The quality—that is, whether the residual stress was compressive or tensile—was then revealed by comparing the effect of the applied stress and whether the applied stress was tensile or compressive on the hardness measurement. At about the same time, Pomey et al. (Ref 73) proposed that residual stresses could be measured by pressing a ball-shaped penetrator into the component in which residual stresses were to be measured and establishing the relationship between the pressing load while it was progressively increased and the electrical resistance at the interface between the penetration and the component. He maintained that a smaller decrease in electrical resistance indicated that portions of material under the ball were plastically yielding and that the corresponding load on the ball could be related to the existing residual stress.

Later, Chiang et al. (Ref 74) provided a critique of several existing indentation analyses and proposed an interpretation of indentations exhibiting hemispherical plasticity. Nevertheless, the applications illustrated in this article were focused on brittle materials and not metals.

There have been numerous papers published proposing various approaches to interpreting the indentation loads and shapes so as to estimate the residual stress field on the surface and near-surface regions of materials. However, indentation methods have not earned the degree of confidence of XRD or hole drilling methods for general applications and, thus, are rarely applied.

Spot Annealing. Another semidestructive method that has been proposed to measure residual stresses in metal surfaces is to reduce the residual stresses in a small volume by annealing the metal in the volume. It has been proposed that this annealing be performed by intense laser light (Ref 52). This technique was envisioned to be similar to relief of residual stresses by removal of the material as accomplished in the hole drilling techniques. However, as Cullity discussed (Ref 53), such localized heating would induce high surface residual tensile stresses in the heat-affected region, and this would be detrimental to the component being tested.

Nondestructive Procedures

The methods for strain measurement described previously all measure the change in some dimension (strain) of the component produced by the removal of a finite volume of stressed metal from that component. Thus, these methods measure the strain induced by removing material so as to perturb the residual stress field. On the other hand, the nondestructive procedures measure a dimension in the crystal lattice of the metal or some physical parameter affected by the crystal lattice dimension. Whenever a mechanical force resulting in stress that is less than the yield strength is placed on a solid metal component, that component distorts (strains) elastically. That elastic strain results in a change in the atomic lattice dimension, and this dimension, or change, is measured by a nondestructive stress measurement procedure. For example, the diffraction methods, x-ray and neutron, measure an actual crystal dimension, and this dimension can be related to the magnitude and direction of the stress that the metal is subject to, whether that stress is residual or applied. Subsequently in this section, the following methods of nondestructive stress measurement are described: XRD, neutron diffraction, ultrasonic velocity, and magnetic Barkhausen noise.

X-ray diffraction techniques exploit the fact that when a metal is under stress (applied or residual), the resulting elastic strains cause the atomic planes in the metallic crystal structure to change their spacings. X-ray diffraction can directly measure this interplanar atomic spacing; from this quantity, the total stress on the metal can then be obtained.

Because metals are composed of atoms arranged in a regular three-dimensional array to form a crystal, most metal components of practical concern consist of many tiny crystallites (grains), randomly oriented with respect to their crystalline arrangement and fused together to make a bulk solid. When such a polycrystalline metal is placed under stress, elastic strains are produced in the crystal lattice of the individual crystallites. In other words, an externally applied stress or one residual within the material, when below the yield strength of the material, is taken up by interatomic strain. X-ray diffraction techniques can actually measure the interatomic spacings, which are indicative of the elastic strain in the specimen. Stress values are obtained from these elastic strains in the crystals by knowing the elastic constants of the material and assuming that stress is proportional to strain, a reasonable assumption for most metals and alloys of practical concern. An article published in *Journal of Metals* describes the XRD method and instrumentation in some detail. References 8 and 75 are excellent sources of practical, more detailed information on XRD stress measurement.

There are three basic techniques for measuring stresses, based on the XRD method. They are the double exposure (or two-angle) technique (DET), the single exposure (or one-angle) technique (SET), and the sin-square-psi (or multiangle) technique. The angle of exposure referred to is that between the incident x-ray beam and the specimen surface normal. It should be noted that in any XRD stress measurement technique, x-ray peaks in the far back-reflection range, that is, peaks with Bragg (θ) angles of near 90° , are much preferred because they show the greatest effect with a given amount of applied or residual stress. This is illustrated in the following equation:

$$\sigma_\phi = (2\theta_1 - 2\theta_2) \frac{\cot\theta_1}{2} \left[\frac{E}{1+\nu} \right] \frac{1}{\sin^2 \psi} \left[\frac{\pi}{180} \right] \quad (\text{Eq 34})$$

In Eq 34, θ_1 is the Bragg angle of the planes diffracting at ψ_1 ; θ_2 is the Bragg angle of the planes diffracting at ψ_2 . In Fig. 13, it can be seen that as θ_1 increases, its cotangent decreases; therefore, a larger difference ($2\theta_1 - 2\theta_\psi$) would result from a given σ_ϕ to maintain an equality.

Fig. 13 One-angle arrangement or the single exposure technique (SET). N_s is the specimen normal, and β is the angle that the incident beam makes with N_s . N_{p1} and N_{p2} are the normals to the diffracting planes 1 and 2 respectively, and ψ_1 and ψ_2 are the angles between N_s , N_{p1} , and N_{p2} respectively. η is the angle between the incident beam and the diffracting plane normals. R_0 is the camera radius, and O is the point of incidence of the x-ray beam of the specimen. 1 and 2 represent the diffracting planes at various attitudes to the specimen surface. S_1 and S_2 are the measured parameters representing the distance from a reference point of known distance from the incident beam and the diffracted x-ray beam position. S_1 and S_2 are directly related to the Bragg angles, θ_1 and θ_2 . The stress being measured is parallel to the specimen surface and in the plane containing the x-ray source vector and the specimen surface normal, N_s .

For a residual stress measurement, the diffracting angle, θ , of interatomic planes of at least two different psi (ψ) angles with respect to the surface normal must be measured (Fig. 13). These planes are crystallographically equivalent (same Miller indices, hkl) and in the unstressed state of the metal would have the same interatomic, d , spacing for the planes labeled 1 and 2 in Fig. 13 (Ref 53, 76, 77). In a stressed material, however, the two or more orientations of diffracting planes are selected so that they are at different angles to the surface; thus their normals are at different (ψ) angles to the surface normal. Then, depending on the angle of these planes to the stress vector, their interplanar atomic spacing is increased or decreased by varying amounts.

The most common sources of errors and misapplications in stress measurements by x-rays are related to stress constant selection, focusing geometry, diffracted peak location, and cold-working, crystallographic texture, grain size, microstructure, and surface condition. The source, significance, and correction techniques for these errors are not elaborated on here; details may be found in an article by Ruud and Farmer (Ref 78) and (Ref 8).

A point of interest in the error sources listed above concerns cold working and microstresses. Microstresses are usually considered to be those manifested by strain variation across single metallic grain. This strain variation is detected in the XRD method as broadening of the x-ray peak—a distinctly different phenomenon from the peak shift caused by residual stresses. However, microstrain variation can be measured simultaneously with stress. This microstrain phenomenon has been proposed as a means of judging cold work, dislocation density, and fatigue damage (Ref 79).

Despite the facts that x-rays provide stress readings only to a depth of less than 0.025 mm. (0.001 in.) and that the error sources listed above must be considered, the noncontact XRD method is presently the only time-proven, generally applicable, truly nondestructive method for measuring residual stresses. Its reliability has been proved and documented by thousands of engineers and scientists over the past four decades beginning with the classic work of Bolstad et al. at Boeing using x-ray film cameras (Ref 80). This documentation includes measurement of stresses in the Brooklyn Bridge (Ref 20) and tempering evaluation of carburized steels. The Society of Automotive Engineers (SAE) considers the method of sufficient practical importance to have printed three handbook supplements on the subject (Ref 8), and another supplement is under revision.

Even so, this nondestructive technology has been largely restricted to the laboratory because of the general lack of knowledge regarding the state-of-the-art instruments and the limitations of the more widely known and available conventional scanning XRD equipment. Instrumentation for bringing this technology into the field and manufacturing area has advanced rapidly in the last two decades, especially toward increased portability, compactness, and speed of operation.

As shown in Fig. 14, instrumentation has been developed and is commercially available for stress measurement in situ on the inside diameter of 10 mm (4 in.) diameter pipe (Ref 39). Position sensitive x-ray detectors have been largely responsible for these improvements to both laboratory-based and field deployable residual stress measuring instruments (Ref 10, 21, 22, 39, 81, 82, and 83). Also, with the speed of data collection being less than 0.1 s with conventional x-ray tube sources in some applications, XRD stress measurement can be performed on moving components (Ref 12). Nevertheless, many engineers have been frustrated in applying XRD to residual stress measurement. This has been largely due to crystallographers inexperienced in residual stress measurement, attempting to apply conventional scanning x-ray diffractometers and techniques to residual stress measurement. For example, in conventional XRD analysis and crystallography, sharp resolution of the diffracted spectra is very beneficial. However, in XRD stress measurement, the need to measure (ψ) angles that are not zero defocuses the beam, and attempts to refocus lead to significant error in the stresses read (Ref 84). In XRD stress measurement, what is more important than sharp resolution is the repeatable ability to measure the position of a defocused diffracted x-ray peak (Ref 85). Thus, it is recommended in most cases that XRD residual stress measurement be performed by trained technologists using x-ray instrumentation specifically designed and built for stress measurement, not conventional scanning diffractometers. Software packages specifically for residual stress measurement used with conventional scanning diffractometers do not in most cases eliminate the mechanical and focusing problems of applying these instruments to residual stress measurement. It is necessary to mount the component (or specimen) in which stresses are to be measured on the conventional scanning diffractometer, which usually requires sectioning of the component and which complicates and adds error to the measurement procedure.

Fig. 14 Photograph of a miniature x-ray diffractometer for the one angle technique arrangement of XRD stress measurement. This device incorporates a Ruud-Barrett position sensitive scintillation detector and is capable of being inserted in a 101.60 mm (4 in.) inside diameter for measuring residual stress (Ref 39).

Neutron diffraction (ND) allows measuring the elastic strains induced by residual stresses throughout the volume of relatively thick steel components with a spatial resolution as small as 1 mm^3 . Such capability provides for the measurement of residual stress inside of components without the necessity of sectioning or layer removal. Principal ND methods, like the XRD methods, measure the spacing between crystallographic planes in a component, and this spacing is affected by residual and applied stress. The spacing between a selected set of crystallographic planes (ϕ) is related to the angle of incidence and diffraction of the neutron radiation, θ , which are equal, and the wavelength of the monochromatic radiation (λ) by Bragg's law:

$$\lambda = 2 d \sin \theta \quad (\text{Eq 35})$$

The elastic strain, ε , induced by the residual stress perpendicular to the diffracting crystallographic plane then is related to d by:

$$\varepsilon = \frac{d - d_0}{d_0} = \left(\frac{\sin \theta_0}{\sin \theta} \right)^{-1} \quad (\text{Eq 36})$$

where d_0 is the distance between the unstressed crystallographic planes. If the orientation of principal stresses is known in the component, the stress in any principal direction may be calculated by:

$$\sigma_A = \frac{E}{(1 + \nu)} \left[\varepsilon_A + \frac{\nu}{(1 - 2\nu)} (\varepsilon_A + \varepsilon_B + \varepsilon_C) \right] \quad (\text{Eq 37})$$

where σ_A , σ_B , and σ_C are the principal stresses and ε_A , ε_B , and ε_C are the strains measured in the corresponding principal stress directions. E and ν are the Young's modulus and Poisson's ratio, respectively. If the principal stress directions are not known, strains in at least six directions must be measured to determine the residual stresses acting on the volume of material in which strains are being measured.

For residual stress measurement in most alloys, the unstressed spacing (d_0) between crystallographic planes at the exact point of strain measurement is not known and not easily measured. This means that d_0 or θ_0 in Eq 36 cannot be precisely established, and this leads to various degrees of error in the accuracy and precision of ND residual stress measurements. This condition is aggravated by the fact that the elemental composition, and thus d_0 , vary considerably within a component and markedly within the phase (e.g., martensite, austenite, and ferrite for steel) of the alloy at various locations. Additional limitations are that the component must be brought to a nuclear reactor, each strain measurement requires over an hour, a single stress determination in one small volume of the component requires at least three strain measurements, and the measurements are very costly.

Nevertheless, the ND methods have been applied to residual stress measurements in weldments (Ref 86), cylindrical forgings (Ref 87), plastically deformed plate (Ref 88), rocket case forgings (Ref 86), and many other types of components.

Ultrasonic Velocity. The principle underlying the measurement of stress and thus elastic strain by ultrasonic (acoustic) techniques is the phenomenon of an approximately linear change in ultrasound velocity with applied stress. It has been shown that under certain restricted conditions, residual stress can be measured by exploiting this phenomenon. Stress is measured by inducing a sound wave in the frequency of several megahertz in the metal specimen and measuring the time of flight or some other velocity-related parameter. Because many other characteristics of metals besides stress-induced elastic strain affect velocity, their effect must be sorted out, but neither the technology nor the fundamental knowledge for such sorting is usually available. The great interest in ultrasonic techniques for residual stress measurement stems from their promise for three-dimensional nondestructive measurements within the material.

Principle. A number of velocity-related phenomena have been used in various methods to measure stress effects by ultrasound. All utilize the deviation of the reaction of the metal from the linearity of Hooke's law of elasticity, $\sigma = M\varepsilon$, where σ = stress, ε = strain, and M = elastic modulus. This has been referred to as the anharmonic property of the solid and may be represented by a power series $\sigma = M\varepsilon + C\varepsilon^2 + D\varepsilon^3 + \dots$, where C = third order anharmonic constant, D = fourth, and so on. Most research done for stress measurement has used expressions in which terms past the third order constant, C , are dropped. Of the several anharmonic property effects that may be used to measure stress, the following are probably the most exploited: velocity dependence on the elastic modulus; dispersion of frequency amplitudes in surface waves; birefringence of orthogonally polarized shear waves; and harmonic generation in surface waves.

A very simplified form of the anharmonic stress strain law has been written as $\sigma = M\varepsilon + C\varepsilon^2$ and rewritten as $\sigma = \varepsilon(M + C\varepsilon)$. The term in parentheses is approximately related to the velocity of sound as $\rho V^2 \cong M + C\varepsilon$, where ρ is the density of the medium and V is the velocity of sound. This may be approximately rewritten in terms of velocity dependence on strain as:

$$V = \sqrt{\frac{M}{\rho} \left[1 + \frac{C}{2M} \varepsilon \right]} \quad (\text{Eq 38})$$

Then, to solve for strain, $\varepsilon = 2(V\sqrt{M\rho} - 2M)/C$ (Ref 89).

A simple view of the dependency of ultrasonic velocity on the elastic modulus and density may be shown by rewriting the equation $\pi V^2 = M + C\varepsilon$ in terms of V , differentiating and dividing by V to yield an expression for $\Delta V/V$. The result will readily show that a fractional change in elastic modulus or density would affect the velocity. The density of metal, for which the Poisson ratio is near 0.3, obviously changes as a compressive or tensile stress is placed on the specimen, and it is reasonable that the speed of sound would then change.

Limitations and Applications. Ultrasonic technology offers a number of types of wave modes in which to probe metals; these include bulk waves, such as longitudinal and shear, and surface waves, usually confined to Rayleigh type. Each mode offers many unique parameters for extracting information. As has been discussed, the primary effect of stress—induced strain on ultrasonic propagation in metals—is on velocity. This may be detected in a number of ways, including measurements of wave velocity, shear wave birefringence, and dispersion. However, there are other characteristics of metals that affect the ultrasonic velocity to the same degree as stress. These include crystallographic texture, microstresses, multiple phases, coherent precipitates, composition gradients, and dislocation density and distribution.

Crecraft (Ref 90) discussed velocity effects, manifested as texture, induced birefringence, and the marked change seen with ultrasonic frequency. He also reported birefringence due to cold work in nickel-steel specimens but did not attempt to separate the cold-work effects in terms of texture, dislocation density, and so on. In the early 1950s, Bradfield and Pursey (Ref 91) and Pursey and Cox (Ref 92) reported showing the influence of small degrees of texture on ultrasonically measured elasticity in polycrystalline bars. They showed how the true isotropic elastic constants can be determined by using measurements of both longitudinal and shear wave speeds along several directions. They presented stereographic charts that illustrated the relationship between elastic behavior of cubic crystals and results of x-ray texture determinations.

McGonagle and Yun (Ref 93) noted the cold-work effects in an article comparing x-ray diffraction results with Rayleigh wave velocity measurements. Boland et al. (Ref 94) also recognized that other material properties can affect ultrasonic velocity and recommended that methods be developed to distinguish stress-induced velocity changes from those from other sources.

James and Buck (Ref 95) pointed out that since the third order elastic constants for most structural materials are not readily available from the literature, ultrasonic stress measurement must be calibrated relative to the particular material being investigated. In the same paper they discounted the possible effect of mobile dislocations on the sound velocity in structural engineering metals with high yield strengths due to the short dislocation loop lengths prevalent. However, they did mention that crystallographic preferred orientation (texture) during deformation or fatigue is capable of severely modifying the elastic constants on which the sound velocity depends.

Papadakis (Ref 96) noted marked velocity changes for ultrasonic waves in various steel microstructures, and Moro et al. (Ref 97) measured the effect of microstructural changes caused by tempering on the ultrasonic velocity in low-alloy steel.

Tittman and Thompson (Ref 98) evaluated the near-surface hardness of case-hardened steel with Rayleigh waves; because hardness in this case is a combination of composition, microstress, and macrostress, the velocity change was due to a combined effect.

The temperature sensitivity of ultrasonic stress measurements has also been cited as an important source of error. Salma et al. (Ref 99, 100) proposed that this dependence be used as a means to measure stress but also noted the marked effect of dislocations and did not address a methodology of separating the stress from the dislocation effect.

Much of the work cited above is concerned with attempts to measure the effects of a variety of material properties on the changes in ultrasonic velocity. However, there apparently is no comprehensive study that demonstrates the capability of quantitatively separating stress effects on ultrasonic propagation from other variables found in structural metals, such as dislocation density or crystallographic texture. Furthermore, most of the studies cited observed velocity changes in bulk waves. Velocity measurements on these waves must be measured through the thickness of a component and, as most metallurgists recognize, obtaining uniform properties through thicknesses greater than a few millimeters, especially in steels, is difficult. The subtle property variations to which ultrasound velocity is sensitive, the inherent lack of homogeneity in engineering metals, and the high residual stress gradients often found in manufactured components present additional serious problems for through-thickness stress measurements.

In spite of the microstructural variations in manufactured steel products, success in the application of ultrasonic methods to residual stress measurement has been achieved in specific cases. One is in the measurement of hoop

stresses in railroad wheels (Ref 101). Here changes or variations of the residual stress in the hoop direction is of concern, while that in the radial or axial direction can often be assumed to be constant or negligible. Some techniques, then, for the measurement of the residual hoop stresses have relied on normalizing the hoop velocity against the axial velocity (Ref 102). Also, European railroads have monitored ultrasonic velocity along the wheel rims during use and attributed changes to residual stress changes (Ref 103). Schramm in his article mentioned a number of approaches for the application of ultrasound to the measurement of residual stresses in railroad wheels, and these examples may find application in the measurement of residual stress in other axially symmetric shapes (Ref 101). Ultrasonic residual stress measurements have also been applied to rails as reported by Egle and Bray (Ref 104) and Bray and Leon-Salamanca (Ref 105).

Magnetic Barkhausen Noise. The Barkhausen noise analysis technique (BNA) is concerned with measuring the number and magnitude of abrupt magnetic reorientations made by expansion and contraction of the magnetic domains in a ferromagnetic metal. These reorientations are observed as pulses somewhat random in amplitude, duration, and temporal separation, and therefore roughly described as noise.

Applications. A few applications of BNA to ferromagnetic metallic components have been made. Gardner (Ref 106) mentions a number of applications, which include helicopter rotor blade spans, autofrettaged gun tubes, gas turbine engine components, and rolling element antifriction bearing components. In these examples the change in residual stresses caused by known service histories was measured.

Chait (Ref 107) qualitatively measured the residual stress condition of a high-hardness laminar composite steel weldment and compared some of the BNA data with XRD stress readings. Sundstrom and Torronen (Ref 108) applied their BNA method to a number of microstructural measurements, including evaluation of grain size measurement for low-carbon ferritic and ferritic-pearlitic steels, evaluation of anisotropy in deep drawing and textured steels for electrical applications, measurement of the degree of aging in rimmed carbon steels, and pearlite morphology in steel wires. These researchers have also measured iron loss in magnetic material used for transformers and have proposed using BNA for residual stress measurements, pointing out that quantitative results can be obtained if the material and its fabrication history are known and calibration is possible.

Most studies and applications of BNA to stress measurement have focused on the uniaxial stress state. However, Sundstrom and Torronen (Ref 108) implied that the instrumentation they used could simultaneously measure stress in two directions to give biaxial stress conditions for magnetic inspection of roller bearing components, including BNA for monitoring residual stress change.

The BNA method certainly has been demonstrated to be sensitive to the stress condition in ferromagnetic materials (Ref 109). Nevertheless, its possibilities for application are limited by the condition that the material must be ferromagnetic, the narrow total range of stress sensitivity (i.e., ± 40 ksi, or 275 MPa), and the shallow depth of measurement. The latter condition might be relieved by using magnetomechanical-acoustic emission (MAE) (Ref 110), an ultrasound analog to BNA. However, the sensitivity of either of these techniques to other characteristics of metallic components and the consequent need for calibration with a nearly identical specimen severely restricts the general applicability of BNA and MAE. Many misapplications have been made that have severely damaged the reputation of the BNA methods (Ref 107, 111). Such restrictions can be removed only if the basic phenomena responsible for the effect of microstructural properties on BNA and MAE are understood and quantified in terms of the signal.

BNA is not recommended where variations in elemental composition, phase composition, grain size, strain hardening, crystallographic texture, grain shape, grain orientation, carbide size and distribution, and other microstructural characteristics accompany variations in residual stress. A recent evaluation of BNA by Allison and Hendricks (Ref 112) confirms the uncertainty of BNA residual stress measurements.

Residual Stress Measurements

Clayton O. Ruud, The Pennsylvania State University

Summary

Only the destructive stress relief, semidestructive hole drilling, or nondestructive XRD methods of residual stress measurement are generally reliable over a broad range of alloys displaying residual stress fields induced by the various manufacturing processes. By and large, failures on metallic components caused or aided by

residual stresses are due to surface stresses and can be measured by surface measuring methods including XRD and, for some cases, hole drilling. In these cases good spatial resolution and identification of the magnitude and location of the highest stresses is of primary importance. On the other hand, when distortion of metallic components presents a problem, the distribution and magnitude of residual stresses through the bulk of the component are of most interest, and high resolution and identification of areas of high stress magnitude are not of primary concern. In either case, stress measurement precision on the order of 5 ksi (35 MPa) is usually sufficient. Measurement of residual stresses can be very expensive and time consuming, and it is often worthwhile to consult experts in the field before deciding on a measurement method. Before an engineer or scientist not experienced in residual stress measurement selects a method and attempts to measure stresses, consultation with an expert experienced in residual stress measurement and analysis should be sought.

Mechanical Testing of Fiber-Reinforced Composites*

Dale Wilson, The Johns Hopkins University, Leif A. Carlsson, Florida Atlantic University

Introduction

THE CHARACTERIZATION of engineering properties is a complex issue for fiber-reinforced composites (FRC) due to their inherent anisotropy and inhomogeneity. In terms of mechanical properties, advanced composite materials are evaluated by a number of specially designed test methods. These test methods are mechanically simple in concept but extremely sensitive to specimen preparation and test-execution procedures, often requiring complex data reduction analysis. The rigor of specimen fabrication and testing practices employed determine the quality and cost of the resulting mechanical property data. It is important to define the purpose of mechanical characterization prior to conducting tests. The purpose determines the type of testing program, specimen fabrication, testing rigor, and, ultimately, the cost of characterization. Costs are controlled and time is saved by matching quality and accuracy requirements to the intended materials usage.

Mechanical Testing of Fiber-Reinforced Composites

Dale Wilson, The Johns Hopkins University, Leif A. Carlsson, Florida Atlantic University

General Concepts

Before describing the principal tests used for mechanical characterization of composites, the authors offer a review of the purposes of such tests and general considerations related to the mechanical properties of anisotropic systems, specimen fabrication, equipment and fixturing, environmental conditioning, and analysis of test results.

Purposes of Mechanical Characterization

The three most common purposes of mechanical property characterization are research and development, quality control (QC), and design data generation. Various levels of rigor are practiced within each category, but, in general, design data generation is the most rigorous. Rigor, as applied here, refers to the process of strictly following processing, fabrication, testing, and data reduction standards and specifications on statistically significant sample sets made from commercially standard materials.

Testing in support of research and development serves a variety of purposes and, by definition, must be flexible. Research and development testing is used to develop and assess the validity of the test methods, to aid in exploring materials science and mechanics concepts, and to support scientific discovery in materials development and applications research. In the materials industry, research and development testing supports the study of materials performance in comparison to program objectives, competitive materials, or other developmental materials. Once a material is developed, the tests can also be used to produce the first generation of property data used to market the new material. The goal of most industrial research and development testing is to control costs, keep turnaround times short, and develop data with accuracy and repeatability sufficient for comparisons. Often this is achieved by using small sample sizes, less rigor in specimen preparation, and minimal levels of test instrumentation. Testing is defined by internal procedures for specimen fabrication, test execution, and data reduction. Flexibility exists to modify specimen preparation and test procedures or to create new test methods, as required to meet research and development objectives.

Quality control characterization is defined primarily by customer acceptance of test methods and/or product specifications. The specimen sampling, specimen preparation, and test procedures must rigorously follow documented specifications. Sample sizes are statistically specified, but reduced levels are often allowed to control costs once production history is demonstrated to be consistent. Quality control tests usually characterize a couple of the most critical characteristics that define a product and strive for comparison against historical values rather than absolute properties. Many QC tests do not measure absolute mechanical properties. For example, flexural strength and modulus do not in general coincide with the strength and modulus of a material tested in uniaxial tension.

Design data generation strives to produce absolute property data. The data must represent the actual mechanical performance of the material under loading conditions like those that will be encountered in service. The tests used must be capable of measuring the material property desired, and specimen preparation must rigorously conform to the standards specified in the test methods. Sample sizes must meet the statistical requirements for A-basis or B-basis design allowables. The number of test-specimen replicates is usually greater than in either of the two previous types of testing. Also, specimen inspection, test instrument calibration, and test method execution are very rigorous.

In summary, different testing approaches are appropriate to meet the range of objectives that one may encounter in materials characterization. The cost of the testing and the time required to generate the results increase with increasing rigor of the characterization process. In order to strike the proper balance in addressing testing needs, the test engineer must fully understand the cause-effect relationships of all aspects of the specimen preparation and testing procedures on the quality and the cost of the results. To that end, this article provides a condensed yet concise presentation of the key concepts of mechanical characterization of composite materials.

Mechanical Properties of Anisotropic Systems

In order to focus on testing, the authors assume that the reader has an understanding of the various types of composite material systems and their special characteristics. If background in laminate mechanics is required, the reader is referred to (Ref 1, 2, 3). Methods for measuring properties of fiber and matrix constituents are not covered, although it is important that the reader understand the relationship that constituent properties, volume

fraction, and void content have to engineering property development in composite systems. This article focuses, thus, exclusively on measuring the engineering and structural performance of laminates and composite structures.

Mechanical properties of a composite material refer to the elastic and strength properties of the material under tensile, shear, or compression loading. Other properties, such as fracture toughness and flexural strength and stiffness, are also useful in characterizing the performance of a composite material. Finally, thermomechanical and hydromechanical properties are of importance under changing temperature and moisture environments. The homogeneity assumption that microstructural features of the material are small enough to be inconsequential to the average behavior of the material on a macroscale may not apply to composites, especially when strength and fracture are considered. Fabrics and laminates are very inhomogeneous in character. The scale of homogeneity of a composite system must be taken into account for fixture design, instrumentation decisions, and in data analysis.

The fundamental description of the engineering properties for a lamina under tension, compression, and shear loading is given in terms of the lamina coordinate system shown in Fig. 1. The strength and stiffness properties are defined in Table 1. If the material is transversely isotropic, then the indicated properties need not be determined. The fracture toughness is sometimes measured as part of durability assessment of a material system. These properties are the mode I and II critical strain energy release rates (G_{Ic} and G_{IIc} , respectively). Flexural properties are also determined routinely and result from bending the material to produce tension, compression, and shear stresses. The result is more a structural property than an intrinsic material property, but it is very useful in materials screening and quality control.

Table 1 Listing of mechanical properties typically determined for composite materials

Symbol	Property
E_1^t	Tensile modulus in the fiber direction
E_2^t	Tensile modulus transverse to the fiber
E_3^t	Tensile modulus transverse through the thickness^(a)
E_1^c	Compression modulus in the fiber direction
E_2^c	Compression modulus transverse to the fiber
E_3^c	Compression modulus transverse through the thickness^(a)
G_{12}	Shear modulus in the 1–2 plane
G_{13}	Shear modulus in the 1–3 plane^(a)
G_{23}	Shear modulus in the 2–3 plane
X_1^t	Tensile strength in the fiber direction
X_2^t	Tensile strength transverse to the fiber
X_3^t	Tensile strength through the thickness^(a)
X_1^c	Compression strength in the fiber direction
X_2^c	Compression strength transverse to the fiber
X_3^c	Compression strength through the thickness^(a)
S_{12}	Shear strength in the 1–2 plane
S_{13}	Shear strength in the 1–3 plane^(a)
S_{23}	Shear strength in the 2–3 plane
ν_{12}	Poisson's ratio in the 1–2 plane
ν_{13}	Poisson's ratio in the 1–3 plane
ν_{23}	Poisson's ratio in the 2–3 plane
ϵ_1^t	Ultimate tensile strain in fiber direction
ϵ_2^t	Ultimate tensile strain transverse to the fiber
ϵ_3^t	Ultimate tensile strain through the thickness^(a)
ϵ_1^c	Ultimate compression strain in the fiber direction
ϵ_2^c	Ultimate compression strain transverse to the fiber
ϵ_3^c	Ultimate compression strain through the thickness^(a)

(a) This property does not need to be determined if the 2–3 plane is transversely isotropic.

Fig. 1 Lamina and plate coordinate designation system for composites. Plate coordinates are labeled x , y , and z . Lamina coordinates are labeled 1, parallel to the fiber axis; 2, perpendicular to the fiber axis; and 3, normal to the fiber plane.

Properties of laminated composites are defined similarly to those for the lamina, except a laminate coordinate system (x , y , z) is employed. The subscripts 1, 2, 3 on the properties defined in Table 1 are respectively changed to x , y , and z , and the properties become the effective laminate properties. The word “effective” is very important because it signifies that the measured response is an average response through the material thickness. In reality, the stresses in a composite are nonuniform. It should also be noted that composites may behave differently in compression and tension; the elastic and strength properties must be characterized in both tension and compression to fully characterize the material.

Role of Specimen Fabrication

The test results from any characterization are critically dependent on material and specimen integrity. Material processing and specimen machining strongly influence the quality and reproducibility of test results. The recently issued ASTM D 5687, “Guide for Preparation of Flat Composite Panels with Processing Guidelines for Specimen Preparation,” provides descriptions of current practices for autoclave processed composites. Machining of test specimens influences the cost of characterization, and trade-offs must often be weighed between machining tolerance (program costs) and the requirements on the end use of that data.

Specific specimen geometry and laminate configuration requirements are defined for each test type and are associated with the discussion of the test methods. Materials for the test specimens are either cast, molded to shape, pultruded, filament wound, or machined from plaques or plates fabricated using autoclave or other processing methods. For laminates, a reference edge must be established, and each ply must be oriented accurately with respect to the reference edge. Before cure, the laminate reference edge is accurately scribed with a reference line that is used to maintain alignment when the cured plate is trimmed. The fiber volume fraction, void content, and the uniformity of fiber wetout in the part are controlled by the processing of the test panel or specimen. All of these factors strongly influence the mechanical properties of the material. Relationships between processing conditions and material microstructure must be understood and controlled to produce valid test specimens that are representative of the actual material being characterized (i.e., specimens that have the same microstructure and properties that the material will have in a structure). The specimen must be fabricated or machined so that the material axes align properly with the test axes.

Specimen Machining. When fabricated from panels, specimens are normally machined using a diamond wafering saw. A cut is first made along the reference edge, and then all subsequent cuts are made relative to the reference edge to preserve the accuracy of the fiber orientation in the panel. When machining specimens to final geometry, make allowances for scrap, and machine specimens from the heart of the material away from edges. A diamond saw blade produces a very smooth surface along the cut edges, and no further finishing is required usually. In specimens requiring holes, a diamond core bit provides satisfactory hole quality. Other methods

include ultrasonic drilling, or drilling with special drill bits in conjunction with templates to guard against punch-through delamination.

If a specimen is designed to have tabs, the tabs are bonded into place before the specimen is machined to its final shape. The tab material is typically 3.2 mm (0.13 in.) thick [0/90°] glass/epoxy or a woven fabric glass/epoxy material, although steel or aluminum can be used. When required, bevels are machined onto the tab, and then the tab is bonded onto the test panel using special jigs to ensure alignment of the tabs with the specimen reference edge. Individual specimens are cut from the tabbed panel, again taking care to maintain alignment with the reference edge (test axis).

Good quality composite specimens should be of uniform dimensions, have a precise fiber alignment, and possess high-quality finish on machined edges. There should be no evidence of delamination along machined edges. The laminate should contain no dry fiber regions, voids, or other obvious flaws. If available, ultrasonic C-scan should be employed to nondestructively evaluate composite panels for flaws prior to specimen fabrication and testing. Flawed panels or flawed regions within panels should be discarded.

Test Equipment and Fixturing Considerations

The availability of suitable, well-maintained, and accurately calibrated testing equipment is essential for reliable characterization of composite materials. Standard test instrumentation is used for load introduction and strain measurement of composite materials, but test fixturing must be specially designed to meet the specific requirements of the composite tests. The drawings and specifications for standard composite test fixtures are available for most test standards, and many fixtures are now available commercially. Testing is usually performed in a screw-driven or a servo-hydraulic universal test machine.

The test machine must have sufficient stiffness and load capacity to insure accurate load application and deformation measurement. A universal test machine with a load capacity greater than or equal to 110 kN (25×10^3 lbf) is recommended to test composite materials. Longitudinal tension and compression properties of some composite specimens require this capacity. Fiber tests, transverse tension, and flex properties require much lower load capacity. Universal test machines allow interchangeability of load cells to accommodate different testing requirements, and, when needed, small capacity load cells can be used in a 110 kN frame. The load cell must be properly matched to the loading requirements of the specimen in order to ensure required levels of accuracy and sensitivity.

Fixturing Issues. Proper fixturing is critically important to composite testing. The special fixtures for each test are designed to perform two important functions: (a) to transfer loads or displacements from the test machine to the test specimen, and (b) to achieve load introduction such that the desired stress state and deformation are produced in the specimen test section. The quality of test results is governed by proper fixture design, accurate machining to design specifications, and meticulous maintenance of the fixture.

No fixture functions perfectly in generating required states of uniform stress in test specimens; good tests closely approximate desired stress states and minimize stress concentrations in the test section. Mechanically, fixtures must provide reproducible alignment of the specimen in the test machine, and specimens should be easy to insert and remove after testing. The fixture must be strong and stiff enough not to change the characteristics of the state of stress in the specimen during the test. It must also be constructed of hardened materials that will not wear excessively with repeated use. Mating surfaces designed to slip relative to each other must be polished to stringent flatness-finish requirements to minimize friction binding during testing. Fixture functionality must conform to specifications in all required test environments.

All fixtures should be inspected routinely before testing to ensure that they are not worn or damaged in any way that will affect the test results. With use, all fixtures wear and eventually decrease the reliability of test results.

Electronic Transducers for Strain Measurement. Strain and deformation measurements are performed on composites using methods and instruments similar to those used for metals (Ref 4, 5, 6). A few issues must be addressed when using standard, bondable-foil strain gages on composites.

Gage heating is a problem that must be addressed when using bondable-foil strain gages on polymeric matrix composites because the polymer does not conduct heat very well. This allows heat to build up in the gage, and the resulting temperature change causes a resistance change, which is falsely recorded as an apparent strain. The use of 350 Ω (or greater) strain gages is recommended for composite testing, and the excitation voltage should be between 2 and 5 V. Measurement sensitivity is related to the excitation voltage, and 2 V is the lowest voltage that will ensure sufficient sensitivity.

Composites, especially woven fabrics and braided structures, have very coarse microstructure. The size of the strain-gage grid area must be large enough to average deformation over a representative area of the specimen. If the material is heterogeneous, such as a woven fabric, the grid must be large enough to cover at least one unit cell of the structure. A comprehensive discussion of this issue is covered by Masters and Ifju (Ref 6), based on their extensive survey of experimental results using strain gages of varying size on different types of fabric and braided composite structures.

The third problem that can occur when using bondable-foil strain gages for testing composites is that transverse strain sensitivity can influence strain measurements. This is especially prevalent for certain types of angle-ply lay-ups, such as the $[\pm 45^\circ]$ laminate. Correction factors must be applied to achieve accurate longitudinal readings measured under such conditions.

Environmental Conditioning

Environmental conditioning is perhaps one of the most controversial aspects of composites testing. It is not just the temperature at which the material is to be tested that is important. The entire temperature and moisture histories of the specimen influence the properties. Specimens should be preconditioned before testing by exposure to the specified temperature and humidity conditions. Specimens to be tested under standard laboratory conditions ($21 \pm 1.0^\circ\text{C}$, $50\% \pm 20\%$ relative humidity) can be conditioned in the laboratory for a period of 24 h prior to testing. Specimens designed to evaluate effects of environmental exposure must be conditioned by using conventional environmental chambers or temperature-controlled baths using the procedures outlined below.

Moisture conditioning is covered under a relatively new method (ASTM D 5229) and is usually specified in one of three ways:

- Exposure at a specific temperature and relative humidity or in a water bath to attain a target percentage weight gain
- Exposure for a specified time duration
- Exposure to attain equilibrium weight gain

Diffusion constants for composites are often very small, and sometimes accelerated conditioning practices are employed. A specimen can be soaked in water for short durations and attain a certain moisture content instead of being conditioned for months at 95% relative humidity to attain the same moisture content. Increase of temperature greatly increases the diffusion rate.

Accelerated conditioning is usually not equivalent to normal conditioning. The aging of the material is a rate process that depends on path; thus, specimens may not yield the same properties when conditioned using accelerated processes. Accelerated conditioning is considered a conservative approach, because accelerated conditioning typically yields larger degradation of properties than tests that are more representative of actual service conditions.

Prior to conditioning, polymeric matrix composites should ideally be fully characterized using infrared spectroscopy, thermomechanical analysis, and differential scanning calorimetry to determine the state of cure, moisture content, and glass transition temperature (T_g) of the matrix material. This information defines the preconditioned state of the material. The material can then be subjected to the specified environmental conditioning regimen. Once conditioned, specimens should again be characterized by analytical equipment. This is best done on travelers, which are dummy specimens conditioned along with the test specimens for this purpose. The test specimen cannot be used, since the analytical tests will influence the conditioning of the specimen and render it useless for testing.

Metal matrix and ceramic matrix composites also have requirements for environmental conditioning. The key difference is that these types of composites have less sensitivity to moisture uptake, because metallic or ceramic materials do not exhibit moisture-induced “aging” phenomena.

Analysis of Test Results

Statistical principles should be employed in test program design and analysis of test results (Ref 7). Variability is normal in all testing, and proper statistical treatment of data ensures that variability is handled properly in

deducing conclusions about the meaning and trends of the measured data. To start, typical variability of a given test should be used to determine the sample sizes needed to meet statistical significance requirements. Sample means, medians, and standard deviations are useful but may not be sufficient if the population is not normally distributed or if variance is large. Analysis of variance techniques may need to be employed to determine significance in comparisons of results.

Many investigators conduct parametric experiments changing one variable at a time to determine relationships among experimental variables. This approach results in huge, costly test matrices and often produces poor results. Design of experiments is a rigorous, statistically based method for testing the relationship of experimental variables. The design minimizes the number of tests necessary to determine the relationships between the test variables to a desired level of statistical significance. Consultation with an expert is advised, since this can save money and produce more reliable results. Several software packages are available to support statistical analysis and design of experiments.

In any experimental test program, failure modes must be carefully noted. Specimen failures should be the proper mode for the test being conducted and be consistent. Improper failures are an indication that the test is poorly designed, the specimen is flawed, or the test fixture or setup is improper. Failed specimens should always be saved, and typical failures should be photographed and documented.

Characterization of Mechanical Properties

The basic building block of laminated composites is the unidirectional lamina (Fig. 1). Specific test methods are available to measure lamina mechanical properties. The unidirectional lamina is highly anisotropic, which complicates mechanical testing. Alignment of the test specimen in the test frame is an important requirement for obtaining adequate test results, and undesirable transverse failures are a common occurrence in such materials. For these reasons, a number of investigators propose to back out unidirectional properties from laminate tests, but no acceptable standards have yet emerged, except for the $[\pm 45^\circ]$ laminate coupon subjected to uniaxial tension for the generation of lamina shear stress-strain response (ASTM D 3518). There exists a host of test fixtures, specimen geometries, and test procedures for the generation of mechanical property data for composite materials. Reviews and further information on the subject are provided in Ref 4, 5, and 8–10. Space limitations prohibit discussion of each test method. Only test methods accepted by the community as ASTM standards or as candidates for ASTM standardization are considered in this article. In cases where more than one method is discussed, the differences are clearly brought out, and guidelines are given about the use of each method.

Tension Testing

The most basic mechanical test is the tension test. For most structural materials, the tensile properties are essential elements of the material design allowables. The tension test is used to measure Young's modulus, Poisson's ratio, tensile strength, and ultimate strain to failure for composites. The properties reduced from tension tests on composite materials are effective (averaged) properties. The test method applies to unidirectional composites but can also be performed on laminates, woven fabrics, or discontinuous fiber composites. For asymmetric and/or unbalanced laminates, extension/bending coupling and extension/shear coupling effects produce nonuniform stress states in the test section. Under these conditions, effective properties cannot be accurately determined from the test results using the standard data reduction methods.

The adequate gripping of the test specimen is the major issue in tension tests. Any tension test specimens (Fig. 2) require gripping regions where loads are introduced through the specimen surfaces, a transition region, and a gage section region that may be of reduced cross-sectional area to promote failures away from the grips. Sufficient volume should be involved in the gage section to achieve adequate sampling of the material being tested.

Fig. 2 Generic tension test specimen

The widthwise tapering popular with metals (Fig. 2) usually leads to splitting failures of highly anisotropic composites in the gripping region prior to ultimate failure of the material in the gage section. This problem is avoided by using uniform width (rectangular) test specimens (Ref 10). The grips of the tension test frame introduce large clamping forces that can cause splitting failures or surface damage in the gripped region. These forces, coupled with normal stress concentrations induced by load introduction, can lead to anomalous failures. Tabs with tapered (beveled) ends, therefore, are bonded on each side of the specimen. The load is transferred into the specimen test section through shear (see Fig. 3). When tabs are used, the properties of the adhesive

must be carefully chosen to meet the strength and elongation requirements of the composite under the temperature and moisture conditions imposed by the test. Figure 4 shows the geometry of the ASTM D 3039 tension test specimen. Stress analysis of tabbed specimens (Ref 11, 12) indicates that intense out-of-plane peel and shear stress exist at the tip of the bevel and that the axial tensile stress in the specimen is increased. Consequently, tabbed specimens may fail at the tab ends or inside the tabs, but low bevel angles will reduce the stress concentration (Ref 11). Typically, bevel angles in the range of 15 to 30° are used because tabs with small taper angles occupy too much of the gage section.

Fig. 3 Load transfer in gripping region of tension test specimen through end tabs

Fig. 4 Specimen for tension testing of composites as defined in ASTM D 3039, L_g = gage length; L_T = tab length; θ = tab bevel angle; w = width

To characterize the tensile response of the unidirectional lamina, 0° and 90° specimens are employed to determine longitudinal and transverse properties. The [±45°] laminate tension test measures shear properties of the lamina and is discussed under shear testing. When characterizing multidirectional laminates, the tabs are sometimes replaced by emery paper inserted between the grips and specimen surface to avoid slippage and minimize surface damage, but in composite laminates with 0° surface plies, fiber damage is likely to occur in the gripping region if tabs are not used.

Specimen Machining and Instrumentation. For unidirectional composites of 0° fiber orientation, a specimen width of 12.7 mm (0.5 in.) and a thickness of 6 plies are common. Unidirectional 90° specimens are typically 25 mm (1 in.) wide and 8 to 16 plies thick. Laminates and sheet molding compound use the same geometry as the 90° specimen and have the specimen thickness defined by laminate configuration or fundamental sheet thickness. Loading eccentricity may arise due to variations in tab and specimen thickness. As proposed in ASTM standard D 3039, tolerances for tab and specimen thicknesses are ±1 and 4%, respectively (Ref 10). Tabs should be made from [±45°] or [0/90°] glass/epoxy or woven fabric composites. Printed circuit board (NVF Co., Kennett Square, PA) is often used because of its tight thickness tolerances. Laminates and sheet molding compound can be tested with or without tabs, although tabs are recommended for thin specimens. Gage length (L_g), (Fig. 4) is commonly 125 to 150 mm (5 to 6 in.).

It is common to bond continuous end tabs on the panels prior to machining the specimens. After careful surface preparation of the bonding surfaces of the specimens and end tabs (Ref 8), the end tabs are attached with an adhesive, typically Hysol 9309, 934 or 929 (Hysol Division, The Dexter Corporation, Pittsburg, CA) or similar epoxy adhesive appropriate to the test conditions specified. The tab length, L_T in Fig. 4, should be at least 38 mm (1.5 in.), and the tab material should be 1.6 to 3.2 mm (0.06 to 0.13 in.) thick. As pointed out in Ref 10 and 13, strips of beveled tab material of similar or slightly larger length than the width of the uncut composite panel should be bonded on both ends of the composite panel prior to machining the specimens. It is desirable to use a special tab-fixturing jig to symmetrically secure the position of the four strips of tabs on the composite panel to maintain positive alignment between the tabs and composite panel. Such fixtures are available commercially, (e.g., Ref 14).

Resin matrix composites are typically machined using a slitting saw or a water-cooled diamond saw (Ref 8). Polishing of the edges has been found to increase the strength, but the finish produced by diamond sawing meets the requirements of ASTM methods and is the commonly accepted industry practice. Alignment of the specimen axis with respect to the fiber direction is an important issue in machining of composites (Ref 8, 15). Hart-Smith (Ref 15) found that specimens cut with 1° of misalignment may cause as much as a 30% decrease in strength due to reduced effective width of the specimen. The variations of the specimen width should not exceed 1% (ASTM D 3039). If Poisson's ratio is desired, a $0/90^\circ$ strain gage rosette should be bonded in the center-gage-section region of the specimen. If only Young's modulus and strength are desired, a longitudinal strain gage or an extensometer attached to the specimen can be used. When load eccentricity is of concern, back-to-back strain gages may be used to detect bending of the specimen. When using strain gages on woven fabric materials, one must select the strain gage size to average deformation over a representative portion of the fabric structure. Failure to use a sufficiently large strain gage will result in large variability in the measured strain.

The specimen geometry and dimensions discussed so far are strictly valid for polymeric resin matrix composites but also apply to other types of composites, after some modifications. Johnson et al. (Ref 16) for example, who studied metal matrix composites containing unidirectional silicon-carbide fibers, found that laminates containing 0° fibers required reduction of the gage-section cross-sectional area (as shown in Fig. 5) so that the specimen would fail in the gage section without slipping or failing in the grips.

Fig. 5 Dog-bone specimen used for tension strength testing of fiber-dominated metal matrix composites. All dimensions are in millimeters. Source: Ref 16

Test Procedure. Use of standard wedge-action grips with hardened steel serrated jaws is the common practice. With such grips, the clamping pressure increases in proportion to the axial load acting on the specimen. Hydraulic grips provide means to adjust the clamping pressure to avoid crushing of the specimen ends at high loads. Alignment of the test specimen is especially important for unidirectional composites. The specimen is tested monotonically to failure while recording load, crosshead displacement, and strain. Normally, the test is run at a crosshead speed of 2 mm/min (0.08 in./min). Failure mode and location should be noted for each test along with ultimate failure load. A failure located outside the test section justifies rejection of the result. Figure

6 shows acceptable and common failure modes for 0 and 90° carbon fiber composites. Some 0° specimens literally explode. Safety glasses and a protective shield are recommended during tension testing.

Fig. 6 Commonly observed, acceptable failure modes of (a) 0°, and (b) 90° carbon/epoxy unidirectional composites

Figure 7 shows a representative example of stress-strain curves for a 0° glass/polyphenylene sulfide (PPS) composite, that is, stress σ_1 versus longitudinal and transverse strains, strains ϵ_1 and ϵ_2 . The stress σ_1 is defined as load divided by cross-sectional area in the test section. Based on the data collected from the test, the modulus E_1 was reduced using a least squares linear fit to the linear initial portion of the curve σ_1 versus ϵ_1 . Poisson's ratio, ν_{12} , was determined from the ratio of the initial slopes of σ_1 versus ϵ_1 and σ_1 versus $-\epsilon_2$, with $\nu_{12} = -\epsilon_2/\epsilon_1$. The ultimate strength in tension $\sigma_1^{\text{ult}} = X_1^T$ is the maximum value of σ_1 . Values of E_1 , ν_{12} and X_1^T are given in Fig. 7.

Fig. 7 Stress-strain response for a unidirectional [0]₈ glass/polyphenylene sulfide (PPS) specimen

Compression Testing

Compression testing is performed by subjecting a test specimen to an increasing compressive load until the specimen fails in a failure mode that is representative of that in an actual structure. As discussed in Ref 10, however, compressive failure is triggered by phenomena on the microlevel that are very difficult to observe, and detailed study is required to reach a clear definition of valid failure modes. It is clear, however, that strength degradation due to stress concentrations in the specimen arising from load introduction or slight eccentricities in load-specimen alignment should be minimized and that failure caused by global specimen buckling must be suppressed. Buckling and kinking of the fibers within the composite are features regarded as representative for the material and should not be inhibited.

To avoid buckling instability, relatively short gage lengths are necessary, but short gage lengths generally tend to amplify sensitivities due to clamping. Thus, for very short gage lengths, the apparent compressive strength tends to decrease (Ref 17, 18, 19). It is likely that nonuniformities in specimen thickness or in the bond or tab thicknesses result in nonuniform loading in the short gage section, leading to premature failure. Figure 8 shows

some typical failure modes. The failure modes shown in Fig. 8(a–c) are acceptable, but the column buckling failure (Fig. 8d) is clearly unacceptable, although difficult to visually observe. Because of the stress concentration at the tab ends, it is common to observe failure at the tabbed region (Ref 20). Such failures are not acceptable in tensile testing but are usually accepted in compression testing, because they rarely can be avoided (Ref 10).

Fig. 8 Typical failure modes for composite compression specimens

Several compression test methods have emerged during the past twenty years, and much confusion exists on their relative virtues. The methods may be grouped into three categories based on load introduction and specimen design: shear loading, end-loading, and sandwich beam specimen testing (Fig. 9). The sandwich beam specimen (Fig. 9c), may be tested in flexure or axial compression. Chatterjee et al. (Ref 10) presented a thorough review of currently available compression test methods and rated the methods according to problems associated with load introduction, uniformity of stress field, sensitivity to imperfections, simplicity, acceptability of failure modes, adequacy of data reduction, specimen preparation and fixture requirements, and consistency of results. Table 2 summarizes the various test methods and their ratings (1, 2, and 3). The test methods included in Table 2 are essentially based on polymer matrix composites but should be applicable to metal matrix and ceramic matrix composites as well. According to Ref 10, the Illinois Institute of Technology Research Institute (IITRI) test method (ASTM standard D 3410) is the most reliable and versatile. Because of space limitations, only the methods with the highest rating (1) are described here with the exception of the Boeing-modified ASTM D 695 method, which has been adopted as a recommended method (SRM 1-88) by the (Suppliers of Advanced Composite Materials Association) (SACMA). It should be emphasized that while all the methods provide adequate measures of modulus, the “true” composite strength may not be determined.

Table 2 Compression test methods for fiber-reinforced composites

Method	Description	Rating ^(a)
Shear-loaded specimen test methods		
Celanese (ASTM D 3410)	Long-established ASTM standard. Results are very sensitive to accuracy of fixture and test procedure.	2
Wyoming-modified Celanese	Cone grips replaced by tapered cylindrical grips. Post and bearing alignment replaces sleeve. Reduced fixture cost. Wider specimen	1
IITRI (Illinois Institute of Technology Research Institute) (ASTM D 3410)	An ASTM standard since 1987. Tapered flat wedges. Post and bearing alignment. Massive, relatively expensive fixture. Wide, thick specimen can be tested.	1

Wyoming-modified IITRI	Smaller, more simply fabricated version of standard IITRI fixture.	2
End-loaded specimen test methods		
ASTM D 695	Designed for unreinforced plastics. Not very suitable for composites.	3
Modified ASTM D 695	Currently a Boeing and SACMA recommended method. Deviates extensively from the ASTM standard. Short (4.8 mm) gage length	2
Wyoming end-loaded, side supported	Very simple fixture. Standard gage length. Limited by end crushing to low and medium-strength materials unless end tabs are used	2
RAE (Royal Aircraft Establishment)	Thickness-tapered specimen. Simple fixture. Few detailed results available	2
Block compression	Limited by end crushing to low-strength composites unless end reinforcement is used	3
Sandwich beam specimen test methods		
ASTM D 3410 Method C-flexure	Large specimen. Expensive to fabricate. Simple fixture. Reliable results if specimen is properly designed to prevent core failure	3
Sandwich column, axial loading	Must fabricate sandwich laminate. End crushing a problem	3
Mini-sandwich column, axial loading	Newly developed. Few data available. Promise of high measured strengths	2

(a) As rated in Ref 10; see text for general description of rating criteria.

IITRI Compression Test Method. Figure 10 is a schematic of the IITRI test fixture (ASTM Standard D 3410) (see also Ref 10 and 21). The upper block of the fixture is bolted to the crosshead of the testing machine. The lower block rests on the base of the test machine. The wedge grips have flat surfaces that rest in the end block cavities. Large diameter (19 mm, or 0.75 in.) rods and linear bearings are used to maintain alignment during linear motion of the upper block during testing. The standard IITRI test specimen is 140 mm (5.5 in.) long and has a width dependent on the design of the wedge grips. The maximum width reported is 38.1 mm (1.5 in.) (Ref 10). Figure 11 shows the specimen geometry and dimensions for unidirectional composites. For laminates and

short-fiber composites, 25 mm (1 in.) wide specimens are recommended (Ref 9). Variations in specimen width and thickness should be within ± 0.03 mm (± 0.001 in.). Untapered tabs are specified (Ref 20). Thickness, materials, and bonding procedures for the end tabs are the same as for the tension test. Extreme care should be taken to achieve tab surfaces parallel within 0.08 mm (0.003 in.).

Fig. 11 Dimensions for unidirectional specimens for the IITRI compression test

As with any compression test, concern about specimen buckling exists, and back-to-back strain gages should be attached to the specimen surfaces in the gage region (Fig. 11). By monitoring the stress-strain response for each gage, loading eccentricity and buckling instability can be detected. For a well-aligned, precisely machined specimen, the strains from both surfaces will be in close agreement (Fig. 12). Bending caused by loading eccentricity will cause the strains to diverge with increasing load until instability causes strain reversal (Fig. 12). When buckling instability occurs, the gage on the convex side will be relieved of some of its compressive stress and the corresponding magnitude of strain will decrease. The gage on the concave side (A in Fig. 12) will correspondingly experience an increased compressive strain. As a result of buckling, the apparent strength is decreased, and the compression test is invalidated.

Fig. 12 Schematic of stress-strain responses for well aligned (good test) and eccentrically loaded (bad test) compression test specimens

Since the compressive load is introduced in the specimen through shear (Fig. 9a) via tabs, there are stress concentrations in the regions at the ends of the end tabs at the beginning of the gage section. Consequently, failures are commonly observed close to the ends of the end tabs, but, as mentioned previously, such failures are difficult to avoid and are commonly accepted.

Test Procedure. Measure the width and thickness of the specimen to within 0.03 mm (0.001 in.) at several locations, and calculate the cross-sectional area. Attach strain gages on both sides of the specimen. Mount the specimen in the grips and place the grips in the fixture, which should be placed between the crosshead and the base on the centerline of the test machine. Set the crosshead speed at 0.59 to 1.2 mm/min (0.02 to 0.05 in./min). The strain readings may be recorded continuously or at discrete load intervals. If discrete data are taken, the strain readings should be captured at small load intervals in order to get at least 25 points in the linear response region. A total of 40 to 50 points is desirable to establish the total stress-strain response. Monitor all specimens to failure. Plot the data for reduction and inspect the stress-strain curves for signs of global bending of the specimen. To obtain the ultimate strain, the response curve may need to be extrapolated, assuming linear elastic behavior or curve fitting to the available stress-strain data. The modulus should be established by a least squares fit of the initial slope and, once established, the procedure should be consistently employed for modulus calculation.

Wyoming Modified Celanese Compression Test Method. The Wyoming-modified Celanese fixture is shown in Fig. 13. This fixture was developed at the University of Wyoming and avoids several shortcomings of the original Celanese fixture (ASTM standard D 3410). The fixture has wedge grips with a constant radius and does not require the troublesome alignment sleeve of the Celanese fixture (see Ref 10, 22). The fixture is much smaller than the IITRI fixture and weighs only about 4.5 kg, (10 lb), compared to about 40 kg (88 lb) for the IITRI. The low weight provides for easier handling and requires less time for reaching thermal equilibrium in nonambient temperature testing. The grips can, like the IITRI fixture (Fig. 10), be pretightened onto the test specimen and allow alignment of each pair of wedges with respect to each other.

Fig. 13 Wyoming-modified Celanese compression test fixture. Source: Ref 10

The test specimen is 114 mm (4.5 in.) long and 12.7 mm (0.5 in.) wide. The gage length is 12.7 mm (0.5 in.). The fixture can accommodate specimens that are between 3.8 and 6.4 mm (0.15 and 0.25 in.) thick in the tab region. Specimen fabrication, bonding of end tabs, tolerances, and testing and failure modes are equivalent to those outlined for the IITRI test.

Boeing Modified ASTM D 695 Test. The ASTM D 695 method as modified by Boeing (Ref 23) is illustrated in Fig. 14. The test method was adopted by SACMA as a recommended test method (SRM 1-88, April 1989) and is also under consideration for adoption by ASTM. As shown in Fig. 14, the specimen is end-loaded and face-supported with a 0° orientation; the test is predominantly used to measure longitudinal properties. To obtain both modulus and strength data, two tests are required. For strength measurement, tabs are bonded onto the specimen, increasing the bearing area in the end-loaded regions. For modulus determination, the specimen is not tested to failure, and the tabs are omitted.

Material	t, mm	D, mm
0° Uni tape	1.00	3.00
90° Uni tape	2.50	7.50
Fabric	2.50	7.50

Fig. 14 Boeing-modified ASTM D 695 compression test fixture. Source: Ref 10

The standard specimen is 80.8 mm (3.2 in.) long and 12.7 mm (0.5 in.) wide. Specimen thickness recommendations are given in the table in Fig. 14. A thin, tabbed specimen subjected to compression is face-supported along its length, except for the 4.8 mm (0.19 in.) long gage section, and buckling is commonly not a problem. For compressive strength determination, two continuous lateral supports without the strain gage recess are used. Typically, untapered [0/90°] or plain-weave fabric tabs made from the same type of material as that being tested are used. To determine the modulus, a strain gage is bonded at the center of an untabbed specimen, and a lateral support with a central cutout to provide clearance for the strain gage and its connections is used. As an alternative, continuous supports may be used with an extensometer attached to the specimen edge. The specimen should be deformed at least to 0.3% (Ref 10).

The end-load introduction can cause axial splitting or bearing failures on the loaded ends. This must be prevented and has prompted the use of tabs and end caps. Another problem is alignment. Alignment depends on the machining precision of the specimen ends; that is, on the parallelism between opposing ends and the perpendicularity of these ends to the specimen loading axis. Not only must the specimen be precise, but the test machine platens must also be precisely parallel and aligned with the axis of the test machine. Tolerances for specimen thickness and thickness of the tabbed region (t and D in Fig. 14) are ± 0.1 mm (± 0.004 in.). Tabs must be flat, parallel, and of equal thickness to within 0.05 mm (0.002 in.). Ends must be surface ground flat to within 0.03 mm (0.001 in.) and perpendicular to the reference axis. The third source of alignment error is specimen insertion. Much of the fixture-design complexity revolves around the preservation of specimen alignment in the test machine.

Because of the end loading, severe stress concentrations exist at the loaded ends. For the untabbed specimens used to measure modulus, this is not considered a problem because the central region is far away from the loaded edges. For the tabbed strength specimen, the use of tabs prevents failure at the loaded ends. For valid strength tests, failure modes and strength values similar to those seen with other compression test methods have been observed (Ref 10). Specimen fabrication, bonding of end tabs, and testing are equivalent to those specified for the IITRI test.

A number of studies have been conducted exploring the use of [0/90°] laminate configurations to obtain better strength results (Ref 24, 25). Results have shown that the highest strengths and lowest variability are measured using [90/0₂/90°]s laminates. Work by Welsh and Adams (Ref 26) confirmed the benefit of using [90/0°] laminate subgroupings to achieve higher strengths for either IITRI or modified ASTM D 695 test configurations. This is one area where serious consideration is being given to develop a standard based on laminate tests for determination of lamina properties.

Extending this concept, Adams and Welsh (Ref 27) have developed a new test method that uses combined loading to measure compression strength. The method uses both shear and end loading to test the [90/0°] laminate specimen and has been shown to produce results that are consistent with properly conducted tests using existing ASTM methods. An advantage of the method is the ease of testing and very consistent (low scatter) results. The method is currently under review for ASTM standardization.

Flexure Testing

Flexure, or bending, tests have emerged because of the simplicity of specimen preparation and testing. Figure 15 shows stresses developed in the three-point flexure test. It is readily observed that gripping, buckling, and end-tapping are not issues for this test and that testing is very simple. Analysis of the test reveals that the bending moment is balanced by a distribution of normal stress, σ_x . The top side is under compression while the bottom surface is under tension. Theoretically, the neutral axis is identically at the midplane where the shear stress, τ_{xy} , is maximum (see, e.g., Ref 28). In practice, differences in the tension and compression moduli exhibited by many composites invalidate this assumption, moving the neutral axis off the midplane of the beam and, unless corrected, making standard data reduction calculations erroneous. Depending on the span-to-

thickness ratio (L/h) and the strengths in tension, compression, and shear, the beam may fail in tension, compression, or shear. It can be shown that shear failure occurs at very short spans, and that failure in tension and compression occurs for longer spans. The three-point bend test for interlaminar shear strength determination is discussed in the section “Shear Testing” in this article. In this section it is assumed that the beam span is long enough to promote failure in tension or compression. Flexure tests are not recommended for determination of design data because deformation and failure of the material occurs under a combined stress state, and stress concentrations at load introduction points and supports may trigger failure (Ref 29). Consequently, the flexural modulus and strength are combinations of the corresponding tensile and compressive properties of the material. The flexure tests, however, may be used as a reference to previously obtained tensile and compressive data.

Fig. 15 Illustration of bending and shear stresses in the three-point flexure test

The flexure test is generally limited to unidirectional materials with the fibers aligned parallel or perpendicular to the beam axis. For laminates, interpretation of the results requires laminated beam theory (Ref 30).

Flexure Test Methods. Flexure testing utilizes the three-point or four-point methods (Fig. 16). The four-point flexure test is commonly performed with load noses located at the quarter-span points (Fig. 16b) but is sometimes configured with the loading at the third span ($L/3$) locations. Flexure tests are most commonly used to generate flexural modulus and strength for the purpose of quality control. Proper testing and data reduction may render the test data of more value than just a quality check. The span-to-thickness ratio, L/h , should be large for materials with a large ratio between the tensile and interlaminar shear strengths. For glass/epoxy tested along the fiber direction and graphite/epoxy tested perpendicular to the fiber direction, $L/h = 16$ is appropriate. For high tensile strength composites such as graphite/epoxy tested along the fiber direction, $L/h = 32$ is recommended (Ref 4). The diameter of the load noses and support pins should, according to ASTM standard D 790, be at least 6.4 mm (0.25 in.). The maximum diameter is three times the specimen thickness.

Fig. 16 Schematic of flexure tests. (a) Three-point loading. (b) Four-point loading

Specimen Preparation and Flexure Testing. The specimen is nominally 130 mm (5.1 in.) long, although longer span lengths would require longer specimens (see ASTM standard D 790). Although the ASTM standard D 790 does not indicate tolerances for the width, the ASTM D 3039 standard for tension testing specifies variations within $\pm 1\%$, which would amount to ± 0.13 mm (± 0.005 in.) for the flexure specimen. The accuracy of the total

length is less critical. Typically, 0° specimens use 12 to 16 plies, and 90° specimens use 16 to 30 plies (0.127 mm or 0.005 in., ply thickness).

Measure the cross-sectional dimensions of the test specimens to obtain an average of six measurements and check for parallelism of the edges. If a strain gage is to be used, bond one longitudinal strain gage at the geometrical center on the intended tension side of the specimen. The flexure fixture should be mounted in a properly aligned and calibrated test fixture. Determine the support span according to the beam thickness and material specifications as discussed previously, and set the support and load spans within 1% of their desired values. The crosshead rate, \dot{x} , should be selected so that the maximum strain rate (for a surface fiber) is $\dot{\epsilon} = 0.01/\text{min}$. For both the three-point and four-point methods (at quarter points), this leads to (Ref 4):

$$\dot{x} = \dot{\epsilon} L^2 / 6h \quad (\text{Eq 1})$$

Commonly, a crosshead rate in the range 1 to 5 mm/min (0.05 to 0.2 in./min) is selected. For three-point loading, place the specimen in the fixture with the strain gage on the tension side centered directly under the central loading pin. For four-point loading, the strain gage may be on either the top (compression) or bottom (tension) surface. If the vertical beam deflection, δ , is measured, place a calibrated linear voltage differential transformer (LVDT) or extensometer at the beam midspan. The vertical displacement may be approximated as the crosshead travel if the additional displacement due to the machine compliance is subtracted. The strain or displacement readings may be recorded continuously or at discrete load intervals. If discrete data are recorded, take the load and strain/displacement readings at small load intervals with at least 25 points in the linear response region. A total of at least 40 points is desirable for description of the response up to failure.

Data Reduction for Three-Point Loading. The flexural stress at the specimen surface at beam midspan is calculated from:

$$\sigma = 3PL/2bh^2 \quad (\text{Eq 2})$$

where P is the applied load, L is the span, b is the specimen width, and h is the specimen thickness.

If specimens with greater than a 16 to 1 span-to-thickness ratio are used, a correction factor must be used to compensate for the geometric nonlinearity caused by the large deflections that occur. By calculating the stress from the load data and plotting it versus the strain gage readings, a stress-strain plot for flexure can be constructed, and flexural modulus, E_f , is evaluated from the initial slope of the curve, and flexural strength, X_f , from the maximum stress. For the case that the specimen is not strain gaged, the flexural modulus is determined from the deflection δ according to (Ref 30):

$$E_f = \frac{PL^3}{4bh^3\delta} \left(1 + \frac{6h^2 E_x}{5L^2 G_{xz}} \right) \quad (\text{Eq 3})$$

where G_{xz} is the interlaminar shear modulus in the x - z plane. The last term in Eq 3 is a shear correction factor that may be significant for high axial modulus specimens with a low interlaminar shear modulus, that is, beams with the fibers along the beam axis.

For beams with the fibers perpendicular to the beam axis, shear deformation is generally not significant in bending, and the flexural modulus is given by the first term only:

$$E_f = PL^3/4bh^3\delta \quad (\text{Eq 4})$$

A problem with the shear correction according to Eq 3 is that the extensional and shear moduli (E_x and G_{xz}) must be known beforehand. For the purpose of correction, the extensional modulus E_x is equivalent to the tension modulus, E_1^t , and the shear modulus can be approximated by the in-plane shear modulus, G_{12} , if the fibers are along the beam axis. If the shear correction factor cannot be determined, the flexural modulus can be evaluated from Eq 4 at increasing span lengths until a constant value is achieved (see Fig. 17).

Fig. 17 Illustration of graphical method to determine flexural modulus free of influence of shear deformation

Data Reduction for Four-Point Loading (Quarter Point). The flexural stress at the specimen surface in the region between the inner load noses is given by:

$$\sigma = 3PL/4bh^2 \quad (\text{Eq 5})$$

If a strain gage is used, calculation of the stress from the load data and plotting stress versus strain allow determination of flexural modulus and strength exactly as previously outlined for three-point loading. If load and midspan deflection are measured, the flexural modulus is evaluated from:

$$E_f = \frac{PL^3}{64bh^3\delta} \left(11 + \frac{48h^2 E_x}{5L^2 G_{xz}} \right) \quad (\text{Eq 6})$$

where the symbols have the meaning as in Eq 3.

If the beam deflection is measured at the quarter points, which would be equal to the crosshead travel compensated for test machine compliance, the flexural modulus is (Ref 30):

$$E_f = \frac{PL^3}{8bh^3\delta_q} \left(1 + \frac{6h^2 E_x}{5L^2 G_{xz}} \right) \quad (\text{Eq 7})$$

where δ_q is the deflection at quarter points. Since the shear correction is proportionally larger for the quarter-point deflection formula Eq 7 than for the center deflection formula, Eq 6, shear deformation is less a factor for a test conducted with center-deflection measurement.

Shear Testing

A shear test is performed to determine shear modulus and shear strength of a composite material. The response of a material subjected to shear is commonly nonlinear, and full characterization requires the entire stress-strain curve. The tests may be grouped as in-plane tests that relate to the structural response of plates and shells, and interlaminar tests that relate to the behavior of local details such as joints. Figure 18 defines in-plane shear stress, τ_{xy} , and out-of-plane (interlaminar) shear stresses τ_{xz} and τ_{yz} . The corresponding shear moduli are denoted by G_{xy} , G_{xz} and G_{yz} and the corresponding shear strengths, S_6 , S_5 and S_4 , according to contracted stress notation.

Fig. 18 Definition of shear stress components. τ_{xy} is the in-plane shear stress, and τ_{xz} and τ_{yz} are out-of-plane shear stresses.

The ideal shear test method should provide a region of pure, uniform shear stress. It is also required that the shear stress and strain can be straightforwardly evaluated from the applied load and deformation measurements. The major difficulty in designing shear tests for composite materials is attaining a uniform state of pure shear stress in the test section. Many shear test methods exist as documented by Chatterjee et al. (Ref 10). Chatterjee et al. (Ref 10) ranked the various shear test methods using the same criteria as for the previously discussed compression test methods. Table 3 presents the various shear tests and their rankings. In this section, only the methods with the highest ranking (1) are discussed except for the $[\pm 45^\circ]_{ns}$ tension test because of its popularity in industry.

Table 3 Shear test methods for fiber-reinforced composites

Method	Description	Rating ^(a)
In-plane shear		
$[\pm 45^\circ]_{ns}$, tension, ASTM D 3518, SACMA SRM 7-88	Ultimate strength and strain not acceptable for thin specimens. Study required for effects of tabs and thickness. Effects of transverse tension may be important in some cases.	2
Iosipescu, ASTM D 5379	Acceptable. Correction factor and measurement of all strains with rosettes and back-to-back gages may be required.	1
Rail shear rectangular or parallelogram, ASTM Guide D 4255	Controlled 0° test required. 90° tests appear to yield good data. Measurement of all strains may be required for $[0/90^\circ]$ lay-ups.	1
Torsion-circular bar	Acceptable, but ultimate strains appear to be lower than Iosipescu and rail shear. Data reduction procedure is simple but needs approval from composites community. Machining required. Damage progression needs study.	2
Torsion-rectangular bar	Acceptable, but ultimate strains appear to be lower than Iosipescu and rail shear. Data reduction procedure is complicated. Damage progression needs study.	2
Torsion tube, ASTM standard under development	Excellent but expensive. Ultimate stress and strain levels high for fibers parallel to longitudinal axis of tube. Effects of this and other fiber orientations (hoop and slightly off from hoop) should be compared.	1
Off-axis tension	Acceptable only for modulus; correction factors based on aspect ratio required	...
Picture frame or cross	May be acceptable but more studies required. Tests are highly	...

beam	complicated.	
Slotted shear, ASTM D 3846	Not acceptable for material property testing, possibly useful for quality control.	...
Interlaminar shear		
Iosipescu, ASTM D 5379	Thick specimens with bonded layers required. Appears to be the best choice for unidirectional and fabric composites. Laminates may suffer from free-edge effects because of small width.	1
Short beam shear, ASM D 2344, SACMA SRM 8-88	Three-point loaded specimens not acceptable because of local failure near loading points and strong influence of bending stresses. Four-point loaded specimens with optimized dimensions may perform better.	...

(a) As rated in Ref 10; see discussion of Table 2 in text for general description of rating criteria.

Source: Ref 10

Short Beam Shear Test. The short beam shear test (ASTM D 2344) is a three-point flexure test with a span-to-thickness ratio constrained to 4 to 1, forcing shear failure prior to tension or compression failure. The specimen is all 0° lay-up, and the beam is usually 6.35 mm (0.25 in.) wide and between 2 and 3.5 mm (0.08 and 0.14 in.) thick. The specimen length should be approximately $4h + 16$ mm ($4h + 0.6$ in.), where h is the thickness. The apparent shear strength is calculated as:

$$\tau_{xz}^{\text{ult}} = 3P^{\text{ult}}/4bh \quad (\text{Eq 8})$$

The test does not always yield a pure shear failure and is not recommended for anything more than a quick and inexpensive QC test of fiber/matrix adhesion.

$[\pm 45^\circ]_{\text{ns}}$ Tension Test. The test geometry for the $[\pm 45^\circ]_{\text{ns}}$ tension specimen is shown in Fig. 19. The ASTM standard D 3518 suggests the same specimen geometry as for the ASTM D 3039 tension test. The specimen width typically ranges between 13 and 25 mm (0.5 and 1 in.). End tabs may not be required for polymer matrix composites. The test measures the in-plane shear stress-strain response in the fiber coordinate system and is only applicable for continuous fiber composites. Commonly, a $[\pm 45^\circ]_{\text{ns}}$ laminate is instrumented with a $0/90^\circ$ strain gage rosette as shown in Fig. 19. The specimen is prepared and tested in tension to ultimate failure following the procedures outlined for the tension test.

Fig. 19 ASTM D 3518 $[\pm 45^\circ]_{\text{ns}}$ tension test specimen for evaluation of in-plane shear stress-strain response of unidirectional composites

Determination of the lamina shear properties from the tension test requires stress analysis of the $[\pm 45^\circ]_{\text{ns}}$ specimen. Using laminated plate theory, Rosen (Ref 31) showed that the shear stress τ_{12} (see Fig. 19), is simply given by:

$$\tau_{12} = \sigma_x/2 \quad (\text{Eq 9})$$

where σ_x is the axial stress (P/A), and the shear strain is given by:

$$\gamma_{12} = \epsilon_x - \epsilon_y \quad (\text{Eq 10})$$

where ϵ_x and ϵ_y are the axial and transverse strains, respectively ($\epsilon_y < 0$). A sample calculation is provided in ASTM D 3518.

Stress State and Failure Modes. In addition to the shear stress τ_{12} , there exist normal stresses, σ_1 and σ_2 , as shown in Fig. 19. Because the stresses σ_1 and σ_2 are tensile, the apparent shear stress at failure may be reduced. It has furthermore been shown that thin $[\pm 45^\circ]_{ns}$ specimens with $n \leq 2$ may fail at load and strain levels that are too low and not representative for the shear strength of the material (Ref 32, 33). The thickness effect is attributed to multiple ply cracks that tend to be more localized and, thus, more detrimental in thinner specimens. V-Notch (Iosipescu) Shear Test (ASTM standard D 5379). The V-notch (Iosipescu) test method shown in Fig. 20 is based on modifications of the original test (Ref 34) by the composites group at the University of Wyoming (Ref 35, 36). Analysis of the specimen under compressive loading reveals that a state of relatively uniform shear stress exists in the center of the notched specimen (Ref 35, 36, 37, 38, 39). Because of the small specimen size and opportunity for interlaminar shear testing, the test has become popular. Figure 21 shows the specimen configuration for measuring shear response of unidirectional composites, but the test has also successfully been used for laminated, woven fabric, and chopped fiber composites.

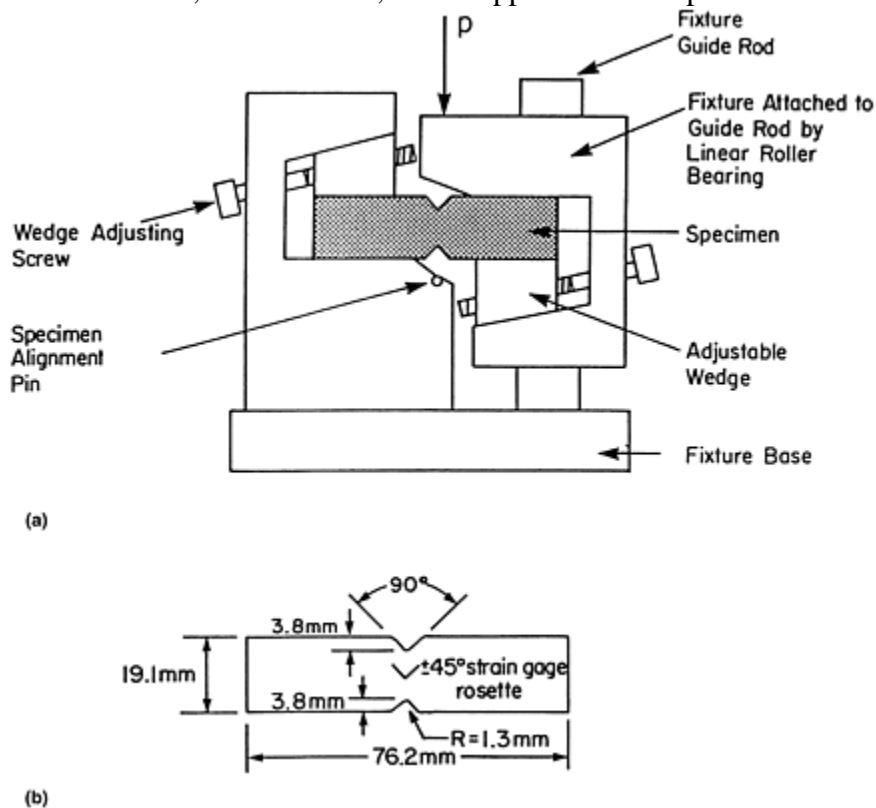

Fig. 20 Iosipescu shear test. (a) Testing configuration. (b) Specimen

Fig. 21 Iosipescu test specimen configurations and active shear stresses

The specimen (Fig. 20b) should be carefully machined. The loading faces should be ground smooth and parallel to avoid out-of-plane bending and twisting. Good quality notches with rounded tips are required to minimize stress concentrations at the notch tips and the occurrence of early failures, such as splitting in unidirectional, 0° specimens. Specimen thickness is nominally 2.5 mm (0.1 in.). A $\pm 45^\circ$ strain gage rosette should be attached to the center test section. If bending and twisting are of concern, the use of back-to-back strain gages has been suggested (Ref 39).

The specimen should be carefully centered and clamped in the test fixture using the specimen alignment pin (see Fig. 20a). Compressive load should be delivered by the crosshead at a rate of 1.5 mm/min (0.05 in./min) while monitoring the load and strain signals until the specimen fails. Determination of the shear stress-strain response of the material is based on shear stress calculated from:

$$\tau_{xy} = P/A \quad (\text{Eq 11})$$

where A is the test-section cross-sectional area in the notched region of the specimen. For 0° specimens, detailed stress analysis (Ref 39) has revealed a nonuniform stress state. Shear stress calculation incorporating a correction factor is suggested below:

$$\tau_{12} = 0.84P/A \quad (\text{Eq 12})$$

for a specimen with 90° angle notches. After early initiation of notch-tip damage, however, the stress becomes more uniform, and the use of the correction factor of 0.84 may be unwarranted (Ref 10). Shear strain, γ_{xy} , is simply calculated from the $\pm 45^\circ$ strain gage readings as:

$$\gamma_{xy} = |\epsilon_{45}| + |\epsilon_{-45}| \quad (\text{Eq 13})$$

or, if only a 45° gage is used:

$$\gamma_{xy} = 2|\epsilon_{45}| \quad (\text{Eq 14})$$

Failure Modes. Damage in the form of longitudinal matrix cracks initiating from the notches is a common occurrence in 0° unidirectional specimens. Load drops are observed when the cracks propagate, but the splits eventually arrest. The specimen can carry further load until final failure occurs, which involves multiple matrix cracks. 90° specimens fail early due to matrix cracking and do not produce a representative failure stress. Cross-ply $[0/90^\circ]$ lay-ups show distributed microcracking, which is representative for laminated composites. $[\pm 45^\circ]$ and quasi-isotropic lay-ups are difficult to test because of the high loads required for failure.

Rail Shear Test. The rail shear test is described in ASTM D 4255. The in-plane shear properties of unidirectional, laminated, and discontinuous fiber composites are determined by imposing axial load on a fixture consisting of two pairs of tensile loaded rails or three pairs of compressive loaded rails (see Fig. 22). Usually the specimen is bolted to the rails, but slippage is common at increasing loads for some composites. Adhesive bonding of the specimen to the rails has been suggested (Ref 40). Figure 23 shows the specimen geometries for the two-rail and three-rail tests. The diameter of the holes in the specimens exceeds that of the fasteners so that load is only transferred through shear. The specimens should be instrumented with $\pm 45^\circ$ strain gage rosettes as indicated in Fig. 22 and 23. To alleviate stress concentrations and cracking, especially in 0° unidirectional specimens at free edges at loaded corners, different specimen designs have been suggested (Ref 40), but such cracking may not be critical in 90° and $[0/90^\circ]$ lay-ups. The specimen thicknesses should be between 1.3 and 3.2 mm (0.05 and 0.13 in.) to avoid shear buckling while failing at reasonable loads. Tolerances for specimen and fixture dimensions are not provided in the ASTM D 4255 guide, but the dimensions are listed within 0.1 mm (0.04 in.), which should indicate the necessary accuracy.

Fig. 22 Rail shear test. (a) Two-rail configuration. (b) Three-rail configuration

Fig. 23 Specimen geometries for rail shear tests. (a) Two-rail test. (b) Three-rail test. All dimensions are in millimeters.

The test specimen should be bolted to the test fixture using a torque wrench (see ASTM D 4255). The crosshead speed should be 1.5 mm/min. (0.06 in./min), and load and strains should be monitored until the specimen fails. The shear stress is calculated from:

$$\tau_{xy} = P/bh \text{ (two rail)} \tag{Eq 15a}$$

$$\tau_{xy} = P/2bh \text{ (three rail)} \tag{Eq 15b}$$

where b and h are specimen length and thickness, respectively. The shear strain is determined from:

$$\gamma_{xy} = |\epsilon_{45}| + |\epsilon_{-45}| \quad (\text{Eq 16})$$

A stress-strain curve can thus be constructed, which enables shear modulus, G_{xy} , to be determined from the initial slope of the curve and the shear strength, S_{xy} , to be determined from the maximum stress.

Failure Modes. Due to stress concentrations at the corners formed at the intersection of the steel rails and the specimen, damage is likely to initiate at these locations. Such damage is usually in the form of matrix cracks that propagate along the fibers in a unidirectional ply. In a 0° lay-up, such cracks cause a large scatter in shear strength (Ref 40, 41). Tests with the fibers perpendicular to the rails or cross-ply $[0/90^\circ]$ laminates produce many ply cracks, but such cracking may not be detrimental and is often considered acceptable. Hussain and Adams (Ref 42) have developed a modification of the two-rail shear test that eliminates the need for holes, thus improving the stress distribution in the specimen. The simplification reduces the cost of fabrication significantly while producing results consistent with expectations from other tests. Tests on quasi-isotropic and $[\pm 45^\circ]$ lay-ups using the standard method have revealed delamination, and the results are not conclusive. The Wyoming-modified method (Ref 42) produced much better results on the $[\pm 45^\circ]$ lay-ups.

Torsion Tube Test. The torsion tube test (Fig. 24), is especially suited for in-plane shear testing of filament-wound structural parts, and has been recognized as an excellent shear test (Table 3) considered for ASTM standardization. The specimen, however, is difficult to fabricate from prepreg and can obviously not be used to test materials in the form of flat sheets. The specimen is bonded to the end fixtures using potting compound, instrumented with at least two three-element strain gage rosettes ($-45/0/45^\circ$) with the reference direction being the tube axis (Ref 43). The gage length-to-inner diameter ratio is unity (see Fig. 24), and wall thickness-to-diameter ratio is 0.02. This small ratio leads to minor variations in the shear stress across the wall, and the tube may be considered as “thin-walled.”

Fig. 24 Torsion tube shear test. All dimensions are in millimeters.

The shear stress is calculated from:

$$\tau_{xy} = Tr/I_p \quad (\text{Eq 17})$$

where T is the torque applied, r is the mean radius, and I_p is the polar moment of inertia. For a thin-walled tube, I_p is given by (Ref 28):

$$I_p = 2\pi r^3 t \quad (\text{Eq 18})$$

where t is the wall thickness. Equation (17) then becomes:

$$\tau_{xy} = T/2\pi r^2 t \quad (\text{Eq 19})$$

Shear strain, γ_{xy} , is evaluated from the gages at 45° and -45° :

$$\gamma_{xy} = |\epsilon_{45}| + |\epsilon_{-45}| \quad (\text{Eq 20})$$

An axial gage may be used to verify the absence of axial strains, that is, for a good shear test, $\epsilon(0^\circ) \sim 0$. Failure Modes. The tube specimen configuration under torque load produces a pure state of shear stress over most of the test specimen volume except near the grips. Hoop wound tubes fail perpendicular to the tube axis, away from the grips at low stress levels. Failure stresses and strains in tubes with axial fiber orientation or cross-ply [0/90°] lay-ups are larger than those for 90° tubes and comparable to other tests, but such tubes are difficult to make. Buckling is a possible failure mode for thin-walled tubes when the shear strength is large (Ref 44), such as in tubes containing $\pm 45^\circ$ angle plies. Such failures invalidate the shear test.

Mechanical Testing of Fiber-Reinforced Composites

Dale Wilson, The Johns Hopkins University, Leif A. Carlsson, Florida Atlantic University

Structural Laminate Properties

The lamina and laminate tests fail to address the effect of holes or cutouts in laminates, a critical requirement for structural design. Also, designers need experimental data quantifying the effect of impact induced damage on laminates. Of particular concern is the compression strength of impact damaged laminates, since sublaminates formed by delamination are susceptible to buckling that can produce failures at substantially lower failure loads than undamaged laminates. Open hole tension, open hole compression, and compression after impact tests have been developed to characterize the behavior of composite laminates with cutouts or damage. Methods have been written for these tests but none are currently standardized. Data from the open hole tests is routinely used in design analysis. The compression after impact test is used primarily in screening candidate materials.

Open Hole Tension Test

Cutouts and holes are requirements in many structural applications. The effect of cutouts in composite laminates is greater than the effect caused by the reduction in load-carrying area alone. Stress concentrations are produced in the laminate adjacent to cutout boundaries that substantially reduce load-carrying capacity.

Stress concentrations are a function of laminate anisotropy and cutout geometry. Sharp notches produce higher stress concentration factors than circular cutouts. However, the notch sensitivity of laminates is significantly influenced by laminate stacking sequence and a host of microstructural materials characteristics like matrix toughness, matrix stiffness, and fiber to matrix adhesion. High stress concentrations produce complex damage zones, which in turn redistribute the stress and increase the energy required to produce failure significantly above that predicted from the stress concentration factor alone. It has been shown that larger notches produce lower strengths, because the stress concentrations involve a larger volume, increasing the probability of failure due to a critical flaw (Ref 45). The stress distribution illustrated in Fig. 25 is the basis for the point stress criterion for notched strength prediction (Ref 46), which states that failure occurs when the stress at some characteristic distance d_0 reaches the unnotched tensile strength of the composite.

Fig. 25 Stress concentration adjacent to a hole in a composite laminate subjected to uniaxial loading

The test method for open hole tension uses a circular cutout in a test specimen (Fig. 26). The method is now standardized as test method ASTM D 5766. It employs a 305 mm long by 38 mm wide (12 in. by 1.5 in.) specimen containing a 6.35 mm (0.25 in.) hole. Quasi-isotropic laminate configurations are specified to be $(+45/0/-45/90^\circ)_{2s}$ for tape or $(\pm 45/(0/90^\circ))_{2s}$ for fabric prepregs. While other laminate configurations and geometries are possible, it is recommended that the width-to-hole diameter ratio of 6 be maintained.

Fig. 26 Open hole tension test specimen geometry. All dimensions are in millimeters.

The specimen should be machined to the specification shown in Fig. 26. Tolerance on the hole location relative to the specimen centerline is critical, since eccentricity can significantly decrease strengths. Specimens can be tabbed or untabbed, although untabbed specimens reduce cost. If ultimate strain and modulus are desired, specimens may be instrumented with a strain gage located on the specimen centerline 25 mm (1 in.) from the hole center. ASTM D 5766, however, covers only notched strength and does not contain provisions for strain measurement.

The test is performed as a uniaxial tension test following ASTM D 3039. The specimen is loaded until tension failure occurs through the notch. If failure occurs outside the notch, the test result should be discarded, since the failure was caused by a flaw in the material. If failures consistently fall outside the notch area, the naturally occurring flaws in the material are larger than the notch (this is possible with some sheet molding compounds). Then, the specimen design must be scaled to reflect the material inhomogeneity level. At least five specimens should be tested per test condition.

The notched strength σ_N is calculated as the tensile strength of the laminate based on the far-field stress:

$$\sigma_N = P/bd \quad (\text{Eq 21})$$

where P is the maximum load, b is the specimen width, and d is the specimen thickness. If the specimen is instrumented, the modulus is determined as:

$$E_x = \frac{P_3 - P_1}{0.002 bd} \quad (\text{Eq 22})$$

where P_1 and P_3 are the loads at 1000 and 3000 microstrain, respectively. The strain at failure is determined from the stress-strain curve.

Notched strength data is typically used for materials screening and for determining design allowables. For design, it is necessary to generate empirical data based on the material, the laminate configuration, and the hole

sizes required. In lieu of generating empirical data for every conceivable material, laminate, and hole size combination, it is possible to use the point stress criterion (PSC) analysis to interpolate notched strength over a range of hole diameters by testing a series of three different notch sizes for the material and laminate construction of interest (Ref 8, 47).

Open Hole Compression Test

Aside from the added complexity associated with specimen loading, much of what was described for the open hole tension test applies to the open hole compression test. Damage develops differently, and the failure mode reflects sensitivity to the microbuckling failure mechanisms that contribute to compression failure in composite materials. Gynn and Bradley (Ref 48) studied the damage mechanisms in open hole compression specimens and found that matrix stiffness plays a significant role in the development of a damage zone and the type of fiber failure mechanism that leads to ultimate failure. In ductile matrix composites, fiber kinking leads to the formation of a shear crippling zone across the net section of the hole, eventually leading to catastrophic failure. Brittle systems fail quickly and catastrophically, without evidence of the shear crippling behavior.

The open hole compression strength can be measured using the same specimen as the open hole tension test. One difference (shown in Fig. 27) is that more stringent tolerances are specified for the machining of the specimen ends. For end loaded compression tests the perpendicularity of the specimen ends with the loading direction is critical. The quality of the hole and the location of the hole relative to the loading centerline are also important. The compression test commonly employs the SACMA fixture shown in Fig. 28. The specimen is face supported during testing (see Fig. 28). The fixture incorporates a cutout around the specimen hole so as not to constrain damage propagation and artificially increase the failure load. It also provides a milled out section located 25 mm (1 in.) from the specimen cutout to accommodate a strain gage.

Fig. 27 Open hole compression test specimen geometry. All dimensions are in millimeters.

Fig. 28 Test fixture for the SACMA SRM-3 open hole compression test

Loading can be accomplished through two methods. The fixture halves can be bolted together, and the specimen is end loaded between compression platens after verifying that the specimen and fixture are perpendicular to the platens. The other method uses hydraulic grips that can simultaneously grip the fixture to

hold the specimen and apply compression through shear developed by friction between the fixture and specimen. This method is preferred but is often not available. The specimen is tested until failure and the following data reduction analysis applied to determine the open hole compression strength:

$$\sigma^{\text{ult}} = P/bd \quad (\text{Eq 23})$$

where P is the maximum load, b is the specimen width, and d is the specimen thickness.

Gripping pressure, a controllable test parameter with hydraulic grips, can influence the strengths measured if carried to an extreme. High clamping pressures induce transverse normal constraint that may raise the compression failure load. Since such transverse normal constraints are not present in most structural applications, the use of high clamping forces to increase open hole compression strength is nonconservative and ill-advised.

If strain is measured, the elastic modulus can be determined using the following equation:

$$E_x = \frac{P_3 - P_1}{0.002bd} \quad (\text{Eq 24})$$

where b and d are the specimen dimensions and P_3 and P_1 are the loads at 3000 and 1000 microstrain. The ultimate open hole compression strain is found from the stress-strain plot.

Another test method is based on the “Northrop specimen and fixture” (Fig. 29), which uses a smaller test specimen than that shown in Fig. 27. It is also end-loaded and face-supported, but due to different geometry and boundary constraints it gives different strength than the SACMA method. There is no technical basis at this time to recommend one method over the other, but the Northrop specimen and fixture are less expensive and the method is easier to use than the SACMA method. Because of its lower mass, it is easier to use for testing under variable temperature and moisture conditions.

Fig. 29 Northrop test fixture and specimen geometry for the open hole compression test

Compression-after-Impact (CAI) Test

Concerns about damage tolerance of composites in primary load bearing aircraft structures prompted the development of test methods to measure fracture toughness and damage tolerance. Fracture mechanics test methods have been adapted to measure interlaminar crack growth resistance and are covered in the next section of this article, "Interlaminar Fracture." Damage tolerance tests have been developed that simulate foreign object impact and then measure residual strength properties of the "damaged" laminates.

The tests are quite complex since they involve two separate and distinct events, damage generation by impact and compression strength testing of impacted specimens that involves post-impact damage propagation. Damage is imparted by striking a test laminate with a projectile or instrumented impact tup having a specified energy. During impact, the test panel, usually a quasi-isotropic laminate, is held by a fixture capable of consistently applying defined boundary conditions. During impact the specimen can be loaded or unloaded. Depending on the geometry of the impactor, the energy applied, and the toughness and lay-up of the test panel, damage can range from through-penetration to nonvisible internal delamination. It is important to have a nondestructive method to assess the level of damage sustained by the specimen before testing for residual strength. While either tension or compression loading can be applied to determine residual strength, compression is most common. Under tension loading, the strength tends to be reduced by an amount equivalent to the laminate having a hole similar in size to the primary damage zone. In compression, sublaminar buckling occurs as a result of the delaminations in the damage zone, amplifying the reduction in strength.

A method popularized by Boeing in specification BSS 7260 became, by virtue of widespread use, a defacto industry standard for materials screening. The method was formalized by publication of SACMA SRM-2 and is currently under development as an ASTM standard test method. This method covers both the impact and compression after impact testing of a composite laminate. The impact is produced by a falling weight with a 15.9 mm (0.625 in.) diameter hemispherical tup dropped from a height so as to produce 170 Nm (1500 lbf · in.) of energy per 25.4 mm (1 in.) of laminate thickness. The test panel is nominally 152 by 102 mm (6 by 4 in.) wide by 5 mm (0.2 in.) thick and is held during impact by mechanical clamps on a steel fixture with a 76 by 127 mm (3 in. by 5 in.) opening (Fig. 30). Subsequent to impact, the laminate is ultrasonically scanned to reveal the extent of damage imparted and then subjected to compression testing. The panel is not loaded during impact and is used to assess damage tolerance due to low-velocity, nonpenetrating impact.

Fig. 30 Fixture used to support the test specimen during impact for the compression-after-impact (CAI) test. Dimensions are in millimeters.

A quasi-isotropic $[45/0/-45/90]_{3s}$ laminate machined to the specifications summarized in Fig. 31 is used as a test specimen. The number of repeating units should be adjusted for different grades of prepreg in order to keep the laminate in the 4 to 6 mm (0.16 to 0.24 in.) cured thickness range. It is highly recommended that the test panel be instrumented with four strain gages located as indicated in Fig. 31 to characterize any eccentricity in loading and to indicate the onset of any excessive delamination growth in the test specimen under compression loading.

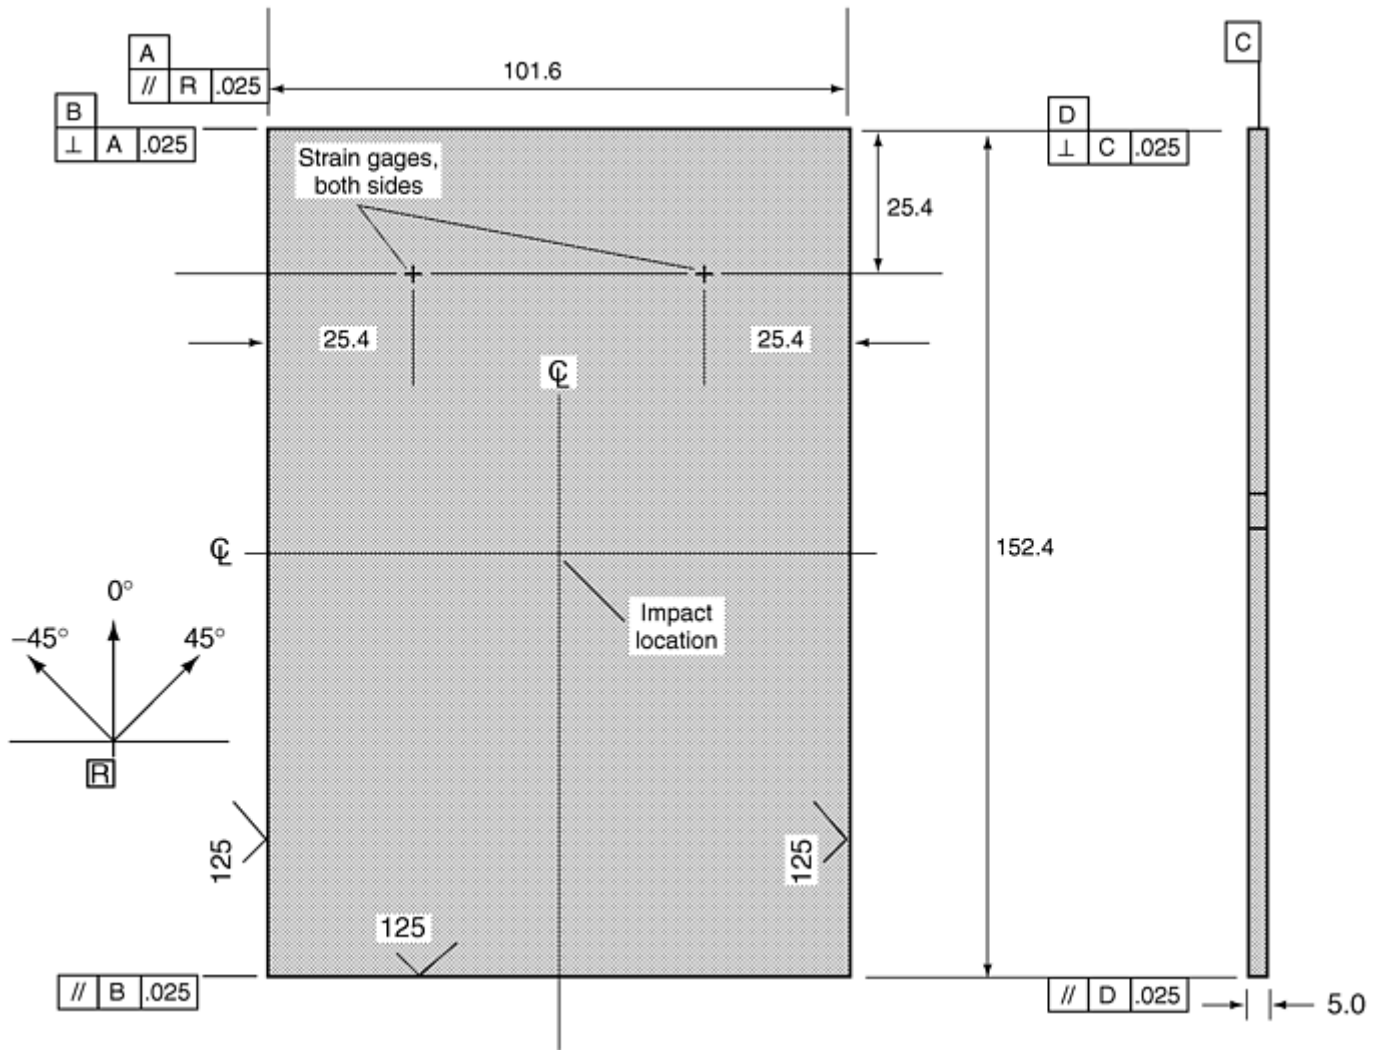

Fig. 31 Specimen geometry for the compression-after-impact test

The compression test is carried out using the fixture shown in Fig. 32. The vertical edges of the specimen are lightly supported by knife edges to simulate simply supported conditions, and the specimen is clamped along the top and bottom edges. The clamping along the top and bottom help constrain brooming failures at the load introduction boundaries. The test is carried out at a loading rate of 1.5 mm/min (0.05 in./min) in a load frame of at least 250 kN capacity until failure occurs as indicated by a drop in the load deflection curve.

Fig. 32 The test fixture used to conduct compression-after-impact testing

Typical stress-strain results are shown in Fig. 33. Ideally, the four strain gages will track closely with each other. Separation is an indication of eccentricity in load introduction. Divergence near the failure load indicates the onset of global buckling, and early divergence is an indication of sublaminar delamination growth and buckling instability. The compression after impact strength, σ^{ult} , is calculated by dividing the failure load by the cross-sectional area:

$$\sigma^{\text{ult}} = P^{\text{ult}}/bd \quad (\text{Eq 25})$$

where P^{ult} is the failure load, and b and d are the specimen width and thickness respectively. The test results are not considered valid if the impact damage area extends to the edge of the test plaque; these specimens are normally removed from the test matrix. Indication of excessive eccentricity during loading, normally caused by improper specimen machining, and failure of the specimen at a location outside the impact damage zone are reasons to invalidate test results. It is important to examine and record failure location and mode as part of the test results.

Fig. 33 Typical stress-strain behavior in a compression-after-impact test

A number of factors pertaining to the impact and compression test can influence the test results. A single impact is specified, and rebound impacts must be prevented. The weight of the tup assembly and the velocity of the impact can influence the type and amount of damage generated. The stiffness of the base assembly holding the specimen during impact affects the energy transfer, and, hence, the damage imparted to the specimen. A study by Fallabella et al. (Ref 49) showed this effect by comparing the plywood base originally employed by Boeing and the steel base specified by SACMA. Specimens impacted on the steel base incurred greater damage and exhibited lower compression-after-impact (CAI) strengths.

The compression test is sensitive to the amount of clamping pressure used to constrain the specimen during testing. The test specifies light constraint. Heavy clamping pressures can produce higher failure loads by changing the boundary conditions along the edges of the plate. Alignment is critical to prevent premature failures due to bending induced by loading eccentricity. Both the fixture and the specimen can be sources of misalignment and eccentric load introduction. Most fixtures have alignment features, so lack of specimen conformance to machining tolerances is the most common source of variability in load introduction.

Compression-after-impact test results from the SACMA method allow comparison of material performances under the specific conditions imparted by this test. The CAI data alone do not completely characterize a materials damage tolerance or toughness properties. CAI strength must be combined with other fracture toughness and mechanical property results to draw significant conclusions about the capabilities of a material. Design allowables should not be based on CAI test results. Subscale component tests must be used to provide the type of data required to assess a material's performance under design conditions.

Mechanical Testing of Fiber-Reinforced Composites

Dale Wilson, The Johns Hopkins University, Leif A. Carlsson, Florida Atlantic University

Interlaminar Fracture

With the introduction of composite materials into primary structures, defect and damage tolerance have become important issues for design and materials selection. While damage tolerance testing such as compression after impact testing is performed on substructure specimens or on prototype parts, the use of fracture tests has become popular for materials screening and qualification programs. Of particular interest is the characterization of interlaminar fracture resistance of laminated composites.

The short beam shear test is one of the methods most commonly applied to determine interlaminar properties, but it has many deficiencies. The fracture mechanics approach to interlaminar fracture characterization has evolved as a more fruitful approach. Fracture mechanics of composites is commonly based on the strain energy release rate, and fracture toughness is expressed as the work of fracture. Some background will be given in support of the description of the fracture tests.

It is generally recognized that the resistance to delamination is minimum at the interface between two unidirectional plies of the same fiber orientation. In composites with angle plies, the delamination may be deflected away from the desired midplane through matrix cracks, which invalidates the test. In composites with a tough matrix interleaf film at the midplane, the crack may deflect into an adjacent composite ply due to less crack growth resistance within the ply than between the plies, which would complicate the interpretation of the test results. Woven fabric composites possess resin pockets at the crack plane and may show significant variation in fracture toughness as the delamination grows. Composites with significant interlaminar strength and toughness, such as metal matrix composites and three-dimensional reinforced composites, may not fail in the desired delamination mode. Interlaminar testing of such composites would require specialized fixtures and

specimens. Consequently, the interlaminar fracture test procedures described here are strictly limited to unidirectional single-resin matrix composites.

Strain Energy Release Rate

The most commonly employed approach to characterize interlaminar fracture resistance of composites is by the strain energy release rate. The energy release rate, G , is a thermodynamic parameter that quantifies the energy available for crack growth. The fracture criterion based on G simply states that fracture (crack growth) will occur if the energy available for crack growth exceeds the work required to create a unit of new crack area (Ref 50). The energy approach does not require a detailed analysis of the stress state at the crack tip, where a stress singularity exists. Several delamination fracture tests employ beam specimens, and analysis of the energy release rate is based on simplified beam theory and strength of materials approaches for the calculation of the energy release rate of the fracture specimen.

For a specimen of width w containing a crack of length a , the condition for crack growth is:

$$\frac{d(W - U)}{dA} = \frac{dS}{dA} \quad (\text{Eq 26})$$

where W is the work performed by external forces, U is the elastic strain energy stored in the body, and S is the energy for crack formation (Ref 50). dA is the increment of new crack area, and $dA = wda$. The quantity $d(W - U)/dA$ is the net driving force for crack extension and is denoted by G . dS/dA is the crack growth resistance. If the crack growth resistance is independent of crack length, dS/dA is a material constant denoted by G_c , and is called “fracture toughness.”

The energy release rate can be related to the rate of change in specimen compliance with change in crack length (Ref 50). The specimen compliance, C , is defined as:

$$C = \delta/P \quad (\text{Eq 27})$$

where δ is the relative displacement of the points of load application, and P is the magnitude of applied load. It may be shown (Ref 50) that the strain energy release rate is:

$$G = \frac{P^2}{2w} \frac{dC}{da} \quad (\text{Eq 28})$$

Crack extension can occur through three distinct fracture modes, as shown in Fig. 34. Mode I is the crack opening mode, mode II is a shearing mode, and mode III is a tearing mode. Fracture may occur as a result of any one or a combination of these modes. In this article, only mode I and mode II and mixed mode (I and II) fracture test methods are covered, although Mode III test methods are being examined (Ref 51, 52).

Fig. 34 Modes of crack surface displacements. (a) Mode I (opening). (b) Mode II (forward shear). (c) Mode III (antiplane shear)

Several delamination fracture tests have been proposed (Ref 51, 52, 53, 54). This article restricts attention to only one test of each type. The double cantilever beam (DCB) and end-notched-flex (ENF) test and the mixed-mode bending (MMB) test methods have been recognized by ASTM Committee D-30 as promising interlaminar fracture tests.

Mode I Fracture

The DCB specimen for mode I fracture is now an ASTM standard (ASTM D 5528). The purpose of the test is to determine the opening mode I (Fig. 34a) interlaminar fracture toughness, G_{IC} , of continuous fiber composite materials with a polymer matrix. First developed in a tapered form by Bascom (Ref 55), the specimen has evolved to a straight-sided geometry, as shown in Fig. 35. The analysis developed for data reduction in the

subsequent sections applies only to the straight-sided specimen. The DCB specimen contains a nonadhesive film insert at the midplane to define a precrack of length a_0 , as shown in Fig. 35. Load is applied to the DCB specimen via the adhesively bonded hinges until the crack begins to propagate. Load, displacement, and crack length are monitored during the fracture test.

Fig. 35 Double cantilever beam (DCB) specimen geometry

DCB Specimen Preparation and Testing. The DCB specimen should be at least 125 mm (5 in.) long and between 20 and 25 mm (0.8 and 1.0 in.) wide. Panels should be manufactured with a nonadhesive Teflon or Kapton film at the laminate midplane. The film thickness should be less than 13 μm , and the film may be sprayed with a mold release agent before it is inserted between the plies. The insert length should extend approximately 63 mm (2.5 in.) from the front edge of the specimen to achieve an approximately 50 mm (2 in.) long precrack ($a_0 \sim 50$ mm), (Fig. 35). Because it is difficult to detect a thin insert film from the edge of a cut specimen, it is recommended that the end of the insert be carefully marked on the panel before cutting the specimens.

The laminate should contain an even number of plies, and the thickness, h , should be between 3 and 5 mm. Variations in thickness should not exceed 0.1 mm. For thin specimens of large fracture resistance, large deflections may lead to nonlinear response, and thicker specimens may be selected. After appropriate surface preparation of the hinges and the composite (see Ref 8), the hinges should be carefully aligned with the specimen axis and loading line and bonded with a room temperature curing adhesive, such as the adhesives recommended for the end tabs or cyanoacrylate (superglue).

Thickness and width of the specimen are measured at three points along the specimen length, close to the ends and at the center, and the results are averaged. The specimen edges are painted with a thin, white coating or typewriter correction fluid to enhance visualization of crack growth. To aid in recording of crack length, the first 5 mm (0.2 in.) from the insert are marked with thin vertical lines 1 mm (0.04 in.) apart. The remaining 20 mm (0.8 in.) of test length is marked every 5 mm (0.2 in.). Crack length, a , is the distance from the line of load application to the crack tip (see Fig. 35).

The DCB specimen is mounted in the grips of a properly calibrated test machine with a sensitive load cell (5 kN, or 1125 lbf, maximum load capacity). The delamination front is observed as the specimen is being loaded. Load is applied at a crosshead rate of 0.5 mm/min (0.02 in./min), and load versus crosshead displacement is recorded on an x - y recorder for real time visual inspection of the load-displacement response. Displacement of the loaded ends, δ in Fig. 36, is estimated from the crosshead travel, provided that the machine and load cell are stiff enough not to deform more than 2% of the total opening displacement.

Fig. 36 Definition of crack opening displacement for a double cantilever beam test

The crack front may not grow uniformly across the width of the specimen, so growth must be monitored on both edges of the specimen. A traveling optical microscope located on one side of the specimen with approximately 10 \times magnification and a crosshair can be used to monitor the crack tip location during the fracture test. A mirror is employed to observe the delamination front on the edge of the specimen away from the scope. The accuracy of crack length measurement should exceed ± 0.5 mm (± 0.02 in.). Prior to loading the specimen, the delamination crack front must be located and marked; this defines the precrack length, a_0 , shown in Fig. 35. On loading, when the delamination grows from the end of the insert, a_0 is used to mark the load on the chart recording as indicated in Fig. 37. This process is continued for each new increment of the crack growth, labeling chart points as 1, 2, 3 ... (see Fig. 37). For the first 5 mm (0.2 in.) of crack growth, the loads associated with each 1 mm (0.04 in.) increment should be marked on the chart. After 5 mm of crack extension, the crosshead rate may be increased to 1.5 mm/min (0.06 in./min) or higher, and load is marked at 5 mm increments of crack length extension. The difference in crack length between the two edges should be less than 2 mm (0.08 in.) at all times during the test. When the delamination has been extended about 25 mm (1 in.), the specimen may be unloaded while recording the unloading load-displacement response. This procedure should result in a load-displacement chart such as the one in Fig. 37.

Fig. 37 Schematic load-displacement record during crack growth for a double cantilever beam test

DCB Data Reduction. As the delamination grows from the insert, a resistance curve may be constructed by calculating and plotting the fracture toughness, G_{Ic} , versus crack extension, Δa , or crack length, a . A common occurrence in DCB testing is “fiber bridging,” which refers to debonded fibers bridging the fracture surfaces as illustrated in Fig. 38. The fiber bridging increases the apparent fracture toughness as a result of the fiber debonding process. This phenomenon may not occur at interfaces between dissimilar ply orientations in laminates used in composite structures. Fiber bridging is thus considered as an artifact I, and the significance of G_{Ic} values incorporating contributions from fiber bridging is questionable. It has been suggested that the only significant G_{Ic} value is the initial value associated with crack extension from the film insert, because fiber bridging occurs only after some crack extension (Ref 56).

Fig. 38 Fiber bridging in DCB testing of unidirectional laminates

Several data reduction methods for evaluating G_{Ic} have been proposed (e.g., Ref 4, 8, 9, 53, 54) (see also ASTM D 5528). The compliance calibration method based on the empirical compliance expression suggested by Berry (Ref 57) has gained substantial acceptance. In this method the beam compliance, $C = \delta/P$, is expressed as:

$$C = a^n/H \quad (\text{Eq 29})$$

where a is the crack length and parameters n and H are determined experimentally. Compliance values, $C_i = \delta_i/P_i$, corresponding to each crack length marked on the DCB specimen are evaluated from the data in Fig. 37. A plot of $\log C$ versus $\log a$ is generated using all data points, and a least squares analysis is used to fit a straight line to the data. The exponent n is obtained as magnitude of the slope of the straight line. Substitution of Eq 29 into Eq 28 yields at fracture:

$$G_{Ic} = nP_c\delta_c/2wa \quad (\text{Eq 30})$$

in which P_c and δ_c are the critical load and displacement associated with each crack length, a , and w is the specimen width.

Three toughnesses corresponding to crack growth from the insert may be defined (Ref 56). $G_{Ic}(NL)$ refers to the critical load and displacement associated with the deviation from linear response (Fig. 37). The second definition of G_{Ic} (visible) refers to the visual observance of crack growth measured with the traveling microscope. The third definition of G_{Ic} (5%) considers the load and displacement corresponding to a 5% increase in compliance or where the load has reached its maximum value. $G_{Ic}(NL)$ is typically the most conservative estimate of the fracture toughness. For subsequent crack growth, G_{Ic} is calculated from the recorded loads and crack lengths (Fig. 37) and Eq 30.

Figure 39 shows an example of a resistance curve R -curve for a graphite/polyetheretherketone composite. At the first loading increment, the delamination grows from the tip of the thin film insert starter crack without any influence from fiber bridging. The three fracture toughnesses, $G_{Ic}(NL)$, $G_{Ic}(\text{visible})$ and $G_{Ic}(5\%)$ are illustrated in Fig. 39. As the crack grows, the crack surfaces become more and more separated and bridged fibers may fracture or become pulled out from the matrix, which causes the apparent fracture toughness to increase. With further crack extension, a steady-state toughness is usually reached, $G_{Ic}(\text{prop.})$, corresponding to an equilibrium number of bridged fibers per unit crack area.

Fig. 39 R -curve describing mode I interlaminar fracture resistance of graphite/PEEK with a 13 μm insert. Source: Ref 56

Mode II Fracture

The end-notched flexure (ENF) beam specimen has emerged as a popular mode II test method since its introduction to the composite community by Russell and Street in 1982 (Ref 58). The purpose of the test is to determine the interlaminar fracture toughness, G_{IIc} , of polymer matrix continuous fiber composites in the forward shear mode (mode II) (see Fig. 34b). Pure shear loading of the crack tip is achieved by loading a cracked three-point flexure specimen (Fig. 40) until the crack propagates. The test has been used primarily with unidirectional laminates. The ENF specimen, like the DCB specimen, has been studied extensively by the ASTM D-30 Committee but the unstable crack growth experienced has delayed ASTM standardization.

Fig. 40 End-notched flexure (ENF) specimen geometry and dimensions

ENF Specimen Preparation and Testing. The ENF specimen (Fig. 40) is typically 120 mm (4.7 in.) long and 20 mm (0.8 in.) wide. Specimen thicknesses for unidirectional graphite and glass fiber composites are typically 3 and 5 mm (0.12 and 0.20 in.), respectively. The specimen is loaded in a three-point bend fixture (Fig. 41) with a distance between the supports, $2L$, of 100 mm (4 in.). The diameter of the loading and support pins should be about 5 mm (0.2 in.). The ratio of crack length to half-span, a/L , should be 0.5 prior to propagation of the crack. Panels should be manufactured with a nonadhesive Teflon or Kapton (i.e., DuPont de Nemours and Co., Wilmington, DE) film of thickness equal to or less than $13\ \mu\text{m}$ placed at the midplane to define a starter crack. As with the mode I test, the exact location of the precrack must be determined.

Fig. 41 End-notched flexure test configuration

After specimens have been cut from the panel, the width and thickness are measured at the center and 1 cm (0.4 in.) from each end. The thickness variations should not exceed 0.1 mm (0.004 in.). Prior to testing, the edges should be painted white. There is presently no consensus on whether or not precracking away from the starter film should be performed.

Precracking in mode I is likely to create fiber bridging and is not recommended (Ref 59). A shear precrack may be achieved by using a long specimen (length $> 150\ \text{mm}$, or 6 in.) with a long insert film ($a > 50\ \text{mm}$, or 2 in.), positioning the specimen so that a crack length of about 40 mm (1.6 in.) is achieved and loading the specimen until a short, stable extension of the crack occurs. The shear crack front, however, is not visible on the fracture surfaces of a broken-apart specimen, and accuracy of crack length measurement may suffer. Therefore, propagation of the crack directly from the insert film is recommended.

ENF Testing. The ENF specimen should be placed in a standard three-point bend fixture, so that a crack length, a , of 25 mm (1 in.) is achieved (see Fig. 41). Mark the support location on the specimen edge for subsequent measurement of crack length. The center beam deflection (load point displacement), δ , should be measured with a linear variable differential transformer (LVDT) or may be obtained from the crosshead displacement corrected for the machine compliance. The specimen is loaded at a crosshead rate in the range of 0.5 to 1 mm/min (0.02 to 0.04 in./min), while the load-displacement response is monitored on a chart recorder. Both

loading and unloading paths should be recorded. Observe the crack tip with the traveling microscope during loading to detect any stable crack propagation prior to fast fracture. Slow crack propagation preceding fast fracture is commonly observed in ductile matrix composites (Ref 60). If this occurs, mark this event on the load deflection curve. Brittle-matrix composites tend to show linear response (see the load-deflection curve for a brittle graphite/epoxy composite in Fig. 42). For such systems, fast fracture tends to occur without noticeable stable crack extension.

Fig. 42 End-notched flexure test load-deflection curve for brittle graphite/epoxy (AS4/3501-6). $L = 50.8$ mm (2 in.), $w = 25.4$ mm (1 in.) and $a = 27.9$ mm (1.1 in.)

After testing, the initial crack length can be verified by cracking the failed specimen in two parts and measuring the distance between the support pin (marked on the specimen edge) and the crack front defined by the insert film. Commonly the outer support pin leaves an imprint on the specimen surface that can be used to further verify the crack length measurements.

ENF Data Reduction. To evaluate the critical strain energy release rate (mode II fracture toughness), G_{IIc} , the load-displacement curve, shown in Fig. 43, is needed. Several toughness values may be determined, namely, $G_{IIc}(NL)$, $G_{IIc}(\text{visible})$ and $G_{IIc}(\text{max})$ referring to the loads at onset of nonlinearity, visual stable crack extension, and maximum load, respectively, as illustrated in Fig. 43. For calculation of G_{IIc} the initial crack length is required. For the specimen with no precrack, the initial crack length is measured directly from the tip of the starter film as already described.

Fig. 43 Schematic load-displacement curve for the end-notched flexure fracture test. $P(NL)$, $P(\text{visible})$ and $P(\text{max})$ denote loads at onset of nonlinearity, onset of visible stable crack growth, and onset of fast fracture, respectively.

The fracture toughness, G_{IIc} , is calculated from the following expression:

$$G_{IIc} = \frac{9a^2 P^2 (C - C_{SH})}{4wL^3 [1 + 1.5(a/L)^3]} \quad (\text{Eq 31})$$

where

$$C_{SH} = \frac{6L + 3a - L^3 / a^2}{20whG_{13}} \quad (\text{Eq 32})$$

The inplane shear modulus G_{12} can be used as an approximation to the interlaminar shear modulus G_{13} . To calculate $G_{IIc}(NL)$, $G_{IIc}(\text{visible})$, and $G_{IIc}(\text{max})$, the loads $P(NL)$, $P(\text{visible})$, and $P(\text{max})$, defined in Fig. 43 are substituted along with the initial crack length in Eq 31.

Mixed Mode Fracture

In most practical situations, delaminations in composite materials tend to grow in mixed-mode stress fields, that is, under combinations of tension and shear stresses ahead of the crack front. Experimental studies, (Ref 61, 62), have shown that the delamination toughness depends on the mode of loading. Consequently, delamination characterization requires mixed mode fracture testing. Several mixed mode fracture specimens exist, but most suffer from complicated test fixturing, a small range of mode mixities (G_{II}/G_I), and varying mode mixity as the crack grows (Ref 63). The most promising mixed mode test specimen for delamination toughness testing is the mixed mode bending (MMB) test (Fig. 44) proposed by Reeder and Crews (Ref 64, 65). The MMB test is currently a candidate for becoming an ASTM standard because of simplicity of testing and the wide range of mode mixities.

Fig. 44 Mixed mode bending (MMB) specimen and loading.

Figure 44 depicts the geometric parameters of the specimen. The MMB test is a superposition of the DCB and ENF tests discussed previously. As shown in Fig. 44, the loading lever adds an opening load to the midspan-loaded ENF specimen. The adjustable distance, c , between the point of load application and the midspan determines the ratio of the downward force to upward force and, hence, the mode mix. Pure mode II corresponds to $c = 0$ with the ratio G_{II}/G_I decreasing with increasing distance c .

MMB Testing. The MMB test employs a 150 mm (6 in.) long, hinged specimen prepared as the DCB specimen discussed above (no precrack). The specimen width, w , and nominal thickness, $2h$, considered by Reeder and Crews (Ref 64, 65) were 25.4 and 3 mm (1.0 and 0.12 in.), respectively. The initial delamination length, a , was 25 mm (1 in.), and the half-span length, L , was 50 mm (2 in.) (Fig. 44). A set of desired mode mixes $G_{II}/G_I = 0.25$ (2 in.), 1, and 4 can be obtained by proper setting of the distance, c .

A crosshead rate in the range of 0.5 to 1 mm/min (0.02 to 0.04 in./min) should be used for consistency with the DCB and ENF tests discussed above. A real time record of the load displacement response should be obtained using an x - y recorder, and the crack tip should be monitored by a low magnification traveling microscope. The occurrence of slow, stable crack growth should be marked on the load-displacement curve. The load-displacement record is principally similar to that for the ENF specimen (Fig. 43) which allows $G(NL)$, $G(\text{visible})$, and $G(\text{max})$ to be evaluated.

MMB Data Reduction. Reeder and Crews (Ref 64, 65) derived the following expressions for the mode I and mode II components of the energy release rate:

$$G_I = \frac{3P^2(3c-L)^2}{4w^2h^3L^2E_1} \times \left(a^2 + \frac{2a}{\lambda} + \frac{1}{\lambda^2} + \frac{h^2E_1}{10G_{13}} \right) \quad (\text{Eq 33a})$$

$$G_{II} = \frac{3P^2(c-L)^2}{16w^2h^3L^2E_1} \left(a^2 + \frac{h^2E_1}{5G_{13}} \right) \quad (\text{Eq 33b})$$

where

$$\lambda = \frac{1}{h} \left(\frac{6E_2}{E_1} \right)^{1/4} \quad (\text{Eq 34})$$

These expressions are quite accurate for the finite beam geometries employed in the MMB test. Study of Eq 33b reveals that the ratio G_{II}/G_I is only slightly dependent on crack length. An approximate equation for the mode mixity is obtained from the asymptotic beam analysis presented in Ref 65:

$$\frac{G_{II}}{G_I} = \frac{3}{4} \left(\frac{c+L}{3c-L} \right)^2 \quad c \geq \frac{L}{3} \quad (\text{Eq 35})$$

For $c < L/3$, crack face contact may occur, which invalidates the analysis above. Equation (35) may be used for initial (approximate) calculation of the mode mix, which ultimately should be calculated using Eq 33b.

The preceding sections of this article have presented a practical overview of the characterization methods used to measure the fundamental mechanical properties of advanced composite materials. Methods for determining basic engineering strength and elastic properties of lamina, structural properties of laminates, including open-hole and damage tolerance performance, and the material fracture properties have been presented. Understanding these static engineering properties and structural performance characteristics is crucial for making material selection decisions and for preliminary design development. While necessary, these properties are not the complete set of data required to design a structure. Design engineers must address numerous other issues, such as environmental effects, fatigue behavior, creep, and behavior under extreme dynamic loading. Two articles that follow provide valuable insights into how high strain rate and fatigue behavior of composites are characterized.

Interlaminar Shear Properties of Fiber-Reinforced Composites at High Strain Rates

John Harding and Stephen Hallet, Oxford University

Delamination damage in composite materials frequently occurs as a result of transverse impact loading. A significant parameter in determining the ability of the composite to resist delamination is its interlaminar shear strength. It is important, therefore, to be able to measure the interlaminar shear strength under impact. However, even at quasi-static rates of loading, the design of a specimen in which interlaminar failure occurs under pure shear is a significant problem. Under impact loading there is an added constraint in that quasi-static equilibrium must be achieved within the specimen well before it fails if the results are to be capable of meaningful interpretation.

Mechanical Testing of Fiber-Reinforced Composites

Dale Wilson, The Johns Hopkins University, Leif A. Carlsson, Florida Atlantic University

Types of Interlaminar Shear Test

In practice, the split Hopkinson pressure bar (SHPB) technique, as described in the Section “High Strain Rate Testing” in this Volume, is probably the best established for producing reliable data at impact rates of strain. Several different types of interlaminar shear specimen have been developed for use with this technique (Ref 66, 67) but all have some limitations. Although very inconvenient to manufacture, thin-walled tubular specimens cut with the axis perpendicular to the interlaminar plane and tested in the torsional SHPB would seem to offer a good chance of success, and excellent results have been obtained this way for a plain-weave glass fiber reinforced plastic (GFRP) (Ref 68). However, the continuous variation of shear direction in relation to the directions of reinforcement leads to problems in specimens with a cross-ply lay-up (Ref 69), problems that are likely to be equally if not more severe with unidirectionally reinforced specimens. This difficulty is overcome by the use of a double-lap design of specimen tested in the tensile SHPB (Ref 70). In these tests, however, the shear stress on the interlaminar failure planes shows some considerable variation, and significant normal stresses are present at the ends of the failure plane. More recently an improved single-lap design of shear specimen has been developed for testing in a modified-compression SHPB. This was first used by Bouette et al. (Ref 71) to determine shear modulus at high rates of strain and later by Bouette et al. (Ref 72) and by Dong and Harding (Ref 73) to determine interlaminar shear strength. This type of specimen has the advantage that the shear stress on the central interlaminar plane is close to uniform and the normal (peeling) stress is very small. More recently, the most commonly used design of single-lap specimen has been the subject of a detailed analysis by Hallett et al. (Ref 74) who have shown that with a cross-ply lay-up, failure may not initiate on the central plane but in a region of stress concentration adjacent to the central interlaminar plane. Nevertheless this remains the best documented and probably the most versatile technique for composites of different lay-ups and so will be the one presented in more detail here.

Mechanical Testing of Fiber-Reinforced Composites

Dale Wilson, The Johns Hopkins University, Leif A. Carlsson, Florida Atlantic University

Split-Hopkinson Pressure Bar Test

Specimen Design. The optimum design of a single-lap specimen and the Hopkinson-bar arrangement in which it is tested are shown in Fig. 45. This design has been used successfully in tests on unidirectional carbon fiber reinforced plastic (CFRP) (Ref 73) but, because of difficulties in fixing the specimen to the loading bars, it could not be used when testing unidirectional carbon/polyetheretherketone (PEEK). A modified design of specimen was therefore developed with a slightly different fixing to the loading bars (see Fig. 46). This has been used successfully in tests on both unidirectional and cross-ply carbon/epoxy and carbon/PEEK specimens and on woven reinforced carbon/epoxy and glass/epoxy specimens (Ref 75). Since very similar results were obtained in tests on carbon/epoxy specimens using the optimum and the modified geometries (Ref 73), the modified geometry is now most commonly used. The specimen is intended to fail on the central interlaminar plane where the shear stress is highest and most uniform and the normal stresses are lowest. In practice, the position of the failure plane will be constrained by the lay-up of the composite. For example, in a cross-ply specimen (see Fig. 46), the positions of the interfaces between the 0 and 90° layers with respect to the centerline between the notches will determine the failure plane.

Fig. 45 Split-Hopkinson pressure bar testing to determine the interlaminar shear properties of composites. (a) Optimum design of a single lap specimen. (b) Arrangement of the Hopkinson loading bars.

Fig. 46 Modified single-lap specimen for Hopkinson pressure bar testing of composites. (a) Specimen dimensions (in millimeters) and ply lay-up arrangement. (b) Arrangement of loading bars.

Test Details. Impact tests may be performed in a standard compression SHPB apparatus where a cylindrical projectile fired from the high-pressure gas gun strikes the input loading bar. The force transmitted through the specimen is recorded on the output bar strain gages, gage station GIII in Fig. 46. In analyzing the data, it is assumed that the specimen central plane is the interlaminar failure plane and that the shear force is uniformly distributed over this plane. Then the interlaminar shear stress may be determined directly from the output bar strain gages.

The shear strain in the region of failure is measured using $\pm 45^\circ$ strain gage rosettes mounted on either side of the specimen, as shown in Fig. 46. Signals from the specimen strain gage rosettes for an impact test on a plain-weave carbon fiber reinforced plastic CFRP specimen are compared in Fig. 47 (Ref 75). In general, signals of equal magnitude and opposite sign, $\epsilon_{+45} = -\epsilon_{-45}$, are obtained, indicating that on this scale the specimen is indeed in a state of pure shear, the engineering shear strain being given by $\gamma = 2\epsilon_{+45} = -2\epsilon_{-45}$. A divergence between the signals from the $+45^\circ$ and the -45° gages in the later stages of the test is apparent in Fig. 47, while at the end of the test the $+45^\circ$ gages fail while the -45° gages unload. This is probably due to the failure plane not being the central interlaminar plane. However a reasonable estimate of the engineering shear strain close to the failure plane may be made from the algebraic sum of ϵ_{+45} and ϵ_{-45} . The average shear stress on the interlaminar plane may be derived from the output bar strain gages so that, with allowance for the time delay for the stress wave to travel between the specimen gages and the output bar gages, a shear stress-strain curve may be obtained. Quasi-static and intermediate rate tests may be performed on the same design of specimen using shorter loading bars and conventional testing machines to apply the load.

Fig. 47 Strain-time signals from specimen strain gages in impact testing of a plain-weave carbon-fiber reinforced plastic single-lap specimen

Example Test Results. Stress-strain curves obtained in this way for cross-ply CFRP at a quasi-static, an intermediate, and an impact rate of strain are shown in Fig. 48. The variation in interlaminar failure stress and strain with strain rate, obtained from a set of five tests at each rate, are shown in Fig. 49. A marked increase in interlaminar failure stress and strain with strain rate is apparent. It is clear from Fig. 48 that the shear modulus is independent of strain rate. In an earlier study (Ref 73) where only the interlaminar failure stress was measured, a somewhat smaller increase with strain rate was generally observed except for carbon/PEEK, where no increase or a slight reduction was seen.

Fig. 48 Effect of strain rate on interlaminar shear stress strain curves for cross-ply carbon-fiber reinforced plastic

Fig. 49 Effect of strain rate on the interlaminar failure stress and strain

An impact test on a cross-ply CFRP specimen (Ref 74) has shown that failure does not occur on the interlaminar plane nearest to the centerline between the notches but, rather on a neighboring plane, which lies closer to the point where the notch tip radius on the input end meets the horizontal section of the notch. Since each reinforcing ply has a finite thickness, the exact position of the plane on which failure occurs will clearly depend on the precise position of the notch with respect to the lay-up. Nevertheless, the same result, that is failure on a plane slightly offset from the centerline in this manner, was also observed in the earlier work on unidirectional carbon/PEEK (Ref 76) where there was less constraint on the position of the failure plane.

Numerical Modeling of the Shear Test. In light of the experimental observation that failure does not occur on the central interlaminar plane, a numerical analysis was performed (Ref 76) to investigate the shear and normal stress distribution on the actual failure plane. For the cross-ply lay-up of Fig. 46, but simplified such that only a single ply that, on the central plane, had the 90° orientation, the highest shear stress concentration was found in the element where the notch tip radius joined the horizontal section of the notch, that is, at the input end of the experimentally observed failure plane. The numerically predicted shear and normal stresses on this plane are shown in Fig. 50. The mean shear stress in this figure corresponds to that which is measured experimentally. The implication of the numerical analysis, therefore, is that failure actually initiates at a shear stress that is approximately twice the mean shear stress determined experimentally and in the presence of a significant normal compressive stress.

Fig. 50 Numerically predicted shear and normal stresses on actual failure plane

However, using a modification form of Chang-Chang failure criteria (Ref 77), we found it possible to predict the initiation and growth of damage by delamination. This was predicted to start in the region of the shear stress concentration at the input end of the failure plane, followed almost immediately by similar damage in the corresponding element at the other end of the specimen and propagation from each end towards the center on the two interlaminar planes, which are then joined by a step in the middle. Such a step has been seen experimentally in unidirectionally reinforced specimens (Ref 76) but was not found in these tests on cross-ply material. In similar tests on woven GFRP (Ref 75), complete failure on the first of these planes was mirrored by extensive damage on the second.

Mechanical Testing of Fiber-Reinforced Composites

Dale Wilson, The Johns Hopkins University, Leif A. Carlsson, Florida Atlantic University

Summary

While the single-lap shear test using the modified specimen geometry (Fig. 46), allows the effect of strain rate on the interlaminar shear failure of laminated composites to be determined, the shear stress on the failure plane is not completely uniform, and failure initiates under a combination of stress concentrations in both shear and normal compression. A similarly detailed analysis has not been performed for the optimum specimen geometry (Fig. 45), so it is possible that the stress concentrations are less severe in this case. However, since in all practical applications, interlaminar shear failure almost certainly initiates in the presence of stress concentrations, the use of numerical analysis in conjunction with experimental testing becomes a necessity if the results obtained are to be capable of useful application. It is encouraging, therefore, that by the use of a modified Chang-Chang failure criterion, features actually observed in the single-lap shear test under impact loading, in particular the initiation and growth of delamination damage associated with the failure plane, have been successfully modeled numerically (Ref 74).

Fatigue Testing and Behavior of Fiber-Reinforced Composites

W. Steven Johnson and Ramesh Talreja, Georgia Institute of Technology

From the preceding discussions, one can see that the mechanical behavior of composites is complex and varied. The mechanisms of fatigue damage are also complex. This section gives an overview of fatigue testing and fatigue damage mechanisms for several classes of composite materials. Several types of mechanical measurements that can be made during the course of testing to assess fatigue damage are reviewed. In addition, some other destructive techniques that can be used to assess fatigue damage are described.

Fatigue Damage Mechanisms

Before attempting to predict life of composite components in service under cyclic loads, one should understand the mechanisms of damage that govern the material behavior. For this purpose, posing the following questions is useful:

- How does the material state (properties of constituents and interfaces) change from the initial to the instant when the first maximum load is applied?
- On reversal of the load from maximum to the initial value, does the material return to its initial state, and if not, what are the irreversible changes?
- How do the irreversible changes affect the response of the material to the next application of the load?
- What are the factors governing the progressiveness in the irreversible changes?
- What is the critical material state (failure), and how is it attained?

For metals, these questions have been addressed for many years, and the knowledge generated forms the basis for safe and reliable structural design as well as for the development of fatigue resistant metals. For composites, much remains to be done to reach the same level of progress. The problems faced for composites are complex due to the roles of constituents and interfaces and the many possible configurations in which composites can be made. It is inevitable that multiple fatigue mechanisms operate simultaneously with differing rates of progression. To facilitate a systematic interpretation of the mechanisms, fatigue life diagrams have been useful for polymer-matrix composites (PMCs) (Ref 78), ceramic-matrix composites (CMCs) (Ref 79), and metal-

matrix composites (MMCs) (Ref 80). In the following sections, the fatigue mechanisms for these material systems are reviewed with the aid of these diagrams.

Fatigue Life Diagram. The basic construction of a fatigue life diagram is shown in Fig. 51 for a unidirectional, continuous fiber reinforced PMC of standard materials (such as carbon/epoxy) subjected to cyclic tension in the fiber direction. Consider first a load cycle in which the maximum strain attained is within the scatter band of the composite failure strain. At the first application of the maximum load in this cycle, a certain number of fibers will fail, assuming the composite survives. The locations of fiber breaks will be determined by the points at which the fiber stress exceeded the fiber strength. A distributed pattern of fiber breaks will result (see Fig. 52, $N = 1$), and the matrix around broken fibers will experience higher stresses than elsewhere and will likely become inelastic. On reversal of the load to its minimum value, the inelastic strains will irreversibly change the material state from the virgin state. In the next and subsequent load cycles, the axial stress in unbroken fibers will progressively change. However, all cross sections containing broken fiber ends will not experience the same rate of growth of fiber breaks, because of the variability of the fiber strength, and failure will result from a cross section that can form a core of fiber failures of a critical size (see Fig. 52, $N = N_f$).

Fig. 51 Fatigue life diagram of a unidirectional composite under cyclic tension in the fiber direction

Fig. 52 Mechanism of fiber failure in region I of the fatigue life diagram

It can now be imagined that the number of cycles to failure, N_f depends on the fiber strength distribution, the geometric distribution of fibers, the matrix deformation characteristics, and the critical size of the core of fiber failures. For stiff and brittle fibers, the critical core size is expected to be small and the number of cycles needed to reach it could vary from a few to several millions, depending on how the initial pattern of broken fibers is formed. This extreme sensitivity to the first-cycle failure pattern overshadows the cycle-by-cycle progression of the fiber failure process. Thus, region 1 in the fatigue life diagram (Fig. 51), where fiber failure is the dominant

mechanism, is viewed as a nonprogressive failure region. The scatter band here is centered about the fiber failure strain, which is also the composite failure strain, and extends to infinite number of cycles.

Consider now a load cycle where the first application of load gives a maximum strain less than the lower limit of the composite failure scatter band. The number of fibers failed in this cycle will be insignificant. In the next and subsequent load cycles, the stress redistribution in the unbroken fibers due to matrix inelasticity would not increase the number of fiber breaks significantly. The inelastic cyclic deformation of matrix will, however, initiate fatigue cracks in the matrix, assuming that the local matrix strain exceeds its fatigue limit. The fatigue crack thus produced will grow progressively as a fiber-bridged crack, breaking some (weak) fibers while debonding others and growing around them (Fig. 53). At a critical crack size, depending on the maximum load applied, unstable crack growth will occur, resulting in composite failure.

Fig. 53 Mechanism of fiber-bridged matrix cracking in region II of the fatigue life diagram

This postulated sequence of events has been documented (Ref 78) for two PMC systems (Ref 81), and the sloping scatter band in Fig. 51 (marked as region 2) represents this progressive mechanism. The rate of progression of this mechanism depends on the maximum strain applied in the first load cycle. It is natural to expect that a threshold value of the maximum strain exists, below which the mechanism either does not progress (e.g., matrix cracks are not able to overcome the resistance given by fibers, Fig. 54) or does not cause further damage (i.e., unstable growth) in a great number of cycles. The region in the fatigue life diagram below such a threshold value is called the composite fatigue limit (region 3 in Fig. 51). It is expected that this threshold value for a given composite will depend on the matrix fatigue limit, the fiber stiffness and strength, the interface strength, and the distribution of fibers in the composite.

Fig. 54 Mechanism of matrix cracking arrested by fibers corresponding to region III of the fatigue life diagram

Effects of Constituents on Fatigue Damage. The fatigue life diagram described for Fig. 51 is based on the mechanisms expected to occur in standard PMCs such as glass/epoxy and graphite/epoxy. When the properties of the constituents are varied, for example, by changing the fiber stiffness, fiber strain to failure, or matrix

ductility, the mechanisms are affected and the resultant effects on the fatigue life can be easily understood by observing changes in the fatigue life diagrams. For instance, an increase in the fiber failure strain will displace region 1 upwards, while increasing fiber stiffness will delay matrix crack growth, shifting region 2 to the right as indicated in Fig. 55. On the other hand, increasing matrix ductility will enlarge the crack-tip plastic zone, thereby increasing crack-tip opening displacement and straining the bridging fibers further. The detrimental effect on fatigue life by this change in the mechanism will shift region 2 (Fig. 51) to the left (Fig. 55). Finally, improved fatigue properties of the matrix material and reduced fiber stiffness will raise the composite fatigue limit, reducing thereby the range of strain in which fatigue failure can occur.

Fig. 55 Trends in the fatigue life diagram induced by fiber stiffness and matrix ductility

In high temperature materials, such as MMCs and CMCS, the residual stresses can be large. For instance, in SCS-6/Ti-15-3, the residual stress on cooldown to the room temperature is compressive in the fibers. The inelastic cyclic deformation can relieve this stress and thereby increase the probability of fiber failure. This changes region 1 of the fatigue life diagram from having a horizontal scatter band of nonprogressive fiber failure to a sloping scatter band of cycle-dependent progressive failure. At high temperatures, the residual compressive stress in fibers decreases while the matrix inelastic deformation increases. These two effects render the fiber failure mechanism of region 1 even more progressive. The slope of region 1, thus, increases with increasing temperature (Ref 80).

In CMCs, where both constituents are brittle, the source of irreversibility in cyclic loading is provided primarily by friction at the debonded fiber/matrix interfaces. The fiber stress redistribution with cycles is caused by load transfer between matrix and fibers through the frictional shear stress at the interface. At room temperature, at which the matrix behaves in a brittle manner, its role in the fatigue process is not significant. Region 1 and region 2 of the fatigue life diagram are then not as easily separable as in PMCs and MMCs. The dominant mechanism in both regions is fiber failure, whose progression is governed by the fiber/matrix interface. A fatigue limit still exists but is not governed by the matrix. As discussed in (Ref 81), the fatigue limit in this case is given by the threshold below which the rate at which fibers are broken in a cycle is exceeded by the rate at which fibers bridge the matrix crack.

Effects of Fiber Architecture. In multidirectional laminates, other mechanisms in addition to those previously described come into play. These additional mechanisms consist primarily of multiple intralaminar cracking of off-axis plies and interlaminar cracking (delamination). These mechanisms can be viewed as subcritical, while those associated with failure of on-axis plies should be viewed as critical. The role of the subcritical mechanisms is thus seen as effecting stress transfer from off-axis plies to on-axis plies. This stress transfer occurs progressively, and failure occurs when the on-axis plies are stressed to their limiting value.

The progression of intralaminar cracking in off-axis plies is conveniently described by the evolution of the average number of cracks per unit length normal to the crack planes (or inverse of the average crack spacing). This crack density parameter is shown plotted against the number of load cycles of different maximum load value for a glass/epoxy cross ply laminate in Fig. 56. The evolution rate of this parameter depends on the

laminates geometry, that is, the thickness of the off-axis plies and the stacking sequence of the laminate, and the relative stiffness of the off-axis plies with respect to the on-axis plies.

Fig. 56 Evolution of transverse cracking under fatigue in a glass/epoxy cross-ply laminate at two stress amplitude. Data from Ref 82

The interlaminar cracking, that is, delamination, results from the local failure of the ply/ply interface due to the high (and complex) stress accompanying the fronts of the intralaminar cracks and by diversion of these fronts into the interlaminar planes. These distributed delaminations grow under cyclic loading and are thought to be responsible for altering the stress states in the plies, giving rise to the progressive cracking of the off-axis plies. In woven fabric composites, the fiber bundles develop multiple cracks in much the same way as intralaminar cracks in laminates. The interbundle planes crack in the crossover regions of the bundles and presumably play a role similar to that of delaminations in laminates.

Fatigue Testing

Strain gages are commonly used to measure the strain response of the specimens. However, strain gages only measure local strains. In general, fatigue damage in unnotched composite laminates may be quite random. Unless the strain gage is quite large, the measured strain may or may not reflect the random damage. O'Brien (Ref 83) has discussed the effect of gage-section size on composite stiffness measurements. In most cases, strain measurement over a 25 mm (1.0 in.) gage section is recommended. This will result in a global measurement of the effect of damage on laminate moduli. There is a trade-off, however; too large a gage length will not be sensitive to local damage, and too small a gage length will miss local damage.

In lieu of strain gages, clip-on extensometers can also provide excellent accuracy without the difficulty of bonding a strain gage in place. Most extensometers only give the strain in the axial direction of the specimen, although there are some special extensometers that can measure the transverse strain in the laminate as well. Since most extensometers are at least 13 mm (0.5 in.) in gage length, they will measure the global deformation of the composite. Extensometers are available for operation at a wide variety of temperatures.

As an example, the cyclic stress-strain response of a boron/aluminum laminate presented in Fig. 57 can be analyzed to yield several mechanical properties. These properties include the following:

- Initial elastic modulus (tangent modulus)
- Stiffness (secant modulus)
- Permanent plastic deformation (strain)
- Elastic unloading modulus after N number of cycles
- Stiffness after N number of cycles
- Cyclic strain
- Number of cycles to fatigue failure
- Strain to static failure
- Residual strength after a set number of cycles

Fig. 57 Schematic of the cyclic stress-strain behavior of a quasi-isotropic laminate of boron/aluminum as a function of number of cycles. Source: Ref 84

A detailed definition of each property along with the physical significance is presented next.

Initial Elastic Modulus. The elastic modulus E is the tangent modulus of the initial linear portion of the loading curve. The initial elastic modulus E_1 is measured on the first loading cycle as shown in Fig. 57. E_1 usually correlates with elastic modulus predicted by lamination theory for an undamaged composite. The initial elastic modulus is significant in that all later measurements of elastic modulus at N cycles will be compared to this initial modulus to give an indication of the amount of fatigue damage accumulated by the composite laminate.

Stiffness. The stiffness E_S is defined as the secant modulus of the loading cycle as indicated in Fig. 58. In order to eliminate permanent plastic deformation from the stiffness measurement, the stiffness is defined utilizing the unloading portion of the cycle (the stress range, ΔS , divided by the unloading strain range, $\Delta \epsilon$). The initial stiffness can be compared to measurements of stiffness at N cycles and is therefore significant.

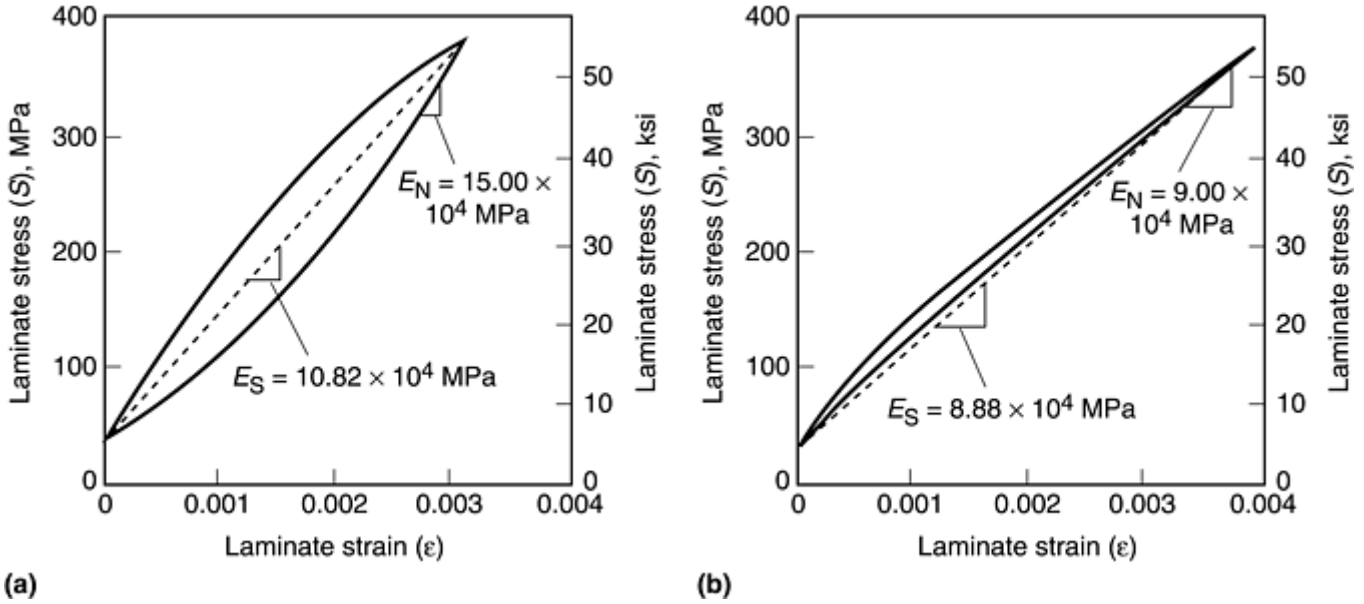

Fig. 58 The cyclic stress-strain response of a boron/aluminum ($[0/\pm 45/90/0/\pm 45/\overline{90}]_s$, $V_f = 0.45$) composite showing a dramatic change due to fatigue damage and cyclic hardening of the matrix material. (a) After 4 cycles. (b) After 500,000 cycles

The stiffness may be a useful measurement to design engineers since this is the total strain of the material in response to an applied load. (This is after no additional permanent plastic strain occurs during cyclic loading.) The stiffness is a combination of the elastic properties of the laminate as well as the plastic behavior of the metal matrix.

The stiffness is, therefore, a function of the matrix yield stress. The matrix may cyclically harden and the stiffness increase during the time damage initiates. (In some metals/heat treat conditions, the material may even cyclically soften. The properties of polymer matrix materials can also change with cycling and time/environmental dependent aging.) However, as the fatigue damage in the laminate grows, the stiffness decreases. Therefore, one cannot determine the onset and extent of fatigue damage in a metal matrix composite using a stiffness (secant modulus) criterion alone.

Permanent Plastic Strain. The permanent plastic strain, ϵ_p , is measured directly from the stress-strain curve. The permanent strain is usually accumulated in the first three or four cycles with little additional permanent strain accumulating thereafter. The accumulated permanent strain gives a good indication of the amount of residual stress in the 0° fibers since all the constituents in the composite are assumed to strain the same.

Elastic Unloading Modulus after N Number of Cycles. The elastic unloading modulus E_N is measured directly from the stress-strain curve at intervals throughout the life of the composite (Fig. 58). The percentage of the elastic unloading modulus at N cycles E_N as divided by the initial elastic modulus:

$$E_N/E_1 \times 100 = \%E_1$$

can be plotted against the number of fatigue cycles N in order to present fatigue damage as a function of constant amplitude cycling at a prescribed stress ratio and maximum stress.

Stiffness After N Number of Cycles. The stiffness (secant modulus) is measured as the stress range divided by the unloading strain range. The percentage of the initial stiffness is calculated by dividing the stiffness at N cycles E_{NS} by the initial stiffness E_{iS} $E_{NS}/E_{iS} \times 100 = \%E_{iS}$.

The $\% E_{iS}$ can be plotted against N in order to compare a “stiffness” and “elastic modulus” criteria for assessing fatigue damage.

Cyclic Strain. The cyclic strain $\Delta\epsilon$ is measured directly from the stress-strain curve. This strain range can be used to examine the possible correlation between the composite strain and fatigue endurance. The cyclic strain can also be multiplied by the elastic fiber modulus to calculate the cyclic fiber stress in the 0° plies.

Number of Cycles to Fatigue Failure. The number of cycles to fatigue failure N_F plotted against the maximum cyclic stresses for a given value of stress ratio is the traditional $S-N$ curve. This type of data can be used to determine the fatigue endurance limit stress and the maximum cyclic stress at a given stress ratio at which the composite laminate can be expected to survive beyond some endurance life. The $S-N$ curve does not, however, indicate the physical condition of the laminate at the established endurance limit other than the fact that the laminate can survive the endurance stress.

Residual Static Strength. Fatigue specimens that survive a given number of cycles without failure can be tested for residual strength to correlate fatigue damage and residual strength. The stress at failure, which is the maximum stress from the stress-strain curve, is defined as the residual static strength S_F .

Strain to Static Failure. For static strength tests, unfatigued composite specimens are loaded to failure. Thus, the strain to static failure $\epsilon_{f\text{tot}}$ is used to estimate the 0° fiber ultimate stress.

Mechanical Testing of Fiber-Reinforced Composites

Dale Wilson, The Johns Hopkins University, Leif A. Carlsson, Florida Atlantic University

Damage Assessment

The common methods of assessing the extent and type of damage can be divided into those techniques that are nondestructive and those that are destructive. The manual edited by Pendleton and Tuttle (Ref 85) is an excellent reference for several of the techniques, which are described further in the following.

Nondestructive Techniques

Edge Replica Technique. In the edge replica technique, a permanent impression of the specimen edge is produced in a cellulose acetate film. The advantage of this technique is that the replica can be taken while the specimen is under load in the test machine. The replica can then be examined later for details of damage, such

as matrix cracks, split fibers, or fiber/matrix separation. This technique can be easily used for replicating any surface for microstructural detail.

A softened acetate film is held against the desired surface to be replicated. Acetone is applied to the face of the film to soften it. The acetone serves to polymerize the acetate, making it viscous enough to flow into the microstructural cavities present on the surface. Pressure is applied to the backside of the film to aid in the flow process. The acetate film is allowed to dry in place for 3 to 5 min and then is carefully peeled from the surface. The replica can now be sputtered with gold (a thin layer of gold-palladium alloy) and viewed in a scanning electron microscope (SEM).

Radiography. As discussed earlier, much of the damage that develops in composite materials is of an internal nature (i.e., not readily observable from the surface). One of the more popular techniques to assess this internal damage is radiography. There has been much written about this technique, and a good summary paper can be found in Ref 85.

Depending on the differences in the x-ray absorptivity between the fiber and matrix, differing details of damage can be determined. Most fibers do not show well in radiographs, and it is nearly impossible to see individual fiber failures in graphite/epoxy composites. However, solutions for penetrant enhancement can allow for clear identification of matrix cracks and delaminations. The penetrant has a significantly higher opacity than the composite, so areas into which it penetrates show up well in the radiograph. For example, zinc-iodine solution enhanced the display of ply cracking and delamination in the radiograph of a composite after static testing (Ref 86). With penetrants, damage must come to a free surface (the specimen edge or radiate from a notch) so that the penetrant can wick into the damage areas. This is usually never a problem since most damage does start at the free edge or from a notch.

Several laboratories have special rooms set up such that specimens can be radiographed while under load in the testing machine (Ref 86). This makes the study of damage progression much more efficient.

Acoustic Emissions. This technique can be used real time to “listen” to damage occurring. Each noise emission has an energy level associated with it. Through much experience with a given composite system, the energy level of a given event can be associated with a damage mode (See Ref 87). The number of events or acoustic emission counts is also used to correlate with the extent of damage. This technique is very indirect, requiring a lot of experience and interpretation of data. Once again, Ref 86 has a good description of this technique.

C-scans. Ultrasonic through transmission C-scans are very popular for assessing initial quality of composite materials and components. They are an excellent way to assess the presence of delaminations, air pockets, or significant changes in density (for example, resin rich areas). The initial quality as indicated by C-scans may provide a good indicator of how the particular laminate will behave under fatigue loading (Ref 88). This technique is a little less useful for monitoring damage evolution since the part or specimen must be removed from the machine/structure and placed into the C-scan tank.

Destructive Techniques

Micrographs. After the specimen fails, the fracture surfaces and interface characteristics can be examined using SEM and energy dispersive x-ray analysis (EDXA). A SEM can be used to distinguish fatigue striation markings from dimple fracture patterns in order to determine if a portion of the fracture surface failed because of fatigue or static fracture. The SEM is also very useful for close-up viewing of any type of microstructural damage. The EDXA is useful for the determination of the chemical composition of the failure surface. This is especially useful for determining whether the failure occurred in the fiber, matrix, or in some reaction zone between the fiber and the matrix. Taking photographs through a 30 to 60 power optical microscope has also been used with considerable success to document damage, such as matrix cracking.

Matrix Etching. After a MMC specimen has been statically or fatigue loaded, matrix etching can be used to reveal two types of composite damage. First, etching away the matrix material will expose the fibers. The fibers can then be inspected for breaks. Second, by carefully etching away the matrix in the outer ply and then removing the exposed fibers, the next layer can be examined for matrix cracking and fiber damage. This technique can be used to systematically examine the damage of each ply in a laminate.

For 6061 aluminum matrix composites, a 30% hydrochloric acid (HCl) solution in distilled water was found to be effective for etching away the matrix without detectable damage to either boron or silicon-carbide fibers. The actual etching process must be carefully controlled if one wishes to remove one layer at a time to inspect the matrix in the underlying layers. Enough matrix material must be etched away to allow the surface layer of

fibers to be removed; however, if too much matrix material is removed, the matrix damage in the underlying ply will be etched away. This process is a trial and error operation at best and often requires several attempts before a satisfactory result is obtained.

Laminate Deply. The specimen-deply technique is a simple destructive-examination method whereby the individual plies of a polymer matrix laminate are separated for easy examination (Ref 85). This technique is excellent for determining the laminate-stacking sequence, studying the details of broken fibers, and determining the extent and precise interface location of delaminations. The interlaminar-bond strength is broken down by a partial pyrolysis of the matrix resin between the plies of the laminate. This allows for the separation (unstacking) of the individual plies, provided the adjacent plies have different fiber angles. The individual plies may then be microscopically examined to study the details of broken fibers. Furthermore, by using a marking agent prior to the pyrolysis, delaminations are clearly visible and matrix cracks in the adjacent ply may also be visible. This procedure is well suited to general angle-ply laminates of graphite/epoxy. The procedure for deplying graphite/epoxy composites was originally developed by S.M. Freeman (Ref 89).

Property Comparison Tables: Hardness and Tensile Properties

Fig. 1 General comparison of hardness scales

Table 1 Hardness of plastics (Rockwell R scale)

Material	High	Low
Melamine, cellulose electrical	125	115
Polyphenylene sulfide; unreinforced	124	...
Polyphenylene sulfide; 40% glass reinforced	123	...
Chlorinated polyvinyl chloride	122	111
Nylon, mineral reinforced	121	119
Polyester, thermoplastic, PBT; unreinforced	120	117

Polyester, thermoplastic, PET, 45 and 30% glass reinforced	120	...
Polyester, thermoplastic, PBT/PET blend, 30 and 15% glass reinforced	120	119
Cellulose acetate	120	49
Nylons, general purpose	120	111
PVC, PVC-acetate; rigid	120	110
Polysulfone; unreinforced	120	...
Phenylene oxide-based resins; unreinforced	119	115
Polyester, thermoplastic, PBT, 45 and 35% glass/minimal reinforced	119	114
Polyester, thermoplastic, PBT, 30% glass reinforced	119	118
Polyester, thermoplastic, PBT, 30 and 10% mineral filled	118	112
ABS/polycarbonate	117	...
ABS/polysulfone (polyaryl ether)	117	...
ABS	115	75
Polypropylene; glass reinforced	115	90
Cellulose acetate butyrate	114	23
Fluorocarbon, PVF ₂	110	...
Cellulose acetate propionate	109	57
ABS/PVC	102	...
Polypropylene, general purpose	100	80
Fluorocarbon, ETFE and ETCFE, unreinforced	95	...
ABS/polyurethane	82	70
Fluorocarbon, PTFE	55	35

PBT, polybutylene terephthalate; PET, polyethylene terephthalate; PVC, polyvinyl chloride; ABS, acrylonitrile-butadiene-styrene; PVF, polyvinyl formal; ETFE, ethylene tetrafluoroethylene; ECTFE, ethylene chlorotrifluoroethylene; PTFE, polytetrafluoroethylene.

Table 2 Hardness of rubber and elastomers (Shore A scale)

Material	High	Low
Thermoplastic elastomers	100	35
Urethane, polyether and polyester	100	80
Styrene butadiene	100	40
Natural rubber	100	30
Chlorinated polyethylene	95	40
Chloroprene	95	40
Chlorosulfonated polyethylene	95	50
Silicone	90	25
Polyacrylate	90	40
Nitrile	90	20
Fluorocarbon	90	65
Ethylene propylene, ethylene propylene diene	90	30
Epichlorohydrin	80	40
Isobutylene-isoprene	80	40
Polybutadiene	80	45
Polysulfide	80	20
Propylene oxide	80	40
Synthetic isoprene	80	40

Table 3 Hardness of ceramics (Mohs scale)

Material	High	Low
Mullite	18	14
Niobium carbide	10	9
Beryllium carbide	9+	...
Tantalum carbide	9+	...
Beryllia	9	...
Alumina	9	...
Titanium carbide	9	8
Zirconium carbide	9	8
Zirconia	8	7
Zircon	8	...
Steatite	7.5	...
Thoria	7	...
Magnesia	6	...
Porcelain enamel	6	3.5
Calcia	6.0	3.3
Boron and aluminum nitrides	2	...

Table 4 Hardness of metals (Brinell scale)

Material	High	Low
White and alloy irons; cast	700	130
Osmium	670	300
Low-alloy steels, wrought; normalized, quenched and tempered	627	202
Stainless steels, wrought martensitics hardened and tempered	580	180
Rhenium	555	331
Molybdenum and its alloys	555	179
Nickel and its alloys	534	75
Stainless steels, cast	470	130
Tungsten	443	330
Low-alloy steels, wrought; carburized, quenched and tempered	429	212
Copper casting alloys	415	35
Alloy steels, cast; quenched and tempered	401	262
Rhodium	401	100
Iridium	351	200
Gray irons; cast	350	140
Ruthenium	350	200
Nickel-base superalloys	341	302
Titanium and its alloys	331	...
Ductile (nodular) irons; cast	300	140
Hafnium	285	277
Malleable irons, pearlitic grades; cast	269	163
Stainless steels, standard martensitic grades, wrought; annealed	260	150
Ductile (nodular) austenitic cast irons	240	130
Tantalum and its alloys	237	...
Alloy steels, cast; normalized and tempered	217	137
High-strength low-alloy steels, 290–450 MPa (42–65 ksi) yield stress, wrought; as rolled	190	149
Depleted uranium	187	...
Zirconium and its alloys	179	112
Stainless steels, standard austenitic grades, wrought; annealed	170	143
Aluminum alloys, 7000 series	160	60

Malleable ferritic cast irons	156	110
Aluminum casting alloys	145	40
Aluminum alloys, 2000 series	135	45
Zinc foundry alloys	125	85
Aluminum alloys, 4000 series	120	...
Aluminum alloys, 6000 series	120	25
Palladium	118	40
Niobium and its alloys	114	...
Platinum	106	40
Aluminum alloys, 5000 series	105	28
Zinc die-casting alloys	91	82
Silver	90	26
Magnesium alloys, wrought	82	46
Magnesium alloys, cast	80	50
Aluminum alloys, 3000 series	77	28
Rare earths	77	17
Gold	66	25
Aluminum alloys, 1000 series	44	19
Tin and its alloys	29	5
Lead and its alloys	17	4.7
Indium	0.9	...

Table 5 Tensile yield strength of metals and plastics at room temperature

Material	Tensile yield strength			
	High		Low	
	MPa	ksi	MPa	ksi
Cobalt and its alloys	1999	290	179	26
Low-alloy hardening steels; wrought, quenched and tempered	1986	288	524	76
Stainless steels, standard martensitic grades; wrought, heat treated	1896	275	414	60
Rhenium	1862	270
Ultrahigh strength steels; wrought, heat treated	1862	270	1172	170
Stainless steels, age hardenable; wrought, aged	1634	237	724	105
Nickel and its alloys	1586	230	69	10
Stainless steels, specialty grades; wrought, 60% cold worked	1558	226	703	102
Tungsten	1517	220
Molybdenum and its alloys	1448	210	565	82
Titanium and its alloys	1317	191	186	27
Carbon steels, wrought; normalized, quenched and tempered	1296	188	400	58
Low-alloy carburizing steels; wrought, quenched and tempered	1227	178	427	62
Nickel-base super alloys	1186	172	276	40
Alloy steels, cast; quenched and tempered	1172	170	772	112
Stainless steels; cast	1138	165	214	31
Tantalum and its alloys	1089	168	331	48
Steel P/M parts; heat treated	1062	154	517	75
Ductile (nodular) irons, cast	1034	150	276	40
Copper casting alloys ^(a)	965	140	62	9
Stainless steels, standard austenitic grades; wrought, cold worked	965	140	517	75
Niobium and its alloys	931	135	241	35
Iron-base superalloys; cast, wrought	924	134	276	40
Cobalt-base superalloys, wrought	800	116	241	35
Bronzes, wrought ^(a)	786	114	97	14
Heat treated low-alloy constructional steels; wrought, mill heat treated	758	110	621	90
High-copper alloys, wrought ^(a)	758	110	62	9
Stainless steels, standard martensitic grades; wrought, annealed	724	105	172	25
Cobalt-base superalloys, cast	689	100	517	75
Heat treated carbon constructional steels; wrought, mill heat treated	690	100	290	42
Hafnium	662	96	221	32
Brasses, wrought ^(a)	638	92.5	69	10
Aluminum alloys, 7000 series	627	91	97	14
Alloy steels, cast; normalized and tempered	627	91	262	38
Copper-nickel-zinc, wrought ^(a)	620	90	124	18
Copper nickels, wrought ^(a)	586	85	90	13
Malleable irons, pearlitic grades; cast	552	80	310	45
High-strength low-alloy steels; wrought, as-rolled	552	80	290	42
Stainless steels, specialty grades; wrought, annealed	552	80	186	27
Stainless steels, standard ferritic grades; wrought, cold worked	552	80	310	45
Carbon steels, wrought; carburized, quenched and tempered	531	77	317	46
Carbon steel, cast; quenched and tempered	517	75
Stainless steel (410) P/M parts; heat treated	517	75
Steel P/M parts; as-sintered	517	75	207	30
Coppers, wrought ^(a)	496	72	69	10
Aluminum alloys, 2000 series	455	66	69	10
Ductile (nodular) austenitic irons, cast	448	65	193	28
Zinc foundry alloys	441	64	207	30

Zinc alloys, wrought	421	61	159	23
Stainless steels, standard ferritic grades; wrought, annealed	414	60	241	35
Aluminum alloys, 5000 series	407	59	41	6
Aluminum alloys, 6000 series	379	55	48	7
Aluminum casting alloys	379	55	55	8
Carbon steels, cast; normalized and tempered	379	55	331	48
Stainless steels, standard austenitic grades; wrought, annealed	379	55	207	30
Stainless steel P/M parts, as sintered	372	54	276	40
Rare earths	365	53	66	9.5
Zirconium and its alloys	365	53	103	15
Depleted uranium	345	50	241	35
Aluminum alloys, 4000 series	317	46
Thorium	310	45	179	26
Magnesium alloys, wrought	303	44	90	13
Silver	303	44	55	8
Carbon steels, cast; normalized	290	42	262	38
Beryllium and its alloys	276	40	34	5
Aluminum alloys, 3000 series	248	36	41	6
Carbon steel, cast; annealed	241	35
Malleable ferritic cast irons	241	35	221	32
Palladium	207	30	34	5
Gold	207	30
Magnesium alloys, cast	207	30	83	12
Polyimides, reinforced	193	28	34	5
Platinum	186	27	14	2
Iron P/M parts; as-sintered	179	26	76	11
Aluminum alloys, 1000 series	165	24	28	4
Polyphenylene sulfide, 40% glass reinforced	145	21
Polysulfone, 30–40% glass reinforced	131	19	117	17
Acetal, copolymer, 25% glass reinforced	128	18.5
Styrene acrylonitrile, 30% glass reinforced	124	18
Phenylene oxide based resins, 20–30% glass reinforced	117	17	100	14.5
Polyamide-imide	117	17	92	13.3
Polystyrene, 30% glass reinforced	97	14
Zinc die-casting alloys	96	14
Polyimides, unreinforced	90	13	52	7.5
Nylons, general purpose	87	12.6	49	7.1
Polyethersulfone	84	12.2
Polyphenylene sulfide, unreinforced	76	11
Polysulfone, unreinforced	70	10.2
Acetal, homopolymer, unreinforced	69	10
Nylon, mineral reinforced	69	10	62	9
Polypropylene, glass reinforced	69	10	41	6
Polystyrene, general purpose	69	10	34	5.0
Phenylene oxide based resins, unreinforced	66	9.6	54	7.8
Acetal, copolymer, unreinforced	61	8.8
ABS/polycarbonate	55	8.0
Lead and its alloys	55	8	11	1.6
Polyarylsulfone	55	8
ABS/polysulfone (polyarylether)	52	7.5
Acrylic/PVC	48	7.0	45	6.5

Tin and its alloys	45	6.6	7	1.3
ABS/PVC, rigid	41	6.0
Polystyrene, impact grades	41	6.0	19	2.8
Polypropylene, general purpose	36	5.2	33	4.8
ABS/polyurethane	31	4.5	26	3.7
Polypropylene, high impact	30	4.3	19	2.8

At 0.2% offset for metals, unless otherwise noted; tensile strength at yield for plastics, per ASTM D 638. P/M, powder metallurgy; ABS, acrylonitrile-butadiene-styrene; PVC, polyvinyl chloride.

(a) At 0.5% offset. Adapted from Guide to Engineering Materials, *Advanced Materials and Processes*, Dec 1999

Table 6 Tensile modulus of elasticity in tension at room temperature

Material	Tensile modulus			
	High		Low	
	GPa	10 ⁶ psi	GPa	10 ⁶ psi
Silicon carbide	655	95	90	13

Polybutylene, copolymer	0.23	0.034	0.08	0.012
Polyacrylate, unfilled	0.20	0.29
Polyethylenes, low density	0.19	0.027	0.14	0.020
PVC, PVC-acetate, nonrigid	0.021	0.003	0.0027	0.0004

PET, polyethylene terephthalate; ECTFE, ethylene tetrafluoroethylene; ETCFE, ethylene chlorotrifluoroethylene; PVC, polyvinyl chloride; PVF, polyvinyl formal; FEP, fluorinated ethylene propylene; PTFE, polytetrafluoroethylene

Glossary of Terms

A

A-basis

Mechanical property value above which at least 99% of the population of values is expected to fall, with a confidence of 95%. Also called A-allowable. See also B-basis, S-basis, and typical basis.

abrasion

Roughening or scratching of a surface due to abrasive wear.

abrasive wear

The removal or displacement of material from a surface when hard particles slide or roll across the surface under pressure. The particles may be loose or may be part of another surface in contact with the surface being worn. Contrast with adhesive wear.

accepted reference value

A value that serves as an agreed-on reference for comparison and which is derived as the following: (1) a theoretical or established value, based on scientific principles, (2) an assigned value, based on experimental work of some national or international standards organization, or (3) a consensus value, based on collaborative experimental work under the auspices of a scientific or engineering group. When the accepted reference value is the theoretical value, it is sometimes referred to as the “true” value.

accuracy

(1) The agreement or correspondence between an experimentally determined value and an accepted reference value for the material undergoing testing. The reference value may be established by an accepted standard (such as those established by ASTM), or, in some cases, the average value obtained by applying the test method to all the sampling units in a lot or batch of the material may be used. (2) The extent to which the result of a calculation or the reading of an instrument approaches the true value of the calculated or measured quantity. Compare with precision.

adhesive wear

The removal or displacement of material from a surface by the welding together and subsequent shearing of minute areas of two surfaces that slide across each other under pressure. In advanced stages, may lead to galling. Contrast with abrasive wear.

alligator skin

See preferred term orange peel.

angle of bend

The angle between the two legs of a specimen after bending is completed. It is measured before release of the bending force, unless otherwise specified.

anisotropy

The characteristic of exhibiting different values of a property in different directions with respect to a fixed reference system in the material. See also planar anisotropy

apparent area of contact

In tribology, the area of contact between two solid surfaces defined by the boundaries of their macroscopic interface.

arbitration bar

A test bar, cast with a heat of material, used to determine chemical composition, hardness, tensile strength, and deflection and strength under transverse loading in order to establish the state of acceptability of the casting.

asperity

In tribology, a protuberance in the small-scale topographical irregularities of a solid surface.

average linear strain

See engineering strain.

axial strain

See uniaxial strain.

B

batch

A definite quantity of some product or material produced under conditions that are considered uniform. A batch is usually smaller than a lot.

Bauschinger effect

The phenomenon by which plastic deformation increases yield strength in the direction of plastic flow and decreases it in other directions.

B-basis

Mechanical property value above which at least 90% of the population of values is expected to fall, with a confidence of 95%. See also A-basis, S-basis, and typical-basis.

bearing area

The product of the pin (or hole) diameter and specimen thickness in a bearing test. See also bearing stress.

bearing strain

The ratio of the deformation of the bearing hole, in the direction of the applied force, to the pin diameter in a bearing test.

bearing strength

The maximum bearing stress that a material is capable of sustaining.

bearing stress

The force per unit of bearing area.

bearing test

A method of determining the response to stress (load) of metal products that are subjected to riveting, bolting, or a similar fastening procedure. The purpose of the test is to determine the bearing strength of the material and to measure the bearing stress versus the deformation of the hole created by a pin or rod of circular cross section that pierces the sheet perpendicular to the surface.

bearing yield strength

The bearing stress at which a material exhibits a specified limiting deviation from the proportionality of bearing stress to bearing strain in a bearing test.

bend radius

(1) The inside radius of a bent section. (2) The radius of a tool around which metal is bent during testing or fabrication.

bend test

A test for determining the relative ductility of metal that is to be formed (usually sheet, strip, plate, or wire) or for determining soundness and toughness of metal (after welding, for example). The specimen is usually repeatedly bent over a specified diameter through a specified angle and then unbent for a specified number of cycles. There are four general types of bend tests, named according to the manner in which the forces are applied to the specimen to make the bend: free bend, guided bend, semiguided bend, and wrap-around bend.

biaxial stress

See principal stress (normal).

blanking shear test

A method used to determine the through-thickness shear strength of sheet material that involves blanking a disk out of flat strip using a simple punch-and-die method. Also known as punching shear test.

breaking load

The maximum load (or force) applied to a test specimen or structural member loaded to rupture.

breaking stress

The stress at failure. Also known as rupture stress. See also fracture stress.

Brinell hardness number, HB

A number related to the applied load and to the surface area of the permanent impression made by a ball indenter computed from the equation:

$$HB = \frac{2P}{\pi D \left(D - \sqrt{D^2 - d^2} \right)}$$

where P is applied load, kgf; D is diameter of ball, mm; and d is mean diameter of the impression, mm.

Brinell hardness test

A test for determining the hardness of a material by forcing a hard steel or carbide ball of specified diameter into it under a specified load. The result is expressed as the Brinell hardness number.

brittle crack propagation

A very sudden propagation of a crack with the absorption of no energy except that stored elastically in the body. Microscopic examination may reveal some deformation not noticeable to the unaided eye. Contrast with ductile crack propagation.

brittle fracture

Separation of a solid accompanied by little or no macroscopic plastic deformation. Typically, brittle fracture occurs by rapid crack propagation with less expenditure of energy than for ductile fracture.

buckling

A compression phenomenon that occurs when, after some critical level of load, a bulge, bend, bow, kink, or other wavy condition is produced in a beam, column, plate, bar, or sheet structural element.

bulk modulus

See bulk modulus of elasticity.

bulk modulus of elasticity (K)

The measure of resistance to change in volume; the ratio of hydrostatic stress to the corresponding unit change in volume. This elastic constant can be expressed by the equation:

$$K = \frac{\sigma_m}{\Delta} = \frac{-p}{\Delta} = \frac{1}{\beta}$$

where K is bulk modulus of elasticity, σ_m is hydrostatic or mean stress tensor, p is hydrostatic pressure, and β is the coefficient of compressibility. Also known as bulk modulus, compression modulus, hydrostatic modulus, and volumetric modulus of elasticity.

button

That part of a weld, including all or part of the weld nugget, that tears out in the destructive testing of a spot, seam, or projection welded specimen.

C

capacity

In tensile testing machines, the maximum load and/or displacement for which a machine is designed. Some testing machines have more than one load capacity. These are equipped with accessories that allow the capacity to be modified as desired.

catastrophic wear

Rapidly occurring or accelerating surface damage, deterioration, or change of shape caused by wear to such a degree that the service life of a part is appreciably shortened or its function is destroyed.

caustic cracking

A form of stress-corrosion cracking most frequently encountered in carbon steels or iron-chromium-nickel alloys that are exposed to concentrated hydroxide solutions at temperatures of 200 to 250 °C (400 to 480 °F). Also known as caustic embrittlement.

caustic embrittlement

See preferred term caustic cracking.

cavitation damage

Erosion of a solid surface through the formation and collapse of cavities or bubbles in an adjacent liquid that contains vapor and/or gas.

cavitation erosion

See preferred term cavitation damage.

central tendency of data

In statistics this is described by the central limit theorem. This theorem states the fact that if one draws samples of size n from the population and calculates the mean of these samples, the means will form a distribution that tends toward normality regardless of the form of the original sample distribution.

chafing fatigue

Fatigue damage initiated in a surface damaged by rubbing against another body. See also fretting.

Charpy test

An impact test in which a V-notched, keyhole-notched, or U-notched specimen, supported at both ends, is struck behind the notch by a striker mounted at the lower end of a bar that can swing as a pendulum. The energy that is absorbed in fracture is calculated from the height to which the striker would have risen had there been no specimen and the height to which it actually rises after fracture of the specimen.

Contrast with Izod test.

chevron pattern

A fractographic pattern of radial marks (shear ledges) that looks like nested letters "V," sometimes called a herringbone pattern. Chevron patterns are typically found on brittle fracture surface in parts whose widths are considerably greater than their thicknesses. The points of the chevrons can be traced back to the fracture origin.

chord modulus

The slope of the chord drawn between any two specific points on a stress-strain curve. Compare with secant modulus. See also modulus of elasticity.

cleavage

The tendency of a material to cleave or split along definite crystallographic planes.

cleavage fracture

A fracture, usually of a polycrystalline metal, in which most of the grains have failed by cleavage, resulting in bright reflecting facets. It is one type of crystalline fracture and is associated with low-energy brittle fracture. Contrast with shear fracture.

coefficient of compressibility

See bulk modulus of elasticity.

coefficient of friction (μ)

The dimensionless ratio of the force (F) between two bodies to the normal force (N) pressing these bodies together: μ (or f) = (F/N)

coefficient of thermal expansion

(1) Change in unit of length (or volume) accompanying a unit change of temperature, at a specified temperature. (2) The linear or volume expansion of a given material per degree rise of temperature, expressed at an arbitrary base temperature or as a more complicated equation applicable to a wide range.

compression modulus

See bulk modulus of elasticity.

compression test

A method for assessing the ability of a material to withstand compressive loads.

compressive modulus

The ratio of compressive stress to compressive strain below the proportional limit. Theoretically equal to Young's modulus determined from tensile experiments.

compressive strength

Maximum compressive stress a material is capable of developing. With a brittle material that fails in compression by fracturing, the compressive strength has a definite value. For ductile, malleable, or semiviscous materials (which do not fail in compression by a shattering fracture), the value obtained for compressive strength is an arbitrary value dependent on the degree of distortion that is regarded as effective failure of the material.

compressive stress

A stress that causes an elastic body to deform (shorten) in the direction of the applied load. Contrast with tensile stress.

compressometer

Instrument for measuring change in length over a given gage length caused by application or removal of a force. Commonly used in compression testing of metal specimens.

constant-life fatigue diagram

A plot (usually on rectangular coordinates) of a family of curves, each of which is for a single fatigue life (number of cycles), relating alternating stress, maximum stress, minimum stress, and mean stress. The constant-life fatigue diagram is generally derived from a family of *S-N* curves, each of which represents a different stress ratio for a 50% probability of survival. See also nominal stress, maximum stress, minimum stress, S-N curve, fatigue life, and stress ratio.

continuous use temperature

The maximum temperature at which material may be subjected to continuous use without fear of premature thermal degradation.

conventional strain

See engineering strain.

conventional stress

See engineering stress.

corrosion fatigue

Cracking produced by the combined action of repeated or fluctuating stress and a corrosive environment at lower stress levels or fewer cycles than would be required in the absence of a corrosive environment.

corrosive wear

Wear in which chemical or electrochemical reaction with the environment is significant. Compare with oxidative wear.

covalent bond

A bond in which two atoms share a pair of electrons. Contrast with ionic bond.

crack arrest

The temporary or permanent cessation of crack extension.

crack extension (Δ_a)

An increase in crack size. See also crack length (depth), effective crack size, original crack size, and physical crack size.

crack-extension force (G)

The elastic energy per unit of new separation area that would be made available at the front of an ideal crack in an elastic solid during a virtual increment of forward crack extension. See also J-integral.

crack-extension resistance (K_R)

A measure of the resistance of a material to crack extension, expressed in terms of the stress-intensity factor, the crack-extension force, or values of J derived using the J-integral concept.

crack-growth rate

Rate of propagation of a crack through a material due to statically or dynamically applied load.

crack length (depth) (a)

In fatigue and stress corrosion cracking, the physical crack size used to determine the crack growth rate and the stress-intensity factor. For the compact-type specimen, crack length is measured from the line connecting the bearing points of load application. For the center-cracked-tension specimen, crack length is measured from the perpendicular bisector of the central crack.

crack-mouth-opening displacement (CMOD)

See crack-opening displacement.

crack-opening displacement (COD)

On a K_{Ic} specimen, the opening displacement of the notch surfaces at the notch and in the direction perpendicular to the plane of the notch and the crack. The displacement at the tip is called the crack-tip-opening displacement (CTOD); at the mouth, it is called the crack-mouth-opening displacement (CMOD).

crack-plane orientation

An identification of the plane and direction of a fracture in relation to product geometry. This identification is designated by a hyphenated code, the first letter(s) representing the direction normal to the crack plane and the second letter(s) designating the expected direction of crack propagation.

crack size (a)

A lineal measure of a principal planar dimension of a crack. This measure is commonly used in the calculation of quantities descriptive of the stress and displacement fields. In practice, the value of crack size is obtained from procedures for measurement of physical crack size, original crack size, or effective crack size, as appropriate to the situation under consideration. See also crack length.

crack-tip-opening displacement (CTOD)

See crack-opening displacement.

crack-tip plane strain

A stress-strain field, near a crack-tip, that approaches plane strain to the degree required by an empirical criterion.

crazing

Region of ultrafine cracks, which may extend in a network on or under the surface of a resin or plastic material. May appear as a white band. Often found in a filament-wound pressure vessel or bottle. In many plastics, craze growth precedes crack growth, often generating additional strength because crazes are load bearing.

creep

Time-dependent strain occurring under stress. The creep strain occurring at a diminishing rate is called primary or transient creep; occurring at a minimum and almost constant rate, secondary or steady-rate creep; that occurring at an accelerating rate, tertiary creep.

creep rate

The slope of the creep-time curve at a given time determined from a Cartesian plot.

creep recovery

The time-dependent decrease in strain in a solid, following the removal of force. Recovery is usually determined at a constant temperature.

creep-rupture strength

The stress that will cause fracture in a creep test at a given time in a specified constant environment. Also known as stress-rupture strength.

creep-rupture test

A method of evaluating elevated temperature durability in which a tension specimen is stressed under constant load until it breaks. Data recorded commonly include initial stress, time to rupture, initial extension, creep extension, and reduction in area at the fracture. Also known as stress-rupture test.

creep strain

The time-dependent total strain (extension plus initial strain) produced by applied stress during a creep test.

creep strength

The stress that will cause a given creep strain in a creep test at a given time in a specified constant environment.

creep stress

The constant load in a creep test divided by the original cross-sectional area of the specimen.

creep test

A method of determining the extension of metals under a given load at a given temperature. The determination usually involves the plotting of time-elongation curves under constant load.

cross linking

With thermosetting and certain thermoplastic polymers, the setting up of chemical links between the molecular chains. When extensive, as in most thermosetting resins, cross linking makes an infusible supermolecule of all the chains. In rubbers, the cross linking is just enough to join all molecules into a network.

crushing test

(1) A radial compressive test applied to tubing, sintered-metal bearings, or other similar products for determining radial crushing strength (maximum load in compression). (2) An axial compressive test for determining quality of tubing, such as soundness of weld in welded tubing.

crystalline

That form of a substance comprised predominantly of (one or more) crystals, as opposed to glassy or amorphous.

crystalline defects

The deviations from a perfect three-dimensional atomic packing that are responsible for much of the structure-sensitive properties of the materials. Crystal defects can be point defects (dislocations) or surface defects (vacancies), line defects (dislocations), or surface defects (grain boundaries).

crystalline fracture

A pattern of brightly reflecting crystal facets on the fracture surface of a polycrystalline metal, resulting from cleavage fracture of many individual crystals. Contrast with fibrous fracture and silky fracture, See also granular fracture.

cup fracture (cup-and-cone fracture)

A mixed-mode fracture, often seen in tensile-test specimens of a ductile material, where the central portion undergoes plane-strain fracture and the surrounding region undergoes plane-stress fracture. One of the mating fracture surfaces looks like a miniature cup; it has a central depressed flat-face region surrounded by a shear lip. The other fracture surface looks like a miniature truncated cone.

cupping test

A mechanical test used to determine the ductility and drawing properties of sheet metal. It consists of measuring the maximum depth of bulge that can be formed before fracture. The test is commonly carried out by drawing the test piece into a circular die by means of a punch with a hemispherical end. See also Erichsen cup test, Olsen cup test, and Swift cup test.

cycle

In fatigue, one complete sequence of values of applied load that is repeated periodically. The symbol N represents the number of cycles. See also S-N curve.

cyclic loads

Loads that change value by following a regular repeating sequence of change.

D

decarburization

Loss of carbon from the surface layer of a carbon-containing alloy due to reaction with one or more chemical substances in a medium that contacts the surface.

deflection temperature under load (DTUL)

The temperature at which a simple cantilever beam deflects a given amount under load. Formerly called heat distortion temperature.

deformation

A change in the form of a body due to stress, thermal change, change in moisture, or other causes. Measured in units of length.

deformation curve

See stress-strain diagram.

deformation energy

See strain energy.

density

The mass per unit volume of a solid material.

design of experiments (DOE)

A methodology involving statistically designed experiments in which the character and sequence of individual experiments are planned in advance so that data are taken in a way that will provide the most unbiased and precise results commensurate with the available time and money. The chief classes of statistically designed experiments are: (1) blocking designs to remove the effect of background variables from the experimental error, (2) factorial designs, in which all levels of each factor in an experiment are combined with all levels of every other factor, and (3) response surface designs, which determine the empirical relation between the factors (independent variables) and the response (performance variable).

diamond pyramid hardness test

See Vickers hardness test

dilatometer

An instrument for measuring length or volume changes in a solid during heating and subsequent cooling or isothermal holding.

dimensional stability

Ability of a plastic part to retain the precise shape in which it was molded, fabricated, or cast.

dimpled rupture

A fractographic term describing ductile fracture that occurs through the formation and coalescence of microvoids along the fracture path. The fracture surface of such a ductile fracture appears dimpled when

observed at high magnification and usually is most clearly resolved when viewed in a scanning electron microscope. See also ductile fracture.

discontinuous yielding

The nonuniform plastic flow of a metal exhibiting a yield point in which plastic deformation is inhomogeneously distributed along its length. Under some circumstances, it may occur in metals not exhibiting a distinct yield point, either at the onset of or during plastic flow.

dislocation

A linear imperfection in a crystalline array of atoms. Two basic types are recognized: (1) an edge dislocation corresponds to the row of mismatched atoms along the edge formed by an extra, partial plane of atoms within the body of a crystal; (2) a screw dislocation corresponds to the axis of a spiral structure in a crystal, characterized by a distortion that joins normally parallel planes together to form a continuous helical ramp (with a pitch of one interplanar distance) winding about the dislocation. Most prevalent is the so-called mixed dislocation, which is any combination of an edge dislocation and a screw dislocation.

dislocation density

The total length of dislocation lines per unit volume, or the number of dislocation lines that cut through a unit cross-sectional area.

displacement

The distance that a chosen measurement point on a cracked specimen displaces normal to the crack plane as the crack grows. See also crack-opening displacement and crack plane orientation.

distortion

Any deviation from an original size, shape, or contour that occurs because of the application of stress or the release of residual stress.

double-shear test

A shear test having two stationary, shear blades and one moving one and that uses solid round bars as test specimens.

ductile crack propagation

Slow crack propagation that is accompanied by noticeable plastic deformation and requires energy to be supplied from outside the body. Contrast with brittle fracture.

ductile fracture

Fracture characterized by tearing of metal accompanied by appreciable gross plastic deformation and expenditure of considerable energy. Contrast with brittle fracture.

ductility

The ability of a material to deform plastically before fracturing. Measured by elongation or reduction in area in a tensile test, by height of cupping in a cupping test, or by the radius or angle of bend in a bend test. See also malleability.

durometer hardness

Measure of the indentation hardness of plastics. It is the extent to which a spring-loaded steel indenter protrudes beyond the pressure foot into the material.

dynamic mechanical measurement

A technique in which either the modulus and/or damping of a substance under oscillatory load or displacement is measured as a function of temperature, frequency, or time, or a combination thereof.

dynamic modulus

The ratio of stress to strain under cyclic conditions (calculated from data obtained from either free or forced vibration tests, in shear, compression, or tension).

dynamic recovery

A process occurring in hot working of metals in which a fine subgrain structure forms within the elongated grains due to annihilation of dislocations due to easy cross slip and climb. It results in a lowering of the flow stress. Dynamic recovery, as opposed to dynamic recrystallization that occurs in hot working, occurs in metals of high stacking fault energy such as aluminum, iron, and most bcc metals.

dynamic strain aging

A behavior in metals in which solute atoms are sufficiently mobile to move toward and interact with dislocations. This results in strengthening over a specific range of elevated temperature and strain rate.

E

edge distance

The distance from the edge of a bearing specimen to the center of the hole in the direction of applied force. See also bearing test.

edge distance ratio

The ratio of the edge distance to the pin diameter in a bearing test.

edge strain

Transverse strain lines or Lüders lines ranging from 25 to 300 mm (1 to 12 in.) in from the edges of cold rolled steel sheet or strip.

effective crack size (a_e)

The physical crack size augmented for the effects of cracking plastic deformation. Sometimes the effective crack size is calculated from a measured value of a physical crack size plus a calculated value of a plastic-zone adjustment. A preferred method for calculation of effective crack size compares compliance from the secant of a load-deflection trace with the elastic compliance from a calibration for the type of specimen.

effective yield strength

An assumed value of uniaxial yield strength that represents the influence of plastic yielding on fracture-test parameters.

elastic calibration device

A device for use in verifying the load readings of a testing machine consisting of an elastic member(s) to which loads may be applied, combined with a mechanism or device for indicating the magnitude (or a quantity proportional to the magnitude) of deformation under load.

elastic constants

The factors of proportionality that relate elastic displacement of a material to applied forces. See also modulus of elasticity, bulk modulus of elasticity, shear modulus, and Poisson's ratio.

elastic deformation

A change in dimensions directly proportional to and in phase with an increase or decrease in applied force.

elastic energy

The amount of energy required to deform a material within its elastic range of behavior, neglecting small heat losses due to internal friction. The energy absorbed by a specimen per unit volume of material contained within the gage length being tested. It is determined by measuring the area under the stress-strain curve up to a specified elastic strain. See also modulus of resilience and strain energy.

elastic hysteresis

See preferred term mechanical hysteresis.

elastic limit

The maximum stress which a material is capable of sustaining without any permanent strain (deformation) remaining on complete release of the stress. Compare with proportional limit.

elastic recovery

Amount the dimension of a stressed elastic material returns to its original (unstressed) dimension on release of an applied load. In hardness testing, the shortening of the original dimensions of the indentation upon release of the applied load.

elastic resilience

The amount of energy absorbed in stressing a material up to the elastic limit; or, the amount of energy that can be recovered when stress is released from the elastic limit.

elastic strain

See elastic deformation.

elastic strain energy

The energy expended by the action of external forces in deforming a body elastically. Essentially, all the work performed during elastic deformation is stored as elastic energy, and this energy is recovered upon release of the applied force.

elasticity

The property of a material by virtue of which deformation caused by stress disappears on removal of the stress. A perfectly elastic body completely recovers its original shape and dimensions after release of stress.

elongation

A term used in mechanical testing to describe the amount of extension of a test piece when stressed. See also elongation, percent.

elongation, percent

The extension of a uniform section of a specimen expressed as percentage of the original gage length:

$$\text{Elongation, \%} = \frac{L_x - L_o}{L_o} = 100$$

where L_o is original gage length, and L_x is final gage length.

endurance

The capacity of a material to withstand repeated application of stress.

endurance limit

The maximum stress below which a material can presumably endure an infinite number of stress cycles.

The value of the maximum stress and the stress ratio also should be stated. Compare with fatigue limit.

engineering strain (e)

A term sometimes used for average linear strain or conventional strain in order to differentiate it from true strain. In tension testing it is calculated by dividing the change in the gage length by the original gage length.

engineering stress (s)

A term sometimes used for conventional stress in order to differentiate it from true stress. In tension testing, it is calculated by dividing the breaking load applied to the specimen by the original cross-sectional area of the specimen.

environmentally assisted cracking

Brittle fracture of a normally ductile material in which the corrosive effect of the environment is a causative factor. Environmental cracking is a general term that includes corrosion fatigue, high-temperature hydrogen attack, hydrogen blistering, hydrogen embrittlement, liquid metal embrittlement, solid metal embrittlement, stress-corrosion cracking, and sulfide stress cracking.

equiaxed grain structure

A structure in which the grains have approximately the same dimensions in all directions.

Erichsen cup test

A cupping test used for assessing the ductility of sheet metal. The method consists of forcing a conical or hemispherical-ended plunger into the specimen and measuring the depth of the impression at fracture. Compare with Olsen cup test and Swift cup test.

erosion

Progressive loss of original material from a solid surface due to mechanical interaction between that surface and a fluid, a multicomponent fluid, or impinging liquid or solid particles.

error

Deviation from the correct value. For a testing machine, the difference obtained by subtracting the load indicated by the calibration device from the load indicated by the testing machine.

extensometer

An instrument for measuring changes in length over a given gage length caused by application or removal of a force. Commonly used in tension testing of metal specimens.

F

fatigue

The phenomenon leading to fracture under repeated or fluctuating stresses having a maximum value less than the ultimate tensile strength of the material. Fatigue failure generally occurs at loads that, applied statically, would produce little perceptible effect. Fatigue fractures are progressive, beginning as minute cracks that grow under the action of the fluctuating stress.

fatigue crack growth rate (da/dN)

The rate of crack extension caused by constant-amplitude fatigue loading, expressed in terms of crack extension per cycle of load application.

fatigue failure

Failure that occurs when a specimen undergoing fatigue completely fractures into two parts or has softened or been otherwise significantly reduced in stiffness by thermal heating or cracking.

fatigue life (N)

The number of cycles of stress or strain of a specified character that a given specimen sustains before failure occurs.

fatigue life for p % survival

An estimate of the fatigue life that $p\%$ of the population would attain or exceed at a given stress level. The observed value of the median fatigue life estimates the fatigue life for 50% survival. Fatigue life for $p\%$ survival values, where p is any number, such as 95, 90, etc., may also be estimated from the individual fatigue life values.

fatigue limit

The maximum stress that presumably leads to fatigue fracture in a specified number of stress cycles. The value of the maximum stress and the stress ratio also should be stated. Compare with endurance limit.

fatigue limit for p % survival

The limiting value of fatigue strength for $p\%$ survival as the number of stress cycles becomes very large; p may be any number, such as 95, 90, etc.

fatigue notch factor (K_f)

The ratio of the fatigue strength of an unnotched specimen to the fatigue strength of a notched specimen of the same material and condition; both strengths are determined at the same number of stress cycles.

fatigue notch sensitivity (q)

An estimate of the effect of a notch or hole of a given size and shape on the fatigue properties of a material; measured by $q = (K_f - 1)/(K_t - 1)$, where K_f is the fatigue notch factor and K_t is the stress-concentration factor. A material is said to be fully notch sensitive if q approaches a value of 1.0; it is not notch sensitive if the ratio approaches 0.

fatigue strength

The maximum stress that can be sustained for a specified number of cycles without failure. The value of the maximum stress and the stress ratio also should be stated.

fatigue strength at N cycles (S_N)

A hypothetical value of stress for failure at exactly N number of cycles as determined from an S-N curve. The value of S_N thus determined is subject to the same conditions as those which apply to the $S-N$ curve. The value of S_N that is commonly found in the literature is the hypothetical value of maximum stress, S_{max} , minimum stress, S_{min} , or stress amplitude, S_a , at which 50% of the specimens of a given sample could survive N number of stress cycles in which the mean stress, S_m , = 0. This is also known as the median fatigue strength at N cycles .

fatigue strength for $p\%$ survival at N cycles

An estimate of the stress level at which $p\%$ of the population would survive N number of cycles; p may be any number, such as 95, 90, etc. The estimates of the fatigue strengths for $p\%$ survival values are derived from particular points of the fatigue-life distribution because there is no test procedure by which a frequency distribution of fatigue strengths at N cycles can be directly observed.

fatigue striations

Parallel lines frequently observed in electron microscope fractographs or fatigue-fracture surfaces. The lines are transverse to the direction of local crack propagation; the distance between successive lines represents the advance of the crack front during the one cycle of stress variation. Compare with Wallner lines.

fatigue test

A method for determining the range of alternating (fluctuating) stresses a material can withstand without failing.

fatigue wear

Wear of a solid surface caused by fracture arising from material fatigue.

fibrous fracture

A gray and amorphous fracture surface that results when a metal is sufficiently ductile for the crystals to elongate before fracture occurs. When a fibrous fracture is obtained in an impact test, it may be regarded as definite evidence of toughness of the metal. Contrast with crystalline fracture and silky fracture.

fibrous structure

(1) In forgings, a structure revealed as laminations, not necessarily detrimental, on an etched section or as a ropy appearance on a fracture. It is not to be confused with the ductile fracture of a clean metal. (2) In wrought iron, a structure consisting of slag fibers embedded in ferrite. (3) In rolled steel plate stock, a uniform, fine-grained structure on a fractured surface, free of laminations or shale-type discontinuities. As contrasted with (1), it is virtually synonymous with ductile fracture.

file hardness

Hardness as determined by the use of a steel file of standardized hardness on the assumption that a material that cannot be cut with the file is as hard as, or harder than, the file. Files covering a range of hardnesses may be employed. See also scratch hardness test.

fixed-load or fixed-displacement crack-extension-force curves

Curves obtained from a fracture mechanics analysis for the test configuration, assuming a fixed applied load or displacement and generating a curve of crack-extension force versus the effective crack size as the independent variable.

flare test

A test applied to tubing, involving tapered expansion over a cone. Similar to pin expansion test.

flattening test

A quality test for tubing in which a specimen is flattened to a specified height between parallel plates.

flexibility

The quality or state of a material that allows it to be flexed or bent repeatedly without undergoing rupture. See also flexure.

flexural modulus

Within the elastic limit, the ratio of the applied stress on a test specimen in flexure to the corresponding strain in the outermost fiber of the specimen. Flexural modulus is the measure of relative stiffness.

flexural strength

The maximum stress in the outer fiber at the moment of crack or break.

flexure

A term used in the study of strength of materials to indicate the property of a body, usually a rod or beam, to bend without fracture. See also flexibility.

flow

Movement (slipping or sliding) of essentially parallel planes within an element of a material in parallel directions; occurs under the action of shear stress. Continuous action in this manner, at constant volume and without disintegration of the material, is termed yield, creep, or plastic deformation.

flow lines

Texture showing the direction of metal flow during hot or cold working. Flow lines often can be revealed by etching the surface or a section of a metal part.

flow stress

The stress required to produce plastic deformation in a solid metal.

forged roll Scleroscope hardness number (HFRSc or HFRSd)

A number related to the height of rebound of a diamond-tipped hammer dropped on a forged steel roll. It is measured on a scale determined by dividing into 100 units the average rebound of a hammer from a forged steel roll of accepted maximum hardness. See also Scleroscope hardness number and Scleroscope hardness test.

formability

The ease with which a metal can be shaped through plastic deformation. The evaluation of the formability of a metal involves measurement of strength and ductility, as well as the amount of deformation required to cause fracture. Workability is used interchangeably with formability; however, formability refers to the shaping of sheet metal, while workability refers to shaping materials by bulk deformation (i.e., forging or rolling).

forming limit diagram (FLD)

A diagram on which the major strains at the onset of necking in sheet metal are plotted vertically and the corresponding minor strains are plotted horizontally. The onset-of-failure line divides all possible strain combinations into two zones: the “safe” zone, in which failure during forming is not expected, and the “failure” zone, in which failure during forming is expected.

fractography

Descriptive explanation of a fracture process, especially in metals, with specific reference to photographs of the fracture surface. Macrofractography involves photographs at low magnification; microfractography, at high magnification.

fracture surface

The irregular surface produced when a piece of metal is broken. See also fracture test, granular fracture, fibrous fracture, silky fracture, and crystalline fracture.

fracture mechanics

See linear-elastic fracture mechanics.

fracture stress

The true normal stress on the minimum cross-sectional area at the beginning of fracture. This term usually applies to tension tests of unnotched specimens.

fracture test

A test in which a specimen is broken and its fracture surface is examined with the unaided eye or with a low-power microscope to determine such factors as composition, grain size, case depth, or internal discontinuities.

fracture toughness

A generic term for measures of resistance to extension of a crack. The term is sometimes restricted to results of fracture mechanics tests, which are directly applicable in fracture control. However, the term commonly includes results from simple tests of notched or precracked specimens not based on fracture-mechanics analysis. Results from tests of the latter type are often useful for fracture control, based on either service experience or empirical correlations with fracture mechanics tests. See also stress-intensity factor.

frame

A list, compiled for sampling purposes, that designates the items(units) of a population or universe to be considered in a study.

free bend

The bend obtained by applying forces to the ends of a specimen without the application of force at the point of maximum bending. In making a free bend, lateral forces first are applied to produce a small amount of bending at two points. The two bends, each a suitable distance from the center, are both in the same direction. Compare with guided bend and semiguided bend.

frequency distribution

The way in which the frequencies of occurrence of members of a population, or a sample, are distributed according to the values of the variable under consideration.

fretting

A type of wear that occurs between tight-fitting surfaces subjected to oscillation at very small amplitude. This type of wear can be a combination of oxidative wear and abrasive wear. See also fretting corrosion.

fretting corrosion

(1) The accelerated deterioration at the interface between contacting surfaces as the result of corrosion and slight oscillatory movement between the two surfaces. (2) A form of fretting in which chemical reaction predominates. Fretting corrosion is often characterized by the removal of particles and subsequent formation of oxides, which are often abrasive and so increase the wear. Fretting corrosion can involve other chemical reaction products, which may not be abrasive.

fretting fatigue

(1) Fatigue fracture that initiate at a surface area where fretting has occurred. The progressive damage to a solid surface that arises from fretting. Note: If particles of wear debris are produced, then the term fretting wear may be applied.

fretting wear

Wear resulting from fretting. See also fretting fatigue.

G

gage length

The original length of the portion of a specimen over which strain, change of length, or other characteristics are determined.

galling

(1) A condition whereby excessive friction between high spots results in localized welding with subsequent spalling and a further roughening of the rubbing surfaces of one or both of two mating parts.
(2) A severe form of scuffing associated with gross damage to the surfaces or failure. Galling has been used in many ways in tribology; therefore, each time it is encountered its meaning must be ascertained from the specific context of the usage. See also scoring, scuffing, and spalling.

glide

See slip.

grain growth

An increase in the average size of the grains in polycrystalline metal, usually as a result of heating at elevated temperature. See also grain size.

grain size

A measure of the areas or volumes of grains in a polycrystalline metal, usually expressed as an average when the individual sizes are fairly uniform. In metals containing two or more phases, the grain size refers to that of the matrix unless otherwise specified. Grain size is reported in terms of number of grains per unit area or volume, average diameter, or as a grain-size number derived from area measurements.

granular fracture

A type of irregular surface produced when metal is broken that is characterized by a rough, grainlike appearance, rather than a smooth or fibrous one. It can be subclassified as transgranular or intergranular. This type of fracture is frequently called crystalline fracture; however, the inference that the metal broke because it “crystallized” is not justified, because all metals are normally crystalline when in the solid state. Contrast with fibrous fracture and silky fracture.

group

The specimens tested at one time, or consecutively, at one stress level. A group may comprise one or more specimens.

guided bend

The bend obtained by use of a plunger to force the specimen into a die in order to produce the desired contour of the outside and inside surfaces of the specimen. Compare with free bend.

guided-bend test

A test in which the specimen is bent to a definite shape by means of a punch (mandrel) and a bottom block.

H

Hall-Petch relationship

A general relationship for metals that shows that the yield strength is linearly related to the reciprocal of the square root of the grain diameter.

hardness

A measure of the resistance of a material to surface indentation or abrasion; may be thought of as a function of the stress required to produce some specified type of surface deformation. There is no absolute scale for hardness; therefore, to express hardness quantitatively, each type of test has its own scale of arbitrarily defined hardness. Indentation hardness can be measured by Brinell hardness test, Rockwell hardness test, Vickers hardness test, Knoop hardness test, and the Scleroscope hardness test.

Hartmann lines

See Lüders lines.

heat distortion temperature (HDT)

See deflection temperature under load (DTUL).

herringbone pattern

See chevron pattern.

hole-expansion test

A simulative test in which a flat sheet specimen with a circular hole in its center is clamped between annular die plates and deformed by a punch, which expands and ultimately cracks the edge of the hole.

Hooke's law

Observation that, in the elastic region of solid material, stress is directly proportional to strain and can be expressed as:

$$\frac{\text{Stress}}{\text{Strain}} = \frac{\sigma}{\epsilon} = \text{constant} = E$$

where E is the modulus of elasticity, or Young's modulus. The constant relationship between stress and strain applies only below the proportional limit. See also modulus of elasticity.

hydrogen damage

A general term for the embrittlement, cracking, blistering, and hydride formation that can occur when hydrogen is present in some metals.

hydrogen embrittlement

A condition of low toughness, low ductility or cracking in metals resulting from the absorption of hydrogen.

hydrogen-induced delayed cracking

A term sometimes used to identify a form of hydrogen embrittlement in which a metal appears to fracture spontaneously under a steady stress less than the yield stress. There is usually a delay between the application of stress (or exposure of the stressed metal to hydrogen) and the onset of cracking. Also referred to as static fatigue.

hydrostatic modulus

See bulk modulus of elasticity.

hysteresis

The phenomenon of permanently absorbed or lost energy that occurs during any cycle of loading or unloading when a material is subjected to repeated loading.

I

ideal crack

A simplified model of a crack used in elastic-stress analysis. In a stress-free body, the crack has two smooth surfaces that are coincident and join within the body along a smooth curve called the crack front; in two-dimensional representations, the crack front is called the crack tip.

ideal-crack-tip stress field

The singular stress field, infinitesimally close to the crack front, that results from the dominant influence of an ideal crack in an elastic body that is deformed. In a linear-elastic homogeneous body, the significant stress components vary inversely as the square root of the distance from the crack tip. In a linear-elastic body, the crack-tip stress field can be regarded as the superposition of three component stress fields called modes.

impact energy

The amount of energy required to fracture a material, usually measured by means of an Izod test or Charpy test. The type of specimen and test conditions affect the values and therefore should be specified.

impact loads

Especially severe shock loads such as those caused by instantaneous arrest of a falling mass, shock meeting of two parts (in a mechanical hammer, for example), or by explosive impact, in which there can be an exceptionally rapid build-up of stress.

impact strength

The resiliency or toughness of a solid as measured by impact energy.

impact test

A test for determining the energy absorbed in fracturing a test piece at high velocity, as distinct from static test. The test may be carried out in tension, bending, or torsion, and the test bar may be notched or unnotched. See also impact energy, Charpy test, and Izod test.

indentation hardness

The resistance of a material to indentation as determined by hardness testing. The indenter, which may be spherical or diamond shaped, is pressed into the surface of a metal under specified load for a given time. See also Brinell hardness test, Knoop hardness test, Rockwell hardness test, and Vickers hardness test.

initial recovery

The decrease in strain in a solid during the removal of force before any creep recovery takes place, usually determined at constant temperature. Sometimes referred to as instantaneous recovery.

initial strain

The strain in a specimen immediately upon achieving the given loading conditions in a creep test (before creep occurs). Sometimes referred to as instantaneous strain.

initial stress

The stress produced by strain in a specimen immediately on achieving the given constant-strain conditions in a stress-relaxation test before stress-relaxation occurs. Sometimes referred to as instantaneous stress.

initial tangent modulus

The slope of the stress-strain curve at the beginning of loading. See also modulus of elasticity.

initiation of stable crack growth

The initiation of slow stable crack advance from the blunted crack tip.

instantaneous recovery

See initial recovery.

instantaneous strain

See initial strain.

instantaneous stress

See initial stress.

instrumented impact test

An impact test in which the load on the specimen is continually recorded as a function of time and/or specimen deflection prior to fracture.

interval estimate

The estimate of a parameter given by two statistics, defining the end points of an interval.

ionic bond

(1) A type of chemical bonding in which one or more electrons are transferred completely from one atom to another, thus converting the neutral atoms into electrically charged ions. These ions are approximately spherical and attract each other because of their opposite charges. (2) A primary bond arising from the electrostatic attraction between two oppositely charged ions. Contrast with covalent bond.

item

(1) An object or quantity of material on which a set of observations can be made. (2) An observed value or test result obtained from an object or quantity of material.

Izod test

A type of impact test in which a V-notched specimen, mounted vertically, is subjected to a sudden blow delivered by the weight at the end of a pendulum arm. The energy required to break off the free end is a measure of the impact strength or toughness of the material. Contrast with Charpy test.

J

J-integral

A mathematical expression describing a line or surface integral that encloses the crack front from one crack surface to the other, used to characterize the fracture toughness of a material having appreciable plasticity before fracture. The *J*-integral eliminates the need to describe the behavior of the material near the crack tip by considering the local stress-strain field around the crack front; J_{Ic} is the critical value of the *J*-integral required to initiate crack extension from a preexisting crack.

K

keel block

A standard test casting, for steel and other high-shrinkage alloys, consisting of a rectangular bar that resembles the keel of a boat, attached to the bottom of a large riser, or shrinkhead. Keel blocks that have only one bar are often called Y-blocks; keel blocks having two bars, double keel blocks. Test specimens are machined from the rectangular bar, and the shrinkhead is discarded.

keyhole specimen

A type of specimen containing a hole-and-slot notch, shaped like a keyhole, usually used in impact and bend tests. See Charpy test.

Knoop hardness number (HK)

A number related to the applied load and to the projected area of the permanent impression made by a rhombic-based pyramidal diamond indenter having included edge angles of $172^{\circ} 30'$ and $130^{\circ} 0'$ computed from the equation:

$$HK = \frac{P}{0.07028d^2}$$

where P is applied load, kgf; and d is long diagonal of the impression, mm. In reporting Knoop hardness numbers, the test load is stated.

Knoop hardness test

An indentation-hardness test using calibrated machines to force a rhombic-based pyramidal diamond indenter having specified edge angles, under specified conditions, into the surface of the material under test and to measure the long diagonal after removal of the load.

L

least count

The smallest value that can be read from an instrument having a graduated scale. Except on instruments provided with a vernier, the least count is that fraction of the smallest division which can be conveniently and reliably estimated; this fraction is ordinarily one-fifth or one-tenth, except where the graduations are very closely spaced. Also known as least reading.

least reading

See least count.

limiting dome height (LDH) test

A mechanical test, usually performed unlubricated on sheet metal, that simulates the fracture conditions in a practical press-forming operation. The results are dependent on the sheet thickness.

linear-elastic fracture mechanics

A method of fracture analysis that can determine the stress (or load) required to induce fracture instability in a structure containing a cracklike flaw of known size and shape. See also stress-intensity factor.

linear (tensile or compressive) strain

The change per unit length due to force in an original linear dimension. An increase in length is considered positive.

load

For testing machines, a force applied to a test piece that is measured in units such as pound-force, newton, or kilogram-force.

load range, P

In fatigue, the algebraic difference between the maximum and minimum loads in a fatigue cycle.

load ratio, R

In fatigue, the algebraic ratio of the minimum to maximum load in a fatigue cycle, that is, $R = P_{\min}/P_{\max}$. Also known as stress ratio.

longitudinal direction

The principal direction of flow in a worked metal. See also normal direction and transverse direction.

long transverse direction

See transverse direction.

lot

A definite quantity of a product or material accumulated under conditions that are considered uniform for sampling purposes. Compare with batch.

lubricant

Any substance interposed between two surfaces for the purpose of reducing the friction or wear between them.

Lüders lines

Elongated surface markings or depressions, often visible with the unaided eye, that form along the length of sheet metal or a tension specimen at an angle of approximately 45° to the loading axis. Caused by localized plastic deformation, they result from discontinuous (inhomogeneous) yielding. Also known as Lüders bands, Hartmann lines, Piobert lines, or stretcher strains. See also edge strain.

M

macrostrain

The mean strain over any finite gage length of measurement large in comparison with interatomic distances. Macrostrain can be measured by several methods, including electrical-resistance strain gages and mechanical or optical extensometers. Elastic macrostrain can be measured by x-ray diffraction. Compare with microstrain.

malleability

The characteristic of metals that permits plastic deformation in compression without fracture. See also ductility.

maximum load (P_{\max})

(1) The load having the highest algebraic value in the load cycle. Tensile loads are considered positive and compressive loads negative. (2) Used to determine the strength of a structural member; the load that can be borne before failure is apparent.

maximum strength

See ultimate strength.

maximum stress (S_{\max})

The stress having the highest algebraic value in the stress cycle, tensile stress being considered positive and compressive stress negative. The nominal stress is used most commonly.

maximum stress-intensity factor (K_{\max})

The maximum value of the stress-intensity factor in a fatigue cycle.

mean stress (or steady component of stress) (S_m)

The algebraic average of the maximum and minimum stresses in one cycle, that is, $S_m = (S_{\max} + S_{\min})/2$.

mechanical hysteresis

Energy absorbed in a complete cycle of loading and unloading within the elastic limit and represented by the closed loop of the stress-strain curves for loading and unloading. Sometimes called elastic hysteresis.

mechanical metallurgy

The science and technology dealing with the behavior of metals when subjected to applied forces.

median fatigue life

The middle value when all of the observed fatigue life values of the individual specimens in a group tested under identical conditions are arranged in order of magnitude. When an even number of specimens are tested, the average of the two middlemost values is used. Use of the sample median rather than the arithmetic mean (that is, the average) is usually preferred.

median fatigue strength at N cycles

An estimate of the stress level at which 50% of the population would survive N cycles. The estimate is derived from a particular point of the fatigue life distribution, because there is no test procedure by which a frequency distribution of fatigue strengths at N cycles can be directly observed. See also fatigue strength at N cycles.

microhardness test

See preferred term microindentation hardness test.

microindentation hardness test

Hardness test using a calibrated machine to force a diamond indenter of specific geometry, under a test load of 1 to 1000 gramforce, into the surface of the test material and to measure the diagonal or diagonals of the indentation optically.

microstrain

The strain over a gage length comparable to interatomic distances. These are the strains being averaged by the macrostrain measurement. Microstrain is not measurable by currently existing techniques. Variance of the microstrain distribution can, however, be measured by x-ray diffraction.

minimum load (P_{\min})

In fatigue, the least algebraic value of applied load in a cycle.

minimum stress (S_{\min})

In fatigue, the stress having the lowest algebraic value in the cycle, tensile stress being considered positive and compressive stress negative.

minimum stress-intensity factor (K_{\min})

In fatigue, the minimum value of the stress-intensity factor in a cycle. This value corresponds to the minimum load when the load ratio is 0 and is taken to be 0 when the load ratio is ≤ 0 .

modes

The three classes of crack (surface) displacements adjacent to the crack tip. These displacement modes are associated with stress-strain fields around the crack tip and are designated I, II, and III and represent opening, sliding, and tearing displacements, respectively. See also crack-tip plane strain and crack opening displacement.

modulus of elasticity (E)

The measure of rigidity or stiffness of a metal; the ratio of stress, below the proportional limit, to the corresponding strain. In terms of the stress-strain diagram, the modulus of elasticity is the slope of the stress-strain curve in the range of linear proportionality of stress to strain. Also known as Young's modulus. For materials that do not conform to Hooke's law throughout the elastic range, the slope of either the tangent to the stress-strain curve at the origin or at low stress, the secant drawn from the origin to any specified point on the stress-strain curve, or the chord connecting any two specific points on the stress-strain curve is usually taken to be the modulus of elasticity. In these cases, the modulus is referred to as the tangent modulus, secant modulus, or chord modulus, respectively.

modulus of resilience

The amount of energy stored in a material when loaded to its elastic limit. It is determined by measuring the area under the stress-strain curve up to the elastic limit. See also elastic energy, resilience, and strain energy.

modulus of rigidity

See shear modulus.

modulus of rupture

Nominal stress at fracture in a bend test or torsion test. In bending, modulus of rupture is the bending moment at fracture divided by the section modulus. In torsion, modulus of rupture is the torque at fracture divided by the polar section modulus. See also modulus of rupture in bending and modulus of rupture in torsion.

modulus of rupture in bending (S_b)

The value of maximum tensile or compressive stress (whichever causes failure) in the extreme fiber of a beam loaded to failure in bending computed from the flexure equation:

$$S_b = \frac{Mc}{I}$$

where M is maximum bending moment, computed from the maximum load and the original moment arm; c is initial distance from the neutral axis to the extreme fiber where failure occurs; and I is initial moment of inertia of the cross section about the neutral axis. See also modulus of rupture.

modulus of rupture in torsion (S_s)

The value of maximum shear stress in the extreme fiber of a member of circular cross section loaded to failure in torsion computed from the equation:

$$S_s = \frac{Tr}{J}$$

where T is maximum twisting moment, r is original outer radius, and J is polar moment of inertia of the original cross section. See also modulus of rupture.

modulus of toughness

The amount of work per unit volume of a material required to carry that material to failure under static loading. See also toughness.

Mohs hardness test

A scratch hardness test for determining comparative hardness using 10 standard minerals—from talc (the softest) to diamond (the hardest).

monotron hardness test

An obsolete method of determining indentation hardness by measuring the load required to force a spherical penetrator into a metal to a specified depth.

multiaxial stress

See principal stress (normal).

m-value

See strain-rate sensitivity.

N

natural strain

See true strain.

necking

(1) Reducing the cross-sectional area of metal in a localized area by stretching. (2) Reducing the diameter of a portion of the length of a cylindrical shell or tube.

nominal strain

See strain.

nominal strength

See ultimate strength.

nominal stress

The stress at a point calculated on the net cross section by simple elasticity theory without taking into account the effect on the stress produced by stress raisers such as holes, grooves, fillets, etc.

normal direction

Direction perpendicular to the plane of working in a worked metal. See also longitudinal direction and transverse direction.

normal stress

The stress component perpendicular to a plane on which forces act. Normal stress may be either tensile stress or compressive stress.

notch brittleness

Susceptibility of a material to brittle fracture at points of stress concentration. For example, in a notch tensile test, the material is said to be notch brittle if the notch strength is less than the tensile strength of an unnotched specimen. Otherwise, it is said to be notch ductile.

notch depth

The distance from the surface of a notched test specimen to the bottom of the notch. In a cylindrical test specimen, the percentage of the original cross-sectional area removed by machining an annular groove.

notch ductility

The percentage reduction in area after complete separation of the metal in a tensile test of a notched specimen.

notch strength

The maximum load on a notched tensile-test specimen divided by the minimum cross-sectional area (the area at the root of the notch). Also known as notch tensile strength.

n-value

See strain hardening exponent.

O

observed value

The particular value of a characteristic determined as a result of a test or measurement.

offset

The distance along the strain coordinate between the initial portion of a stress-strain curve and a line parallel to the initial portion that intersects the stress-strain curve at a value of stress (commonly 0.2%) that is used as a measure of the yield strength. Used for materials that have no obvious yield point.

offset modulus

The ratio of the offset yield stress to the extension at the offset point (plastics).

offset yield strength

The stress at which the strain exceeds by a specified amount (the offset) an extension of the initial proportional portion of the stress-strain curve. Expressed in force per unit area.

Olsen cup test

A cupping test in which a piece of sheet metal, restrained except at the center, is deformed by a standard steel ball until fracture occurs. The height of the cup at time of fracture is a measure of the ductility. Compare with Erichsen cup test and Swift cup test.

orange peel

A surface roughening in the form of a pebble-grained pattern where a metal of unusually coarse grain is stressed beyond its elastic limit. Also known as pebbles and alligator skin.

original crack size (a_0)

The physical crack size at the start of testing

oxidative wear

A type of wear resulting from the sliding action between two metallic components that generates oxide films on the metal surfaces. These oxide films prevent the formation of a metallic bond between the sliding surfaces, resulting in fine wear debris and low wear rates. Compare with corrosive wear.

P

parameter

In statistics, a constant (usually unknown) defining some property of the frequency distribution of a population, such as a population median or a population standard deviation.

pebbles

See preferred term orange peel.

percent error

For testing machines, the ratio, expressed as a percentage, of the error to the correct value of the applied load.

permanent set

The deformation or strain remaining in a previously stressed body after release of load.

permissible variation

For testing machines, the maximum allowable error in the value of the quantity indicated. It is convenient to express permissible variation in terms of the percent error.

physical crack size (a_p)

The distance from a reference plane to the observed crack front. This distance may represent an average of several measurements along the crack front. The reference plane depends on the specimen form, and it is normally taken to be either the boundary or a plane containing either the load line or the centerline of a specimen or plate.

physical properties

Properties of a material the determination of which does not involve the deformation or destruction of the specimen—for example, density, electrical conductivity, coefficient of thermal expansion, magnetic permeability, and lattice parameter. Does not include chemical reactivity or the properties more appropriately regarded as mechanical properties.

physical testing

Methods used to determine the entire range of physical properties of a material. In addition to density and thermal, electrical, and magnetic properties, physical testing methods can be used to assess simple fundamental physical properties such as color, crystalline form, and melting point.

pin expansion test

A test for determining the ability of a tube to be expanded or for revealing the presence of cracks or other longitudinal weaknesses in it, made by forcing a tapered pin into the open end of the tube, similar to flare test.

pin or mandrel

In bend testing, the plunger or tool used in making semiguided, guided, or wrap-around tests to apply the bending force to the inside surface of the bend. In free bends or semiguided bends to an angle of 180°, a shim or block of the proper thickness may be placed between the legs of the specimen as bending is completed. This shim or block is also referred to as a pin or mandrel.

pin shear test

See shear test.

Piobert lines

See Lüders lines.

pitting

In tribology, a type of wear characterized by the presence of small, sharp surface cavities formed by processes such as fatigue, local adhesion, wear, corrosion, or cavitation.

planar anisotropy

A variation in physical and/or mechanical properties with respect to direction within the plane of material in sheet form. See also plastic strain ratio.

plane strain

The stress condition in linear-elastic fracture mechanics in which there is zero strain in a direction normal to both the axis of applied tensile stress and the direction of crack growth (i.e., parallel to the crack front); most nearly achieved in loading thick plates along a direction parallel to the plate surface. Under plane-strain conditions, the plane of fracture instability is normal to the axis of the principal tensile stress.

plane-strain fracture toughness (K_{Ic})

The crack extension resistance under conditions of crack-tip plane strain. See also stress-intensity factor.

plane stress

The stress condition in linear-elastic fracture mechanics in which the stress in the thickness direction is zero; most nearly achieved in loading very thin sheet along a direction parallel to the surface of the sheet. Under plane-stress conditions, the plane of fracture instability is inclined 45° to the axis of the principal tensile stress.

plane-stress fracture toughness (K_c)

In linear-elastic fracture mechanics, the value of the crack-extension resistance at the instability condition determined from the tangency between the R-curve and the critical crack-extension force curve of the specimen. See also stress intensity factor.

plastic deformation

The permanent (inelastic) distortion of a material under applied stress that strains the material beyond its elastic limit.

plastic flow

See yielding.

plastic instability

The stage of deformation in a tensile test where the plastic flow becomes nonuniform and necking begins.

plasticity

The property that enables a material to undergo permanent deformation without rupture.

plastic strain

Dimensional change that does not disappear when the initiating stress is removed. Usually accompanied by some elastic deformation.

plastic strain ratio (r -value)

The ratio of the true width strain to the true thickness strain in a tensile test, $r = \epsilon_w/\epsilon_t$. Because of the difficulty in making precise measurement of thickness strain in sheet material, it is more convenient to express r in terms of initial and final length and width dimensions. It can be shown that

$$r = (\ln W_o W_f) - (\ln L_f W_f / L_o W_o)$$

where L_o and W_o are initial length and width of gage section, respectively; and L_f and W_f are final length and width, respectively.

plastic-zone adjustment, r_Y

An addition to the physical crack size to account for plastic crack-tip deformation enclosed by a linear-elastic stress field.

plowing

In tribology, the formation of grooves by plastic deformation of the softer of two surfaces in relative motion.

point estimate

The estimate of a parameter given by a single statistic.

Poisson's ratio (ν)

The absolute value of the ratio of transverse (lateral) strain to the corresponding axial strain resulting from uniformly distributed axial stress below the proportional limit of the material.

population

The hypothetical collection of all possible test specimens that could be prepared in the specified way from the material under consideration. Also known as universe.

precision

The closeness of agreement between the results of individual replicated measurements or tests. The standard deviation of the error of measurement may be used as a measure of “imprecision.”

principal stress (normal)

The maximum or minimum value of the normal stress at a point in a plane considered with respect to all possible orientations of the considered plane. On such principal planes the shear stress is zero. There are three principal stresses on three mutually perpendicular planes. The state of stress at a point may be: (1) uniaxial, a state of stress in which two of the three principal stresses are zero; (2) biaxial, a state of stress in which only one of the three principal stresses is zero; or (3) triaxial, a state of stress in which none of the principal stresses is zero. Multiaxial stress refers to either biaxial or triaxial stress.

proof stress

(1) The stress that will cause a specified small permanent set in a material. (2) A specified stress to be applied to a member or structure to indicate its ability to withstand service loads.

proportional limit

The greatest stress a material is capable of developing without a deviation from straight-line proportionality between stress and strain. Compare with elastic limit. See also Hooke's law.

punching shear test

See blanking shear test.

R

radial marks

Lines on a fracture surface that radiate from the fracture origin and are visible to the unaided eye or at low magnification. Radial lines result from the intersection and connection of brittle fractures propagating at different levels. Also known as shear ledges. See also chevron pattern.

radius of bend

The radius of the cylindrical surface of the pin or mandrel that comes in contact with the inside surface of the bend during bending. For free or semiguided bends to 180° in which a shim or block is used, the radius of bend is one-half the thickness of the shim or block.

range of stress (S_r)

The algebraic difference between the maximum and minimum stress in one cycle—that is,

$$S_r = S_{\max} - S_{\min}$$

ratchet marks

Lines on a fatigue fracture surface that result from the intersection and connection of fatigue fractures propagating from multiple origins. Ratchet marks are parallel to the overall direction of crack propagation and are visible to the unaided eye or at low magnification.

rate of creep

See creep rate.

R-curve

In linear-elastic fracture mechanics, a plot of crack-extension resistance as a function of stable crack extension, which is either the difference between the physical crack size, or the effective crack size, and the original crack size. *R*-curves normally depend on specimen thickness and, for some materials, on temperature and strain rate.

reduction in area (RA)

The difference between the original cross-sectional area of a tensile specimen and the smallest area at or after fracture as specified for the material undergoing testing. Also known as reduction of area.

relaxation curve

A plot of either the remaining, or relaxed, stress as a function of time. See also relaxation rate.

relaxation rate

The absolute value of the slope of a stress-relaxation curve at a given time.

relaxed stress

The initial stress minus the remaining stress at a given time during a stress-relaxation test. See also stress relaxation.

remaining stress

The stress remaining at a given time during a stress-relaxation test. See also stress relaxation.

repeatability

A term used to refer to the test-result variability associated with a limited set of specifically defined sources of variability within a single laboratory.

reproducibility

A term used to describe test-result variability associated with specifically defined components of variance obtained both from within a single laboratory and between laboratories.

residual stress

Stresses that remain within a body as the result of thermal or mechanical treatment or both.

resilience

The ability of a material to absorb energy when deformed elastically and return to its original shape on release of load. See also modulus of resilience.

response curve for *N* cycles

In fatigue-data analysis, a curve fitted to observed values of percentage survival at *N* number of cycles for several stress levels, where *N* is a preassigned number such as 10^6 , 10^7 , etc. It is an estimate of the relationship between applied stress and the percentage of the population that would survive *N* cycles. See also S-N curve.

Rockwell hardness number (HR)

A number derived from the net increase in the depth of impression in a Rockwell hardness test as the load on an indenter is increased from a fixed minor load to a major load and then returned to the minor load. Rockwell hardness numbers are always quoted with a scale symbol representing the penetrator, load, and dial used.

Rockwell hardness test

An indentation-hardness test using a calibrated machine that utilizes the depth of indentation, under constant load, as a measure of hardness. Either a 120° diamond cone with a slightly rounded point, or a $\frac{1}{16}$ or $\frac{1}{8}$ in. diameter steel ball is used as the indenter.

Rockwell superficial hardness number

See Rockwell hardness number.

Rockwell superficial hardness test

Same as Rockwell hardness test, except that smaller minor and major loads are used.

rosette

Strain gages arranged to indicate, at a single position, strain in three different directions.

rupture stress

The stress at failure. Also known as breaking stress. See also fracture stress.

r-value

See plastic-strain ratio.

S

sample

- (1) One or more units of product (or a relatively small quantity of a bulk material) that are withdrawn from a lot or process stream and that are tested or inspected to provide information about the properties, dimensions, or other quality characteristics of the lot or process stream. Not be confused with specimen.
- (2) A portion of a material intended to be representative of the whole.

sample average

The sum of all the observed values in a sample divided by the sample size. It is a point estimate of the population mean. Also known as arithmetic mean.

sample median

The middle value when all observed values in a sample are arranged in order of magnitude. If an even number of samples are tested, the average of the two middlemost values is used. It is a point estimate of the population median, or 50% point.

sample percentage

The percentage of observed values between two stated values of the variable under consideration. It is a point estimate of the percentage of the population between the same two stated values. (One stated value may be $-\infty$ or $+\infty$.)

sample standard deviation (s)

The square root of the sample variance. It is a point estimate of the population standard deviation, a measure of the “spread” of the frequency distribution of a population. This value of s provides a statistic that is used in computing interval estimates and several test statistics. For small sample sizes, s underestimates the population standard deviation.

sample variance (s^2)

The sum of the squares of the differences between each observed value and the sample average divided by the sample size minus one. It is a point estimate of the population variance.

S-basis

Minimum property value specified by the appropriate federal, military, Society of Automotive Engineers, American Society for Testing and Materials, or other recognized and approved specifications for the material. See also A-basis, B-basis, and typical basis.

Scleroscope hardness number (HSc or HSd)

A number related to the height of rebound of a diamond-tipped hammer dropped on the material being tested. It is measured on a scale determined by dividing into 100 units the average rebound of the hammer from a quenched (to maximum hardness) and untempered AISI W5 tool steel test block.

Scleroscope hardness test

A dynamic indentation-hardness test using a calibrated instrument that drops a diamond-tipped hammer from a fixed height onto the surface of the material being tested. The height of rebound of the hammer is a measure of the hardness of the material. Also known as Shore hardness test.

scoring

In tribology, a severe form of wear characterized by the formation of extensive grooves and scratches in the direction of sliding.

scratch hardness test

A form of hardness test in which a sharp-pointed stylus or corner of a mineral specimen is traversed along a surface so as to determine the resistance of that surface to cutting or abrasion. See also file hardness and Mohs hardness test.

scratching

In tribology, the mechanical removal or displacement, or both, of material from a surface by the action of abrasive particles or protuberances sliding across the surfaces. See also plowing.

scuffing

A form of adhesive wear that produces superficial scratches or a high polish on the rubbing surfaces. It is observed most often on inadequately lubricated parts.

secant modulus

The slope of the secant drawn from the origin to any specified point on a stress-strain curve. Compare with chord modulus. See also modulus of elasticity.

semiguided bend

The bend obtained by applying a force directly to the specimen in the portion that is to be bent. The specimen is either held at one end and forced around a pin or rounded edge, or is supported near the ends and bent by a force applied on the side of the specimen opposite the supports and midway between them. In some instances, the bend is started in this manner and finished in the manner of a free bend.

set

See permanent set.

sharp-notch strength

The notch tensile strength measured using specimens with very small notch root radii (approaching the limit for machining capability); values of sharp-notch strength usually depend on notch root radius.

shear

The type of force that causes or tends to cause two contiguous parts of the same body to slide relative to each other in a direction parallel to their plane of contact.

shear fracture

A ductile fracture in which a crystal (or a polycrystalline mass) has separated by sliding or tearing under the action of shear stresses. Contrast with cleavage fracture.

shear lip

A narrow, slanting ridge along the edge of a fracture surface. The term sometimes also denotes a narrow, often crescent-shaped, fibrous region at the edge of a fracture that is otherwise of the cleavage type, even though this fibrous region is in the same plane as the rest of the fracture surface.

shear modulus (G)

The ratio of shear stress to the corresponding shear strain for shear stresses below the proportional limit of the material. Values of shear modulus are usually determined by torsion testing. Also known as modulus of rigidity.

shear strain

The tangent of the angular change, as a response to force, between two lines originally perpendicular to each other through a point in a body. Also known as shearing strain.

shear strength

The maximum shear stress that a material is capable of sustaining. Shear strength is calculated from the maximum load during a shear or torsion test and is based on the original dimensions of the cross section of the specimen.

shear stress

(1) A stress that exists when parallel planes in metal crystals slide across each other. (2) The stress component tangential to the plane on which the forces act. Also known as tangential stress.

shear test

Any of several tests to obtain shear strength of a metal. Common tests used on mill products include the double-shear test, single-shear test, the blanking shear test (also known as the punching shear test) and the torsion test.

shock load

The sudden application of an external force that results in a very rapid build-up of stress.

Shore hardness test

See Scleroscope hardness test.

short transverse

See transverse direction.

significance level

The stated probability (risk) that a given test of significance will reject the hypothesis that a specified effect is absent when the hypothesis is true.

significant

Statistically significant. An effect of difference between populations is said to be present if the value of a test statistic is significant, that is, lies outside predetermined limits. See also population.

silky fracture

A metal fracture in which the broken metal surface has a fine texture, usually dull in appearance. Characteristic of tough and strong metals. Contrast with crystalline fracture and granular fracture.

single-shear test

(1) A shear test similar to the double-shear test used for round-bar specimens, but that uses only one stationary shear blade. (2) A shear test that uses a sheet or thin-plate specimen.

size effect

Effect of the dimensions of a piece of metal on its mechanical and other properties and on manufacturing variables such as forging reduction and heat treatment. In general, the mechanical properties are lower for a larger size.

slant fracture

A type of fracture appearance, typical of plane-stress fractures, in which the plane of metal separation is inclined at an angle (usually about 45°) to the axis of the applied stress.

slenderness ratio

The effective unsupported length of a uniform column divided by the least radius of gyration of the cross-sectional area.

slip

Plastic deformation by the irreversible shear displacement (translation) of one part of a crystal relative to another in a definite crystallographic direction and usually on a specific crystallographic plane. Sometimes called glide.

slip band

A group of parallel slip lines so closely spaced as to appear as a single line when observed under an optical microscope. See also slip line.

slip line

The trace of the slip plane on a viewing surface; the trace is usually observable only if the surface has been polished before deformation. The usual observation on metal crystals (under the light microscope) is of a cluster of slip lines known as a slip band.

S-N curve

A plot of stress, S , against the number of cycles to failure, N . The stress can be the maximum stress, S_{\max} , or the alternating stress amplitude, S_a . The stress values are usually nominal stresses; i.e., there is no adjustment for stress concentration. The curve indicates the *S-N* relationship for a specified value of the mean stress, S_m or the stress ratio, A , or R and a specified probability of survival. For N , a log scale is almost always used. For S , a linear scale is used most often, but a log scale is sometimes used. Also known as *S-N* diagram.

S-N curve for 50% survival

A curve fitted to the median value of fatigue life at each of several stress levels. It is an estimate of the relation between applied stress and the number of cycles-to-failure that 50% of the population would survive.

S-N curve for $p\%$ survival

A curve fitted to the fatigue life for $p\%$ survival values at each of several stress levels. It is an estimate of the relationship between applied stress and the number of cycles-to-failure that $p\%$ of the population would survive. p may be any number, such as 95, 90, and so forth.

spalling

The separation of macroscopic particles from a surface in the form of flakes or chips.

specimen

A test object, often of standard dimensions or configuration, that is used for destructive or nondestructive testing. One or more specimens may be cut from each unit of a sample.

springback

The extent to which metal tends to return to its original shape or contour after undergoing a forming operation.

standard deviation

The most usual measure of the dispersion of observed values or results expressed as the positive square root of the variance.

static fatigue

A term referring to a time-dependent reduction in strength with a static (noncyclic) load. The term may refer to hydrogen-induced delayed cracking or the effect of creep on the strength of plastics.

statistic

A summary value calculated from the observed values in a sample.

steady loads

Loads that do not change in intensity or that change so slowly they may be regarded as steady.

stiffness

(1) The ability of a metal or shape to resist elastic deflection.(2) The rate of stress increase with respect to the rate of increase in strain induced in the metal or shape; the greater the stress required to produce a given strain, the stiffer the material is said to be.

strain

The unit of change in the size or shape of a body due to force. Also known as nominal strain. See also engineering strain, linear strain, and true strain.

strain-age embrittlement

A loss in ductility accompanied by an increase in hardness and strength that occurs when low-carbon steel (especially rimmed or capped steel) is aged following plastic deformation. The degree of embrittlement is a function of aging time and temperature, occurring in a matter of minutes at about 200°C (400 °F), but requiring a few hours to a year at room temperature.

strain aging

The changes in ductility, hardness, yield point, and tensile strength that occur when a metal or alloy that has been cold worked is stored for some time. In steel, strain aging is characterized by a loss of ductility and a corresponding increase in hardness, yield point, and tensile strength.

strain energy

A measure of the energy absorption characteristics of a material determined by measuring the area under the stress-strain diagram. Also known as deformation energy. See also elastic energy, resilience, and toughness.

strain gage

A device for measuring small amounts of strain produced during tensile and similar tests on metal. A coil of fine wire is mounted on a piece of paper, plastic, or similar carrier matrix (backing material), which is rectangular in shape and usually about 25 mm (1.0 in.) long. This is glued to a portion of metal under test. As the coil extends with the specimen, its electrical resistance increases in direct proportion. This is known as bonded resistance-strain gage. Other types of gages measure the actual deformation. Mechanical, optical, or electronic devices are sometimes used to magnify the strain for easier reading. See also rosette.

strain hardening

An increase in hardness and strength caused by plastic deformation at temperatures below the recrystallization range. Also known as work hardening.

strain-hardening coefficient

See strain-hardening exponent.

strain-hardening exponent (*n* value)

The value *n* in the relationship $\sigma = K\varepsilon^n$, where σ is the true stress, ε is the true strain, and *K*, the strength coefficient, is equal to the true stress at a true strain of 1.0. The strain hardening exponent is equal to the slope of the true stress/true strain curve up to maximum load, when plotted on log-log coordinates. The *n*-value relates to the ability of a sheet of material to be stretched in metalworking operations. The higher the *n*-value, the better the formability(stretchability). Also known as the strain-hardening coefficient.

strain rate

The time rate of straining for the usual tensile test. Strain as measured directly on the specimen gage length is used for determining strain rate. Because strain is dimensionless, the units of strain rate are reciprocal time.

strain-rate sensitivity (*m* value)

The increase in stress (σ) needed to cause a certain increase in plastic-strain rate ($\dot{\varepsilon}$) at a given level of plastic strain (ε) and a given temperature(*T*).

$$\text{Strain -rate sensitivity} = m = \left(\frac{\Delta \log \sigma}{\Delta \log \dot{\varepsilon}} \right)_{\varepsilon T}$$

strength

The maximum nominal stress a material can sustain. Always qualified by the type of stress (tensile, compressive, or shear).

strength coefficient

See strain-hardening exponent (n -value).

stress

The intensity of the internally distributed forces or components of forces that resist a change in the volume or shape of a material that is or has been subjected to external forces. Stress is expressed in force per unit area and is calculated on the basis of the original dimensions of the cross section of the specimen. Stress can be either direct (tension or compression) or shear. See also engineering stress, mean stress, nominal stress, normal stress, residual stress, and true stress.

stress amplitude

One-half the algebraic difference between the maximum and minimum stress in one cycle of a repetitively varying stress.

stress-concentration factor (K_t)

A multiplying factor for applied stress that allows for the presence of a structural discontinuity such as a notch or hole; K_t equals the ratio of the greatest stress in the region of the discontinuity to the nominal stress for the entire section. Also known as theoretical stress-concentration factor.

stress-corrosion cracking (SCC)

A time-dependent process in which a metallurgically susceptible material fractures prematurely under conditions of simultaneous corrosion and sustained loading at lower stress levels than would be required in the absence of a corrosive environment. Tensile stress is required at the metal surface and may be a residual stress resulting from heat treatment or fabrication of the metal or the result of external loading. Cracking may be intergranular or transgranular, depending on the combination of alloy and environment.

stress cycle

The smallest segment of the stress-time function that is repeated periodically.

stress cycles endured (N)

The number of cycles of a specified character (that produce fluctuating stress and strain) that a specimen has endured at any time in its stress history.

stress-intensity calibration

A mathematical expression, based on empirical or analytical results, that relates the stress-intensity factor to load and crack length for a specific specimen planar geometry. Also known as K calibration.

stress-intensity factor

A scaling factor, usually denoted by the symbol K , used in linear-elastic fracture mechanics to describe the intensification of applied stress at the tip of a crack of known size and shape. At the onset of rapid crack propagation in any structure containing a crack, the factor is called the critical stress-intensity factor, or the fracture toughness. Various subscripts are used to denote different loading conditions or fracture toughnesses:

stress-intensity factor range (ΔK)

The variation in the stress-intensity factor in a fatigue cycle, that is, $K_{\max} - K_{\min}$.

stress raisers

Changes in contour or discontinuities in structure that cause local increases in stress.

stress ratio (A or R)

The algebraic ratio of two specified stress values in a stress cycle. Two commonly used stress ratios are the ratio of the alternating stress amplitude to the mean stress, $A = S_a/S_m$, and the ratio of the minimum stress to the maximum stress, $R = S_{\min}/S_{\max}$.

stress relaxation

The time-dependent decrease in stress in a solid under constant strain at constant temperature due to creep. The stress-relaxation behavior of a metal is usually shown in a stress-relaxation curve.

stress-relaxation curve

A plot of the remaining, or relaxed, stress in a stress-relaxation test as a function of time. The relaxed stress equals the initial stress minus the remaining stress. Also known as a stress-time curve.

stress-rupture strength

See creep-rupture strength.

stress-rupture test

See creep-rupture test.

stress-strain curve

See stress-strain diagram.

stress-strain diagram

A graph in which corresponding values of stress and strain are plotted against each other. Values of stress are usually plotted vertically (ordinates or y-axis) and values of strain horizontally (abscissas or x-axis). Also known as deformation curve and stress-strain curve.

stress-time curve

See stress-relaxation curve.

stretch-bending test

A simulative test for sheet metal formability in which a strip of sheet metal is clamped at its ends in lock beads and deformed in the center by a punch. Test conditions are chosen so that fracture occurs in the region of punch contact.

stretcher strains

See Lüders lines.

striation

A fatigue fracture feature, often observed in electron micrographs, that indicates the position of the crack front after each succeeding cycle of stress. The distance between striations indicates the advance of the crack front across that crystal during one stress cycle, and a line normal to the striation indicates the direction of local crack propagation.

Swift cup test

A simulative cupping test in which circular blanks of various diameters are clamped in a die ring and deep drawn into cups by a flat-bottomed cylindrical punch. Compare with Erichsen cup test and Olsen cup test.

T

tangent modulus

The slope of the stress-strain curve at any specified stress or strain. See also modulus of elasticity.

temper embrittlement

Brittleness that results when certain steels are held within, or are cooled slowly through, a certain range of temperature below the transformation range. The brittleness is manifested as an upward shift in ductile-to-brittle transition temperature but only rarely produces a low value of reduction in area in a smooth-bar tension test of the embrittled material.

tensile strength

In tension testing, the ratio of maximum load to original cross-sectional area. Also known as ultimate strength. Compare with yield strength.

tensile stress

A stress that causes two parts of an elastic body, on either side of a typical stress plane, to pull apart. Contrast with compressive stress.

tensile testing

See tension testing.

tension

The force or load that produces elongation.

tension testing

A method of determining the behavior of materials subjected to uniaxial loading, which tends to stretch the metal. A longitudinal specimen of known length and diameter is gripped at both ends and stretched at a slow, controlled rate until rupture occurs. Also known as tensile testing.

testing machine (load-measuring type)

A mechanical device for applying a load (force) to a specimen.

theoretical stress concentration factor

See stress-concentration factor.

thermal fatigue

Fatigue resulting from the presence of temperature gradients that vary with time in such a manner as to produce cyclic stresses in a structure.

thermocouple

A device for measuring temperature, consisting of lengths of two dissimilar metals or alloys that are electrically joined at one end and connected to a voltage-measuring instrument at the other end. When one junction is hotter than the other, a thermal electromotive force is produced that is roughly proportional to the difference in temperature between the hot and cold junctions.

threshold stress for stress-corrosion cracking (σ_{th})

An experimentally determined critical gross-section stress below which stress-corrosion cracking will not occur under specified test conditions.

tolerance limits

The extreme values (upper and lower) that define the range of permissible variation in size or other quality characteristic of a part.

torsion

A twisting deformation of a solid body about an axis in which lines that were initially parallel to the axis become helices.

torsion test

A test designed to provide data for the calculation of the shear modulus, modulus of rupture in torsion, and yield strength in shear.

torsional stress

The shear stress on a transverse cross section resulting from a twisting action.

total elongation

A total amount of permanent extension of a test piece broken in a tensile test. See also elongation, percent.

total-extension-under-load yield strength

See yield strength.

toughness

The ability of a metal to absorb energy and deform plastically before fracturing.

transgranular

Through or across crystals or grains. Also known as intracrystalline or transcrystalline.

transition temperature

(1) An arbitrarily defined temperature that lies within the temperature range in which metal fracture characteristics (as usually determined by tests of notched specimens) change rapidly, such as from primarily fibrous (shear) to primarily crystalline (cleavage) fracture. (2) Sometimes used to denote an arbitrarily defined temperature within a range in which the ductility changes rapidly with temperature.

transverse direction

Literally, the "across" direction, usually signifying a direction or plane perpendicular to the direction of working. In rolled plate or sheet, the direction across the width is often called long transverse, and the direction through the thickness, short transverse.

transverse strain

Linear strain in a plane perpendicular to the loading axis of a specimen.

triaxial stress

See principal stress (normal).

tribology

The science and technology concerned with interacting surfaces in relative motion.

true strain

(1) The ratio of the change in dimension, resulting from a given load increment, to the magnitude of the dimension immediately prior to applying the load increment. (2) In a body subjected to axial force, the natural logarithm of the ratio of the gage length at the moment of observation to the original gage length. Also known as natural strain. Compare with engineering strain.

true stress

The value obtained by dividing the load applied to a member at a given instant by the cross-sectional area over which it acts. Compare with engineering stress.

typical basis

The typical property value is an average value. No statistical assurance is associated with this basis. See also A-basis, B-basis, and S-basis.

U

ultimate strength

The maximum stress (tensile, compressive, or shear) a material can sustain without fracture, determined by dividing maximum load by the original cross-sectional area of the specimen. Also known as nominal strength or maximum strength.

uniaxial strain

Increase (or decrease) in length resulting from a stress acting parallel to the longitudinal axis of the specimen.

uniaxial stress

See principal stress (normal).

uniform elongation

The elongation at maximum load and immediately preceding the onset of necking in a tension test.

uniform strain

The strain occurring prior to the beginning of localization of strain (necking); the strain to maximum load in the tension test.

V

variance

A measure of the squared dispersion of observed values or measurements expressed as a function of the sum of the squared deviations from the population mean or sample average.

verification

Checking or testing an instrument to ensure conformance with a specification.

verified loading range

For testing machines, the range of indicated loads for which the testing machine gives results within the permissible variation specified.

vernier

A short auxiliary scale that slides along the main instrument scale to permit more accurate fractional reading of the least main division of the main scale. See also least count.

Vicat softening point

The temperature at which a flat-ended needle of 1 mm²(0.0015 in.²) circular or square cross section will penetrate a thermoplastic specimen to a depth of 1 mm (0.040 in.) under a specified load, using a uniform rate of temperature rise.

Vickers hardness number (HV)

A number related to the applied load and the surface area of the permanent impression made by a square-based pyramidal diamond indenter having included face angles of 136°, computed from the equation:

$$HV = 2P \sin \frac{\alpha}{2} = \frac{1.8544P}{d^2} \quad (\text{Eq 1})$$

where P is applied load, kgf; d is mean diagonal of the impression, mm; and α is face angle of diamond, 136°.

Vickers hardness test

An indentation hardness test employing a 136° diamond pyramid indenter (Vickers) and variable loads, enabling the use of one hardness scale for all ranges of hardness—from very soft lead to tungsten carbide. Also known as diamond pyramid hardness test.

viscoelasticity

A property involving a combination of elastic and viscous behavior. A material having this property is considered to combine the features of a perfectly elastic solid and a perfect fluid. A phenomenon of time-dependent, in addition to elastic, deformation (or recovery) in response to load.

volumetric modulus of elasticity

See bulk modulus of elasticity.

W

Wallner lines

A distinct pattern of intersecting sets of parallel lines, usually producing a set of V-shaped lines, sometimes observed when viewing brittle fracture surfaces at high magnification in an electron microscope. Wallner lines are attributed to interaction between a shock wave and a brittle crack front propagating at high velocity. Sometimes Wallner lines are misinterpreted as fatigue striations.

wear

Damage to a solid surface, generally involving progressive loss of material, due to relative motion between that surface and a contacting surface or substance.

wear rate

The rate of material removal or dimensional change due to wear per unit of exposure parameter—for example, quantity of material removed (mass, volume, thickness) in unit distance of sliding or unit time.

welding

In tribology, the bonding between metallic surfaces in direct contact, at any temperature.

Widmanstätten structure

A structure characterized by a geometrical pattern resulting from the formation of a new phase along certain crystallographic planes of the parent solid solution. The orientation of the lattice in the new phase is related crystallographically to the orientation of the lattice in the parent phase. The structure is readily produced in many alloys by appropriate heat treatment.

workability

See formability.

work hardening

See strain hardening.

wrap-around bend

The bend obtained when a specimen is wrapped in a closed helix around a cylindrical mandrel. This term is sometimes applied to a semiguided bend of 180° or less.

wrinkling

A wavy condition obtained in deep drawing of sheet metal, in the area of the metal between the edge of the flange and the draw radius. Wrinkling may also occur in other forming operations when unbalanced compressive forces are set up.

Y

yielding

Evidence of plastic deformation in structural materials. Also known as plastic flow or creep. See also flow.

yield point

The first stress in a material, usually less than the maximum attainable stress, at which an increase in strain occurs without an increase in stress. Only certain metals—those which exhibit a localized, heterogeneous type of transition from elastic to plastic deformation—produce a yield point. If there is a decrease in stress after yielding, a distinction may be made between upper and lower yield points. The load at which a sudden drop in the flow curve occurs is called the upper yield point. The constant load shown on the flow curve is the lower yield point.

yield-point elongation

During discontinuous yielding, the amount of strain measured from the onset of yielding to the beginning of strain hardening.

yield strength

The stress at which a material exhibits a specified deviation from proportionality of stress and strain. An offset of 0.2% is used for many metals. Compare with tensile strength.

yield stress

The stress level of highly ductile materials, such as structural steels, at which large strains take place without further increase in stress.

Young's modulus

A term used synonymously with modulus of elasticity. The ratio of tensile or compressive stresses to the resulting strain.

Z

zero time

The time when the given loading or constraint conditions are initially obtained in creep or stress-relaxation tests, respectively.
