ASM HANDBOOK®

VOLUME 14

Forming and Forging

ASM INTERNATIONAL®

Forming and Forging was published in 1988 as Volume 14 of the 9th Edition Metals Handbook. With the third printing (1993), the series title was changed to ASM Handbook. The Volume was prepared under the direction of the ASM Handbook Committee.

Volume Chair

The Volume Chair was S.L. Semiatin.

Foreword

Forming and forging processes are among the oldest and most important of materials-related technologies. Volume 14 of the 9th Edition of Metals Handbook describes these processes comprehensively, with accuracy and clarity.

Today, industry must continuously evaluate the costs of competitive materials and the operations necessary for converting each material into finished products. Manufacturing economy with no sacrifice in quality is paramount. Therefore, "precision" forming methods, net and near-net shape processing, and modern statistical and computer-based process design and control techniques are more important than ever. This book serves as an invaluable introduction to this new technology, and also provides a strong foundation with regard to more standard, well-established metalworking operations.

This is the second of three volumes in the 9th Edition devoted to the technologies used to form metal parts. Volume 7, Powder Metallurgy, was published in 1984; Volume 15, Casting, will follow the present volume. The combination of these significant contributions to the metallurgical literature will provide Handbook readers with unprecedented coverage of metal forming methods.

A successful Handbook is the culmination of the time and efforts of hundreds of contributors. To those individuals listed in the next several pages, we extend our sincere thanks. The Society is especially indebted to Dr. S.L. Semiatin for his tireless efforts in organizing and editing this volume. Finally, we are grateful for the support and guidance provided by the ASM Handbook Committee and the skill of an experienced editorial staff. As a result of these combined efforts, the tradition of excellence associated with the Metals Handbook continues.

William G. Wood

President, ASM International

Edward L. Langer

Managing Director, ASM International

Preface

Metalworking is one of the oldest of materials-related technologies and accounts for a large percentage of fabricated metal products. The usefulness of the deformation processes that comprise metalworking technology is indicated by the wide variety of parts of simple and complex shape with carefully tailored mechanical and physical properties that are made routinely in industry. It is difficult to imagine what our lives would be like without such products.

The 8th Edition of Metals Handbook treated various aspects of metalworking in two separate volumes: forging was addressed in the volume Forging and Casting, and sheet forming in the one on Forming. In the present 9th Edition, the decision was made to bring all this information together in one Handbook.

During the editing process, all of the articles from the 8th Edition volumes were reviewed for technical content. Some required only minor revision, others were totally rewritten. A section on other bulk forming processes was added to provide a balance to the extensive collection of articles on forging. In this new section, topics such as conventional hot extrusion; hydrostatic extrusion; wire, rod, and tube drawing; and flat, bar, and shape rolling are discussed.

In addition, approximately 20 new articles have been added to describe advances in metalworking technology that have occurred since publication of the 8th Edition. These advances can be broadly grouped in the categories of new processes, new materials technologies, and new methods of process design and control. New processes include isothermal and hot-die forging, precision forging, and superplastic forming of sheet metals. New materials technologies center on the development and widespread use of thermal-mechanical processing, particularly for aerospace alloys, and concepts of metal workability and formability. In the area of process design and control, several articles were written to summarize the powerful mathematical and statistical methods that have been developed to take metalworking from an experienced-based art into the realm of scientific technology. These techniques have allowed forming engineers to design dies and preforms for single and multistage processes without actually constructing tooling or tying up expensive production equipment. With the development of user-friendly computer programs and low-cost computers, such techniques are finding increasing acceptance by manufacturers worldwide.

Thanks are due to the various individuals who organized, wrote, edited, and reviewed various sections and articles in this Handbook; their voluntary contributions of time and expertise are invaluable in a project such as this. We would also like to extend thanks to the ASM Handbook staff. The amount of careful and devoted work that the staff put into the Handbook cannot really be appreciated until one actually works with them on one of these volumes.

Staff

ASM International staff who contributed to the development of the Volume included Kathleen M. Mills, Manager of Editorial Operations; Joseph R. Davis, Senior Editor; James D. Destefani, Technical Editor; Theodore B. Zorc, Technical Editor; Heather J. Frissell, Editorial Supervisor; George M. Crankovic, Assistant Editor; Alice W. Ronke, Assistant Editor; Diane M. Jenkins, Word Processing Specialist; and Karen Lynn O'Keefe, Word Processing Specialist. Editorial assistance was provided by J. Harold Johnson, Robert T. Kiepura, Dorene A. Humphries, and Penelope Thomas. The Volume was prepared under the direction of Robert L. Stedfeld, Director of Reference Publications.

Conversion to Electronic Files

ASM Handbook, Volume 14, Forming and Forging was converted to electronic files in 1998. The conversion was based on the fourth printing (1996). No substantive changes were made to the content of the Volume, but some minor corrections and clarifications were made as needed.

ASM International staff who contributed to the conversion of the Volume included Sally Fahrenholz-Mann, Bonnie Sanders, Marlene Seuffert, Gayle Kalman, Scott Henry, Robert Braddock, Alexandra Hoskins, and Erika Baxter. The electronic version was prepared under the direction of William W. Scott, Jr., Technical Director, and Michael J. DeHaemer, Managing Director.

Introduction to Forming and Forging Processes

S.L. Semiatin, Battelle Columbus Division

Introduction

METALWORKING consists of deformation processes in which a metal billet or blank is shaped by tools or dies. The design and control of such precesses depend on an understanding of the characteristics of the workpiece material, the conditions at the tool/workpiece interface, the mechanics of plastic deformation (metal flow), the equipment used, and the finished-product requirements. These factors influence the selection of tool geometry and material as well as processing conditions (for example, workpiece and die temperatures and lubrication). Because of the complexity of many metalworking operations, models of various types, such as analytic, physical, or numerical models, are often relied upon to design such processes.

This Volume presents the state of the art in metalworking processes. Various major sections of this Volume deal with descriptions of specific processes, selection of equipment and die materials, forming practice for specific alloys, and various aspects of process design and control. This article will provide a brief historical perspective, a classification of metalworking processes and equipment, and a summary of some of the more recent developments in the field.

Introduction to Forming and Forging Processes

S.L. Semiatin, Battelle Columbus Division

Historical Perspective

Metalworking is one of three major technologies used to fabricate metal products; the others are casting and powder metallurgy. However, metalworking is perhaps the oldest and most mature of the three. The earliest records of metalworking describe the simple hammering of gold and copper in various regions of the Middle East around 8000 B.C. The forming of these metals was crude because the art of refining by smelting was unknown and because the ability to work the material was limited by impurities that remained after the metal had been separated from the ore. With the advent of copper smelting around 4000 B.C., a useful method became available for purifying metals through chemical reactions in the liquid state. Later, in the Copper Age, it was found that the hammering of metal brought about desirable increases in strength (a phenomenon now known as strain hardening). The quest for strength spurred a search for alloys that were inherently strong and led to the utilization of alloys of copper and tin (the Bronze Age) and iron and carbon (the Iron Age). The Iron Age, which can be dated as beginning around 1200 B.C., followed the beginning of the Bronze Age by some 1300 years. The reason for the delay was the absence of methods for achieving the high temperatures needed to melt and to refine iron ore.

Most metalworking was done by hand until the 13th century. At this time, the tilt hammer was developed and used primarily for forging bars and plates. The machine used water power to raise a lever arm that had a hammering tool at one end; it was called a tilt hammer because the arm tilted as the hammering tool was rised. After raising the hammer, the blacksmith let it fall under the force of gravity, thus generating the forging blow. This relatively simple device remained in service for some centuries.

The development of rolling mills followed that of forging equipment. Leonardo da Vinci's notebook includes a sketch of a machine designed in 1480 for the rolling of lead for stained glass windows. In 1945, da Vinci is reported to have rolled flat sheets of precious metal on a hand-operated two-roll mill for coin-making purposes. In the following years, several designs for rolling mills were utilized in Germany, Italy, France, and England. However, the development of large mills capable of hot rolling ferrous materials took almost 200 years. This relatively slow progress was primarily due to the limited supply of iron. Early mills employed flat rolls for making sheet and plate, and until the middle of the 18th century, these mills were driven by water wheels.

During the Industrial Revolution at the end of the 18th century, processes were devised for making iron and steel in large quantities to satisfy the demand for metal products. A need arose for forging equipment with larger capacity. This need was answered with the invention of the high-speed steam hammer, in which the hammer is raised by steam power, and the hydraulic press, in which the force is supplied by hydraulic pressure. From such equipment came products ranging from firearms to locomotive parts. Similarly, the steam engine spurred developments in rolling, and in the 19th century, a variety of steel products were rolled in significant quantities.

The past 100 years have seen the development of new types of metalworking equipment and new materials with special properties and applications. The new types of equipment have included mechanical and screw presses and high-speed tandem rolling mills. The materials that have benefited from such developments in equipment range from the ubiquitous low-carbon steel used in automobiles and appliances to specialty aluminum-, titanium-, and nickel-base alloys. In the last 20 years, the formulation of sophisticated mathematical analyses of forming processes has led to higher-quality products and increased efficiency in the metalworking industry.

S.L. Semiatin, Battelle Columbus Division

Classification of Metalworking Processes

In metalworking, an initially simple part--a billet or a blanked sheet, for example--is plastically deformed between tools (or dies) to obtain the desired final configuration. Metal-forming processes are usually classified according to two broad categories:

- Bulk, or massive, forming operations
- Sheet forming operations*

In both types of process, the surfaces of the deforming metal and the tools are in contact, and friction between them may have a major influence on material flow. In bulk forming, the input material is in billet, rod, or slab form, and the surface-to-volume ratio in the formed part increases considerably under the action of largely compressive loading. In sheet forming, on the other hand, a piece of sheet metal is plastically deformed by tensile loads into a three-dimensional shape, often without significant changes in sheet thickness or surface characteristic.

Processes that fall under the category of bulk forming have the following distinguishing features (Ref 1):

- The deforming material, or workpiece, undergoes large plastic (permanent) deformation, resulting in an appreciable change in shape or cross section
- The portion of the workpiece undergoing plastic deformation is generally much larger than the portion undergoing elastic deformation; therefore, elastic recovery after deformation is negligible

Examples of generic bulk forming processes are extrusion, forging, rolling, and drawing. Specific bulk forming processes are listed in Table 1.

Table 1 Classification of bulk (massive) forming processes

Forging
Closed-die forging with flash
Closed-die forging without flash
Coining
Electro-upsetting

Sheet rolling
Shape rolling

Tube rolling Ring rolling Rotary tube piercing Gear rolling Roll forging Cross rolling Surface rolling Shear forming Tube reducing
Extrusion Nonlubricated hot extrusion Lubricated direct hot extrusion Hydrostatic extrusion
Drawing Drawing Drawing with rolls Ironing Tube sinking

Source: Ref 1

The characteristics of sheet metal forming processes are as follows (Ref 1):

- The workpiece is a sheet or a part fabricated from a sheet
- The deformation usually causes significant changes in the shape, but not the cross-sectional area, of the sheet.
- In some cases, the magnitudes of the plastic and the elastic (recoverable) deformations are comparable; therefore, elastic recovery or springback may be significant.

Examples of processes that fall under the category of sheet metal forming are deep drawing, stretching, bending, and rubber-pad forming. Other processes are listed in Table 2.

Table 2 Classification of sheet metal forming processes

Bending and straight flanging Brake bending Roll bending
Surface contouring of sheet Contour stretch forming (stretch forming) Androforming Age forming Creep forming Die-quench forming Bulging Vacuum forming

Linear stretch forming (stretch forming) Linear roll forming (roll forming)
Deep recessing and flanging

Note cited in this section

* Sheet forming is also referred to as forming. In the broadest and most accepted sense, however, the term forming is used to described bulk as well as sheet forming processes.

Introduction to Forming and Forging Processes

S.L. Semiatin, Battelle Columbus Division

Types of Metalworking Equipment

The various forming processes discussed above are associated with a large variety of forming machines or equipment, including the following (Ref 1):

- Rolling mills for plate, strip, and shapes
- Machines for profile rolling from strip
- Ring-rolling machines
- Thread-rolling and surface-rolling machines
- Magnetic and explosive forming machines
- Draw benches for tube and rod; wire- and rod-drawing machines
- Machines for pressing-type operations (presses)

Among those listed above, pressing-type machines are the most widely used and are applied to both bulk and sheet forming processes. These machines can be classified into three types: load-restricted machines (hydraulic presses), stroke-restricted machines (crank and eccentric, or mechanical, presses), and energy-restricted machines (hammers and screw presses). The significant characteristics of pressing-type machines comprise all machine design and performance data that are pertinent to the economical use of the machine. These characteristics include:

- Characteristics for load and energy: Available load, available energy, and efficiency factor (which equals the energy available for workpiece deformation/energy supplied to the machine)
- Time-related characteristics: Number of strokes per minute, contact time under pressure, and velocity under pressure.
- Characteristics for accuracy: For example, deflection of the ram and frame, particularly under off-center loading, and press stiffness

Introduction to Forming and Forging Processes

S.L. Semiatin, Battelle Columbus Division

Recent Developments in Metalworking

Over the last 20 years, metalworking practice has seen advances with regard to the development of new processes and new materials, the understanding and control of material response during forming, and the application of sophisticated process design tools. Some of these technological advances will be summarized in the following sections in this article.

New Processes

A number of processes have recently been introduced or accepted. These include a variety of forging processes, such as radial, precision, rotary, metal powder, and isothermal forging, as well as sheet forming processes, such as superplastic forming. Laser cutting and abrasive waterjet cutting of sheet and plate materials are also finding increased use. Each of these processes is described in greater detail in subsequent articles in this Volume.

Radial forging is a technique that is most often used to manufacture axisymmetrical parts, such as gun barrels. Radial forging machines (Fig. 1) use the radial hot- or cold-forging principle with three, four, or six hammers to produce solid or hollow round, square, rectangular, or profiled sections. The machines used for forging large gun barrels are of a horizontal type and can size the bore of the gun barrel to the exact rifling that is machined on the mandrel. Products produced by radial forging often have improved mechanical and metallurgical properties as compared to those produced by other, more conventional techniques.

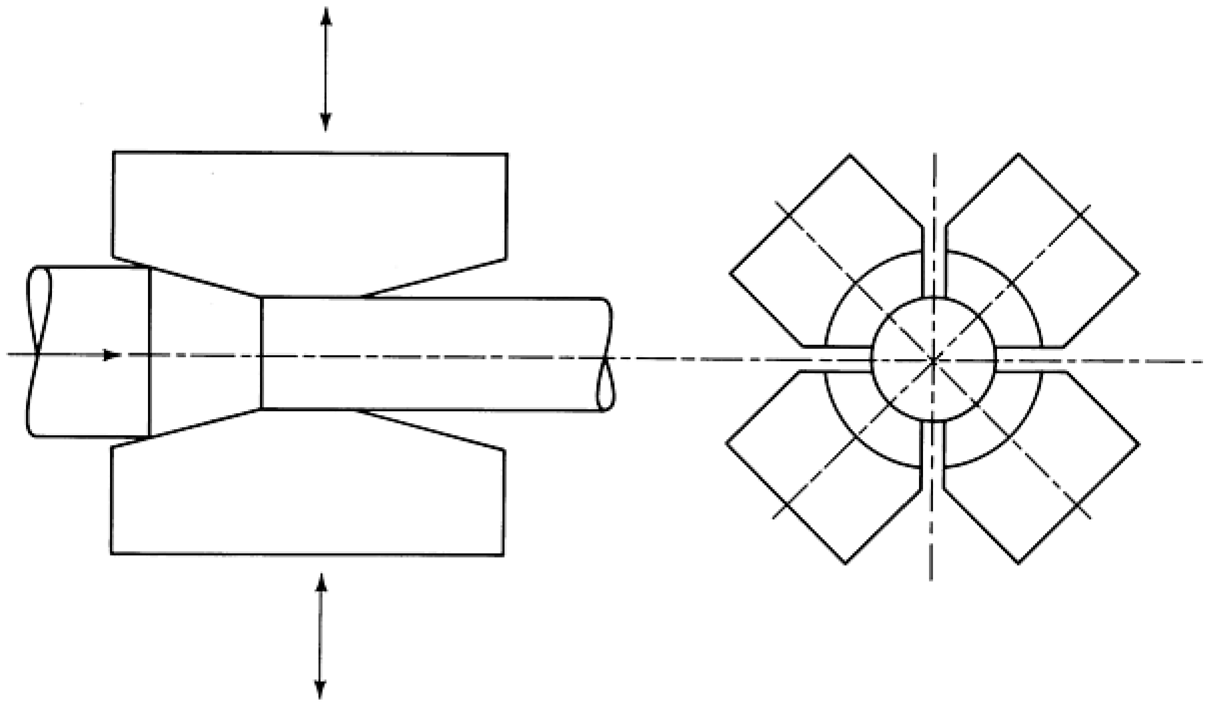

Fig. 1 Workpiece and tooling configurations for radial forging. Source: Ref 2.

Rotary, or orbital, forging is a two-die forging process that deforms only a small portion of the workpiece at a time in a continuous manner. As shown in Fig. 2, the axis of the upper die is tilted at a slight angle with respect to the axis of the lower die, causing the forging force to be applied to only a small area of the workpiece. As one die rotates relative to the other, the contact area between die and workpiece (called the footprint) continually progresses through the workpiece until the final shape is obtained. The tilt angle between the two dies has a major effect on the size of the footprint and therefore on the amount of forging force applied to the workpiece. Rotary forging requires as little as one-tenth the force needed for conventional forging processes. The smaller forging forces result in lower die and machine deflections and therefore in the ability to make intricate parts to a high degree of accuracy.

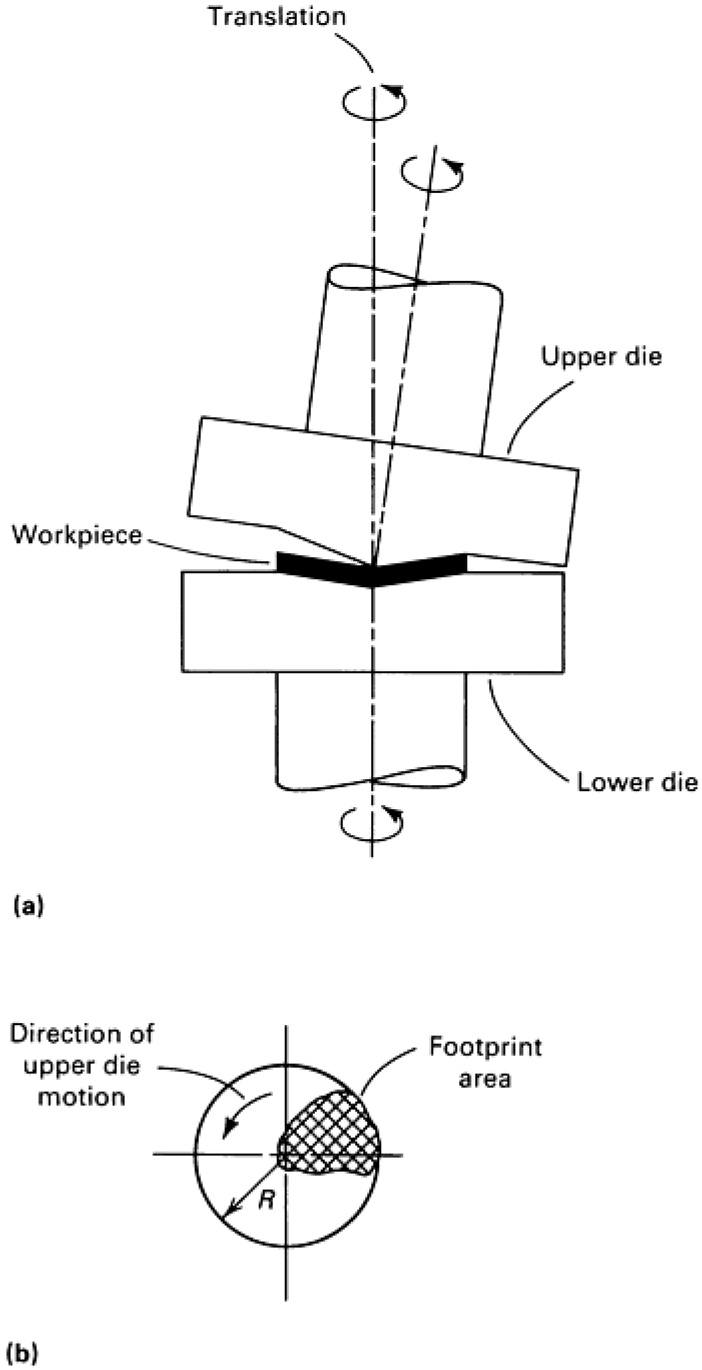

Fig. 2 Rotary (orbital) forging. Die arrangement (a) and top view (b) of the workpiece indicating the die-workpiece contact area (footprint). Source: Ref 3.

Precision forging, also known as draftless forging, is a relatively recent development that is distinguished from other types of forging principally by finished products with thinner and more detailed geometric features, virtual elimination of drafted surfaces and machining allowances, varying die parting line locations, and closer dimensional tolerances. These types of parts are most commonly manufactured from light metals, such as aluminum, and more recently from titanium for aerospace applications in which weight, strength, and intricate shaping are important considerations, along with price and delivery (see the articles "Forging of Aluminum Alloys" and "Forging of Titanium Alloys," respectively, in this Volume).

Precision forging achieves close tolerances and low drafts through the use of die inserts, improved accuracy in die sinking, and close control of process temperatures and pressures during forging. Modified die designs are also frequently used. One such design is known as through die (Fig. 3), and it derives its name from the fact that the outer periphery of the forging cavity is machined completely through the die. An upper and lower punch enter and forge the part entirely within this ring. The top punch is then retracted by the press stroke, and the completed forging is ejected by raising the lower punch attached to a knockout mechanism below.

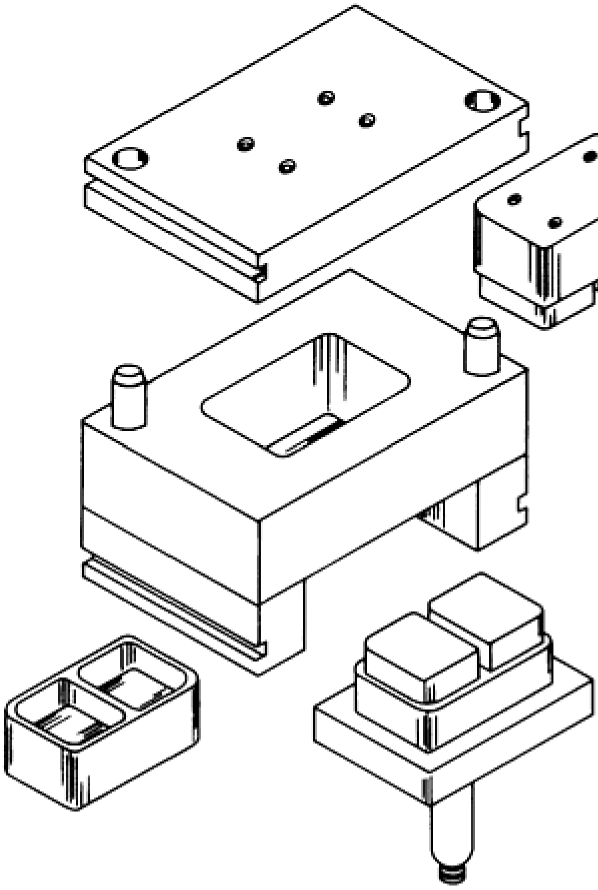

Fig. 3 Through-die design for precision forging. Source: Aluminum Precision Products, Inc.

Powder forging is a process in which sintered preforms are hot forged to 100% of theoretical density. Powder forging is primarily used for ferrous parts and difficult-to-work superalloys that require high service integrity, and it is most suitable for symmetrical shapes containing large holes and parts that would otherwise require a large amount of machining. In addition to the article "Powder Forging" in this Volume, detailed information and property data related to forged powder metallurgy products can be found in Powder Metal Technologies and Applications, Volume 7 of the ASM Handbook.

Isothermal and hot-die forging are hot-forging processes in which the dies are at the same (isothermal forging) or nearly the same (hot-die forging) temperature as the workpiece. The processes are primarily used for costly materials, such as titanium and nickel-base alloys, which possess fine, stable two-phase microstructures at hot-working temperatures. Such microstructures often give rise to a property known as superplasticity. Superplasticity is characterized by good die-filling capacity in bulk forming processes and high tensile elongations in sheet forming applications.

The total (or partial) elimination of die chilling in isothermal (or hot-die) forging, in addition to the superplastic properties of the workpiece material, allows forging to closer tolerance than is possible with conventional hot forging, in which the die temperature is typically only slightly above ambient. As a result, machining and material costs are reduced. Moreover, elimination of die chilling permits a reduction in the number of preforming and blocking dies necessary for forging a given part. In addition, because die chilling is not a problem, a slow ram speed machine, such as a hydraulic press, can be used. The lower strain rate imposed gives rise to a lower material flow stress and therefore a lower forging pressure. The net result is that larger parts can be forged in equipment of capacity smaller than that required for conventional forging. Figure 4 shows a number of Alloy 100 (UNS N13100) jet engine disks made using a version of isothermal forging known as "Gatorizing."

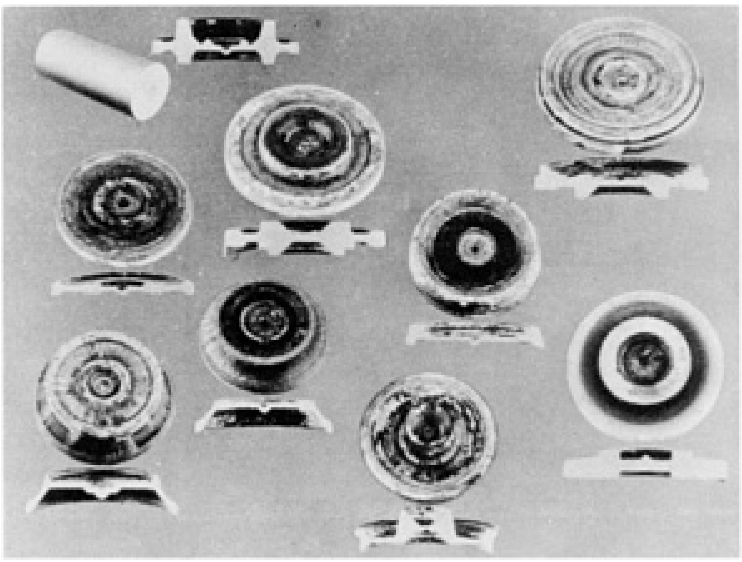

Fig. 4 Typical isothermally forged (Gatorized) jet engine disks made from Alloy 100. A starting billet preform is shown in the upper left-hand corner of the photograph. Source: Ref 4.

Superplastic forming is the sheet forming counterpart to isothermal forging. The isothermal, low strain rate conditions in superplastic forming result in low workpiece flow stress. Therefore, gas pressure, rather than a hard punch, is most often used to carry out a stretching-type operation; the only tooling requirement is a female die (Fig. 5). The very high tensile ductilities characteristic of superplastically formed sheet alloys such as Ti-6Al-4V, Zn-22Al, and aluminum alloy 7475 enable the forming of parts of very complex shape. Although cycle times for superplastic forming are relatively long (of the order of 10 min per part), economies of manufacture are realized primarily through reduced machining and assembly costs. The latter savings is a result of the fact that individual superplastically formed parts are usually used as replacements for assemblies of many separate component parts.

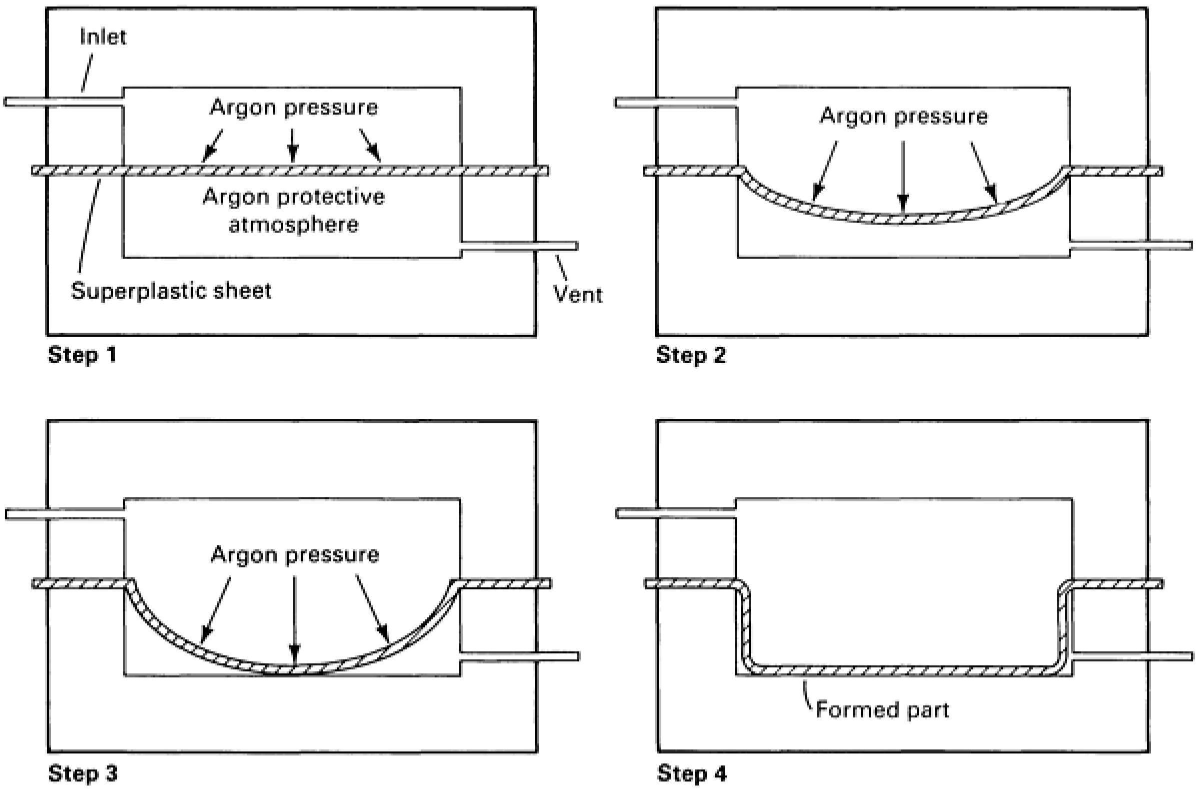

Fig. 5 Illustration of the blow-forming method of superplastic forming. Source: Ref 5.

Laser cutting is an increasingly popular method of cutting sheet materials accurately. Laser cutting typically makes use of a computer numerical control program that allows new cutting paths to be quickly generated. In addition to rapid cutting, laser cutting offers such advantages as precision (cutting accuracy of 0.13 mm, or 0.005 in., or less), the ability to cut most materials (including metals, ceramics, plastics, and glass), minimal heat-induced distortion, and very clean straight-sided cuts. The fact that cutting is done under computer control also provides ease of cutting complex shapes in sheet stock, high material utilization, excellent pattern reproducibility, and economical low-volume production. Laser cutting systems are generally used for cutting prototypes or small production runs from sheet stock. Hard tooling is usually more economical for high volumes. However, one high-volume application of lasers is the trimming of automobile parts. These parts, are being made of thinner materials, and trim dies capable of cutting to the required tolerances are so expensive that laser cutting is cost-competitive even for the large lot sizes involved.

Abrasive waterjet cutting is a process developed in the late 1960s which relies on the impingement of a high-velocity, high-pressure, abrasive-laden waterjet onto the workpiece for the purpose of cutting. Among the advantages of the technique are high cutting rates, high quality of the cut surface, almost total absence of heat generation within the workpiece (thus minimizing the development of a heat-affected zone), and a relatively narrow kerf. Applications of abrasive waterjet cutting can be found in the machining of hard metals (for example, superalloys, high-strength steels, and titanium alloys) and a number of nonmetals (for example, concrete, ceramics, composites, and plastics). The only major limitation of the process is the inability to mill, turn, or drill blind holes or perform other operations that involve cutting or drilling to a partial depth.

New Materials Developments

An increased understanding of material behavior during deformation has led to the improved design of metalworking processes. Two areas of particular significance in this regard are the emergence of thermal-mechanical processing techniques and the development of metal workability/formability relationships.

Thermal-mechanical processing refers to the design and control of the individual metalworking and heat treatment steps in a manufacturing process in order to enhance final properties. Originally used as a method of producing high-strength or high-toughness alloy steels, thermal-mechanical processing is now routinely used for other alloy systems, especially those based on nickel.

Most thermal-mechanical processing treatments for steels rely on deformation that is imposed before, during, or after austenite transformation. The various types of treatments are summarized in Table 3. This classification, based on the relative positions of deformation and transformation in the treatment cycle, has other justification in that the tensile stress-strain curves and the rate of increase in yield strength with increasing deformation (Fig. 6) have been found to be broadly similar for a variety of steels subjected to a given class of treatment and have been found to differ for each of the classes.

Table 3 Classification of thermal-mechanical processing treatments for high-strength steels

Type I

Deformation before austenite transformation
Normal hot-working processes
Deformation before transformation to martensite

Type II

Deformation during austenite transformation
Deformation during transformation to martensite
Deformation during transformation to ferrite-carbide aggregates

Type III

Deformation after austenite transformation
Deformation of martensite followed by tempering
Deformation of tempered martensite followed by aging
Deformation of isothermal transformation products

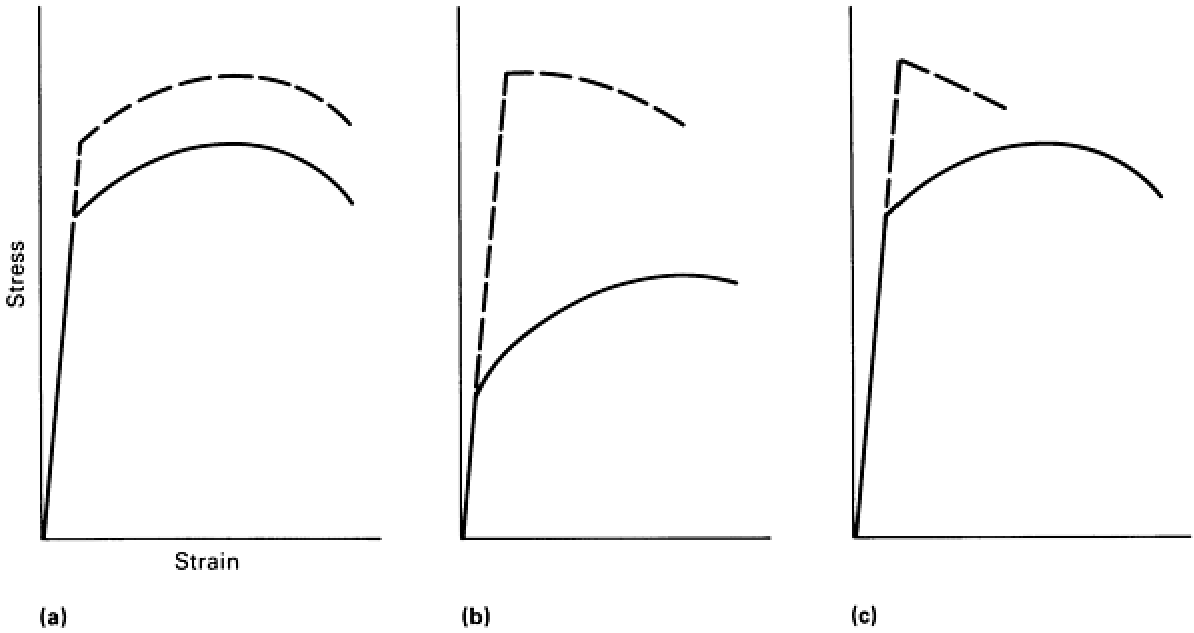

Fig. 6 Effects of different classes of thermal-mechanical treatments on the shape of the tensile stress-strain curve. (a) Type I. (b) Type II. (c) Type III. See Table 3 for description of the types of treatments. Source: Ref 6.

In the thermal-mechanical processing of nickel-base superalloys, metalworking temperature is carefully controlled (especially during finish forming) to make use of the structure control effects of second phases (see, for example, the articles "Forging of Heat-Resistant Alloys" and "Forging of Nickel-Base Alloys" in this Volume). Above the optimal working temperature range, the structure control phases go into solution and lose their effect in controlling grain size and structure. Below this range, extensive fine precipitates are formed, and the alloy becomes too stiff to process. Proper thermal-mechanical processing leads to excellent combinations of tensile, fatigue, and creep properties.

Workability and formability are the terms that are commonly used to refer to the ease with which metal can be shaped during bulk and sheet forming operations, respectively. In the broadest sense, workability and formability indices provide quantitative estimates of the strength properties of a metal (and therefore the required working loads) and its resistance to failure. However, the latter characteristics (that is, ductility or failure resistance) is usually of primary concern. The techniques used to estimate this property vary, depending on the class of forming operation.

In bulk forming, the most common types of failures are those known as free surface fracture (at cold-working temperatures) or triple-point cracking/cavitation (at hot-working temperatures). A vast array of mechanical tests and theoretical analyses have been developed for predicting failures of these and other types during forging, extrusion, rolling, and other bulk forming operations. These tests and analyses are summarized in Ref 7 and are discussed in the Section "Evaluation of Workability" in this Volume. Other common test techniques used to gage bulk workability include the uniaxial upset, flanged or tapered compression, notched-bar upset, and wedge tests.

One of the most successful and useful design tools to come from bulk workability research is the workability diagram for free surface fracture during the cold working of wrought and powder metals. An example of a workability diagram of this type is shown in Fig. 7. The graph indicates the locus of free surface normal strains (one tensile and one compressive) that cause fracture. These diagrams are determined by mechanical tests such as those mentioned above. For many metals, the fracture locus is a straight line of slope $-\frac{1}{2}$. Some metals have a bilinear failure locus. The workability diagrams are used during process design by plotting calculated or estimated surface strain paths that are to be imposed during forming on the fracture locus diagram (Fig. 7). If the final strains lie above the locus, part failure is likely, and changes are necessary in preform design, lubrication, and/or material. The fracture locus concept has been used to prevent free surface cracking in forging and to prevent edge cracking in rolling. With modifications, the fracture locus approach has also provided insight into such failure modes as center bursting in extrusion and forging and die-workpiece contact fractures in forging.

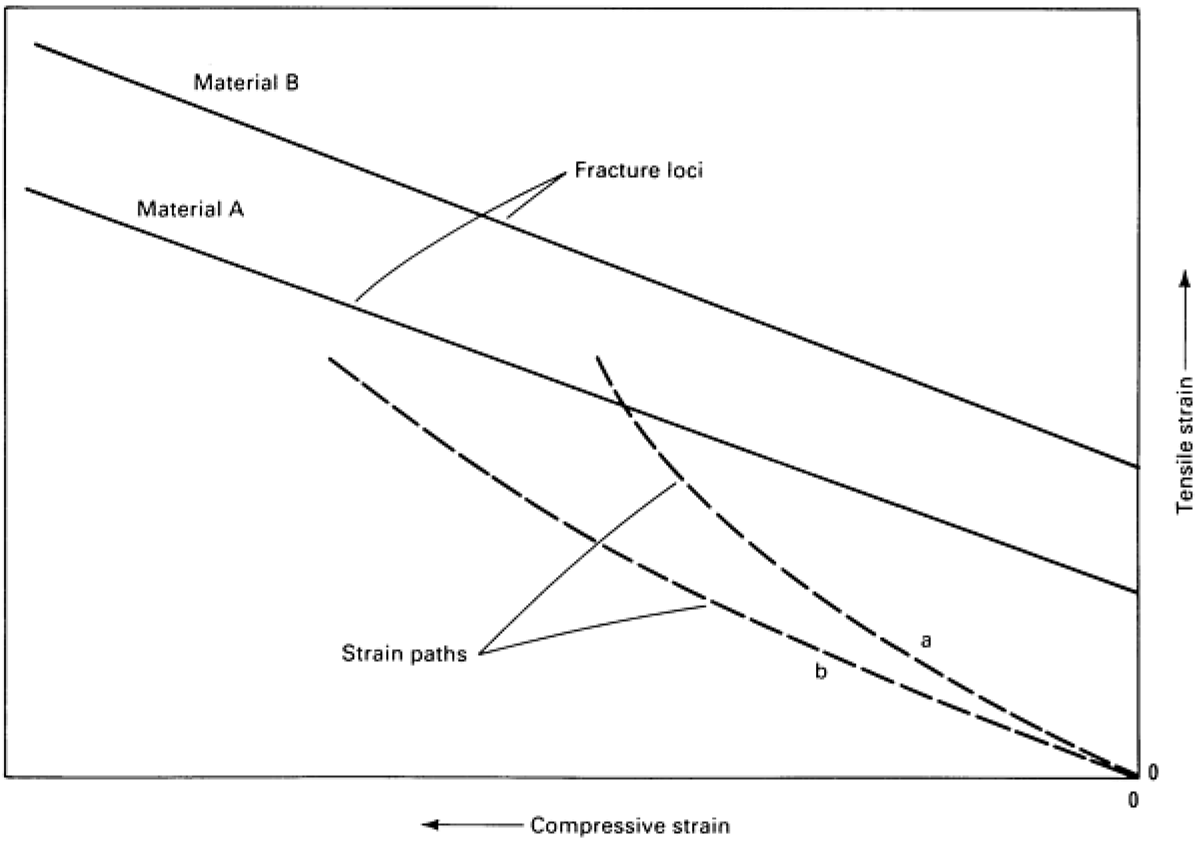

Fig. 7 Schematic workability diagrams for bulk forming processes. Strain path (a) would lead to failure for material A. Both strain paths (a and b) can be used for the successful forming of material B. Source: Ref 8.

A related concept is the forming limit diagram used to quantify sheet metal formability. An example is shown in Fig. 8. As for the bulk workability fracture locus, the sheet metal forming limit diagram is the locus of normal surface strains that give rise to failure. The magnitudes of the failure strains are usually controlled by one of two processes: localized through-thickness thinning or fracture prior to localized thinning. In either case, the forming limit diagram is most easily determined by stretching experiments using a hemispherical punch. Strain path and failure strains (in terms of the so-called major and minor strains) are varied by changes in lubrication and test blank width. Experimentally determined forming limit diagrams are then compared to the strains that are to be developed during forming to determine the possibility for failure. Additional information on forming limit diagrams can be found in the article "Formability Testing of Sheet Metals" in this Volume.

Process Simulation

The development of powerful computer-based simulation techniques, such as those based on the finite-element method, has provided a vital link between advances in tooling and equipment design, on the one hand, and an improved understanding of materials behavior on the other. Inputs to finite-element codes include the characteristics of the workpiece material (flow stress and thermal properties) and the tool/workpiece interface (friction and heat transfer properties), as well as workpiece and tooling geometries. Typical outputs include predictions of forming load; strain, strain rate, and temperature contour plots; and tooling deflections. This information can serve a number of design functions, such as selection of press capacity, determination of success or failure with regard to material workability or formability, and estimation of likely sources of tooling failure (abrasive wear, thermal fatigue, and so on).

Process simulation techniques also provide a method for preform and die design through the ability to determine metal flow patterns without constructing tooling or conducting expensive in-plant trials. In addition, the output from process simulations can be helpful in selecting variables that are useful in process control (for example, ram speed or load monitoring) or finished-product quality control. The advent of these computer-based technologies will help in eliminating the hidden costs of trial-and-error design and in increasing productivity in the metalworking industries. Detailed information on finite-element method process simulation for bulk and sheet forming operations can be found in the articles "Modeling Techniques Used in Forging Process Design" and "Process Modeling and Simulation for Sheet Forming" in this Volume.

Future Trends

The metalworking industry is likely to see changes in the major areas of materials, processes, and process design. Some of these changes will include the following.

Materials. Developments in materials will greatly affect the metals that are formed. These will range from aluminum- and titanium-base alloys to alloy steels and superalloys. New classes of aluminum alloys that will be processed include aluminum-lithium alloys, SiC whisker-reinforced aluminum metal-matrix composites, and high-strength high-temperature powder metallurgy alloys. More use will be made of β-titanium alloys, which combine good strength and toughness, and there will be increased use of thermal-mechanical processing for titanium alloys and superalloys. In the ferrous area, microalloyed steels, which permit elimination of final heat treatment by controlled cooling afer hot working, are becoming increasingly popular for a variety of automotive applications.

Processes. In the forming process area, metalworking methods that give rise to net or near-net shape will be increasingly used to conserve materials and to reduce machining costs. These processes include precision forging, isothermal and hot-die forging, and superplastic forming of sheet materials. There will also be increased use of automatic tool change systems as lot sizes and delivery times decrease.

Process Design. With the development of user-friendly programs and the decreasing cost of computer hardware, there will be significant growth in computer-aided techniques in tooling design and process control. In particular, there will be more interaction between parts users and parts vendors during the design stage. Process simulation will streamline the design process, and this will decrease delivery times as well as the overall cost of fabricated components.

Hammers and Presses for Forging

Revised by Taylan Altan, The Ohio State University

Introduction

FORGING MACHINES can be classified according to their principle of operation. Hammers and high-energy-rate forging machines deform the workpiece by the kinetic energy of the hammer ram; they are therefore classed as energy-restricted machines. The ability of mechanical presses to deform the work material is determined by the length of the press stroke and the available force at various stroke positions. Mechanical presses are therefore classified as stroke-restricted machines. Hydraulic presses are termed force-restricted machines because their ability to deform the material depends on the maximum force rating of the press. Although they are similar in construction to mechanical and hydraulic presses, screw-type presses are classified as energy-restricted machines.

Hammers and Presses for Forging

Revised by Taylan Altan, The Ohio State University

Hammers

Historically, hammers have been the most widely used type of equipment for forging. They are the least expensive and most flexible type of forging equipment in the variety of forging operations they can perform. Hammers are capable of developing large forces and have short die contact times. The main components of a hammer are a ram, frame assembly, anvil, and anvil cap. The anvil is directly connected to the frame assembly, the upper die is attached to the ram, and lower die is attached to the anvil cap.

In operation, the workpiece is placed on the lower die. The ram moves downward, exerting a force on the anvil and causing the workpiece to deform. Forging hammers can be classified according to the method used to drive the ram downward. Various types of hammers are described in the following sections; Table 1 compares the capacities of some of these types.

Table 1 Capacities of various types of forging hammers

Type of hammer	Ram weight		Maximum blow energy		Impact speed		Number of blows per minute
	kg	lb	kJ	ft·lb	m/s	ft/s	
Board drop	45-3400	100-7500	47.5	35,000	3-4.5	10-15	45-60
Air or steam lift	225-7250	500-16,000	122	90,000	3.7-4.9	12-16	60
Electrohydraulic drop	450-9980	1000-22,000	108.5	80,000	3-4.5	10-15	50-75
Power drop	680-31,750	1500-70,000	1153	850,000	4.5-9	15-30	60-100

Gravity-Drop Hammers

Gravity-drop hammers consist of an anvil or base, supporting columns that contain the ram guides, and a device that returns the ram to its starting position. The energy that deforms the workpiece is derived from the downward drop of the ram; the height of the fall and the weight of the ram determine the force of the blow.

Board-drop hammers (Fig. 1) are widely used, especially for producing forgings weighing no more than a few kilograms. In the board-drop hammer, the ram is lifted by one or more boards keyed to it and passing between two friction rolls at the top of the hammer. The boards are rolled upward and are then mechanically released, permitting the ram to drop from the desired height. Power for lifting the ram is supplied by one or more motors. The hammers have a falling weight, or rated size, of 180 to 4500 kg (400 to 10,000 lb); standard sizes range from 450 to 2250 kg (1000 to 5000 lb) in increments of 225 and 450 kg (500 and 1000 lb). The height of fall of the ram varies with hammer size, ranging from about 900 mm (35 in.) for a 180 kg (400 lb) hammer to about 2 m (75 in.) for a 3400 kg (7500 lb) hammer. The height of fall, and therefore the striking force, of the hammer is approximately constant for a given setting and cannot be altered without stopping the machine and adjusting the length of stroke. Anvils on board-drop hammers are 20 to 25 times as heavy as the rams.

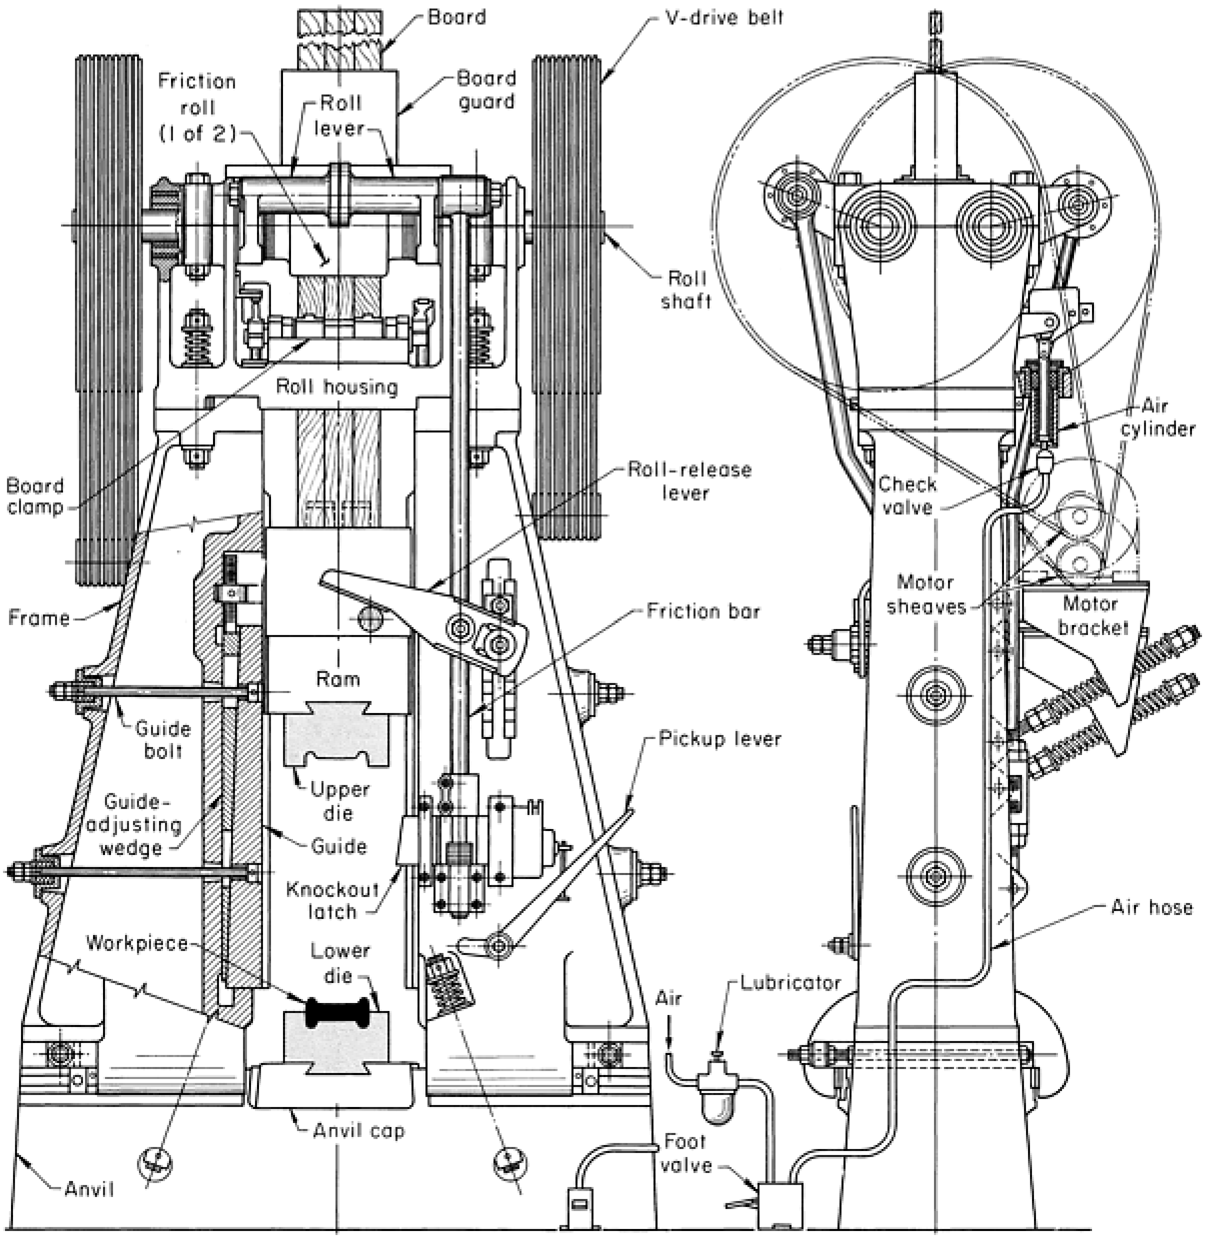

Fig. 1 Principal components of a board-drop hammer

The air-lift gravity-drop hammer is similar to the board-drop hammer in that the forging force is derived from the weight of the falling ram assembly and upper die. It differs in that the ram in the air-lift hammer is raised by air or steam power. Stroke-control dogs, preset on a rocker and actuated by the ram, control power to the ram cylinder. With the hammer shut down, the dogs can be reset on the rocker to adjust stroke length. A device is available that allows both a long stroke and a short stroke in a variable sequence.

The ram is held in the raised position by a piston-rod clamp, which is operated by its own cylinder using a separate compressed-air supply. When the clamp is oblique, the piston rod is clamped. When the operator's treadle is depressed, air enters the cylinder and raises the clamp horizontally, and the ram cycles. Cycling will continue until the treadle is released, causing the rod clamp to drop obliquely and grip the rod. The treadle should not be released on the downstroke of the ram, because this will produce excessive strain in the rod and clamp parts.

The range of sizes generally available in air-lift hammers is 225 to 4500 kg (500 to 10,000 lb). The weight of forging that can be produced in an air-lift hammer of a given size is about the same as that which can be produced in its board-drop hammer counterpart.

Electrohydraulic Gravity-Drop Hammers. In recent years, two significant innovations have been introduced in hammer design. The first is the electrohydraulic gravity-drop hammer. In this type of hammer, the ram is lifted with oil pressure against an air cushion. The compressed air slows the upstroke of the ram and contributes to its acceleration during the downstroke blow. Therefore, the electrohydraulic drop hammer also has a minor power hammer action.

The second innovation in hammer design is the use of electronic blow-energy control. Such control allows the user to program the drop height of the ram for each individual blow. As a result, the operator can set automatically the number of blows desired in forging in each die cavity and the intensity of each individual blow. The electronic blow control increases the efficiency of the hammer operations and decreases the noise and vibration associated with unnecessarily strong hammer blows.

Power-Drop Hammers

In a power-drop hammer, the ram is accelerated during the downstroke by air, steam, or hydraulic pressure. The components of a steam- or air-actuated power-drop hammer are shown in Fig. 2. This equipment is used almost exclusively for closed-die (impression-die) forging.

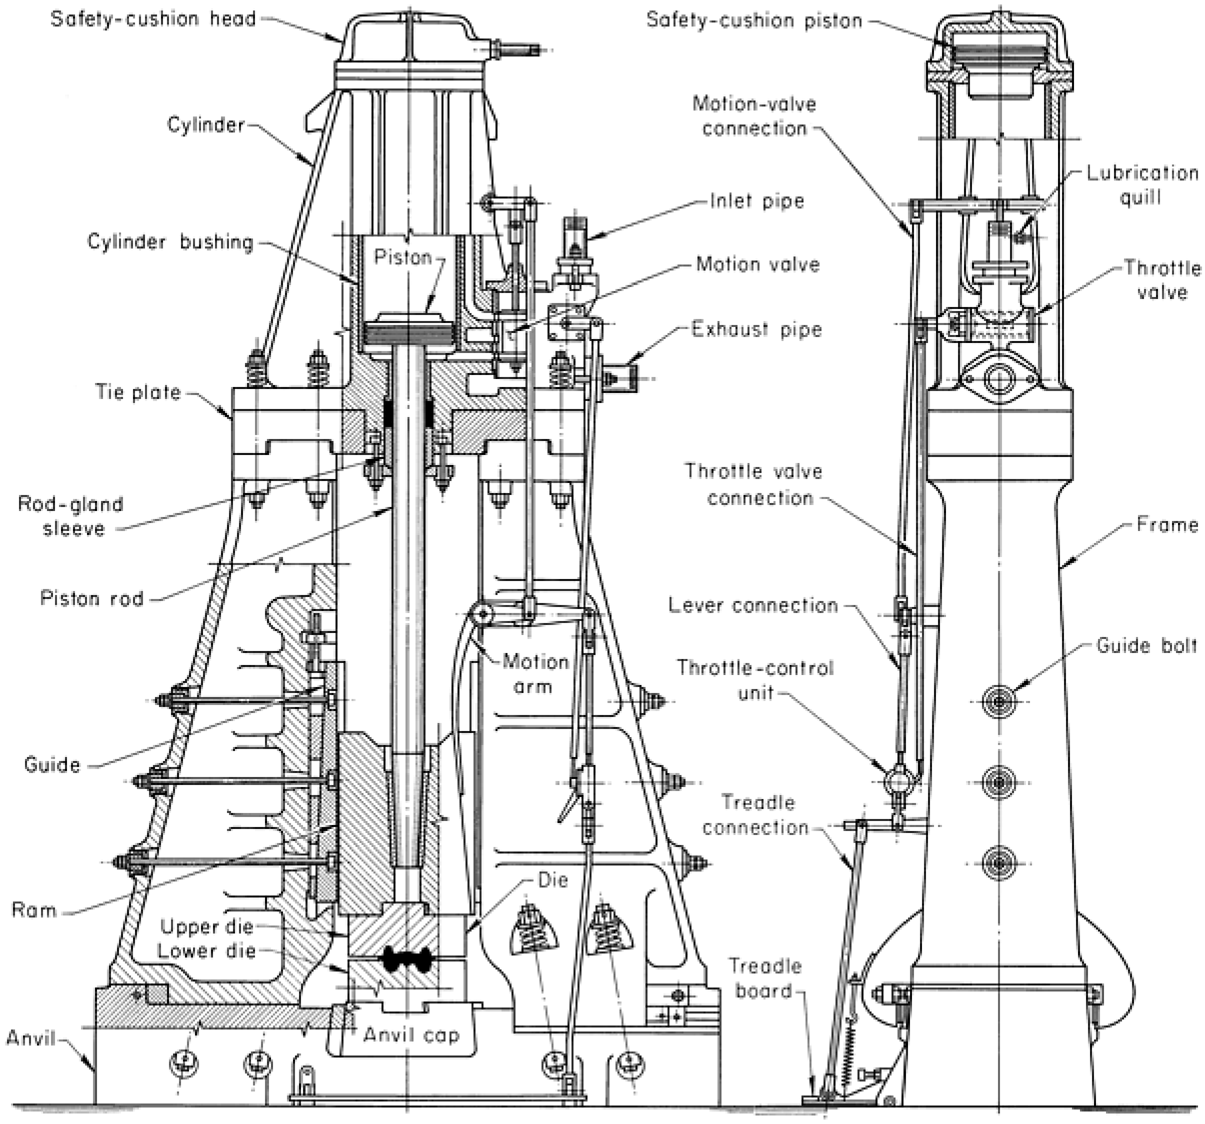

Fig. 2 Principal components of a power-drop hammer with foot control to regulate the force of the blow

The steam- or air-powered drop hammer is the most powerful machine in general use for the production of forgings by impact pressure. In a power-drop hammer, a heavy anvil block supports two frame members that accurately guide a vertically moving ram; the frame also supports a cylinder that, through a piston and piston rod, drives the ram. In its lower face, the ram carries an upper die, which contains one part of the impression that shapes the forging. The lower die, which contains the remainder of the impression, is keyed into an anvil cap that is firmly wedged in place on the anvil. The motion of the piston is controlled by a valve, which admits steam, air, or hydraulic oil to the upper or lower side of the piston. The valve, in turn, is usually controlled electronically. Most modern power-drop hammers are equipped with programmable electronic blow control that permits adjustment of the intensity of each individual blow.

Power-drop hammers are rated by the weight of the striking mass, not including the upper die. Hammer ratings range from 450 to 31,750 kg (1000 to 70,000 lb). The large mass of a power-drop hammer is not apparent, because a great deal of it is beneath the floor. A hammer rated at 22,700 kg (50,000 lb) will have a sectional steel anvil block weighing 453,600 kg (1,000,000 lb) or more. The ram, piston, and piston rod will have an aggregate weight of approximately 20,400 kg (45,000 lb). The striking velocity obtained by the downward pressure on the piston sometimes exceeds 7.6 m/s (25 ft/s).

Rating hammers by the weight of the striking mass is not correct, although it has been the common practice. The more realistic method of rating hammers is by the maximum energy, in joules or foot-pounds, that the ram can impart to the hot metal during a single blow at the maximum energy setting of the hammer controls. The useful energy supplied to the forged metal by the hammer ram depends on the hammer design (weight of the ram and the pressure on the top of the piston), the ratio of the anvil weight versus the ram weight, and the hammer foundation design.

Apart from the size of power-drop hammers and the force they make available for the production of large forgings (forgings commonly produced in power-drop hammers range in weight from 23 kg, or 50 lb, to several megagrams), another important advantage is that the striking intensity is entirely under the control of the operator or is preset by the electronic blow-control system. Consequently, effective use can be made of auxiliary impressions in the dies to preform the billet to a shape that will best fill the finishing impressions in the dies and result in proper grain flow, soundness, and metal economy, with minimum die wear. When adequate preliminary impressions cannot be incorporated into the same set of die blocks, two or more hammers are used to produce adequate shaping or blocking before the final die is used.

Although there are many advantages associated with the use of power-drop hammers, the greater striking forces they develop give rise to several disadvantages. As much as 15 to 25% (and, in hard finishing blows, up to 80%) of the kinetic energy of the ram is dissipated in the anvil block and foundation, and therefore does not contribute to deformation of the workpiece. This loss of energy is most critical when finishing blows are struck and the actual deformation per stroke is relatively slight. The transmitted energy imposes a high stress on the anvil block and may even break it. The transmitted energy also develops violent, and potentially damaging, shocks in the surrounding floor area. This necessitates the use of shock-absorbing materials, such as timber or iron felt, in anvil-block foundations and adds appreciably to the cost of the foundation.

Die Forger Hammers

Die forger hammers are similar in operation to power-drop hammers, but have shorter strokes and more rapid striking rates. The ram is held at the top of the stroke by a constant source of pressurized air, which is admitted to and exhausted from the cylinder to energize the blow. The die forger hammers from one manufacturer are capable of delivering 5.5 to 89.5 kJ (4000 to 66,000 ft · lb) of energy per blow. Blow energy and the forging program (that is, the number of die stations and the number and intensity of blows at each station) are preprogrammed by the operator.

Counterblow Hammers

The counterblow hammer, another variation of the power-drop hammer, is widely used in Europe. These hammers develop striking force by the movement of two rams, simultaneously approaching from opposite directions and meeting at a midway point. Some hammers are pneumatically or hydraulically actuated; others incorporate a mechanical-hydraulic or a mechanical-pneumatic system.

A vertical counterblow hammer with a steam-hydraulic actuating system is illustrated in Fig. 3 (air-hydraulic systems are also available). In this hammer, steam is admitted to the upper cylinder and drives the upper ram downward. At the same time, pistons connected to the upper ram act through a hydraulic linkage in forcing the lower ram upward. Retraction speed is increased by steam (or air) pressure acting upward on the piston. Through proper design relative to weights (including tooling and workpiece) and hydraulics (slower lower-assembly velocities), the kinetic energy of the upper and lower assemblies can be balanced at impact.

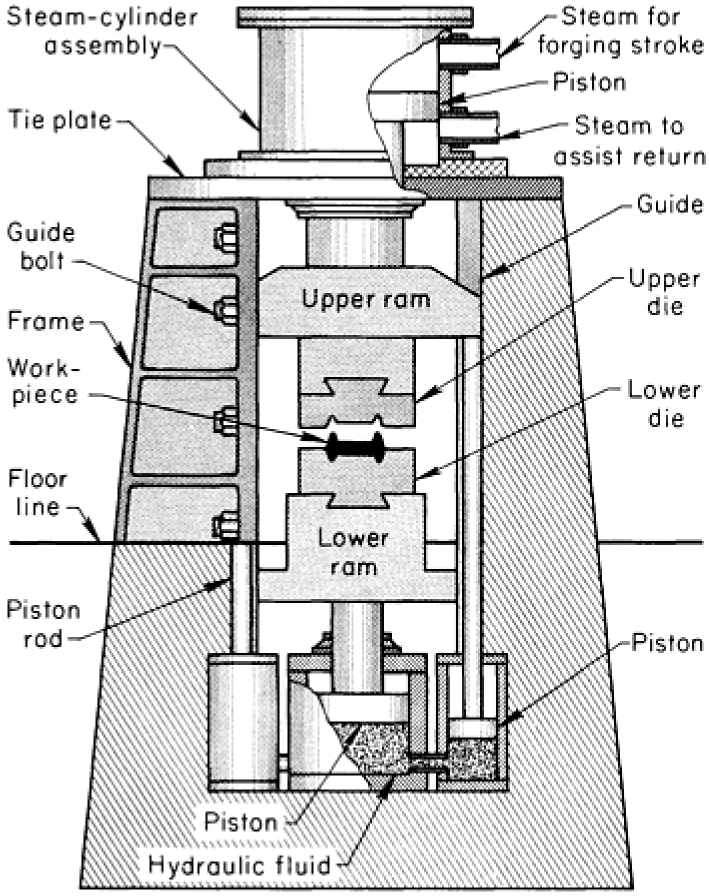

Fig. 3 Principal components of a vertical counter-blow hammer with a steam-hydraulic actuating system

The rams of a counterblow hammer are capable of striking repeated blows; they develop combined velocities of 5 to 6 m/s (6 to 20 ft/s). Compared to single-action hammers, the vibration of impact is reduced, and approximately the full energy of each blow is delivered to the workpiece, without loss to an anvil. As a result, the wear of moving hammer parts is minimized, contributing to longer operating life. At the time of impact, forces are canceled out, and no energy is lost to foundations. In fact, counterblow hammers do not require the large inertia blocks and foundations needed for conventional power-drop hammers.

Horizontal counterblow hammers have two opposing, die-carrying rams that are moved horizontally by compressed air. Heated stock is positioned automatically at each die impression by a preset pattern of accurately timed movements of a stock handling device. A 90° rotation of stock can be programmed between blows.

Open-Die Forging Hammers

Open-die forging hammers are made with either a single frame (often termed C-frame or single-arch hammers) or a double frame (often called double-arch hammers) (Fig. 4). Open-die forging hammers are used to make a large percentage of open-die forgings. The rated sizes of double-frame open-die forging hammers range from about 2720 to 10,900 kg (6000 to 24,000 lb), although larger hammers have been built.

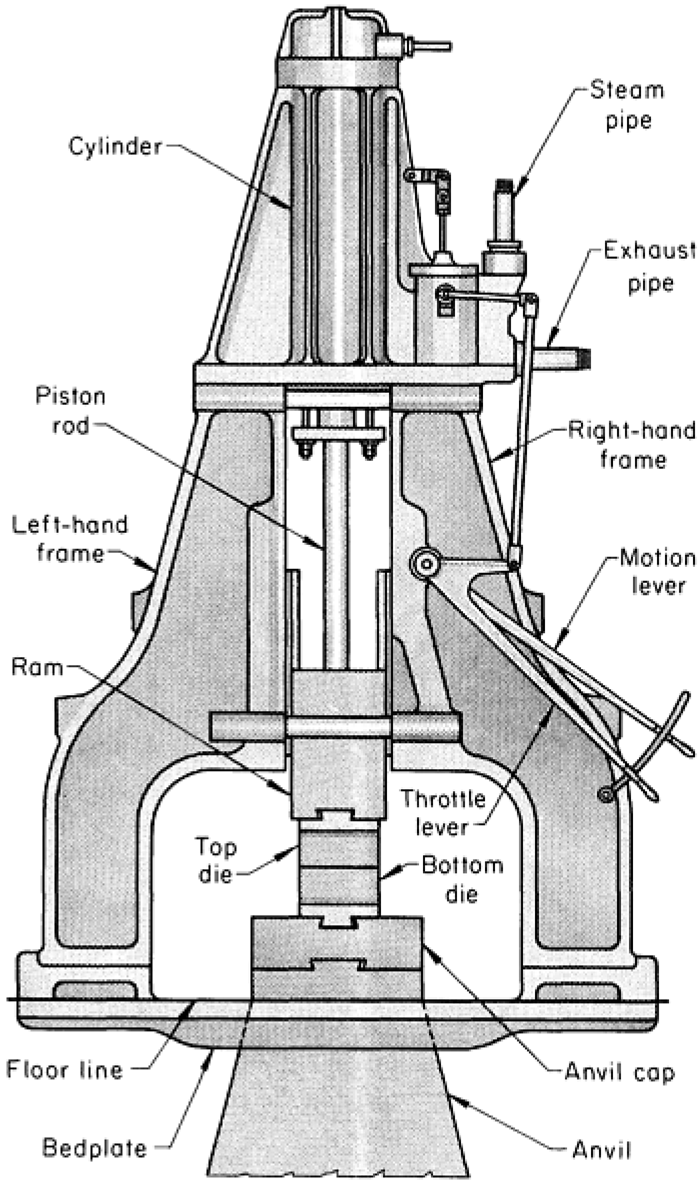

Fig. 4 Double-frame power hammer used for open-die forging

A typical open-die forging hammer is operated by steam or compressed air--usually at pressures of 690 to 825 kPa (100 to 120 psi) for steam and 620 to 690 kPa (90 to 100 psi) for air. These pressures are similar to those used for power-drop hammers.

There are two basic differences between power-drop hammers used for closed-die forging and those used for open-die forging. First, a modern power-drop hammer has blow-energy control to assist the operator in setting the intensity of each blow. In hammers for closed-die forging, the hammer stroke is limited by the upper die surface contacting the surface of the lower die face. In open-die forging, the upper and lower dies do not make contact; stroke-position control is provided through control of the air or steam valve that actuates the hammer piston.

The second difference between closed- and open-die forging hammers is that the anvil of an open-die hammer is separate and independent of the hammer frame that contains the striking ram and the top die. Separation of the anvil from the frame allows the anvil to give way under a heavy blow or series of blows, without disturbing the frame. The anvil may rest on oak timbers, which absorb the hammering shock.

High-Energy-Rate Forging (HERF) Machines

High-energy-rate forging machines are essentially high-speed hammers. They can be grouped into three basic designs: ram and inner frame, two-ram, and controlled energy flow. Each differs from the others in engineering and operating features, but all are essentially very-high-velocity single-blow hammers that require less moving weight than conventional hammers to achieve the same impact energy per blow. All of the designs employ counterblow principles to minimize foundation requirements and energy losses, and they all use inert high-pressure gas controlled by a quick-release mechanism for rapid acceleration of the ram. In none of the designs is the machine frame required to resist the forging forces.

Ram and inner frame machines are produced in several sizes, ranging in capacity from 17 to 745 kJ (12,500 to 550,000 ft · lb) of impact energy. The machine illustrated in Fig. 5(a) has a frame consisting of two units: an inner, or working, frame connected to a firing chamber and an outer, or guiding, frame within which the inner frame is free to move vertically. As the trigger-gas seal is opened, high-pressure gas from the firing chamber acts on the top face of the piston and forces the ram and upper die downward. Reaction to the downward acceleration of the ram raises the inner frame and lower die.

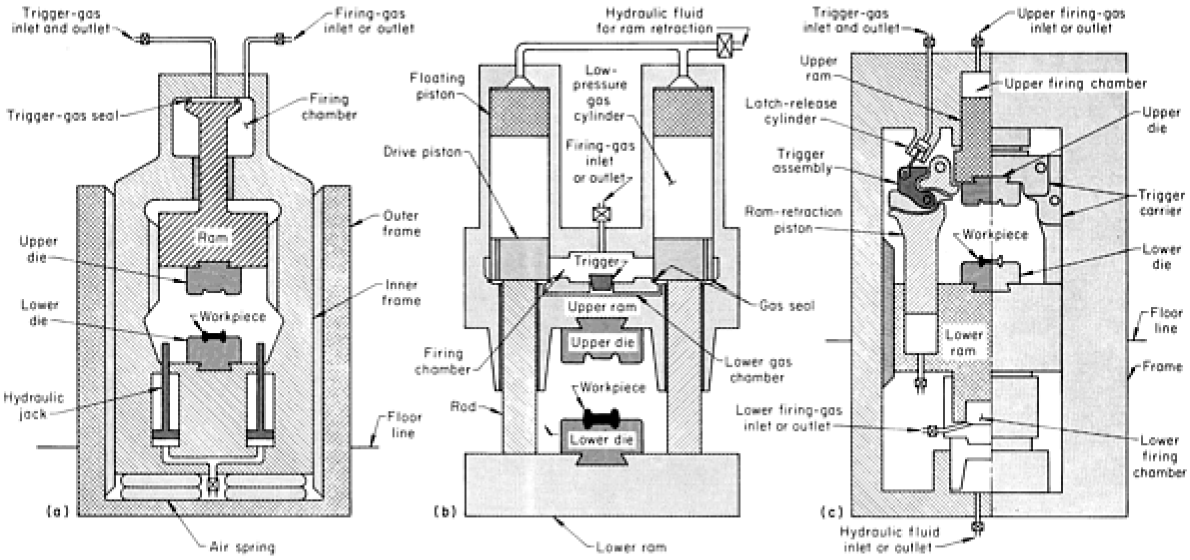

Fig. 5 The three basic machine concepts of high-energy-rate forging. (a) Ram and inner frame machine. (b) Two-ram machine. (c) Controlled-energy-flow machine. Triggering and expansion of the gas in the firing chamber cause the upper and lower rams to move toward each other at high speed. An outer frame provides guiding surfaces for the rams.

The machine is made ready for the next blow by means of hydraulic jacks that elevate the ram until the trigger-gas seal between the upper surface of the firing chamber and the ram piston is reestablished. Venting of the seal gas, as well as gas pressure on the lower lip of the piston, then holds the ram in the elevated position.

Two-ram machines are available in several sizes; the largest has a rating of 407 kJ (300,000 ft · lb) of impact energy. In a two-ram machine (Fig. 5b), the counterblow is achieved by means of an upper ram and a lower ram. An outer frame (not shown in Fig. 5) provides vertical guidance for the two rams. Vertical movement of the trigger permits high-pressure gas to enter the lower chamber and the space beneath the drive piston. This forces and drive piston, rod, lower ram, and lower die upward. The reaction to this force drives the floating piston, cylinder, upper ram, and upper die downward. The rods provide relative guidance between the moving upper and lower assemblies.

After the blow, hydraulic fluid enters the cylinder, returning the upper and lower rams to their starting positions. The gas is recompressed by the floating pistons, and the gas seals at the lower edges of the drive pistons are reestablished. When the trigger is closed, the hydraulic pressure is released, the high-pressure gas in the lower chamber expands through the drive-piston ports and forces the floating pistons up, and the machine is ready for the next blow.

Controlled energy flow forging machines have been made in two sizes, with ratings of 99 and 542 kJ (73,000 and 400,000 ft · lb) of maximum impact energy. These machines (Fig. 5c) are counterblow machines from the standpoint of having separately adjustable gas cylinders and separate rams for the upper and lower dies; however, self-reacting principles are not employed. The lower ram has a hydraulically actuated vertical-adjustment cylinder so that different stroke lengths may be preset.

The trigger, although pneumatically, operated, is a massive mechanical latch that returns and holds the rams through mechanical support of the upper ram and hydraulic connection with the lower ram. With this arrangement, simultaneous release of the two rams is ensured.

Applicability. High-energy-rate forging machines are basically limited to fully symmetrical or concentric forgings such as wheels and gears or coining applications in which little metal movement but high die forces are required. Information on the HERF process, as well as examples of parts forged using high-energy-rate forging, are available in the article "High-Energy-Rate Forging" in this Volume.

Revised by Taylan Altan, The Ohio State University

Mechanical Presses

All mechanical presses employ flywheel energy, which is transferred to the workpiece by a network of gears, cracks, eccentrics, or levers. Driven by an electric motor and controlled by means of an air clutch, mechanical presses have a full-eccentric type of drive shaft that imparts a constant-length stroke to a vertically operating ram (Fig. 6). Various mechanisms are used to translate the rotary motion of the eccentric shaft into linear motion to move the ram (see the section "Drive Mechanisms" in this article). The ram carries the top, or moving, die, while the bottom, or stationary, die is clamped to the die seat of the main frame. The ram stroke is shorter than that of a forging hammer or a hydraulic press. Ram speed is greatest at the center of the stroke, but force is greatest at the bottom of the stroke. The capacities of these forging presses are rated on the maximum force they can apply and range from about 2.7 to 142 MN (300 to 16,000 tonf).

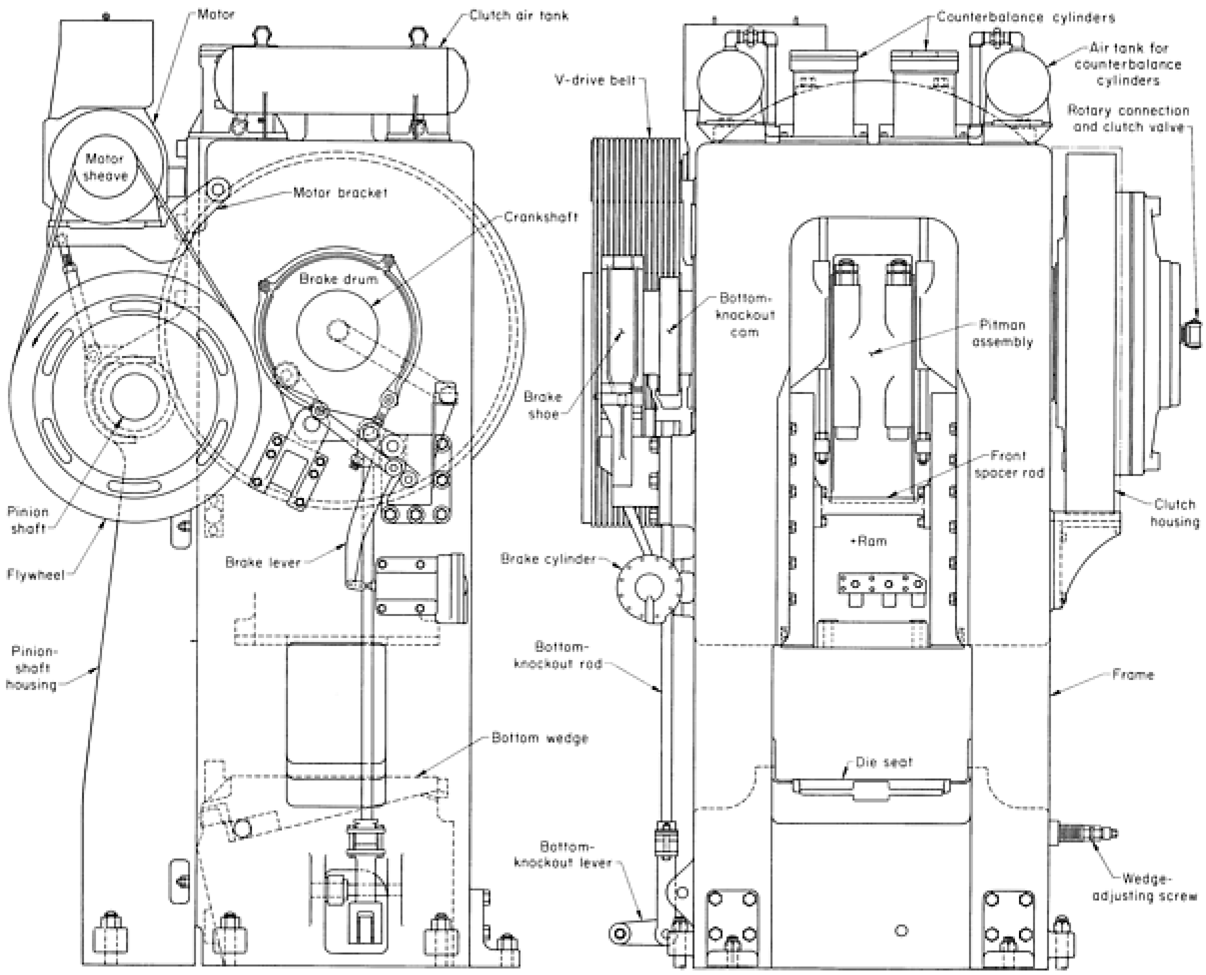

Fig. 6 Principal components of a mechanical forging press

Mechanical forging presses have principal components that are similar to those of eccentric-shaft, straight-side, single-action presses used for forming sheet metal (see the article "Presses and Auxiliary Equipment for Forming of Sheet Metal" in this Volume). In detail, however, mechanical forging presses are considerably different from mechanical presses that are used for forming sheet. The principal differences are:

- Forging presses, particularly their side frames, are built stronger than presses for forming sheet metal.
- Forging presses deliver their maximum force within 3.2mm ($\frac{1}{8}$ in.) of the end of the stroke, because maximum pressures is required to form the flash
- The slide velocity in a forging press is faster than in a sheet metal deep-drawing press, because in forging it is desirable to strike the metal and retrieve the ram quickly to minimize the time the dies are in contact with the hot metal

Unlike the blow of a forging hammer, a press blow is more of a squeeze than an impact and is delivered by uniform stroke length. The character of the blow in a forging press resembles that of an upsetting machine, thus combining some features of hammers and upsetters. Mechanical forging presses use drive mechanisms similar to those of upsetters, although an upsetter is generally a horizontal machine.

Advantages and Limitations

Compared to hammer forging, mechanical press forging results in accurate close-tolerance parts. Mechanical presses permit automatic feed and transfer mechanisms to feed, pick up, and move the part from one die to the next, and they have higher production rates than forging hammers (stroke rates vary from 30 to 100 strokes per minute). Because the dies used with mechanical presses are subject to squeezing forces instead of impact forces, harder die materials can be used in order to extend die life. Dies can also be less massive in mechanical press forging.

One limitation of mechanical presses is their high initial cost--approximately three times as much as forging hammers that can do the same amount of work. Because the force of the stroke cannot be varied, mechanical presses are also not capable of performing as many preliminary operations as hammers. Generally, mechanical presses forge the preform and final shape in one, two, or three blows; hammers are capable of delivering up to ten or more blows at varying intensities.

Drive Mechanisms

In most mechanical presses, the rotary motion of the eccentric shaft is translated into linear motion in one of three ways: through a pitman arm, through a pitman arm and wedge, or through a Scotch-yoke mechanism.

In a pitman arm press drive (Fig. 7), the torque derived from the rotating flywheel is transmitted from the eccentric shaft to the ram through a pitman arm (connecting rod). Presses using single- or twin-pitman design are available. Twin-pitman design limits the tilting or eccentric action resulting from off-center loading on wide presses. The shut height of the press can be adjusted mechanically or hydraulically through wedges. Mechanical presses with this type of drive are capable of forging parts that are located in an off-center position.

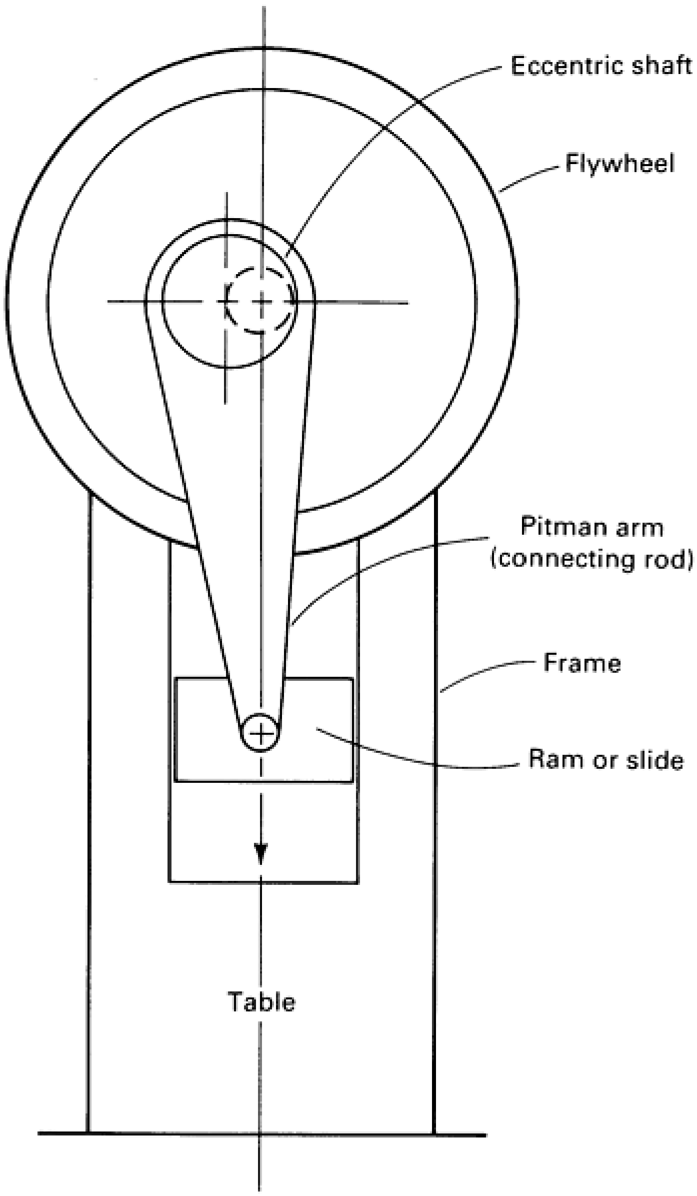

Fig. 7 Principle of operation of a mechanical press driven by a pitman arm (connecting rod)

A wedge drive (Fig. 8) consists of a massive wedge sloped upward at an angle of 30° toward the pitman, an adjustable pitman arm, and an eccentric driveshaft. The torque form the rotating flywheel is transmitted into horizontal motion through the pitman arm and the wedge. As the wedge is forced between the frame and the ram, the ram is pushed downward; this provides the force required to forge the part. The amount of wedge penetration between the ram and frame determines the shut height of the ram. The shut height can be adjusted by rotating the eccentric bushing on the eccentric shaft by means of a worm gear. A ratchet mechanism prevents the adjustment from changing during press operation.

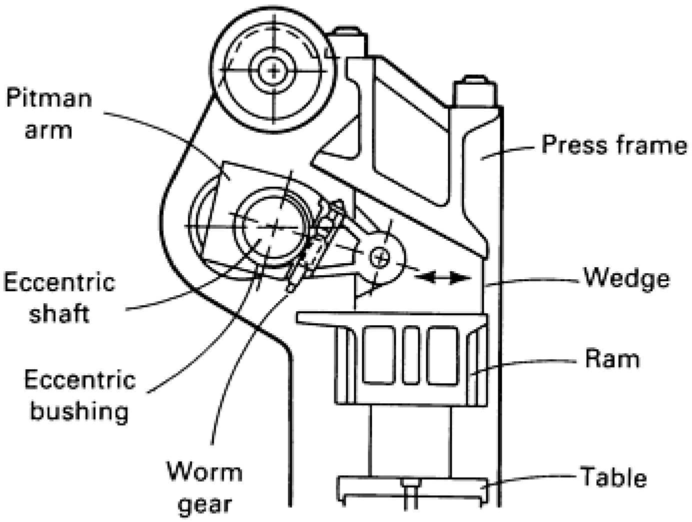

Fig. 8 Principle of operation of a wedge-driven press. See text for details of operation.

Wedge drives transmit the forging force more uniformly over the entire die surface than pitman arm drives. Wedge drives also reduce ram tilting due to off-center loading. Increases in forging accuracies during on-center and off-center loading conditions and the ability to adjust the shut height are the main advantages of wedge-driven mechanical presses. A disadvantage is the relatively long contact time between the die and the forged part.

The Scotch-yoke drive (Fig. 9) contains an eccentric block that wraps around the eccentric shaft and is contained within the ram. As the shaft rotates, the eccentric block moves in both horizontal and vertical directions, while the ram is actuated by the eccentric block only in a vertical direction. The shut height of the ram can be adjusted mechanically or hydropneumatically through wedges.

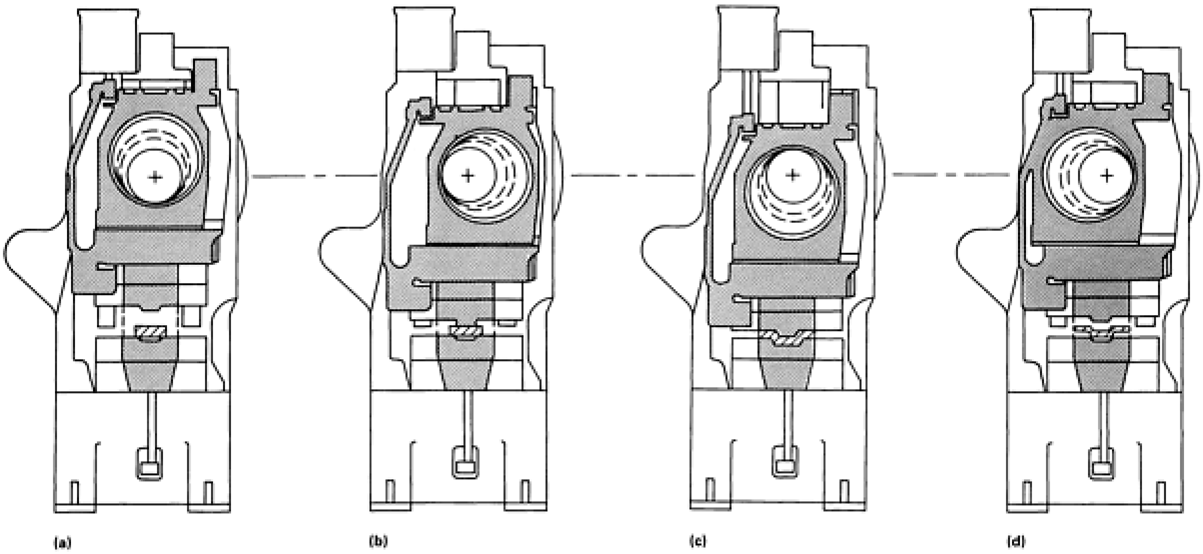

Fig. 9 Principle of operation of mechanical press with a Scotch yoke drive. (a) The ram is at the top of the stroke; the Scotch yoke is centered. (b) Scotch yoke is in the extreme forward position midway through the downward stroke. (c) At bottom dead center, the Scotch yoke is in the center of the ram. (d) Midway through the upward stroke, the Scotch yoke is in the extreme rear position.

This press design provides more rigid guidance for the ram, which results in more accurate forgings. Forging of parts off-center is also possible with this type of drive. Because the drive system is more compact than the pitman arm drive, the press has a shorter overall height.

Capacity

Mechanical presses are considered stroke-restricted machines because the forging capability of the press is determined by the length of the stroke and the available force at the various stroke positions. Because the maximum force attainable by a mechanical press is at the bottom of the work stroke, the forging force of the press is usually determined by measuring the force at a distance of 3.2 or 6.4 mm ($\frac{1}{8}$ or $\frac{1}{4}$ in.) before bottom dead center. Table 2 compares the capacities of mechanical presses with those of hydraulic and screw presses. More information on determining the capacities of mechanical presses and other types of forging equipment is available in the article "Selection of Forging Equipment" in this Volume.

Table 2 Capacities of forging presses

Type of press	Force		Pressing speed	
	MN	tonf	m/s	ft/s
Mechanical	2.2-142.3	250-16,000	0.06-1.5	0.2-5
Hydraulic	2.2-623	250-70,000	0.03-0.8	0.1-2.5

Hydraulic Presses

Hydraulic presses are used for both open- and closed-die forging. The ram of a hydraulic press is driven by hydraulic cylinders and pistons, which are part of a high-pressure hydraulic or hydropneumatic system. After a rapid approach speed, the ram (with upper die attached) moves at a slow speed while exerting a squeezing force on the work metal. Pressing speeds can be accurately controlled to permit control of metal-flow velocities; this is particularly advantageous in producing close-tolerance forgings. The principal components of a hydraulic press are shown in Fig. 10.

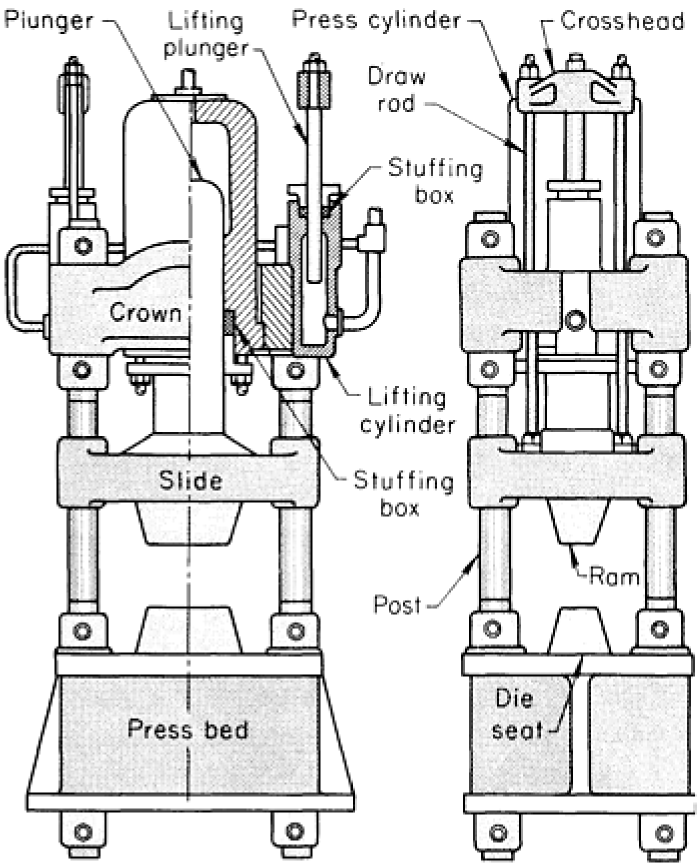

Fig. 10 Principal components of a four-post hydraulic press for closed-die forging

Some presses are equipped with a hydraulic control circuit designed specifically for precision forging (see the article "Precision Forging" in this Volume). With this circuit, it is possible to obtain a rapid advance stroke, followed by preselected first and second pressing speeds. If necessary, the maximum force of the press can be used at the end of the second pressing stroke with no limits on dwell time. The same circuit also provides for a slow pullout speed and can actuate ejectors and strippers at selected intervals during the return stroke.

Advantages and Limitations

The principal advantages of hydraulic presses include:

- Pressure can be changed as desired at any point in the stroke by adjusting the pressure control valve
- Deformation rate can be controlled or varied during the stroke if required. This is especially important

when forging metals that are susceptible to rupture at high deformation rates

- Split dies can be used to make parts with such features as offset flanges, projections, and backdraft, which would be difficult or impossible to incorporate into hammer forgings
- When excessive heat transfer from the hot workpiece to the dies is not a problem or can be eliminated, the gentle squeezing action of a hydraulic press results in lower maintenance costs and increased die life because of less shock as compared to other types of forging equipment
- Maximum press force can be limited to protect tooling

Some of the disadvantages of hydraulic presses are:

- The initial cost of a hydraulic press is higher than that of an equivalent mechanical press
- The action of a hydraulic press is slower than that of a mechanical press
- The slower action of a hydraulic press increases contact time between the dies and the workpiece. When forging materials at high temperatures (such as nickel-base alloys and titanium alloys), this results in shortened die life because of heat transfer from the hot work metal to the dies

Press Drives

The operation of a hydraulic press is simple and based on the motion of a hydraulic piston guided in a cylinder. Two types of drive systems are used on hydraulic presses: direct drive and accumulator drive. These are shown in Fig. 11.

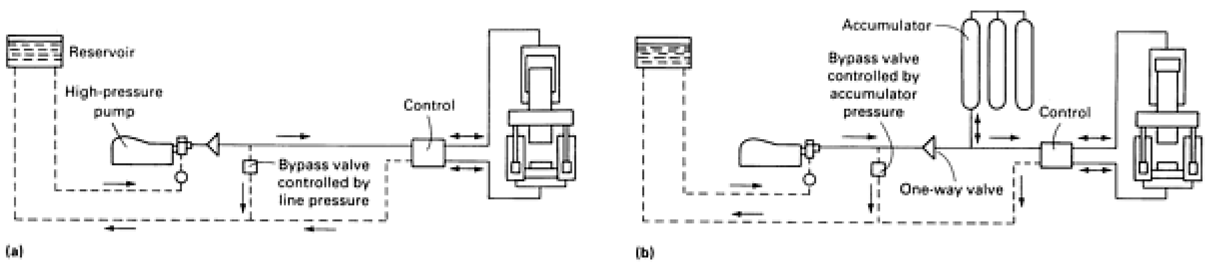

Fig. 11 Schematic of drive systems for hydraulic presses. (a) Direct drive. (b) Accumulator drive. See text for details.

Direct drive presses for closed-die forging usually have hydraulic oil as the working medium. At the start of the downstroke, the return cylinders are vented allowing the ram/slide assembly to fall by gravity. The reservoir used to fill the cylinder as the ram is withdrawn can be pressurized to improve hydraulic flow characteristics, but this is not mandatory. When the ram contacts the workpiece, the pilot operated check valve between the ram cylinder and the reservoir closes, and the pump builds up pressure in the ram cylinder. Modern control systems are capable of very smooth transitions from the advance mode to the forging mode.

In modern direct drive systems used for open die work (see Fig. 11a), a residual pressure is maintained in the return cylinders during the downstroke by means of a pressure control valve. The ram/slide assembly is pumped down against the return system backpressure, and dwell inherent in free fall is eliminated. When the press stroke is completed, that is, when the upper ram reaches a predetermined position or when the pressure reaches a certain value, the oil pressure is released and diverted to lift the ram. With this drive system, the maximum press load is available at any point during the working stroke.

Accumulator-drive presses (Fig. 11b) usually have a water-oil emulsion as a working medium and use nitrogen or air-loaded accumulators to keep the medium under pressure. Accumulator drives are used on presses with 25 MN (2800 tonf) capacity or greater. The sequence of operations is essentially similar to that for the direct-drive press except that the pressure is built up by means of the pressurized water-oil emulsion in the accumulators. Consequently, the ram speed under load is not directly dependent on pump characteristics and can vary, depending on the pressure in the accumulator, the compressibility of the pressure medium, and the resistance of the workpiece to deformation.

Accumulator-drive presses can operate at faster speeds than direct-drive presses. The faster press speed permits rapid working of materials, reduces the contact time between the tool and workpiece, and maximizes the amount of work performed between reheats. Pressure build-up is related to workpiece resistance. Modern pumps can fully load in 100 ms--not much different than the opening time for large valves.

Capacity and Speed

Hydraulic presses are rated by the maximum amount of forging force available. Open-die presses are built with capacities ranging from 1.8 to 125 MN (200 to 14,000 tonf), and closed-die presses range in size from 4.5 to 640 MN (500 to 72,000 tonf). Ram speeds during normal forging conditions vary from 635 to 7620 mm/min (25 to 300 in./min). Press speeds have been slowed to a fraction of an inch per minute to forge materials that are extremely sensitive to deformation rate.

Hammers and Presses for Forging

Revised by Taylan Altan, The Ohio State University

Screw Presses

Screw presses are energy-restricted machines, and they use energy stored in a flywheel to provide the force for forging. The rotating energy of inertia of the flywheel is converted to linear motion by a threaded screw attached to the flywheel on one end and to the ram on the other end.

Screw presses are widely used in Europe for job-shop hardware forging, forging of brass and aluminum parts, precision forging of turbine and compressor blades, hand tools, and gearlike parts. Recently, screw presses have also been introduced in North America for a wide range of applications, notably, for forging steam turbine and jet engine compressor blades and diesel engine crankshafts.

The screw press uses a friction, gear, electric, or hydraulic drive to accelerate the flywheel and the screw assembly, and it converts the angular kinetic energy into the linear energy of the slide or ram. Figure 12 shows two basic designs of screw presses.

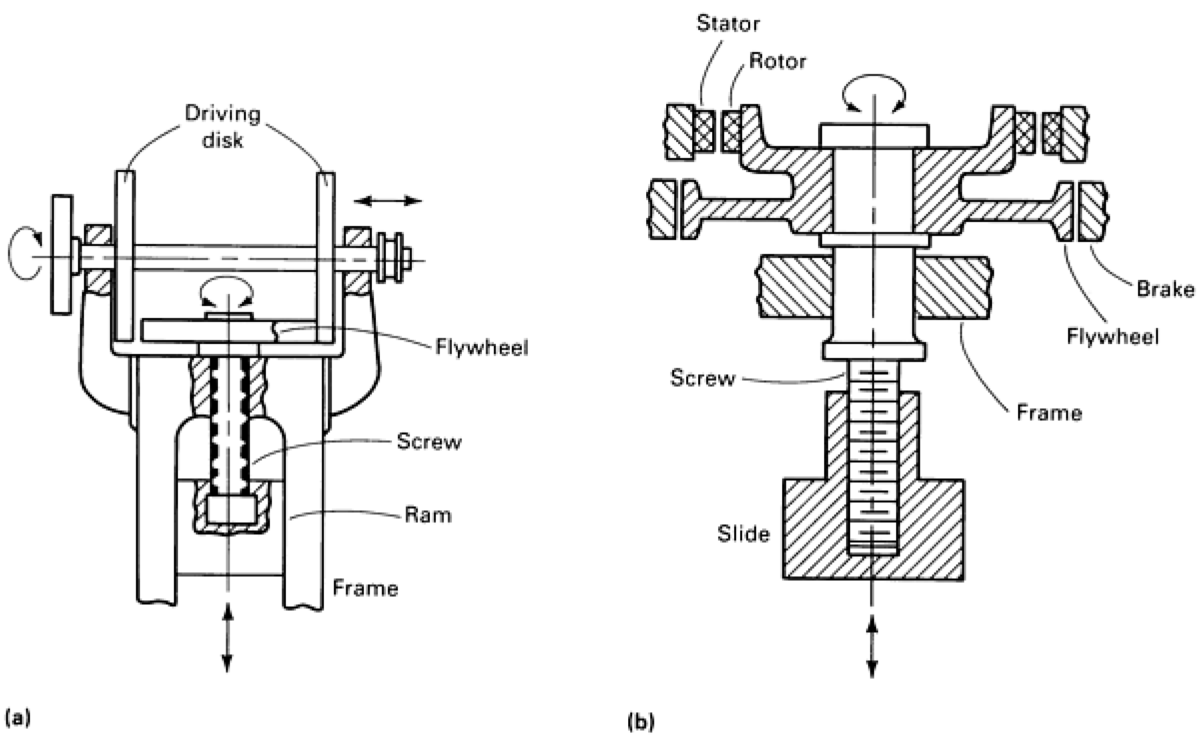

Fig. 12 Two common types of screw press drives. (a) Friction drive. (b) Direct electric drive

Advantages and Limitations

Screw presses are used for open- and closed-die forging. They usually have more energy available per stroke than mechanical presses with similar tonnage ratings, permitting them to accomplish more work per stroke. When the energy has been dissipated, the ram comes to a halt, even though the dies may not have closed. Stopping the ram permits multiple blows to be made to the workpiece in the same die impression. Die height adjustment is not critical, and the press cannot jam. Die stresses and the effects of temperature and height of the workpiece are minimized; this results in good die life. Impact speed is much greater than with mechanical presses. Most screw presses, however, permit full-force operation only near the center of the bed and ram bolsters.

Drive Systems

In the friction drive press (Fig. 12a), two large energy-storing driving disks are mounted on a horizontal shaft and rotated continuously by an electric motor. For a downstroke, one of the driving disks is pressed against the flywheel by a servomotor. The flywheel, which is connected to the screw either positively or by a friction-slip clutch, is accelerated by this driving disk through friction. The flywheel energy and the ram speed continue to increase until the ram hits the workpiece. Thus, the load necessary for forming is built up and transmitted through the slide, the screw, and the bed to the press frame. The flywheel, the screw, and the slide stop when the entire energy in the flywheel is used in deforming the workpiece and elastically deflecting the press. At this moment, the servomotor activates the horizontal shaft and presses the upstroke-driving disk wheel against the flywheel. Thus, the flywheel and the screw are accelerated in the reverse direction, and the slide is lifted to its top position.

In the direct-electric-drive press (Fig. 12b), a reversible electric motor is built directly on the screw and on the frame, above the flywheel. The screw is threaded into the ram or slide and does not move vertically. To reverse the direction of flywheel rotation, the electric motor is reversed after each downstroke and upstroke.

Other Drive Systems. In addition to direct friction and electric drives, several other types of mechanical, electric, and hydraulic drives are commonly used in screw presses. A relatively new screw press drive is shown in Fig. 13. A flywheel (1) supported on the press frame is driven by one or more electric motors and rotates at a constant speed. When the stroke is initiated, a hydraulically-operated clutch (2) engages the rotating flywheel against the stationary screw (3). This feature is similar to that used to initiate the stroke of an eccentric mechanical forging press. Upon engagement of the clutch, the screw is accelerated rapidly and reaches the speed of the fly-wheel. As a result, the ram (4), which acts as a large nut, moves downward. The downstroke charges a hydropneumatic lift cylinder system. The downstroke is terminated by controlling the ram position through the use of a position switch or by controlling the maximum load on the ram by disengaging the clutch and the flywheel from the screw when the preset forming load is reached. The ram is then lifted by the lift-up cylinders (5), releasing the elastic energy stored in the press frame, the screw, and the lift-up cylinders. At the end of the upstroke, the ram is stopped and held in position by a hydraulic brake.

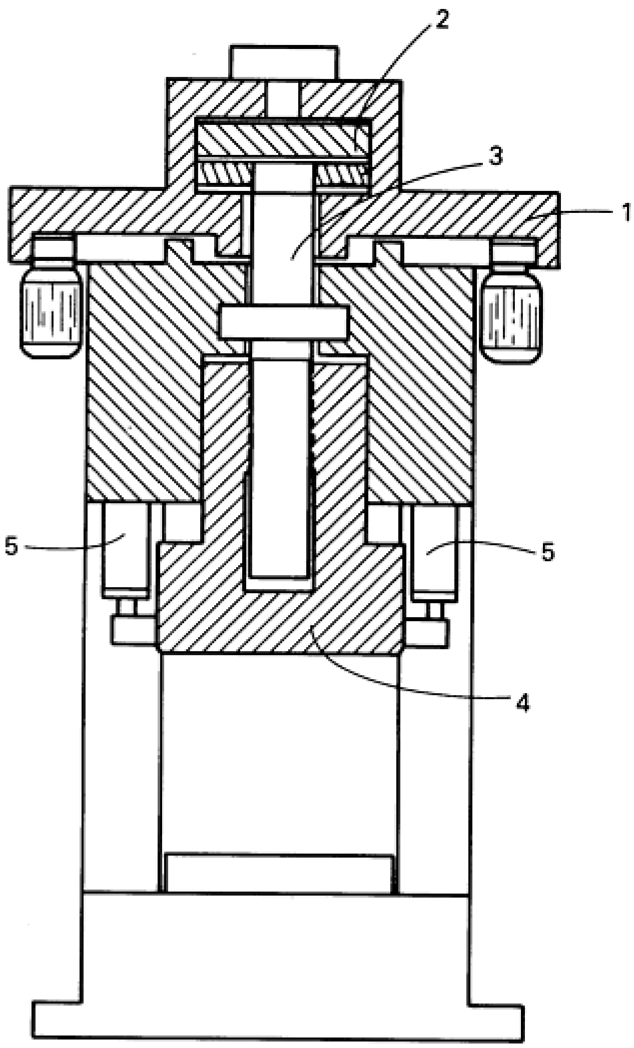

Fig. 13 Screw press drive combining the characteristics of mechanical and screw presses. 1, flywheel; 2, air-operated clutch; 3, screw; 4, ram; 5, lift-up cylinders

This press provides several distinct advantages:

- A high and nearly constant ram speed throughout the stroke
- Full press load at any position of the stroke
- High deformation energy
- Overload protection
- Short contact time between the workpiece and the tools

Limitations of this type of drive system include:

- Only two levels of energy are available, high and low
- Maintenance is increased on the clutch and hydraulic cylinders
- Force is controlled through slippage of the clutch, which can lead to unpredictable application of power
- The large amount of energy available can create material flow problems

Capacities and Speed

Screw presses are generally rated by the diameter of the screw. This diameter, however, is comparable to a listing to nominal forces that can be produced by the press. The nominal force is the force that the press is capable of delivering to deform the workpiece while maintaining maximum energy. The coining, or working, force is approximately double the nominal force when forging occurs near the bottom of the stroke.

Friction screw presses have screw diameters ranging from 100 to 635 mm (4 to 25 in.). These sizes translate to nominal forces of 1.4 to 35.6 MN (160 to 4000 tonf). Direct-electric-drive screw presses have been built with 600 mm (24 in.) diam screws, or 37.3 MN (4190 tonf) of nominal force capacity.

Hydraulically driven screw presses with hard-on-hand blow capacities up to 310 MN (35,000 tonf) have been built.

Press speed, in terms of the number of strokes per minute, depends largely on the energy required by the specific forming process and on the capacity of the drive mechanism to accelerate the screw and the flywheel. In general, however, the production rate of a screw press is lower than that of a mechanical press, especially in automated high-volume operations. Small screw presses operate at speeds of up to 40 to 50 strokes per minute, while larger presses operate at about 12 to 16 strokes per minute.

Revised by Taylan Altan, The Ohio State University

Multiple-Ram Presses

Hollow, flashless forgings that are suitable for use in the manufacture of valve bodies, hydraulic cylinders, seamless tubes, and a variety of pressure vessels can be produced in a hydraulic press with multiple rams. The rams converge on the workpiece in vertical and horizontal planes, alternately or in combination, and fill the die by displacement of metal outward from a central cavity developed by one or more of the punches. Figure 14 illustrates the multiple-ram principle, with central displacement of metal proceeding from the vertical and horizontal planes.

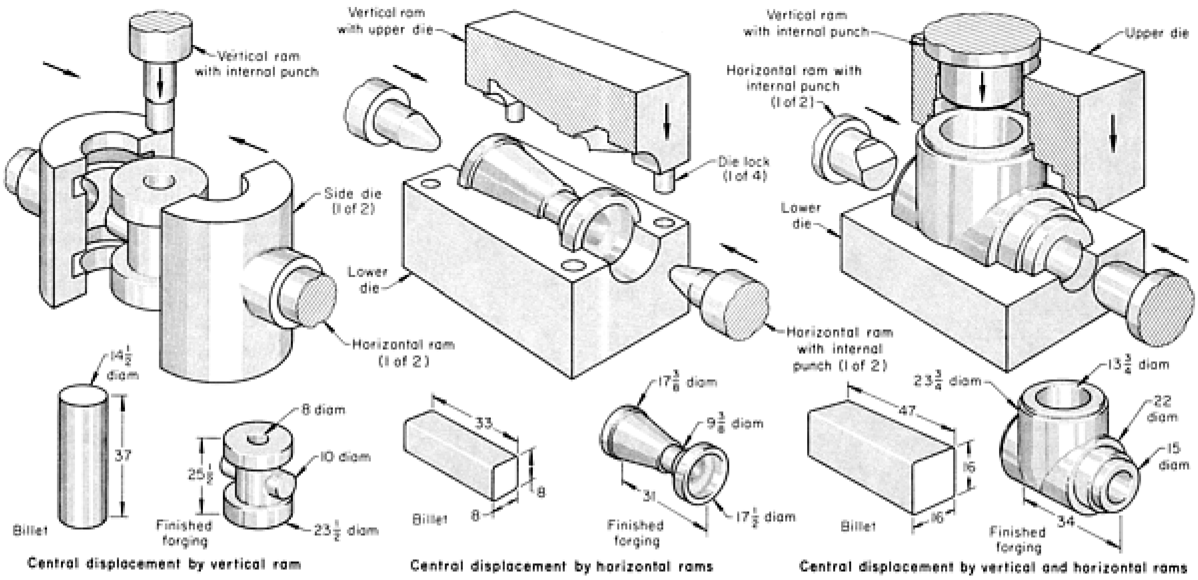

Fig. 14 Examples of multiple-ram forgings. Displacement of metal can take place from vertical, horizontal, and combined vertical and horizontal planes. Dimensions given in inches

Piercing holes in a forging at an angle to the normal direction of forging force can result in considerable material savings, as well as savings in the machining time required to generate such holes.

In addition to having the forging versatility provided by multiple rams, these presses can be used for forward or reverse extrusion. Elimination of flash at the parting line is a major factor in decreasing stress-corrosion cracking in forging alloys susceptible to this type of failure, and the multidirectional hot working that is characteristic of processing in these presses decreases the adverse directional effects on mechanical properties.

Safety

A primary consideration in forging is the safety of the operator. Therefore, each operator must be properly trained before being allowed to operate any forging equipment. Protective equipment must be distributed and used by the operator to protect against injuries to the head, eyes, ears, feet, and body. This equipment is described in ANSI standard B24.1.

The forging machines should be equipped with the necessary controls to prevent accidental operation. This can be achieved through dual pushbutton controls and/or point-of-operation devices. Guards should be installed on all exterior moving parts to prevent accidental insertion of the hands or other extremities. Guards should also be installed to protect against flying scale or falling objects during the forging operation.

All forging equipment must be properly maintained according to manufacturer's recommendations. During machine repair or die changing, the power to the machine should be locked out to prevent accidental operation; the ram should be blocked with blocks, wedges, or tubing capable of supporting the load. The strength and dimensions of the blocking material are given in ANSI B24.1. More information on safety is available in the publications cited in the Selected References at the end of this article.

Introduction

FORGING EQUIPMENT influences the forging process because it affects deformation rate, forging temperature, and rate of production. The forging engineer must have sound knowledge of the different forging machines in order to:

- Use existing machinery more efficiently
- Define the existing plant capacity accurately
- Communicate better with, and at times request improved performance from, the machine builder.
- Develop, if necessary, in-house proprietary machines and processes not available in the machine tool market
- Utilize them in the most cost-effective manner

This article will detail the significant factors in the selection of forging equipment for a particular process. The article "Hammers and Presses for Forging" in this Volume contains information on the principles of operation and the capacities of various types of forging machines.

Selection of Forging Equipment

Taylan Altan, The Ohio State University

Process Requirements and Forging Machines

Figure 1 illustrates the interaction between the principal machine and process variable for hot forging conducted in presses. As shown at the left in Fig. 1, flow stress σ, interface friction conditions, and part geometry (dimensions and shape) determine the load L_p at each position of the stroke and the energy E_p required by the forming process. The flow stress $\bar{s}$ increases with increasing deformation rate $\dot{e}$ and with decreasing work metal temperature, θ. The magnitudes of these variations depend on the specific work material (see the Sections on forging of specific metals and alloys in this Volume). The frictional conditions deteriorate with increasing die chilling.

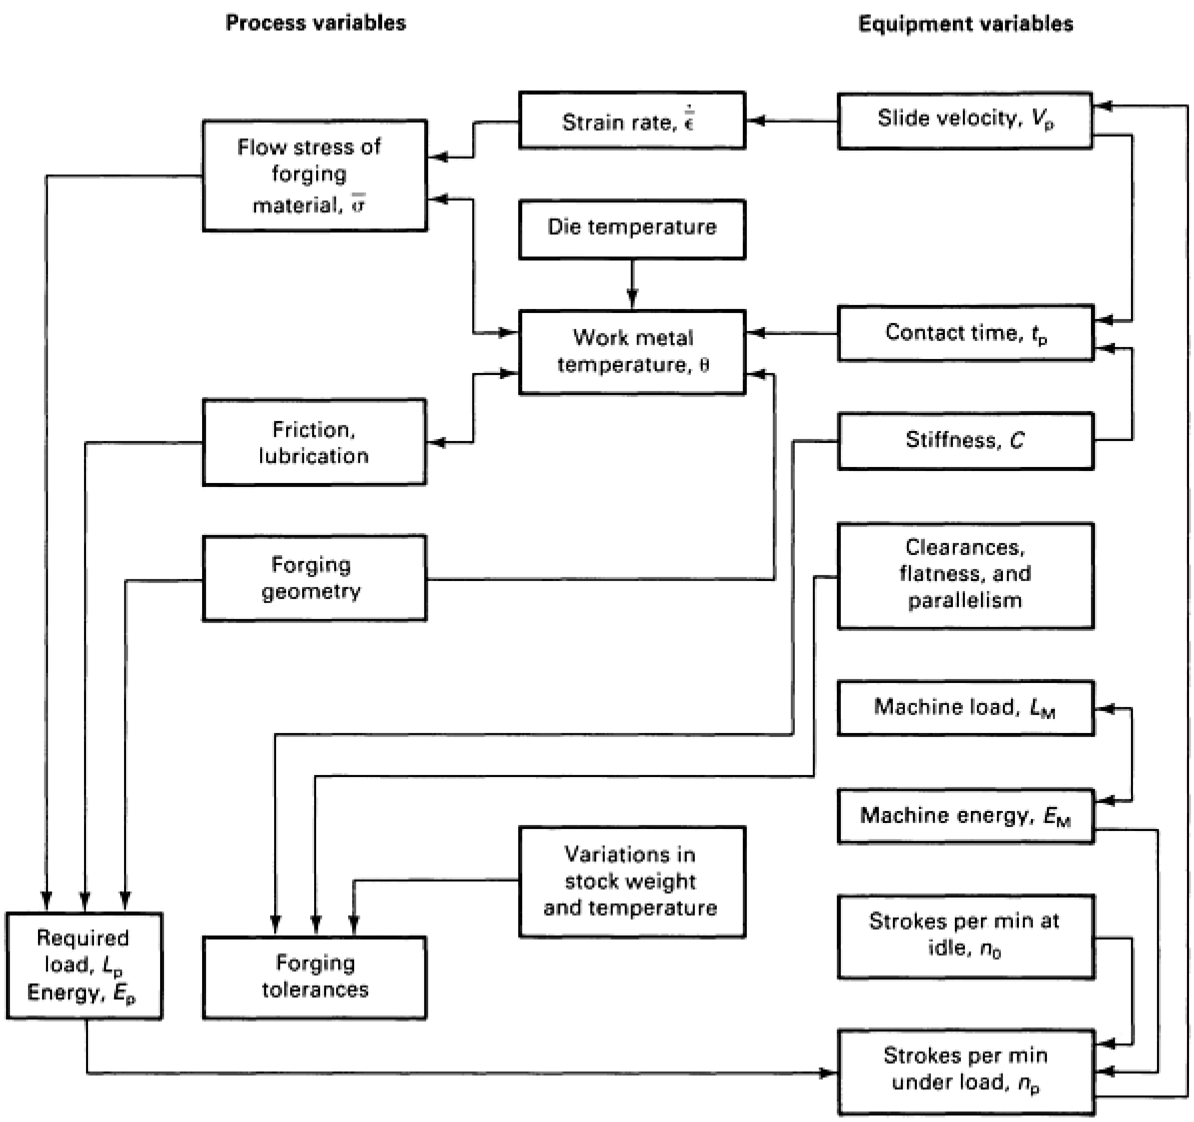

Fig. 1 Relationships between process and machine variables in hot-forging processes conducted in presses

As indicated by the lines connected to the "Work metal temperature" block in Fig. 1, for a given initial stock temperature, the temperature variations in the part are largely influenced by the surface area of contact between the dies and the part, the part thickness or volume, the die temperature, the amount of heat generated by deformation and friction, and the contact time under pressure t_p.

The velocity of the slide under pressure V_p determines mainly t_p and the deformation rate $\dot{\bar{\varepsilon}}$. The number of strokes per minute under no-load conditions n_0, the machine energy E_M, and the deformation energy E_p required by the process influence the slide velocity under load V_p and the number of strokes under load n_p; n_p determines the maximum number of parts formed per minute (the production rate) if the feed and unloading of the machine can be carried out at that speed. The relationships illustrated in Fig. 1 apply directly to hot forging in hydraulic, mechanical, and screw presses.

For a given material, a specific forging operation, such as closed-die forging with flash, forward or backward extrusion, upset forging, or bending, requires a certain variation of the load over the slide displacement (or stroke). This is illustrated qualitatively in Fig. 2, which shows load versus displacement curves characteristic of various forming operations. For a given part geometry, the absolute load values will vary with the flow stress of the material and with frictional conditions. In forming, the equipment must supply the maximum load as well as the energy required by the process.

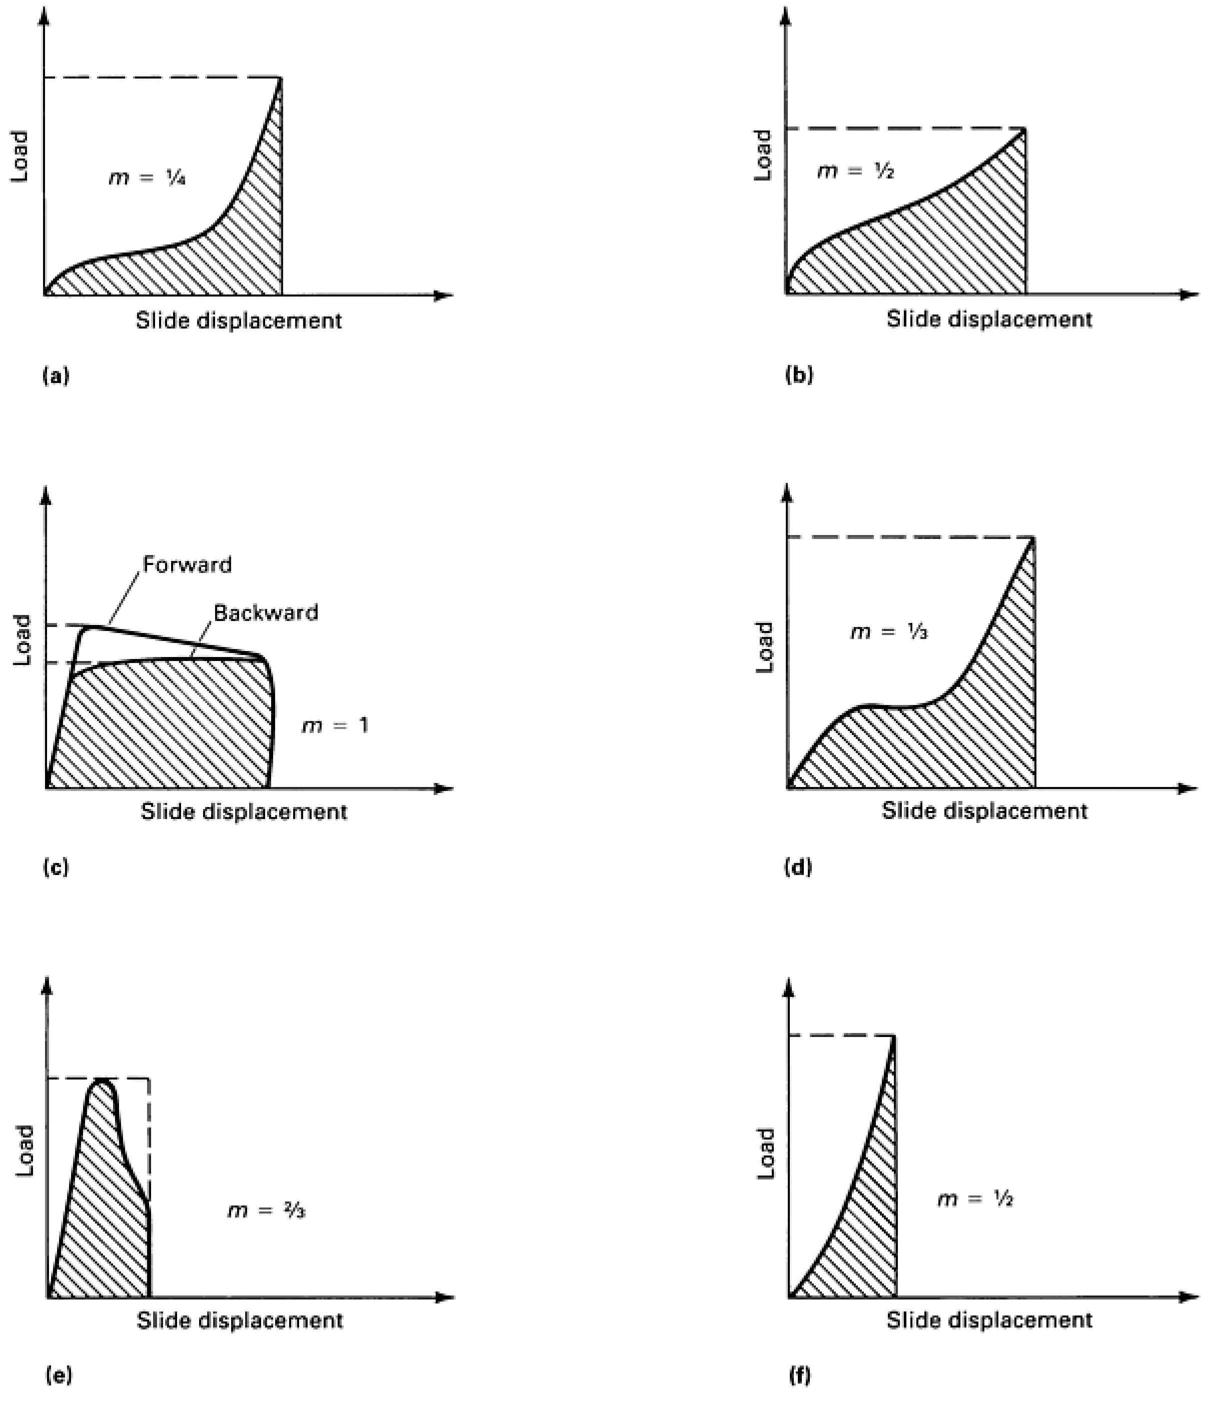

Fig. 2 Load versus displacement curves for various forming operations. Energy developed in the process = load × displacement × *m*, where *m* is a factor characteristic of the specific forming operation. (a) Closed-die forging with flash. (b) Upset forging without flash. (c) Forward and backward extrusion. (d) Bending. (e) Blanking. (f) Coining. Source: Ref 1, 2

Classification and Characterization of Forging Machines

Forging machines can be classified into three types:

- Force-restricted machines (hydraulic presses)
- Stroke-restricted machines (mechanical presses)
- Energy-restricted machines (hammers and screw presses)

The significant characteristics of these machines constitute all machine design and performance data that are pertinent to the economical use of the machine, including characteristics of load and energy, time-related characteristics, and characteristics of accuracy. More information on these machines is available in the article "Hammers and Presses for Forging" in this Volume.

Hydraulic Presses

The operation of hydraulic presses is relatively simple and is based on the motion of a hydraulic piston guided in a cylinder. Hydraulic presses are essentially force-restricted machines; that is, their capability for carrying out a forming operation is limited mainly by the maximum available force.

The operational characteristics of a hydraulic press are essentially determined by the type and design of its hydraulic drive system. The two types of hydraulic drive systems--direct drive and accumulator drive (see Fig. 11 in the article "Hammers and Presses for Forging" in this Volume)--provide different time-dependent characteristic data.

In both direct and accumulator drives, a slowdown in penetration rate occurs as the pressure builds and the working medium is compressed. This slowdown is larger in direct oil-driven presses, mainly because oil is more compressible than a water emulsion.

Approach and initial deformation speeds are higher in accumulator-drive presses. This improves hot-forging conditions by reducing die contact times, but wear in the hydraulic elements of the system also increases. Wear is a function of fluid cleanliness; no dirt equals no wear. Sealing problems are somewhat less severe in direct drives, and control and accuracy in manual operation are generally about the same for both types of drives.

From a practical point of view, in a new installation, the choice between direct and accumulator drive is based on the capital cost and the economics of operation. The accumulator drive is usually more economical if one accumulator system can be used by several presses or if very large press capacities (89 to 445 MN, or 10,000 to 50,000 tonf) are considered. In direct-drive hydraulic presses, the maximum press load is established by the pressure capability of the pumping system and is available throughout the entire press stroke. Therefore, hydraulic presses are ideally suited to extrusion-type operations requiring very large amounts of energy. With adequate dimensioning of the pressure system, an accumulator-drive press exhibits only a slight reduction in available press load as the forming operation proceeds.

In comparison with direct drive, the accumulator drive usually offers higher approach and penetration speeds and a shorter dwell time before forging. However, the dwell at the end of processing and prior to unloading is longer in accumulator drives. This is shown in Fig. 3, in which the load and displacement variations are given for a forming process using a 22 MN (2500 tonf) hydraulic press equipped with either direct-(Fig. 3a) or accumulator-drive (Fig. 3b) systems.

Mechanical Presses

The drive system used in most mechanical presses is based on a slider-crank mechanism that translates rotary motion into reciprocating linear motion. The eccentric shaft is connected, through a clutch and brake system, directly to the flywheel (see Fig. 7 in the article "Hammers and Presses for Forging" in this Volume). In designs for larger capacities, the flywheel is located on the pinion shaft, which drives the eccentric shaft.

Kinematics of the Slider-Crank Mechanism. The slider-crank mechanism is illustrated in Fig. 4(a). The following valid relationships can be derived from the geometry illustrated.

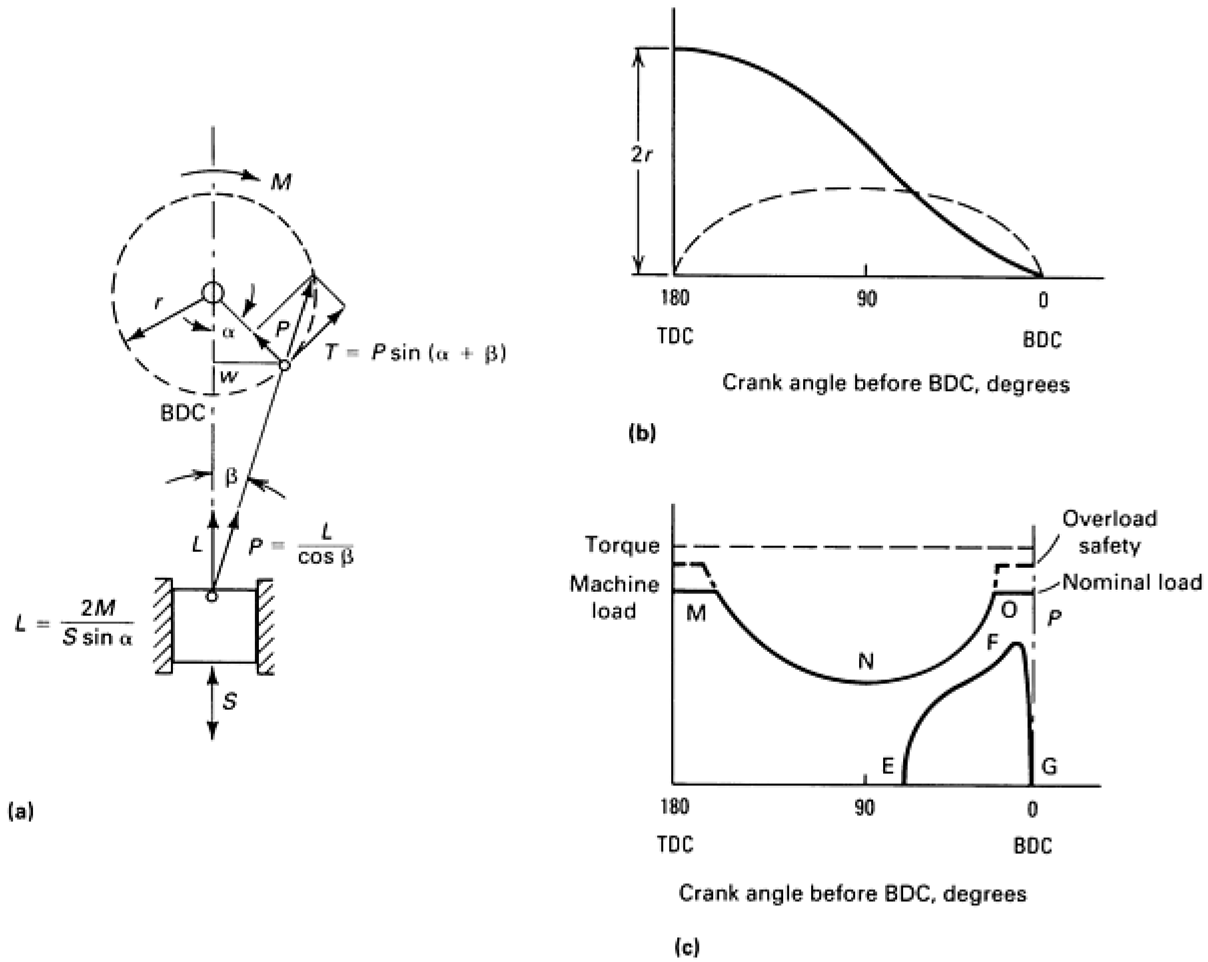

Fig. 4 Load, displacement, velocity, and torque in a simple slider-crank mechanism. (a) Schematic of slider-crank mechanism. (b) Displacement (solid curve) and velocity (dashed curve). (c) Clutch torque *M* and machine load L_M. Source: Ref 3

The distance *w* of the slide from the lowest possible ram position (bottom dead center, BDC; the highest possible position is top dead center, TDC) can be expressed in terms of *r*, *l*, *S*, and α, where (from Fig. 4) *r* is the radius of the crank or one-half of the total stroke *S*, *l* is the length of the pitman arm, and α is the crank angle before bottom dead center.

Because the ratio of *r*/*l* is usually small, a close approximation is:

$$w = \frac{S}{2}(1 - \cos \alpha) \qquad \textbf{(Eq 1)}$$

Equation 1 gives the location of the slide at a crank angle α before bottom dead center. This curve is plotted in Fig. 4(b) along with the slide velocity *V*, which is given by the close approximation:

$$V = \frac{S \pi n}{60} \sin \alpha \qquad \textbf{(Eq 2)}$$

where *n* is the number of strokes per minute.

The slide velocity *V* with respect to slide location *w* before bottom dead center is given by:

$$V = 0.105\, wn \sqrt{\frac{S}{w} - 1} \quad \textbf{(Eq 3)}$$

Therefore, Eq 1 and 2 give the slide position and the slide velocity at an angle α above bottom dead center. Equation 3 gives the slide velocity for a given position *w* above bottom dead center if the number of strokes per minute *n* and the press stroke *S* are known.

Load and Energy Characteristics. An exact relationship exists between the torque *M* of the crankshaft and the available load *L* at the slide (Fig. 4a and c). The torque *M* is constant, and for all practical purposes, angle β is small enough to be ignored (Fig. 4a). A very close approximation then is given by:

$$L = \frac{2M}{S \sin \alpha} \quad \textbf{(Eq 4)}$$

Equation 4 gives the variation of the available slide load *L* with respect to the crank angle α above bottom dead center (Fig. 4c). From Eq 4, it is apparent that as the slide approaches bottom dead center--that is, as angle α approaches zero--the available load *L* may become infinitely large without exceeding the constant clutch torque *M* or without causing the friction clutch to slip.

The following conclusions can be drawn from the observations that have been made thus far. Crank and the eccentric presses are displacement-restricted machines. The slide velocity *V* and the available slide load *L* vary accordingly with the position of the slide before bottom dead center. Most manufacturers in the United States and the United Kingdom rate their presses by specifying the nominal load at 12.7 mm ($\frac{1}{2}$ in.) before bottom dead center. For different applications, the nominal load can be specified at different positions before bottom dead center, according to the standards established by the American Joint Industry Conference. If the load required by the forming process is smaller than the load available at the press--that is, if curve EFG in Fig. 4(c) remains below curve NOP--then the process can be carried out, provided the flywheel can supply the necessary energy per stroke.

For small angles α above bottom dead center, within the OP portion of curve NOP in Fig. 4(c), the slide load *L* can become larger than the nominal press load if no overload safety (hydraulic or mechanical) is available on the press. In this case, the press stalls, the flywheel stops, and the entire flywheel energy is transformed into deflection energy by straining the press frame, the pitman arm, and the drive mechanism. The press can be freed in most cases only by burning out the tooling.

If the applied load curve EFG exceeds the press load curve NOP (Fig. 4c) before point O is reached, the friction clutch slides and the press slide stops, but the flywheel continues to turn. In this case, the press can be freed by increasing the clutch pressure and by reversing the flywheel rotation if the slide has stopped before bottom dead center.

The energy needed for the forming process during each stroke is supplied by the flywheel, which slows to a permissible percentage, usually 10 to 20% of its idle speed. The total energy stored in a flywheel is:

$$E_{FT} = \frac{I\omega^2}{2} = \frac{I}{2}\left(\frac{\pi N}{30}\right)^2 \quad \textbf{(Eq 5)}$$

where *I* is the moment of inertia of the flywheel, ω is the angular velocity in radians per second, and *N* is the rotation speed of the flywheel.

The total energy, *E*, used during one stroke is:

$$E_s = \frac{I}{2}(\omega_0^2 - \omega_1^2) = \frac{I}{2}\left(\frac{\pi}{30}\right)^2 (N_0^2 - N_1^2) \qquad \textbf{(Eq 6)}$$

where ω_0 is the initial angular velocity, ω_1 is the angular velocity after the work is done, N_0 is the initial flywheel speed, and N_1 is the flywheel speed after the work is done.

The total energy E_s also includes the friction and elastic deflection losses. The electric motor must bring the flywheel from its slowed speed N_1 to its idle speed N_0 before the next stroke for forging starts. The time available between two strokes depends on the mode of operation, namely, continuous or intermittent. In a continuously operating mechanical press, less time is available to bring the flywheel to its idle speed; consequently, a larger horsepower motor is necessary.

Frequently, the allowable slowdown of the flywheel is given as a percentage of the nominal speed. For example, if a 13% slowdown is permissible, then:

$$\frac{N_0 - N_1}{N_0} = \frac{13}{100} \text{ or } N_1 = 0.87\, N_0 \qquad \textbf{(Eq 7)}$$

The percentage energy supplied by the flywheel is obtained by using Eq 5 and 6 to give:

$$\frac{E_s}{E_{FT}} = \frac{N_0^2 - N_1^2}{N_0^2} = 1 - (0.87)^2 = 0.25 \qquad \textbf{(Eq 8)}$$

Equations 7 and 8 illustrate that for a 13% slowdown of the flywheel, 25% of the flywheel energy will be used during one stroke.

Time-Dependent Characteristics. The number of strokes per minute n has been discussed previously as an energy consideration. For a given idle flywheel speed, the contact time under pressure t_p and the velocity under pressure V_p depend primarily on the dimensions of the slide-crank mechanism and on the total stiffness C of the press. The effect of press stiffness on contact time under pressure t_p is shown in Fig. 5. As the load builds, the press deflects elastically. A stiffer press (larger C) requires less time t_{p1} for pressure to build and less time t_{p2} for pressure release (Fig. 5a). Consequently, the total contact time under pressure ($t_p = t_{p1} + t_{p2}$) is less for a stiffer press.

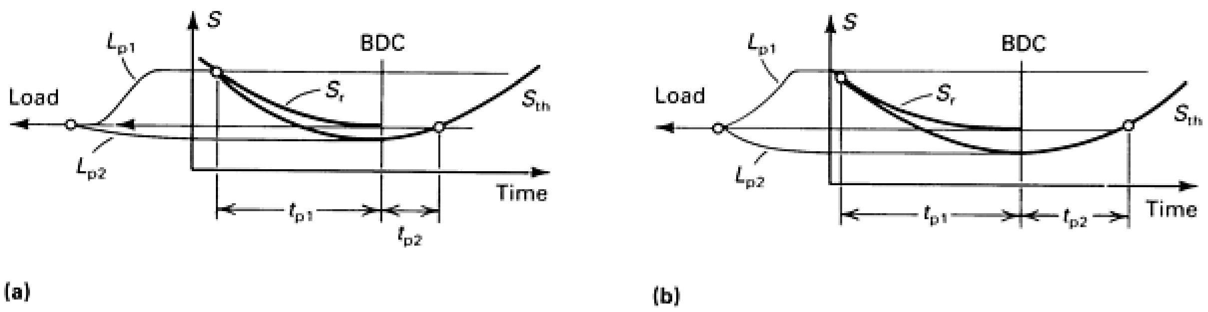

Fig. 5 Effect of press stiffness C on contact time under pressure t_p. (a) Stiffer press (larger C). (b) Less stiff press (smaller C). S_r and S_{th} are the real and theoretical displacement-time curves, respectively; L_{p1}, and L_{p2} are load change during pressure buildup and pressure release, respectively. Source: Ref 4

Characteristics for Accuracy. The working accuracy of a forging press is substantially characterized by two features: the tilting angle of the ram under off-center loading and the total deflection under load (stiffness) of the press. The tilting of the ram produces skewed surfaces and an offset on the forging; the stiffness influences the thickness tolerance.

Under off-center loading conditions, two- or four-point presses perform better than single-point presses, because the tilting of the ram and the reaction forces into gibways are minimized. The wedge-type press, developed in the 1960s, has been claimed to reduce tilting under off-center stiffness. The design principle of the wedge-type press is shown in Fig. 8 in the article "Hammers and Presses for Forging" in this Volume. In this press, the load acting on the ram is supported by the wedge, which is driven by a two-point crank mechanism.

Assuming the total deflection under load for a one-point eccentric press to be 100%, the distribution of the total deflections was obtained after measurement under nominal load on equal-capacity two-point and wedge-type presses (Table 1). It is interesting to note that a large percentage of the total deflection is in the drive mechanism, that is, slide, pitman arm, drive shaft, and bearings.

Table 1 Distribution of total deflection in three types of mechanical presses

Type of press	Distribution of total deflection, %			
	Slide and pitman arm	**Frame**	**Drive shaft and bearings**	Total deflection
One-point eccentric	30	33	37	**100**
Two-point eccentric	21	31	33	**85**
Wedge-type	**21**[(a)]	**29**	**10**	**60**

Source: Ref 5

(a) Includes wedge.

Figure 6 shows table-load diagrams for the same presses discussed above. Table-load diagrams show, in percentage of the nominal load, the amount and location of off-center load that causes the tilting of the ram. The wedge-type press has advantages, particularly in front-to-back off-center loading. In this respect, it performs like a four-point press.

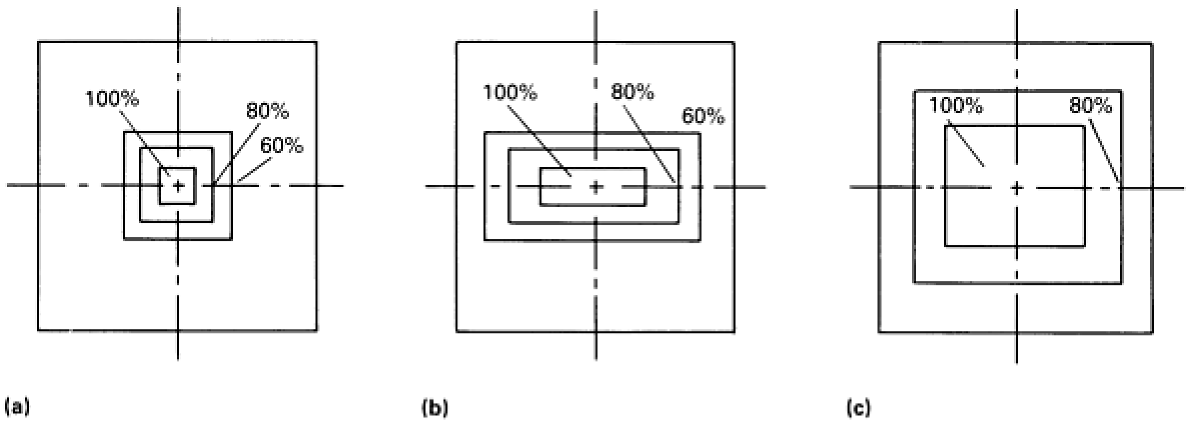

Fig. 6 Amount and location of off-center load that causes tilting of the ram in eccentric one-point presses (a), eccentric two-point presses (b), and wedge-type presses (c). Source: Ref 5

Another type of press designed to minimize deflection under eccentric loading uses a scotch-yoke drive system. The operating principle of this type of press is shown in Fig. 9 in the article "Hammers and Presses for Forging" in this Volume.

Crank Presses With Modified Drives. The velocity versus stroke and load versus stroke characteristics of crank presses can be modified by using different press drives. A well-known variation of the crank press is the knuckle-joint design (Fig. 7), which is capable of generating high forces with a relatively small crank drive. In the knuckle-joint drive, the ram velocity slows much more rapidly toward bottom dead center than the regular crank drive. This machine is successfully used primarily for cold-forming and coining applications.

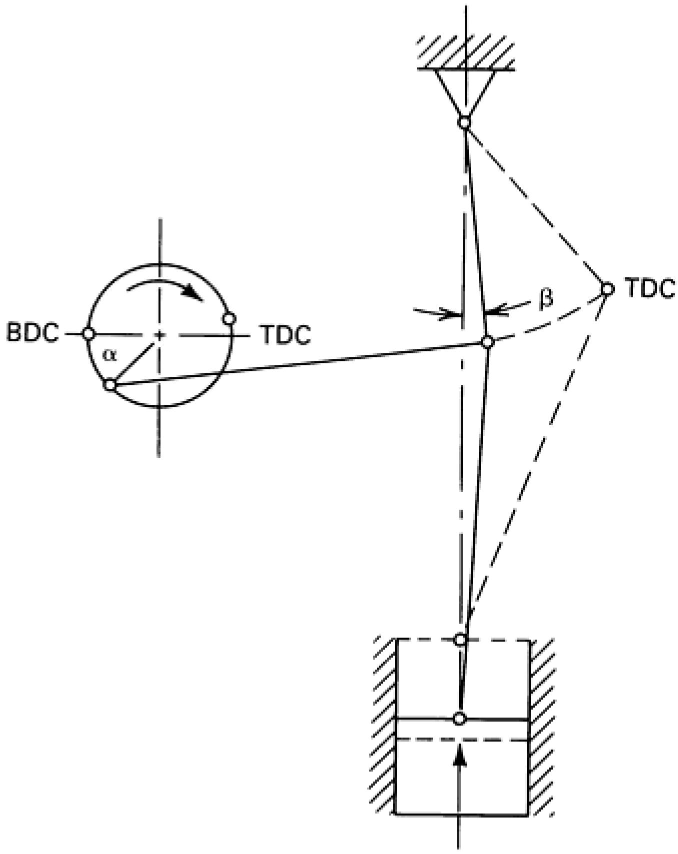

Fig. 7 Schematic of a knuckle-joint mechanical press. Source: Ref 6

Another relatively new mechanical press drive uses a four-bar linkage mechanism (Fig. 8). In this mechanism, the load-stroke and velocity-stroke behavior of the slide can be established at the design stage by adjusting the length of one of the four links or by varying the connection point of the slider link with the drag link. Therefore, with this press, it is possible to maintain maximum load, as specified by press capacity, over a relatively long deformation stroke. Using a conventional slider-crank-type press, this capability can be achieved only by using a much larger capacity press.

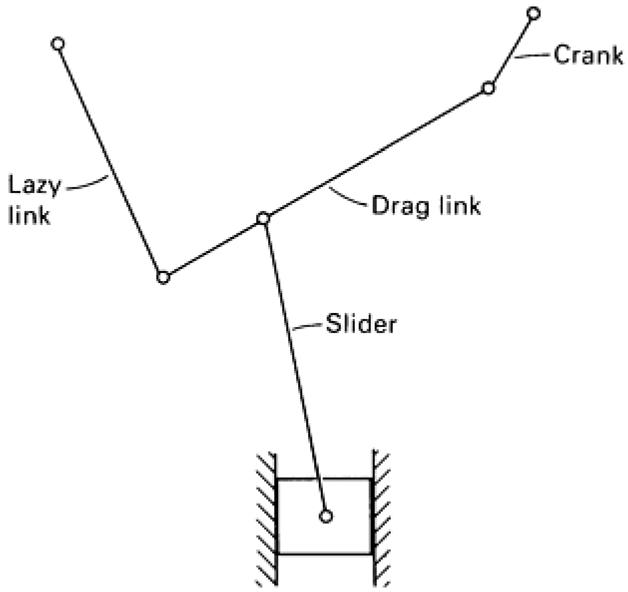

Fig. 8 Four-bar linkage mechanism for mechanical press drives. Source: Ref 7

Figure 9 compares the load-stroke curves for a four-bar linkage press and a conventional slider-crank press. It is apparent that a slider-crank press equipped with a 384 kJ (1700 ton · in.) torque drive can generate a force of about 13.3 MN (1500 tonf) at 0.8 mm ($\frac{1}{32}$ in.) above bottom dead center. The four-bar press equipped with a 135 kJ (600 ton · in.) drive generates a force of about 6.7 MN (750 tonf) at the same location. However, in both machines, a 1.8 MN (200 tonf) force is available at 152 mm (6 in.) above bottom dead center. Therefore, a 6.7 MN (750 tonf) four-bar press could perform the same forming operation, requiring 1.8 MN (200 tonf) over 152 mm (6 in.), as a 13.3 MN (1500 tonf) eccentric press. The four-bar press, which was originally developed for sheet metal forming and cold extrusion, is well suited to extrusion-type forming operations, in which a nearly constant load is required over a long stroke.

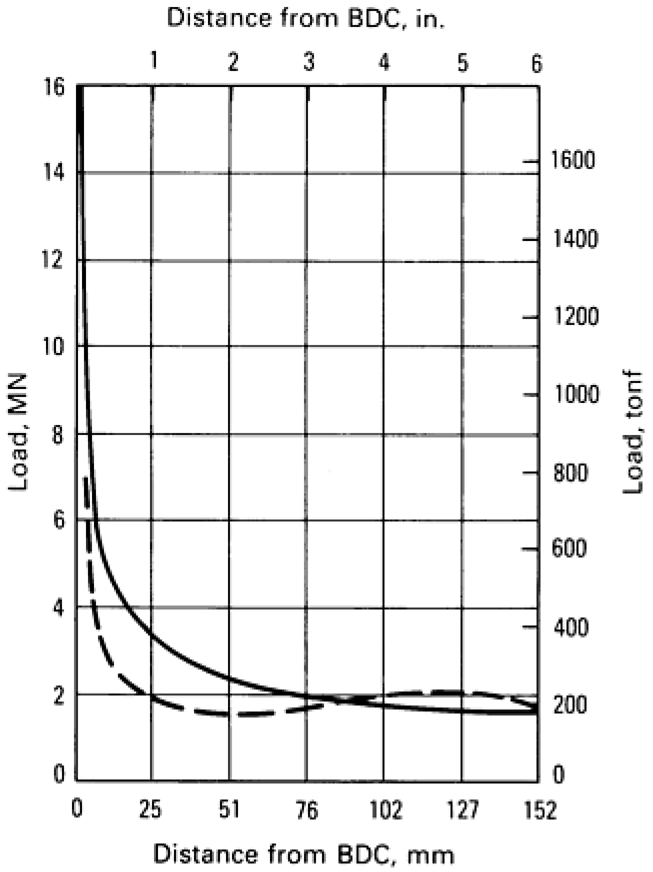

Fig. 9 Load-stroke curves for a 6.7 MN (750 tonf) four-bar linkage press (dashed curve) and a 13.3 MN (1500 tonf) slider-crank press with a 384 kJ (1700 ton · in.) drive (solid curve). Source: Ref 7

Screw Presses

The screw press uses a friction, gear, electric, or hydraulic drive to accelerate the flywheel and the screw assembly, and it converts the angular kinetic energy into the linear energy of the slide or ram. Figure 12 in the article "Hammers and Presses for Forging" in this Volume shows two basic designs of screw presses.

Load and Energy. In screw presses, the forging load is transmitted through the slide, screw, and bed to the press frame. The available load at a given stroke position is supplied by the stored energy in the flywheel. At the end of the downstroke after the forging blow, the flywheel comes to a standstill and begins its reversed rotation. During the standstill, the flywheel no longer contains any energy. Therefore, the total flywheel energy E_{FT} has been transformed into:

- Energy available for deformation E_p to carry out the forging process
- Friction energy E_f to overcome frictional resistance in the screw and in the gibs
- Deflection energy E_d to elastically deflect various parts of the press

At the end of a downstroke, the deflection energy E_d is stored in the machine and can be released only during the upward stroke.

Load versus displacement diagrams for a forging operation are illustrated in Fig. 10. The flywheel in Fig. 10(a) is accelerated to such a velocity that at the end of downstroke the deformation is carried out, and no unnecessary energy is left in the flywheel. This is done by using an energy-metering device that controls flywheel velocity. The flywheel shown in Fig. 10(b) has excess energy at the end of the downstroke. The excess energy from the flywheel stored in the press frame at the end of the stroke is used to begin the acceleration of the slide back to the starting position immediately at the end of the stroke. The screw is not self-locking and is easily moved.

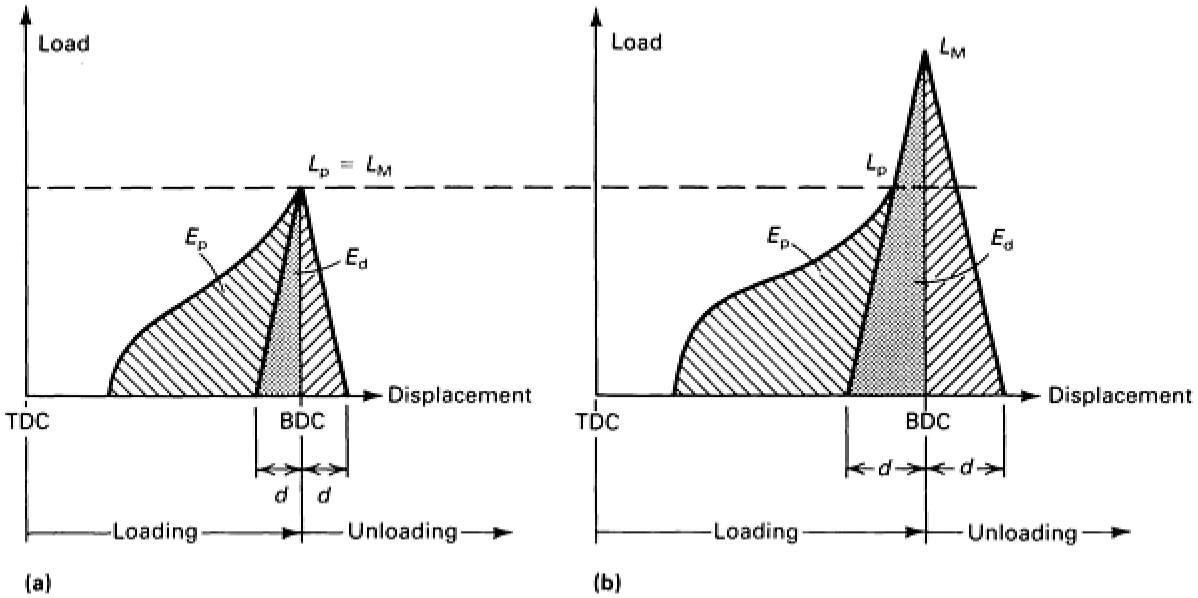

Fig. 10 Load versus displacement curves for die forging using a screw press. (a) Press with energy or load metering. (b) Press without energy or load metering. E_p, energy required for deformation; L_p, load required for deformation; L_M, maximum machine load; E_d, elastic deflection energy; d, elastic deflection of the press. Source: Ref 8

It is apparent from the above discussion that in screw presses the load and energy are inversely proportional. For given friction losses, elastic deflection properties, and available flywheel energy, the load available at the end of the stroke depends mainly on the deformation energy required by the process. Therefore, for a constant flywheel energy, low deformation energy E_p results in high end load L_M, and high E_p results in low L_M. These relationships are shown in Fig. 11.

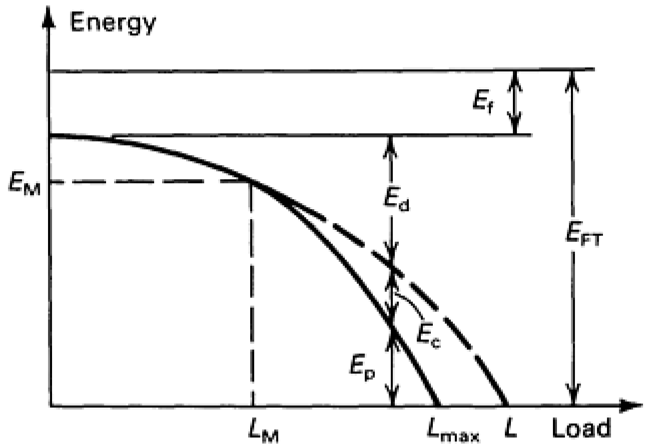

Fig. 11 Energy versus load diagram for a screw press both without a friction clutch at the flywheel (broken line) and with a slipping friction clutch at the flywheel (solid line). E_M, nominal machine energy available for forging; L_M, nominal machine load; E_p, energy required for deformation; E_c, energy lost in slipping clutch; E_d, deflection energy; E_f, friction energy; E_{FT}, total flywheel energy. Source: Ref 9

The screw press can generally sustain maximum loads L_{max} up to 160 to 200% of its nominal load L_M. Therefore, the nominal load of a screw press is set rather arbitrarily. The significant information about the press load is obtained from its energy versus load diagram (Fig. 11). Many screw presses have a friction clutch between the flywheel and the screw. At a preset load, this clutch starts to slip and uses part of the flywheel energy as friction heat energy E_c at the clutch. Consequently, the maximum load at the end of downstroke is reduced to L from L_{max}.

The energy versus load curve has a parabolic shape so that energy decreases with increasing load. This is because the deflection energy E_d, is given by a second-order equation:

$$E_d = \frac{L^2}{2C} \qquad \textbf{(Eq 9)}$$

where L is load and C is the total stiffness of the press.

A screw press can be designed so that it can sustain die-to-die blows without any workpiece for maximum energy of the flywheel. In this case, a friction clutch between the flywheel and the screw is not required. It is important to note that a screw press can be designed and used for forging operations in which large deformation energies are required or for coining operations in which small energies but high loads are required. Another interesting feature of screw presses is that they cannot be loaded beyond the calculated overload limit of the press.

Time-Dependent Characteristics. For a screw press, the number of strokes per minute n is a dependent characteristic. Because modern screw presses are equipped with energy-metering devices, the number of strokes per minute depends on the energy required by the process. In general, however, the production rate of screw presses is comparable with that of mechanical presses.

The velocity under pressure V_p is generally higher than in mechanical presses, but lower than in hammers. This is because the slide velocity of a mechanical press slows toward bottom dead center and the velocity of the slide in a screw press increases until deformation starts and the load builds. This fact is more pronounced in forging thin parts such as airfoils or in coining and sizing operations.

The contact time under pressure t_p is related directly to the ram velocity and to the stiffness of the press. In this respect, the screw press ranks between the hammer and the mechanical press. Contact times for screw presses are 20 to 30 times longer than for hammers. A similar comparison with mechanical presses cannot be made without specifying the thickness of the forged part. In forging turbine blades, which require small displacement but large loads, contact times for screw presses have been estimated to be 10 to 25% of those for mechanical presses.

Variations in Screw Press Drives. In addition to direct friction and electric drives, several other types of mechanical, electric, and hydraulic drives are commonly used in screw presses. A relatively new screw press drive is shown in Fig. 13 in the article "Hammers and Presses for Forging" in this Volume; the principle of operation of this press is also detailed in that article.

Selection of Forging Equipment

Taylan Altan, The Ohio State University

Hammers

The hammer is the least expensive and most versatile type of equipment for generating load and energy to carry out a forming process. Hammers are primarily used for the hot forging, coining, and, to a limited extent, sheet metal forming of parts manufactured in small quantities--for example, in the aircraft industry. The hammer is an energy-restricted machine. During a working stroke, the deformation proceeds until the total kinetic energy is dissipated by plastic deformation of the material and by elastic deformation of the ram and anvil when the die faces contact each other. Therefore, the capacities of these machines should be rated in terms of energy. The practice of specifying a hammer by its ram weight, although fairly common, is not useful for the user. Ram weight can be regarded only as model or specification number.

There are basically two types of anvil hammers: gravity-drop and power-drop. In a simple gravity-drop hammer, the upper ram is positively connected to a board (board-drop hammer), a belt (belt-drop hammer), a chain (chain-drop hammer), or a piston (oil-, air-, or steam-lift drop hammer) (see the article "Hammers and Presses for Forging" in this Volume). The ram is lifted to a certain height and then dropped on the stock placed on the anvil. During the downstroke, the ram is accelerated by gravity and builds up the blow energy. The upstroke takes place immediately after the blow; the force necessary to ensure quick lift-up of the ram can be three to five times the ram weight.

The operation principle of a power-drop hammer is similar to that of an air-drop hammer. In the downstroke, in addition to gravity, the ram is accelerated by steam, cold air, or hot air pressure.

Electrohydraulic gravity-drop hammers, introduced in the United States in recent years, are more commonly used in Europe. In this hammer, the ram is lifted with oil pressure against an air cushion. The compressed air slows the upstroke of the ram and contributes to its acceleration during the downstroke. Therefore, the electrohydraulic hammer also has a minor power hammer action.

Counterblow hammers are widely used in Europe; their use in the United States is limited to a relatively small number of companies. The principal components of a counterblow hammer are illustrated in Fig. 3 in the article "Hammers and Presses for Forging" in this Volume. In this machine, the upper ram is accelerated downward by steam, but it can also be accelerated by cold or hot air. At the same time, the lower ram is accelerated by a steel band (for smaller capacities) or by a hydraulic coupling system (for larger capacities). The lower ram, including the die assembly, is approximately 10% heavier than the upper ram. Therefore, after the blow, the lower ram accelerates downward and pulls the upper ram back up to its starting position. The combined speed of the rams is about 7.6 m/s (25 ft/s); both rams move with exactly one-half the total closure speed. Due to the counterblow effect, relatively little energy is lost through vibration in the foundation and environment. Therefore, for comparable capacities, a counterblow hammer requires a smaller foundation than an anvil hammer.

Characteristics of Hammers. In a gravity-drop hammer, the total blow energy E_T is equal to the kinetic energy of the ram and is generated solely through free-fall velocity, or:

$$E_T = \frac{1}{2} m_1 V_1^2 = \frac{1}{2} \frac{G_1}{g} V_1^2 = G_1 H \qquad \textbf{(Eq 10)}$$

where m_1 is the mass of the dropping ram, V_1 is the velocity of the ram at the start of deformation, G_1 is the weight of the ram, g is the acceleration of gravity, and H is the height of the ram drop.

In a power-drop hammer, the total blow energy is generated by the free fall of the ram and by the pressure acting on the ram cylinder, or:

$$E_T = \frac{1}{2} m_1 V_1^2 + pAH = (G_1 + pA)H \quad \textbf{(Eq 11)}$$

where, in addition to the symbols given above, p is the air, steam, or oil pressure acting on the ram cylinder in the downstroke and A is the surface area of the ram cylinder.

In counterblow hammers, when both rams have approximately the same weight, the total energy per blow is given by:

$$E_T = 2\left(\frac{m_1 V_1^2}{2}\right) = \frac{m_1 V_t^2}{4} = \frac{G_1 V_t^2}{4g} \quad \textbf{(Eq 12)}$$

where m_1 is the mass of one ram; V_1 is the velocity of one ram; V_t is the actual velocity of the blow of the two rams, which is equal to $2V_1$; and G_1 is the weight of one ram.

During a working stroke, the total nominal energy E_T of a hammer is not entirely transformed into useful energy available for deformation, E_A. A small amount of energy is lost in the form of noise and vibration to the environment. Therefore, the blow efficiency $\eta(\eta = E_A/E_T)$ of hammers varies from 0.8 to 0.9 for soft blows (small load and large displacement) and from 0.2 to 0.5 for hard blows (high load and small displacement).

The transformation of kinetic energy into deformation energy during a working blow can develop considerable force. An example is a deformation blow in which the load P increases from $P/3$ at the start to P at the end of the stroke h. The available energy E_A is the area under the curve shown in Fig. 12. Therefore:

$$E_A = \frac{P/3 + P}{2} h = \frac{4Ph}{6} \quad \textbf{(Eq 13)}$$

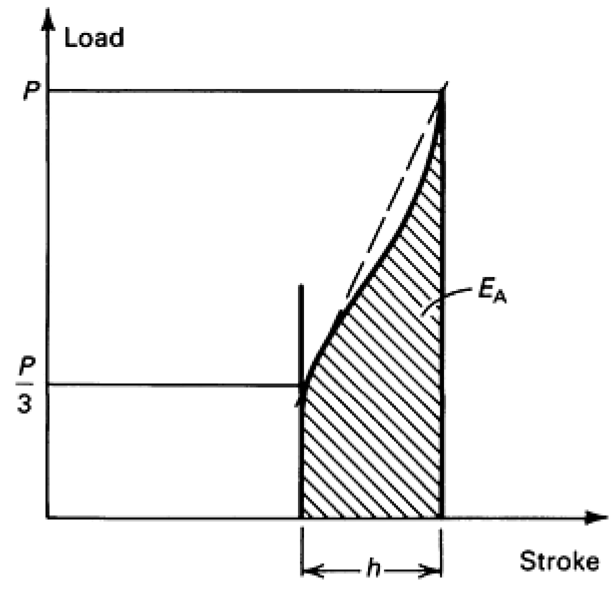

Fig. 12 Example of a load-stroke curve in a hammer blow. Energy available for forging: $E_A = \eta E_T$ (see text for explanation). Source: Ref 10.

For a hammer with a total nominal energy E_T of 47.5 kJ (35,000 ft · lb) and a blow efficiency $\eta$of 0.4, the available energy is $E_A = \eta E_T$ = 19 kJ (14,000 ft · lb). With this value, for a working stroke h of 5 mm (0.2 in.) Eq 13 gives:

$$P = \frac{6E_A}{4h} = 1\ 260\ 000\ \text{lbf} = 630\ \text{tonf} \quad \textbf{(Eq 14)}$$

If the same energy were dissipated over a stroke *h* of 2.5 mm (0.1 in.), the load would reach approximately double the calculated value. The simple hypothetical calculations given above illustrate the capabilities of relatively inexpensive hammers in exerting high forming loads.

Dies and Die Materials for Hot Forging

Introduction

DIE MATERIALS used for hot forging include hot-work tool steels (AISI H series), some alloy steels such as the AISI 4300 or 4100 series, and a small number of proprietary, lower-alloy materials. The AISI hot-work tool steels can be loosely grouped according to composition (see Table 1). Die materials for hot forging should have good hardenability as well as resistance to wear, plastic deformation, thermal fatigue and heat checking, and mechanical fatigue (see the section "Factors in the Selection of Die Materials" in this article). Die design is also important in ensuring adequate die life; poor design can result in premature wear or breakage.

Table 1 Compositions of tool and die materials for hot forging

This article will address dies and die materials used for hot forging in vertical presses, hammers, and horizontal forging machines (upsetters). Dies used in other forging processes, such as rotary forging and isothermal forging, are discussed in the articles in the Section "Forging Processes" in this Volume.

Open Dies

Most open-die forgings are produced in a pair of flat dies--one attached to the hammer or to the press ram, and the other to the anvil. Swage (semicircular) dies and V-dies are also commonly used. These different types of die sets are shown in Fig. 1. In some applications, forging is done with a combination of a flat die and a swage die.

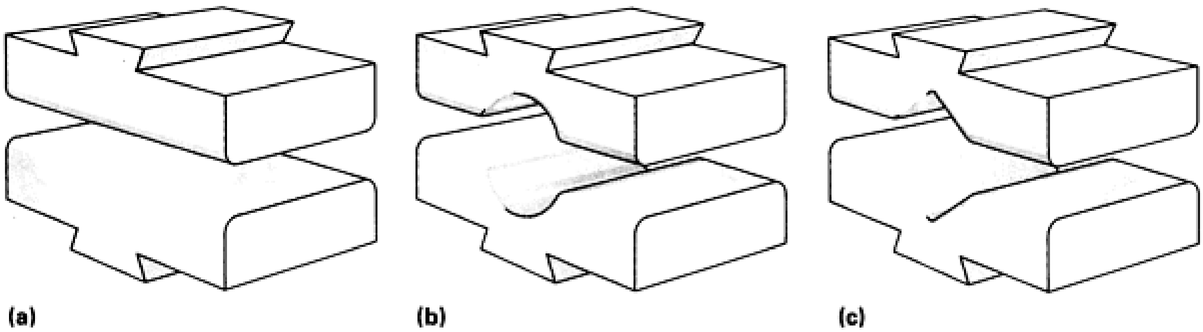

Fig. 1 Three types of die sets used for open-die forging

Flat Dies. The surfaces of flat dies (Fig. 1a) should be parallel to avoid tapering of the workpiece. Flat dies may range from 305 to 510 mm (12 to 20 in.) in width, although most are from 405 to 455 mm (16 to 18 in.) in width. The edges of flat dies are rounded to prevent pinching or tearing of the workpiece and the formation of laps during forging.

Flat dies are used to form bars, flat forgings, and round shapes. Wide dies are used when transverse flow (sideways movement) is desired or when the workpiece is drawn out using repeated blows. Narrower dies are used for cutting off or for necking down larger cross sections.

Swage dies are basically flat dies with a semicircular shape cut into their centers (Fig. 1b). The radius of the semicircle corresponds to the smallest-diameter shaft that can be produced. Swage dies offer the following advantages over flat dies in the forging of round bars:

- Minimal side bulging
- Longitudinal movement of all metal
- Greater deformation in the center of the bar
- Faster operation

Disadvantages of swage dies include the inability to:

- Forge bars of more than one size, in most cases
- Mark or cut off parts (in contrast to flat-die use)

V-dies (Fig. 1c) can be used to produce round parts, but they are usually used to forge hollow cylinders from a hollow billet. A mandrel is used with the V-dies to form the inside of the cylinder. The optimum angle for the V is usually between 90 and 120°.

Impression Dies

Dies for closed-die (impression-die) forging on presses are often designed to forge the part in one blow, and some sort of ejection mechanism (for example, knockout pins) is often incorporated into the die. Dies may contain impressions for several parts.

Hammer forgings are usually made using several blows in successive die impressions. A typical die used for hammer forging is shown in Fig. 2. Such dies usually contain several different types of impressions, each serving a specific function. These are discussed below.

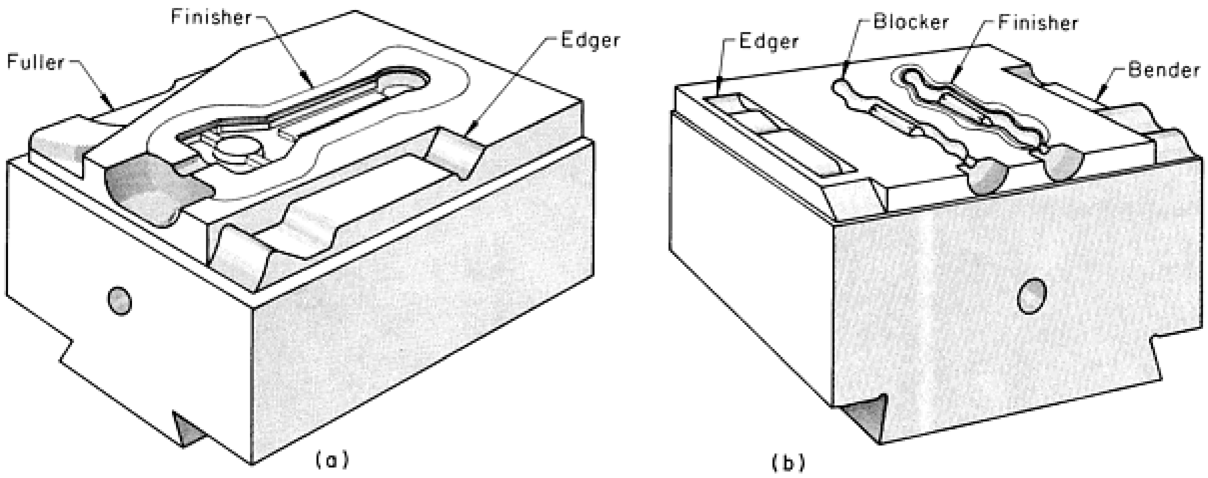

Fig. 2 Typical multiple-impression dies for closed-die forging

Fullers. A fuller is a die impression used to reduce the cross section and to lengthen a portion of the forging stock. In longitudinal cross section, the fuller is usually elliptical or oval to obtain optimum metal flow without producing laps, folds, or cold shuts. Fullers are used in combination with edgers or rollers, or as the only impression before use of the blocker or finisher.

Because fullering usually is the first step in the forging sequence, and generally uses the least amount of forging energy, the fuller is almost always placed on the extreme edge of the die, as shown in Fig. 2(a).

Edgers are used to redistribute and proportion stock for heavy sections that will be further shaped in blocker or finisher impressions. Thus, the action of the edger is opposite to that of the fuller. A connecting rod is an example of a forging in which stock is first reduced in a fuller to prepare the slender central part of the rod and then worked in an edger to proportion the ends of the boss and crank shapes (Fig. 2a).

The edger impression may be open at the side of the die block, as in Fig. 2(a), or confined, as in Fig. 2(b). An edger is sometimes used in combination with a bender in a single die impression to reduce the number of forging blows necessary to produce a forging.

Rollers are used to round the stock (for example, from a square billet to a round, barlike shape) and often to cause some redistribution of mass in preparation for the next impression. The stock usually is rotated, and two or more blows are needed to roll the stock.

The operation of a roller impression is similar to that of an edger, but the metal is partially confined on all sides, with shapes in the top and bottom dies resembling a pair of shallow bowls. Because of the cost of sinking the die impressions, rollering is more expensive than edging, provided both operations can be done in the same number of blows.

Flatteners are used to widen the work metal, so that it more nearly covers the next impression or, with a 90° rotation, to reduce the width to within the dimensions of the next impression. The flattener station can be either a flat area on the face of the die or an impression in the die to give the exact size required.

Benders. A portion of the die can be used to bend the stock, generally along its longitudinal axis, in two or more planes. There are two basic designs of bender impressions: free-flow and trapped-stock.

In bending with a free-flow bender (Fig. 2b), either one end or both ends of the forging are free to move into the bender. A single bend is usually made. This type of bending may cause folds or small wrinkles on the inside of the bend.

The trapped-stock bender usually is employed for making multiple bends. With this technique, the stock is gripped at both ends as the blow is struck, and the stock in between is bent. Because the metal is held at both ends, it is usually stretched during bending. There is a slight reduction in cross-sectional area in the bend, and the work metal is less likely to wrinkle or fold than in a free-flow bender.

Stock that is to be bent may require preforming by fullering, edging, or rollering. Bulges of extra material may be provided at the bends to prevent the formation of kinks or folds in free-flow bending. This is particularly necessary when sharp bends are made. The bent preform usually is rotated 90° as it is placed in the next impression.

Splitters. In making fork-type forgings, frequently part of the work metal is split so that it conforms more closely to the subsequent blocker impression. In a splitting operation, the stock is forced outward from its longitudinal axis by the action of the splitter. Generous radii should be used to prevent the formation of cold shuts, laps, and folds.

Blockers. The blocker impression immediately precedes the finisher impression and serves to prepare the shape of the metal before it is forged to final shape in the finisher. Usually, the blocker imparts the general final shape to the forging, omitting those details that restrict metal flow in finishing, and including those details that will permit smooth metal flow and complete filling in the finisher impression.

Finishers. The finisher impression gives the final overall shape to the workpiece. It is in this impression that any excess work metal is forced out into the flash. Despite its name, the finisher impression is not necessarily the last step in the production of a forging. A bending or hot coining operation is sometimes used to give the final shape or dimensions to a forged part after it has passed through the finisher impression and the trimming die.

A blocker may be a streamlined model of the finisher, used to provide a smooth transition from partially finished to finished forging. Streamlining helps the metal flow around radii, reducing the possibility of cold shuts or other defects.

Sometimes, the blocker impression is made by duplicating the finisher impression in the die block and then rounding it off as required for smooth flow of metal. When this practice is used, the volume of metal in the blockered preform is greater than will be needed in the finisher impression. Also, the blocker impression is larger at the parting line than is the finisher impression. The excess metal causes the finisher impression to wear at the flash land--where the excess metal must be extruded as flash--and around the top of the impression. With wear, the finisher will produce forgings that cannot be properly trimmed or that are out of tolerance. The impression must be reworked more frequently, or the die must be scrapped prematurely.

It is better practice to make the blocker impression slightly narrower and deeper than the finisher impression, with a volume that is equal to, or only slightly greater than, that of the finisher. The use of a blocker impression having this narrower design minimizes die wear at the parting line in the finisher impression. Moreover, it eliminates the occurrence of the type of lap that is likely to be produced in a finished forging made from a blockered preform of the rounded, finisher-duplicate sort described above, namely, the lap made when the finisher shaves excess metal from the sides of the blockered preform. An added benefit of the narrower design is that it allows for some wear of the blocker impression.

Forging of parts that include deep holes or bosses can cause trouble in the finisher. For producing such parts, the blocker sometimes serves as a gathering operation: A volume of metal that is sunk to one side of a forging in the blocker impression can be forced through to the other side in the finisher impression, filling a high boss.

Use of a blocker impression, in addition to promoting smooth metal flow in the finisher impression, reduces wear.

Die Materials

Hot-work die steels are commonly used for hot-forging dies subjected to temperatures ranging from 315 to 650 °C (600 to 1200 °F). These materials contain chromium, tungsten, and in some cases, vanadium or molybdenum or both. These alloying elements induce deep hardening characteristics and resistance to abrasion and softening. These steels usually are hardened by quenching in air or molten salt baths. The chromium-base steels contain about 5% Cr (Table 1). High molybdenum content gives these materials resistance to softening; vanadium increases resistance to abrasion and softening. Tungsten improves toughness and hot hardness; tungsten-containing steels, however, are not resistant to thermal shock and cannot be cooled intermittently with water. The tungsten-base hot-work die steels contain 9 to 18% W, 2 to 12% Cr, and sometimes small amounts of vanadium. The high tungsten content provides resistance to softening at high temperatures while maintaining adequate toughness, but it also makes water cooling of these steels impossible.

Low-alloy proprietary steels are also used frequently as die materials for hot forging. Steels with ASM designations 6G, 6F2, and 6F3 have good toughness and shock resistance, with good resistance to abrasion and heat checking. These steels are tempered at lower temperatures (usually 450 to 500 °C, or 840 to 930 °F); therefore, they are more suited for applications that do not result in high die surface temperatures, for example, die holders for hot forging or hammer die blocks.

The origin of the "ASM" designations for these steels dates back to the 1948 edition of *Metals Handbook.* ASM International does not issue standards of any kind. However, because these steels were never given designations by AISI, SAE, or the Unified Numbering System (UNS), they are still often referred to by their ASM designations. In the 1948 *Handbook*, tool steels were grouped into six broad categories. The steels under discussion here were grouped under category VI (6), "Miscellaneous Tool Steels." The letters of the designation referred to the principal alloying elements. Thus, 6G is a chromium-molybdenum steel, while the 6F steels are nickel-chromium-molybdenum compositions. The difference between 6F2 and 6F3 is in the amounts of these principal alloying elements (see Table 1).

Factors in the Selection of Die Materials

Properties of materials that determine their selection as die materials for hot forging are:

- Ability to harden uniformly
- Wear resistance (ability to resist the abrasive action of hot metal during forging)
- Resistance to plastic deformation (ability to withstand pressure and resist deformation under load)
- Toughness
- Resistance to thermal fatigue and heat checking
- Resistance to mechanical fatigue

Ability to Harden Uniformly. The higher the hardenability of a material, the greater the depth to which it can be hardened. Hardenability depends on the composition of the tool steel. In general, the higher the alloy content of a steel, the higher its hardenability, as measured by the hardenability factor D_1 (in inches). The D_1 of a steel is the diameter of an infinitely long cylinder which would just transform to a specific microstructure (50% martensite) at the center if heat transfer during cooling were ideal, that is, if the surface attained the temperature of the quenching medium instantly. A larger hardenability factor D_1 means that the steel will harden to a greater depth on quenching, not that it will have a higher hardness. For example, the approximate nominal hardenability factors D_1 (inches) for a few die steels are as follows: ASM 6G, 0.6; ASM 6F2, 0.6; ASM 6F3, 1.4; AISI H10, 5; AISI H12, 3.5.

Wear Resistance. Wear is a gradual change in the dimensions or shape of a component caused by corrosion, dissolution, or abrasion and removal or transportation of the wear products. Abrasion resulting from friction is the most important of these mechanisms in terms of die wear. The higher the strength and hardness of the steel near the surface of the die, the greater its resistance to abrasion. Thus, in hot forming, the die steel should have a high hot hardness and should retain this hardness over extended periods of exposure to elevated temperatures.

Figure 4 shows hot hardnesses of five AISI hot-work die steels at various temperatures. All of these steels were heat treated to about the same initial hardness. Hardness measurements were made after holding the specimens at testing temperature for 30 min. Except for H12, all the die steels considered have about the same hot hardness at temperatures below about 315 °C (600 °F). The differences in hot hardness show up only at temperatures above 480 °C (900 °F).

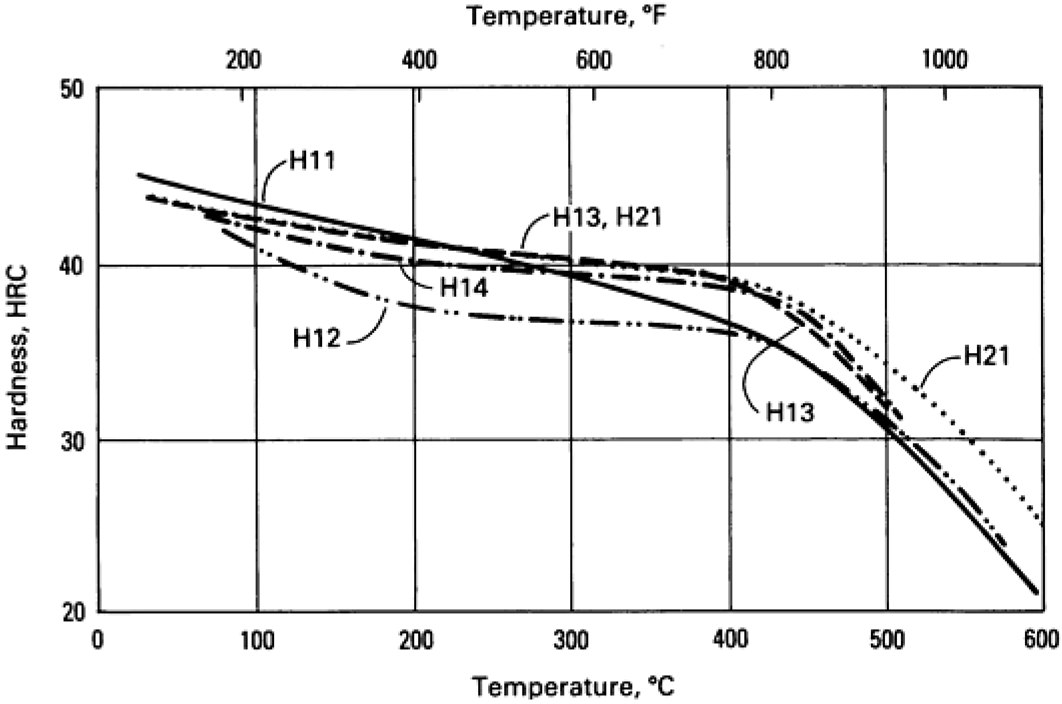

Fig. 4 Hot hardnesses of AISI hot-work tool steels. Measurements were made after holding at the test temperature for 30 min. Source: Ref 1

Figure 5 shows the resistance of some hot-work die steels to softening at elevated temperatures after 10 h of exposure. All of these steels have about the same initial hardness after heat treatment. For the die steels shown, there is not much variation in resistance to softening at temperatures below 540 °C (1000 °F). However, for longer periods of exposure at higher temperatures, high-alloy hot-work steels, such as H19, H21, and H10 modified, retain hardness better than do medium-alloy steels, such as H11.

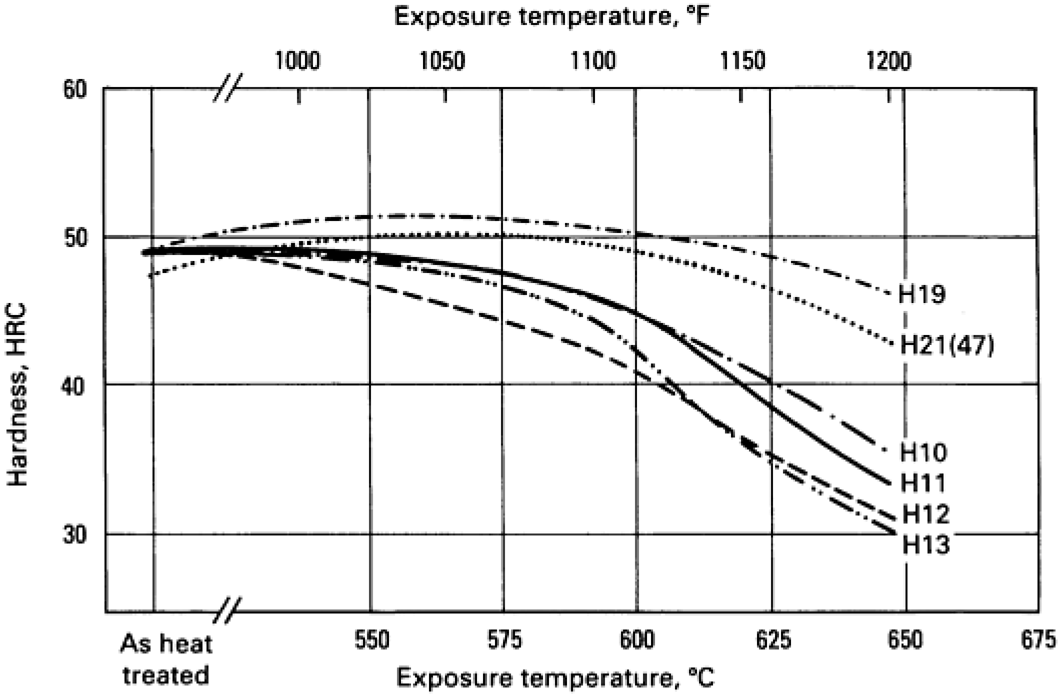

Fig. 5 Resistance of AISI hot-work tool steels to softening during 10 h elevated-temperature exposure as measured by room-temperature hardness. Unless otherwise specified by values in parentheses, initial hardness of all specimens was 49 HRC. Source: Ref 2

Resistance to Plastic Deformation. As shown in Fig. 6, the yield strengths of steels decrease at higher temperatures. However, yield strength also depends on prior heat treatment, composition, and hardness. The higher the initial hardness, the greater the yield strength at various temperatures. In normal practice, the level to which a die steel is hardened is determined by toughness requirements: the higher the hardness, the lower the toughness of a steel. Thus, in metal-forming applications, the die block is hardened to a level at which it should have enough toughness to avoid cracking. Figure 6 shows that, for the same initial hardness, 5% Cr-Mo steels (H11, and so forth) have better hot strengths than 6F2 and 6F3 at temperatures above 370 °C (700 °F).

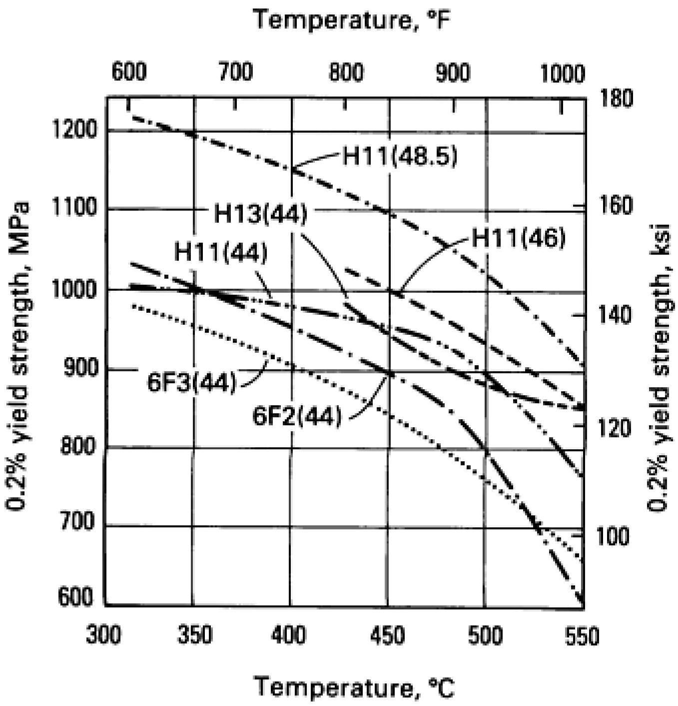

Fig. 6 Resistance of die steels to plastic deformation at elevated temperatures. Values in parentheses indicate room-temperature Rockwell C hardness. Source: Ref 2, 3

Toughness can be defined as the ability to absorb energy without breaking. The energy absorbed before fracture is a combination of strength and ductility. The higher the strength and ductility, the higher the toughness. Ductility, as measured by reduction in area or percent elongation in a tensile test, can therefore be used as a partial index of toughness at low strain rates.

Figure 7 shows the ductility of various hot-work steels at elevated temperatures, as measured by percent reduction in area of a specimen before fracture in a standard tensile test. As the curves show, high-alloy hot-work steels, such as H19 and H21, have less ductility than medium-alloy hot-work steels, such as H11. This explains the lower toughness of H19 and H21 in comparison to that of H11.

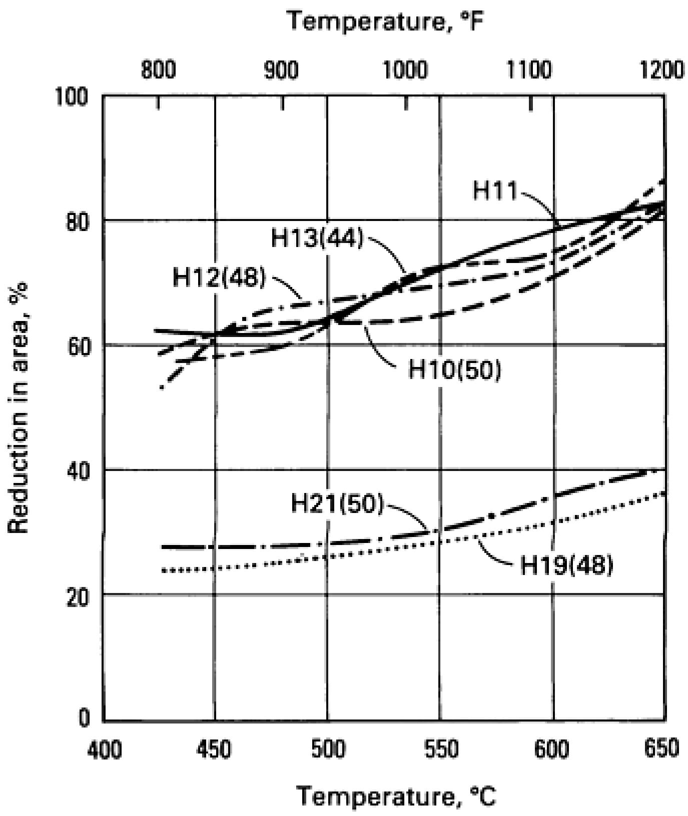

Fig. 7 Elevated-temperature ductilities of various hot-work die steels. Values in parentheses indicate room-temperature Rockwell C hardness.

Fracture toughness and resistance to shock loading are often measured by the notched-bar Charpy test. This test measures the amount of energy absorbed in introducing and propagating fracture, or the toughness of a material at high rates of deformation (impact loading). Figure 8 shows the results of Charpy V-notch tests on various die steels. The data show that toughness decreases as the alloy content of the steel increases. Medium-alloy steels, such as H11, H12, and H13, have better resistance to brittle fracture in comparison with H14, H19, and H21, which have higher alloy contents. Increasing the hardness of a steel lowers its impact strength. On the other hand, wear resistance and hot strength decrease with decreasing hardness. Thus, a compromise is made in actual practice, and the dies are tempered to near-maximum hardness levels at which they have sufficient toughness to withstand loading.

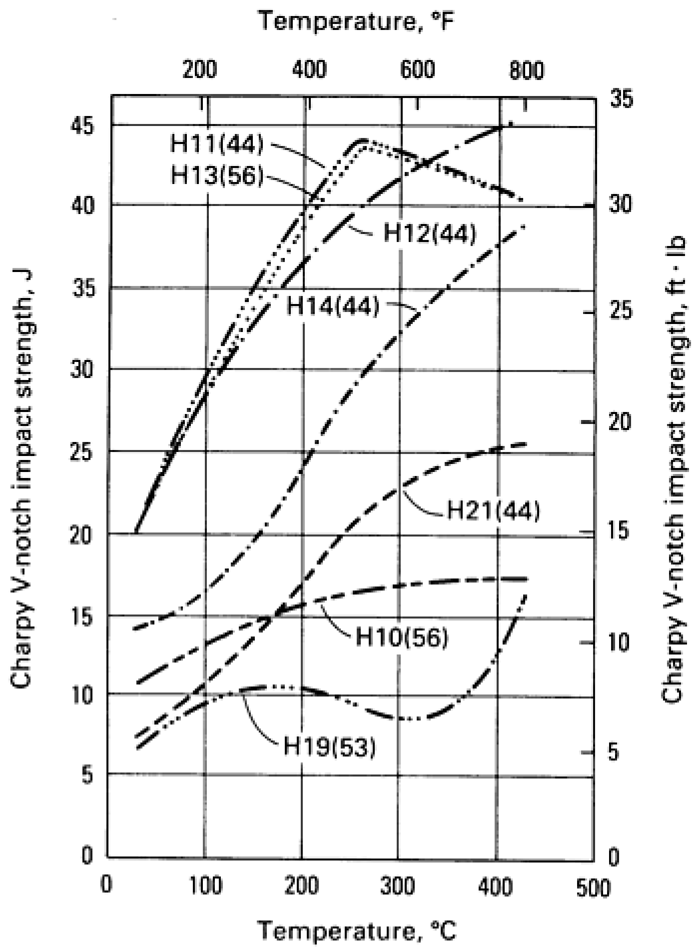

Fig. 8 Effect of hardness, composition, and testing temperature on Charpy V-notch impact strength of hot-work die steels. Values in parentheses indicate Rockwell C hardness at room temperature. Source: Ref 4

The data shown in Fig. 8 also illustrate the importance of preheating the dies before hot forming. Steels such as H10 and H21 require preheating and attain reasonable toughness only at high temperatures. For general-purpose steels, such as 6F2 and 6G, preheating to a minimum temperature of 150 °C (300 °F) is recommended; for high-alloy steels, such as H14 and H19, a higher preheating temperature is desirable to improve toughness.

Resistance to Heat Checking. Nonuniform expansion, caused by thermal gradients from the surface to the center of a die, is the chief factor contributing to heat checking. Therefore, a material with high thermal conductivity will make dies less prone to heat checking by conducting heat rapidly away from the die surface, reducing surface-to-center temperature gradients, and lessening expansion/contraction stresses. The magnitudes of thermal stresses caused by nonuniform expansion or temperature gradients also depend on the coefficient of thermal expansion of the steel; the higher the coefficient of thermal expansion, the greater the stresses.

From tests in which the temperature of the specimen fluctuated between 650 °C (1200 °F) and the water-quench bath temperature, it was determined that H10 was slightly more resistant to heat checking or cracking after 1740 cycles than were H11, H12, and H13. After 3488 cycles, H10 exhibited significantly more resistance to cracking than did H11, H12, and H13.

Fatigue Resistance. Mechanical fatigue of forging dies is affected by the magnitude of the applied loads, the average die temperature, and the condition of the die surface. Fatigue cracks usually initiate at points at which the stresses are highest, such as at cavities with sharp radii of curvature whose effects on the fatigue process are similar to notches (Fig. 9). Other regions where cracks may initiate include holes, keyways, and deep stamp markings used to identify die sets.

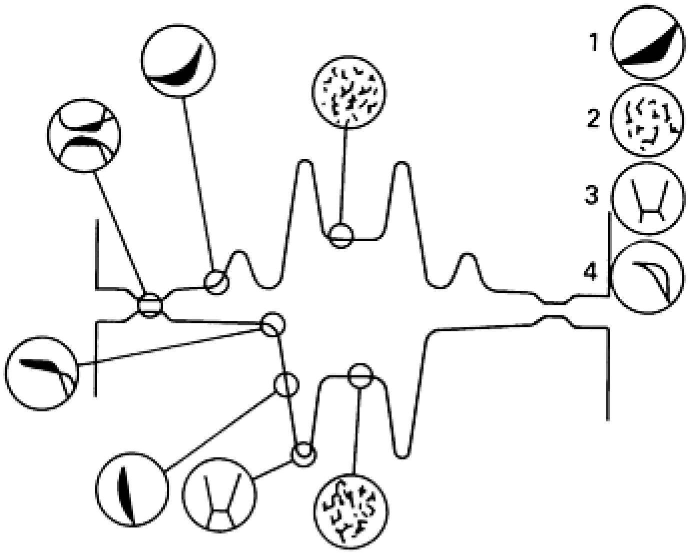

Fig. 9 Common failure mechanisms for forging dies. 1, Abrasive wear; 2, thermal fatigue; 3, mechanical fatigue; 4, plastic deformation. Source: Ref 5

Redesigning to lower the stresses is probably the best way to minimize fatigue crack initiation and growth. Redesigning may include changes in the die impression itself or modification of the flash configuration to lower the overall stresses. Surface treatments may also be beneficial in reducing fatigue-related problems. Nitriding, mechanical polishing, and shot peening are effective because they induce surface residual (compressive) stresses or eliminate notch effects, both of which delay fatigue crack initiation. On the other hand, surface treatments such as nickel, chromium, and zinc plating, which may be beneficial with respect to abrasive wear, have been found to be deleterious to fatigue properties.

Die Inserts

Die inserts are used for economy in the production of some forgings. In general, they prolong the life of the die block into which they fit. The use of inserts can decrease production costs when several inserts can be made for the cost of making one solid die. The time required for changeover or replacement of inserts is brief, because a second set of inserts can be made while the first set is being used. Finally, more forgings can be made accurately in a die with inserts than in a solid die, because steel of higher alloy content and greater hardness can be used in inserts than would be safe or economical to use in solid dies. However, some commercial forge shops in which most of the forging units are gravity drop hammers make only limited use of die inserts.

Inserts can contain the impression of only the portion of a forging that is subject to greatest wear, or they can contain the impression of a whole forging. An example of the first type of insert is a plug type used for forging deep cavities.

Examples of the second type include master-block inserts that permit the forging of a variety of shallow parts in a single die block, and inserts for replacement of impressions that wear the most rapidly in multiple-impression dies.

A plug-type insert (Fig. 10) is usually a projection in the center of the die, such as would be required for making a hub or cup forging. In some impressions, the plug may not be in the center, and more than one plug can be used in a single impression.

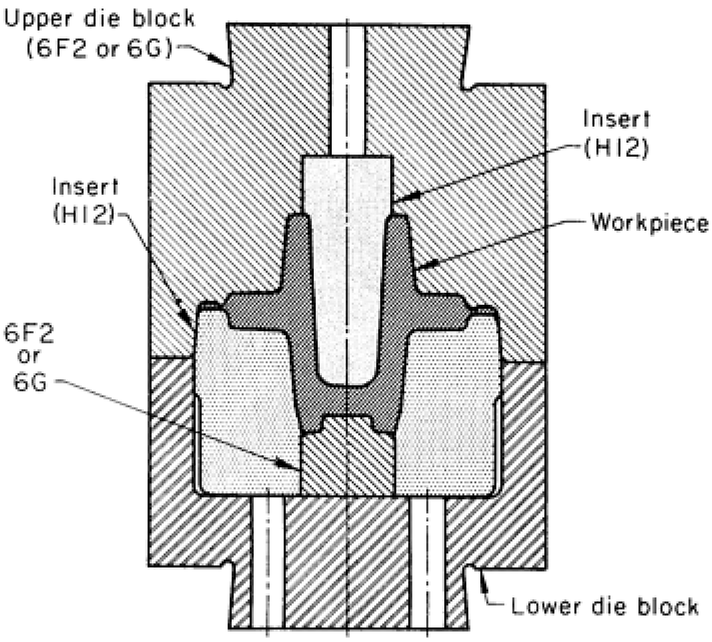

Fig. 10 Use of a plug-type insert in combination with a nearly complete insert in the lower die block for making a forging of extreme severity

Although plugs are used in either shallow or deep impressions, the need is usually greater in deep impressions. For impressions of moderate depth, an insert is advantageous if medium or large quantities of forgings are required. For deep, narrow impressions like that shown in Fig. 10, a plug-type insert is always recommended. Sometimes it is advantageous to use a plug in combination with a complete or nearly complete insert, as in Fig. 10, where a long H12 steel plug is used in the upper die and an almost complete female insert is used in the lower die.

Plug inserts can be made either from prehardened die steel at a higher hardness than the main die part or, for still longer life, from one of the hot-work tool steels. If wear is extremely high, the plug can be hard faced. Plugs are held in place by press fitting, by shrink fitting (by packing in dry ice before insertion), or by the use of plug keys.

Full inserts are generally used for making relatively shallow forgings. They offer one or more of the following advantages: the insert can be of high hardness with less danger of breakage, because it has the softer block as a backing; a higher-alloy steel can be used for the insert portion without a large increase in cost; changes in forging design are less costly when inserts are used; the same die block can be used for slightly different forgings by changing inserts; and inserts can be readily replaced if breakage occurs. Full inserts are used in many commercial forge shops, where a set of standard master blocks is kept available for use.

Another type of insert is for use in multiple-impression dies in which the impressions wear at different rates. Fuller, edger, or bender impressions are seldom used for close-tolerance work and may wear slowly compared with other impressions. Inserts are used only for the impressions that wear most rapidly.

This type of insert is not necessarily limited to shallow impressions. If the insert contains a single impression, the impression can be of any practical depth. However, if it contains several impressions, the impression depth is limited to about 64 mm ($2\frac{1}{2}$ in.) or less. Width of the insert must be considered: Sufficient wall thickness must be allowed between the edge of the impression and the edge of the insert, so that the die-block walls are not weakened too greatly.

Inserts for Hot Upset Forging. Inserts are widely used in upset forging. Solid dies are used in less severe stock gathering in short runs. A particular exception occurs with gripper dies in which the initial impressions are sunk in solid die blocks and used until worn out. The blocks are then resunk and used thereafter with inserts. Another exception occurs when the size of the available block and the number of required passes do not allow enough space between impressions for the sinking of inserts.

Heading tools for punching, trimming, and bending are often made with inserts. Most individual inserts can be replaced readily, and breakage of one heading tool in a multiple operation will not require replacement of the complete heading tool set. In operations in which wear is a major factor and replacement is frequent, as in deep punching, the use of inserts results in considerable savings in both die material and labor. Figure 11 shows heading tool and gripper die inserts used in horizontal forging machines.

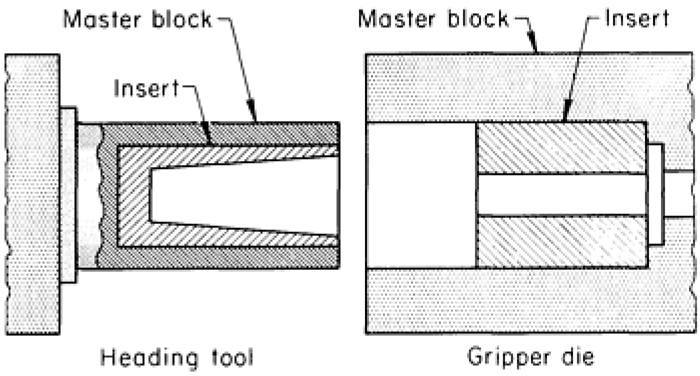

Fig. 11 Heading tool and gripper die inserts used in horizontal forging machines

Dies and Die Materials for Hot Forging

Parting Line

The parting line is the line along the forging where the dies meet. It may be in a single plane or it may be curved or irregular with respect to the forging plane, depending on the design of the forging. The shape and location of the parting line determine die cost, draft requirements, grain flow, and trimming procedures. A few of the considerations that determine the most effective location and shape of the parting line are described below.

In most forgings, the parting line is at the largest cross section of the part, because it is easier to spread metal by forging action than to force it into deep die impressions. If the largest cross section coincides with a flat side of a forging, there may be a particular advantage in locating the parting line along the edges of the flat section, thus placing the entire impression in one die half. Die costs can be reduced, because one die is simply a flat surface. Also, mismatch between upper and lower dies cannot occur, and forging flash can be trimmed readily.

When a die set having one flat die cannot be used, the position of the parting line should allow location of the preform in the finisher impression of the forging die and of the finished forging in the trimming die.

Because part of the metal flow is toward the parting line during forging, the location of the parting line affects the grain flow characteristics of a forged piece (Fig. 12). For good metal flow patterns in, for example, a forging having a vertical wall adjacent to a bottom web section, a parting line on the outer side of the wall should be placed either adjacent to the web section and near the bottom of the wall, or at the top of the wall. Placing the parting line at any point above the center of the bottom web but below the top of the wall may disrupt the grain flow and cause defects in the forging.

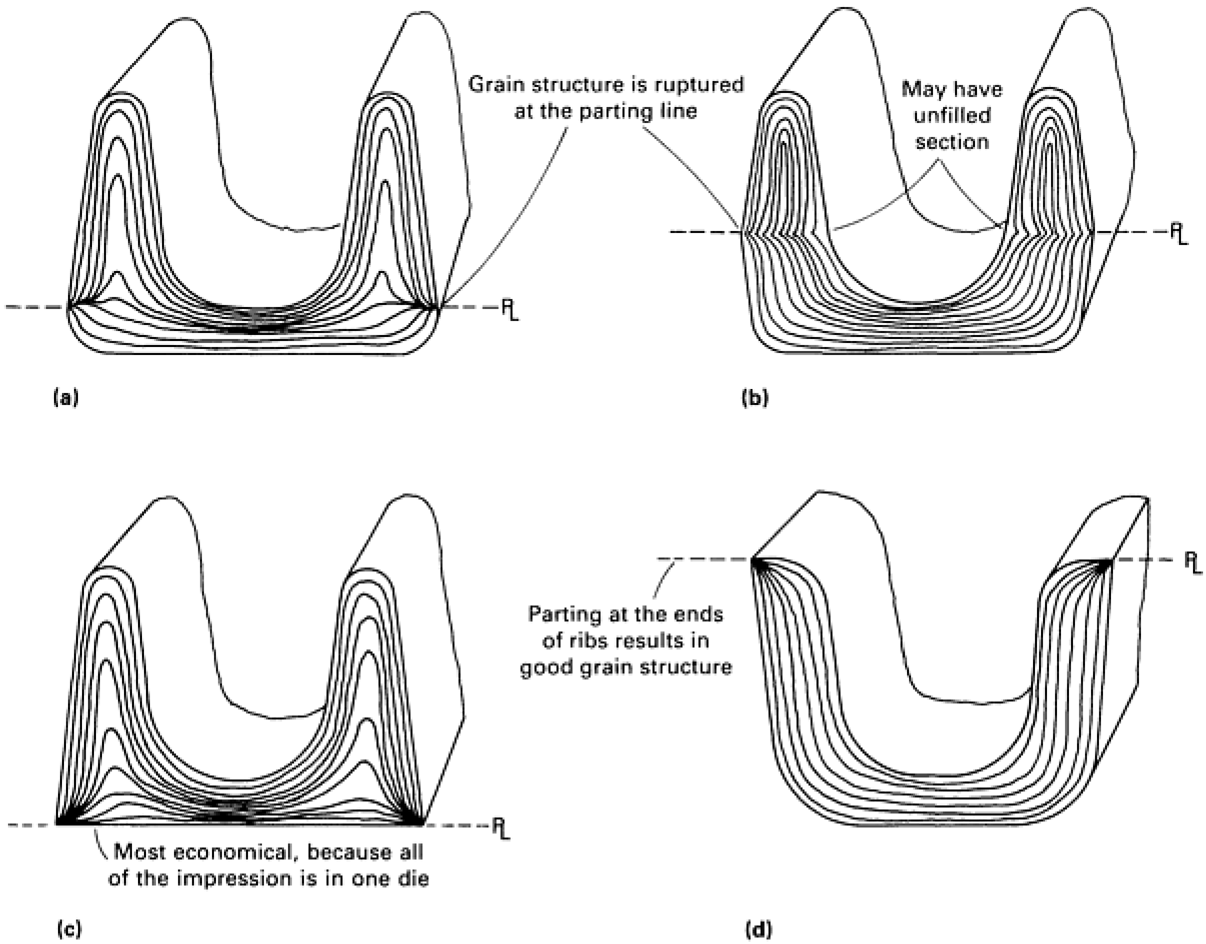

Fig. 12 Effect on metal flow patterns of various parting line locations on a channel section. (a) and (b) Undesirable; these parting lines result in metal flow patterns that cause forging defects. (c) and (d) Recommended; metal flow patterns are smooth at stressed sections with these parting lines. Source: Ref 6

Because the dies move only in a straight line, and because the forging must be removed from the die without damage either to the impression or to the forging, there can be no undercuts in the die impressions. Frequently, the forging can be inclined, with respect to the forging plane, to overcome the effect of an undercut.

Locks and Counterlocks

Many forgings require a parting line that is not flat and, correspondingly, die parting surfaces that are neither planar nor perpendicular to the direction in which the forging force is applied. Dies that have a change in the plane of their mating surfaces, and that therefore mesh ("lock") in a vertical direction when closed, are called locked dies.

In forging with locked dies, side or end thrust is frequently a problem. A strong lateral thrust during forging may cause mismatch of the dies or breakage of the forging equipment. There are several ways to eliminate or control side thrust. Individual forgings can be inclined, rotated, or otherwise placed in the dies so that the lateral forces are balanced (see Fig. 13c). Flash can be used to cushion the shock and help absorb the lateral forces. When the production quantity is large enough and the size of the forging is small enough to permit forging in multiple-part dies, the impressions can be arranged so that the side thrusts cancel one another out.

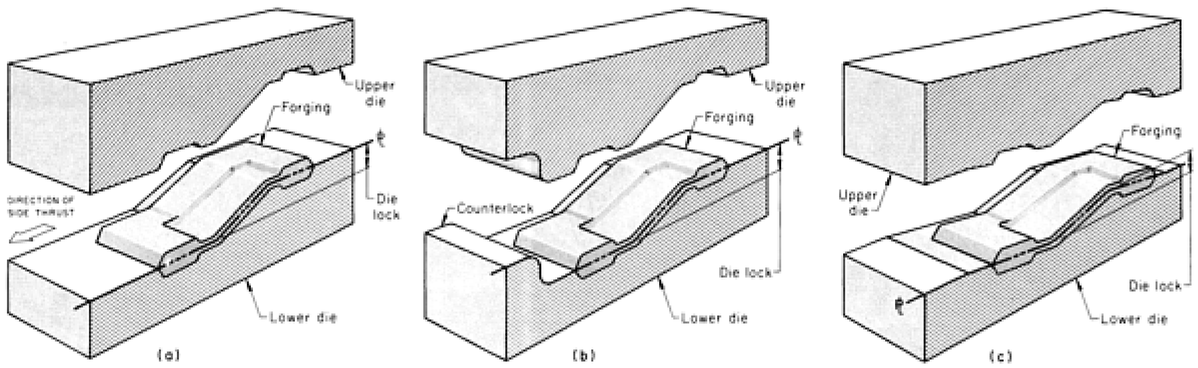

Fig. 13 Locked and counterlocked dies. (a) Locked dies with no means to counteract side thrust. (b) Counterlocked dies. (c) Dies requiring no counterlock because the forging has been rotated to minimize side thrust

Generally, with optimum placement of the impression in the die, and with the clearance between the guides on the hammer or press absorbing some side thrust, alignment between the upper and lower die impression can be maintained. Sometimes, however, the methods suggested above are insufficient or unsuitable for maintaining the required alignment, and it is necessary to counteract side thrust by machining mating projections and recesses (counterlocks) into the parting surfaces of the dies.

Counterlocks can be relatively simple. A pin lock that consists of a round or square peglike section with a mating section may be all that is required to control mismatch. Two such sections, or even sections at each corner of the die, may be necessary. A simple raised section with a mating countersunk section running the width and the length of the die can control side and end match. Counterlocks of these types should not be used in long production runs.

Counterlocks in high-production dies should be carefully designed and constructed. The height of the counterlock usually is equal to, or slightly greater than, the depth of the locking portion of the die. The thickness of the counterlock should be at least 1.5 times the height, so that it will have adequate strength to resist side thrust. Adequate lubrication of the sliding surfaces is difficult to maintain, because of the temperature of the die and the heat radiated from the workpiece. Therefore, the surfaces of the counterlock wear rapidly and need frequent reworking. Because of the cost of constructing and maintaining counterlocks, they should be used only if a forging cannot be produced more economically without them.

To forge the connecting link shown in Fig. 13 requires a locked die because of the part shape. With the die design shown in Fig. 13(a), side thrust is particularly large because of the angle at which the die faces meet the inclined portion of the work metal. Because no means is provided to counteract side thrust, it is impossible to avoid mismatch of the upper and lower dies. The position of the forging in the die in Fig. 13(b) is the same as in Fig. 13(a), but a counterlock is machined into the die to counteract side thrust. With this arrangement, the possibility of mismatch is eliminated, but the cost of making and maintaining the dies is high. Figure 13(c) shows a position of the forging in the die that is preferable for production. The workpiece has been rotated so that the side thrusts produced when forging the ends and the web cancel each other out. No counterlock is required, and accurate forgings can be produced.

Mismatch

Mismatch between the top and bottom dies is sometimes the cause of serious forging problems. Such mismatch can often be related to the design of the forging dies. An unacceptable amount of mismatch may persist despite optimum die design. When this happens, it may be possible to compensate for mismatch in forgings by the use of dies with built-in mismatch. For example, nonsymmetrical parts like connecting rods can often be forged in pairs (Fig. 14a), minimizing off-center force. Furthermore, ram deflection is minimized by locating the blocker and finisher impressions as close to the center of the die as possible. Some deflection still occurs, but it can be corrected by building a compensating mismatch into the die impressions. Because the blocker impression does most of the work in the forging of connecting rods, the mismatch is built into this impression, in a direction opposite that of ram deflection, as shown in Fig. 14(b). The amount of built-in mismatch varies with the offset from center, the size and shape of the forging stock, and the equipment used. In the forging of automotive connecting rods from 35 mm ($1\frac{3}{8}$ in.) diam stock in a 13.3 kN (3000 lbf) hammer, a 0.76 mm (0.030 in.) mismatch in the dies (Fig. 14b) was optimum.

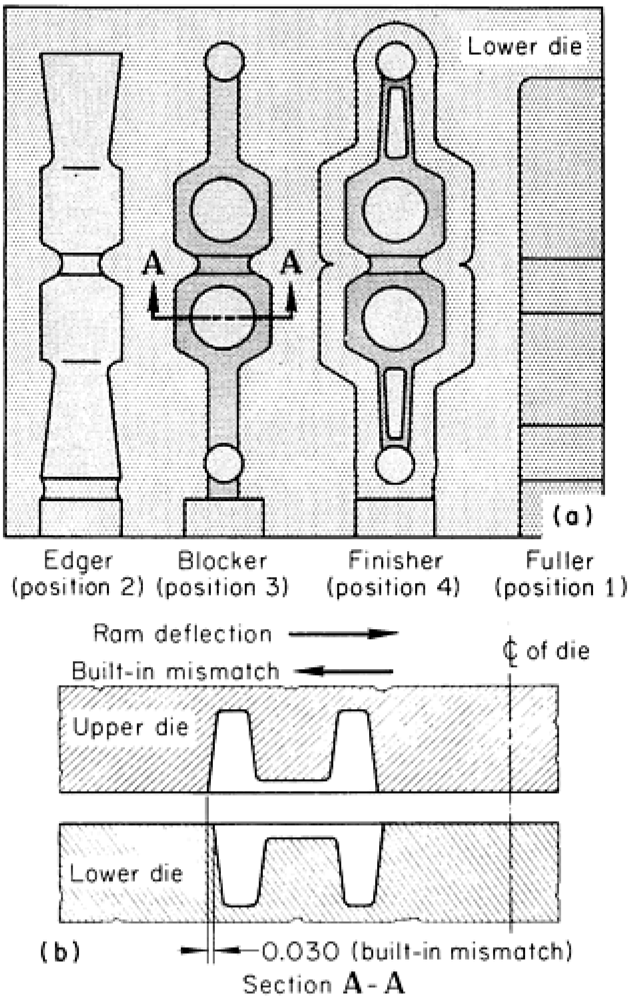

Fig. 14 Built-in die mismatch to compensate for ram deflection. (a) Arrangement of die impression for forging pairs of connecting rods. (b) Upper and lower dies with mismatch built into the blocker impression

Die locks and counterlocks are sometimes used to ensure proper alignment of the upper and lower dies. These locks consist of male and female components (projections and recesses) that are located on the parting surfaces of the dies to provide close-fitting junctions when the dies are closed. Because they are expensive to produce and require frequent maintenance or replacement, die locks are generally used only when the contours of the forging prevent the use of alternative methods for limiting or eliminating mismatch.

Draft

Draft, or taper, is added to straight sidewalls of a forging to permit easier removal from the die impression. Forgings having round or oval cross sections or slanted sidewalls form their own draft. Forgings having straight sidewalls, such as square or rectangular sections, can be forged by parting them across the diagonal and tilting the impression in the die so that the parting line is parallel to the forging plane. Another method is to place the parting line at an angle to the forging plane and machine a straight-wall cavity and a counterlock in each die. If ejectors or die kickouts are used, draft angles can be minimized.

The draft used in die impressions normally varies from 3 to 7° for external walls of the forging. Surfaces that surround holes or recesses have draft angles ranging from 5 to 10°. More draft is used on walls surrounding recesses to prevent the forging from sticking in the die as a result of natural shrinkage of the metal as it cools.

Dies and Die Materials for Hot Forging

Flash

The excess material in an impression die surrounds the forged part at the parting plane and is referred to as flash. Flash consists of two parts: the flash at the land and that in the gutter. The flash land is the portion of the flash adjacent to the part, and the gutter is outside the land. Flash is normally cut off in the trimming die.

The flash land impression in the die is designed so that as the dies close and metal is forced between the dies, the pressure in the part cavity is sufficient to fill the cavity without breaking the die. The pressure is controlled through land geometry, which determines the flash thickness and width. The flash land is generally constructed as two parallel surfaces that have the proper thickness-to-width ratio when the dies are closed.

The land thickness is determined by the forging equipment used, the material being forged, the weight of the forging, and the complexity of the forged part. The ratio of flash land width to flash land thickness varies from 2:1 to 5:1. Lower ratios are used in presses, and higher ratios are used in hammers.

Flash Gutter. The gutter is thicker than the flash land and provides a cavity in the die halves for the excess material. The gutter should be large enough so that it does not fill up with excess material or become pressurized. The four gutter designs commonly used are parallel, conventional, tapered open, and tapered closed (Fig. 15). Choice of gutter design is generally determined by the type of forging equipment used, the properties of the material being forged, the forging temperature, and the overall pressures exerted in the die cavity.

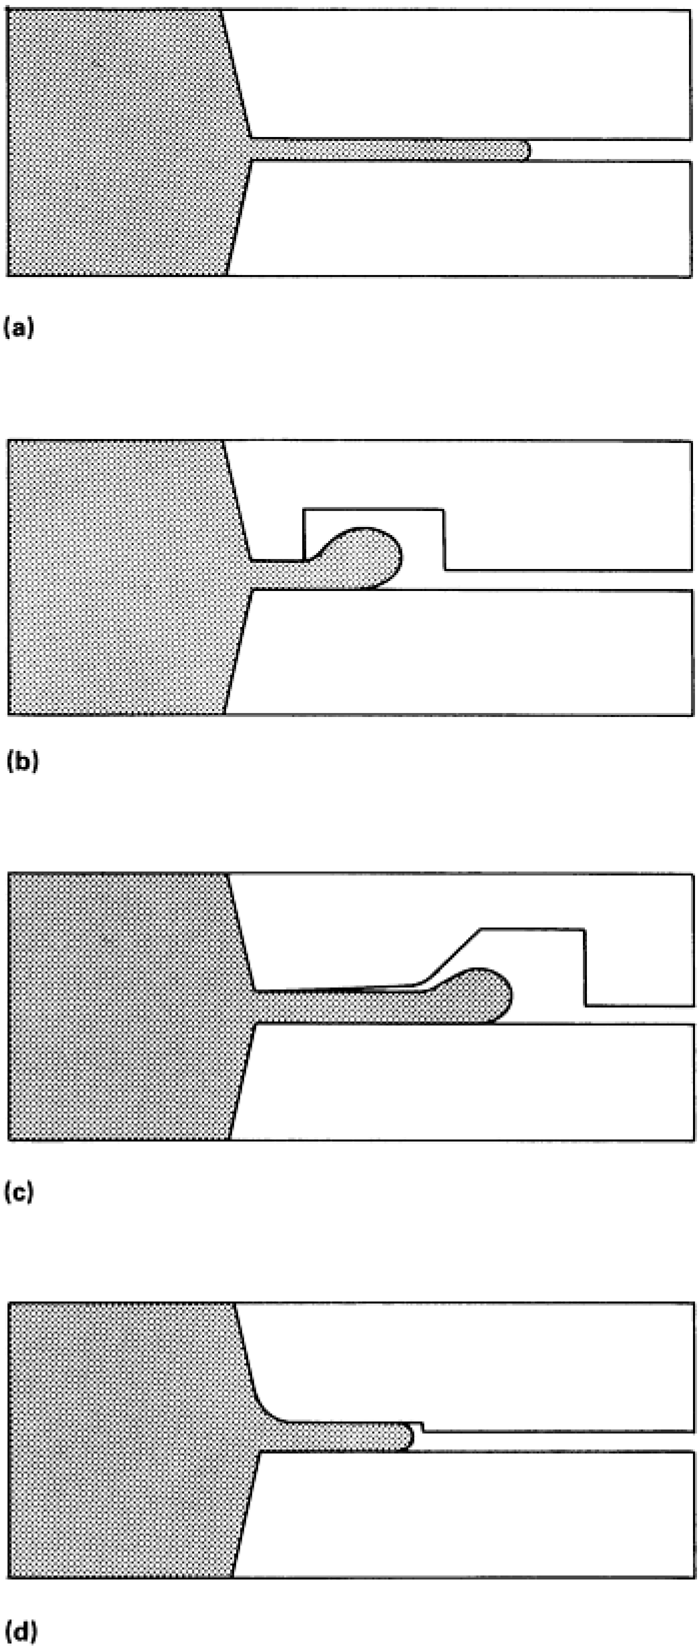

Fig. 15 Four designs commonly used for flash gutters. (a) Parallel. (b) Conventional. (c) Tapered open. (d) Tapered closed

Preform Design

One of the most important aspects of the closed-die forging process is the design of preforms (or blockers) to achieve adequate metal distribution. With proper preform design, defect-free metal flow and complete die fill can be achieved in the final forging operation and metal losses into flash can be minimized. The determination of the preform configuration is an especially difficult task and art in itself requiring skills achieved only with years of experience. In attempting to develop quantitative and objective engineering guidelines for preform design, one must have a thorough understanding of metal flow. Metal flow during forging can be considered to take place in two basic modes: extrusion (parallel to the direction of die motion) and upsetting (perpendicular to the direction of die motion). In most forgings, the geometry of the part is such that both modes of flow occur simultaneously. In the study of metal flow for designing the preform, it is very useful to consider various cross sections of a forging at which the flow is approximately in one plane. Figure 16 illustrates the planes of metal flow for some simple parts. The surface connecting the centers of the planes of flow is the neutral surface of the forging. The neutral surface can be thought of as the surface on which all movement of metal is parallel to the direction of die motion. Thus, metal flows away from the neutral surface, in a direction perpendicular to die motion.

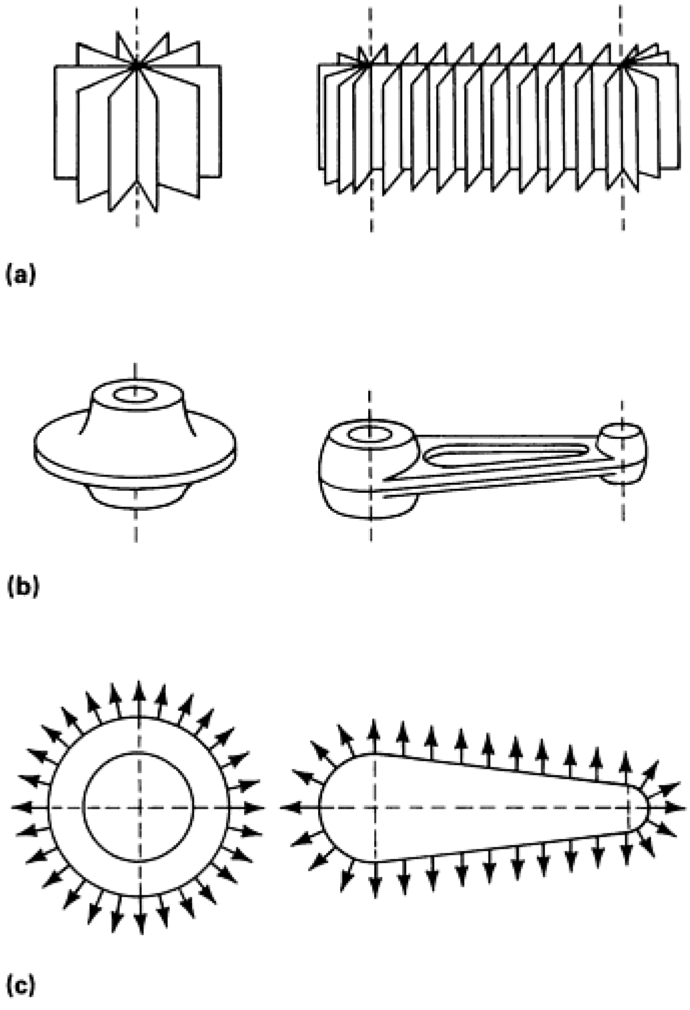

Fig. 16 Planes and directions of metal flow in the forging of two simple shapes. (a) Planes of flow. (b) Finished forging shape. (c) Directions of flow. Source: Ref 7

It is common practice in designing a preform to consider planes of metal flow, that is, selected cross sections of the forging, and to design the preform configuration for each cross section based on metal flow. The basic design guidelines are given below.

First, the area of each cross section along the length of the preform must be equal to the area of the finished cross section augmented by the area necessary for flash. Thus, the initial stock distribution is obtained by determining the areas of cross sections along the main axis of the forging. Second, all the concave radii (including fillet radii) of the preform should be larger than the radii of the forged part. Finally, whenever practical, the dimensions of the preform should be larger than those of the finished part in the forging direction so that metal flow is mostly of the upsetting type rather than of the extrusion type. During the finishing operation the material then will be squeezed laterally toward the die cavity without additional shear at the die/material interface. Such conditions minimize friction and forging load and reduce wear along the die surfaces. The application of the three principles for forging steel parts is illustrated for some solid cross sections in Fig. 17.

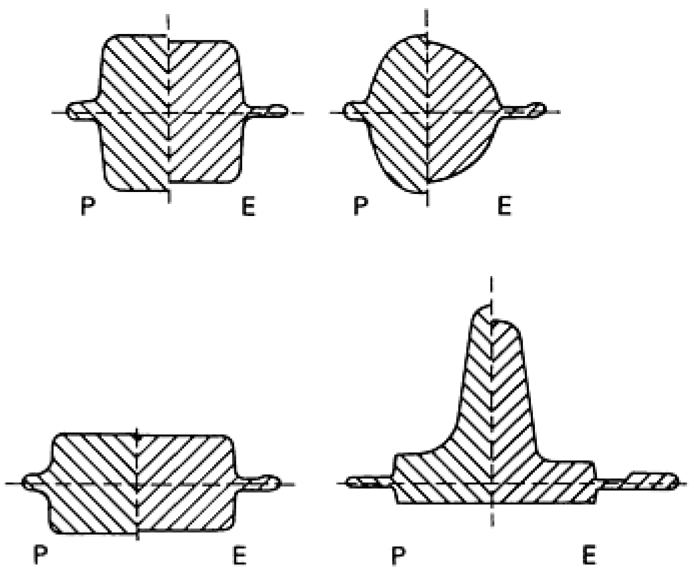

Fig. 17 Examples of suggested preform cross section designs for various steel forging end shapes. P, preform; E, end form. Source: Ref 8

Experimental and Modeling Methods for Preform Design. In order to ensure filling of a die cavity, without any forging defects, a preform of geometry determined by experimentation may be used. In this case, an initial preform geometry is selected based on an "educated guess," the part is forged, and if adequate cavity filling is not obtained, the preform shape is modified by machining or open-die forging until an adequate finishing operation is designed. Once the preform geometry is determined, the preforming dies can be modified accordingly. This trial-and-error procedure may be time consuming and expensive and therefore practical only for rather simple finish shapes.

A more systematic and well-proved method for developing the preform shape is by use of physical modeling, using a soft material such as lead, plasticine, or wax as model forging material, and hard plastic or mild steel dies as tooling. Thus, with relatively low cost tooling and with some experimentation, preform shapes can be determined.

More information on the use of physical modeling is available in the article "Modeling Techniques Used in Forging Process Design" in this Volume.

Location of Impressions

The preform and finisher impressions should be positioned across the die block such that the forging force is as close to the center of the striking force (ram) as possible. This minimizes tipping of the ram, reduces wear on the ram guides, and helps maintain the thickness dimensions of the forging. When the forging is transferred manually to each impression, the impression for the operation requiring the greatest forging force is placed at the center of the die block, and the remaining impressions are distributed as nearly equally as possible on each side of the die block.

Symmetrical forgings usually have their centerline along the front-to-back centerline of the die block. For asymmetrical forgings, the center of gravity can be used as a reference for positioning the preform and finisher impressions in the die block.

The center of gravity of a forging does not necessarily correspond to the center of the forging force, because of the influence of thin sections on the forging force. Because the increase in force is not always directly proportional to the decrease in thickness, both the flash and the location of the thin sections must be considered when locating the impressions in a die block. Evenly distributed flash has little effect on an out-of-balance condition; very thin sections have a marked effect.

When the forgings are automatically transferred from station to station, the impressions must be in operational sequence across the die block. The machine construction usually counteracts the effects of off-center loading.

Multiple-Part Dies

Forging of more than one part in a single die is desirable under certain conditions, including:

- Costs for forging without multiple-part dies are prohibitively high because machine time is long and the proportion of metal lost to flash, sprues, and tonghold is high
- Production requirements are large
- Parting face of the die is uneven, and a balance of forces is needed to avoid incorporating a counterlock in the die
- The forging is so small that it cannot be produced economically in the equipment available

There are conditions, however, under which it is not practical to consider making more than one forging in a single die. These include:

- The parts are too large to be made in multiples in the available equipment
- The parts are too large to be handled more than one at a time
- Production requirements are not sufficient to make full use of the life of a multiple-part die

The above conditions generally cannot be considered singly, because there are many applications for which labor and machine costs, along with savings in metal, may or may not offset the cost of multiple-part dies.

Forgings that are best suited to production in multiple-part dies are those that can be arranged in pairs or other multiples in such a way that the forging forces are balanced. A forging in which the distribution of stock is uneven from one end to another, such as a connecting rod, is an example. When forged singly in a hammer, parts of this type require several blows in fuller and roller impressions, but when forged in multiples, they can be nested, grain flow permitting, to eliminate some of the blows required and to improve the production rate. A second example is a forging that, produced singly, must be made in dies having a single plane of lock (locked dies in which the nonhorizontal parting surface is planar). When such parts are forged in multiples in alternating positions, the forces imparted by the opposing planes of lock can be balanced.

Forgings of uniform section can be made either singly or in multiples. For making such forgings, multiple-part dies are used mainly to reduce per-piece forging costs or to increase the rate of production.

An advantage of multiple-part dies is that by more fully using the machine capacity and operator time they allow a reduction in forging piece costs, even though a larger-capacity forging hammer or press may be required or the machine cycle time may be longer.

The flash allowance for a part made in a multiple-part die is generally less than for a part made in a single-part die.

Dies for Precision Forging

The aircraft industry requires aluminum alloy and titanium alloy airframe forgings that undergo a minimum of machining. The forging industry has responded by developing precision, or no-draft, dies that produce forgings that require little or no machining before assembly.

Dies are being designed and fabricated not only with zero draft, but also with an undercut and closer tolerances. These dies consist of several pieces of steel that lock together to form a single unit. The simplest precision die has only a top and bottom die with a knockout pin to help remove the forging during the forging operation. As the complexity of a forging increases, the design of the die requires more pieces to form the part. The die may consist of two or more pieces to form the outside of the forging (wraps), and a bottom and top punch to form the inside configuration. All of these pieces must fit together--the wraps and the bottom punch, which fits into the wraps to make a bottom die, and top punch, which then fits into the bottom assembly to make a complete set of forging dies (Fig. 18). For the forging operation, the dies are contained in a holder or ring die designed to accept several different precision dies. During the forging operation, the bottom assembly has to separate so that the forging can be removed.

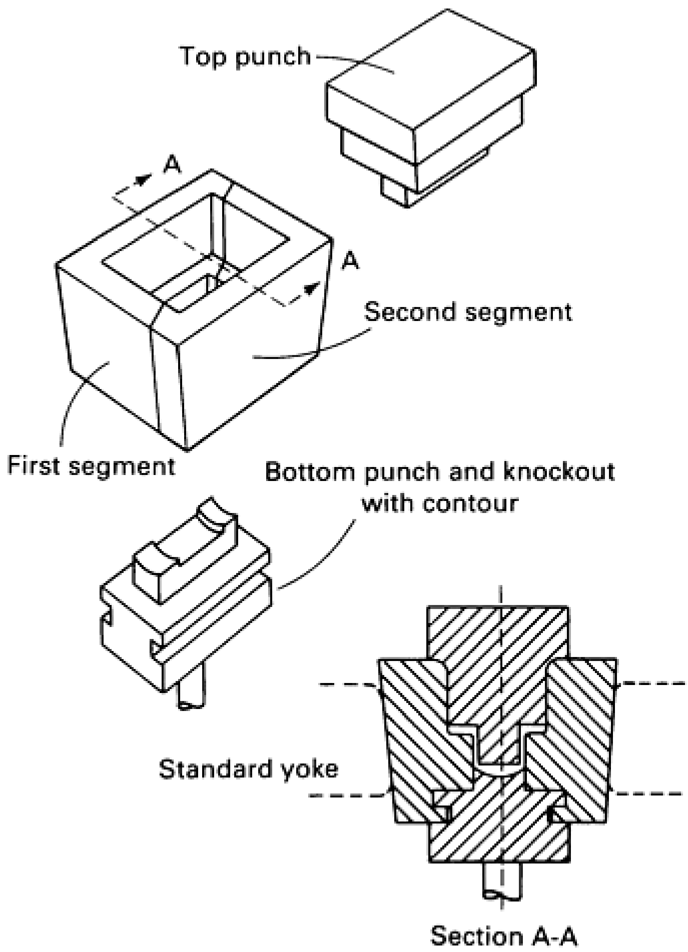

Fig. 18 Typical wrap dies for precision forging

More information on precision forging is available in the articles "Precision Forging," "Forging of Aluminum Alloys," and "Forging of Titanium Alloys" in this Volume.

Fabrication of Impression Dies

Die sinking is a machine trade whereby a craftsman known as a die sinker performs certain steps to produce a forging die. In addition to personal skills, the die sinker needs the appropriate machines and hand tools. As the forging industry has increasingly demanded more complex forgings, the machine tool industry has developed more sophisticated machine tools to facilitate the production of these complex dies. The die sinker still uses the same basic steps that have been used for years, but with new machine tools and refined techniques that permit fabrication of dies that can furnish extremely complex and close-tolerance forgings. The die-making process includes selection of materials for the die; die preparation, taking into consideration the forging machine that will produce that particular forging; design preparation; machining the dies; benching the dies; and taking a cast of the dies.

Quality forging dies are achieved through a blending of the skill and knowledge of both the forging engineer and the die sinker. When the forging design has been completed and approved, the die sinker, after consulting with the designer on any special details of the job, begins the process of sinking the desired impression in the die blocks of alloy steel. Rough die blocks, carefully forged and heat treated, usually are obtained from firms that specialize in their manufacture. Blocks may be purchased in a variety of shapes, sizes, and tempers, depending on the type and size of forging intended and, accordingly, the type and size of equipment to be used. They may range from a few hundred pounds to several tons in weight.

Generally, the die shop begins its work by following this sequence of operations: top, bottom, one side, and one end need to be finish surfaced either on a planer, a milling machine, and/or a surface grinder. All surfaces must be flat, parallel, and 90° to each other. Because of the size and weight of the die block, handling holes are drilled in the ends or sides so that the dies can be handled more easily. The rough blocks are then moved to a planer or planer mill where they are paired as upper and lower die blocks of a die set. Die faces are often ground to a fine finish to obtain a smooth surface for layout work.

After the material has been selected and prepared, the die sinker is given a print of the customer's forging and a die design. He is now ready to sink the die. In order to make the layout lines on the die steel more visible, a solution of copper sulfate or die blue is applied to the face of each die. The outline of the forging is scribed on the face of the dies to the exact dimensions dictated by the drawing. Mold lines are identified first, and the draft lines are added (3°, 5°, 7°, and so forth). Dimensions for the draft are determined by the depths of the impressions. To ensure that impressions in each die match, the layout is located on the dies in relation to the side and end match edges. Special shrink scales are used that are based on the shrink factor of the material to be forged. The design dictates the number of impressions--roller, fuller, edger, cutoff, and gate--in each set of dies.

Layout lines are scribed on each die using a square and a blade protractor, dividers, and a hardened scriber. If it is possible to stand the dies on end or on their sides on a surface plate, a height gage can be used to scribe lines that are parallel to the match edges. This method is very accurate; some tools have digital readouts and a programmable shrink factor. The finishing impression is usually positioned such that its weight center will be aligned as nearly as possible with the center of the hammer or press ram, as measured from all sides. This helps ensure perfect balance in the forging equipment, permits full utilization of maximum ram impact as the forging is in the finishing impression, and eliminates wear-causing side thrusts and pressures during forging. After the layout is finished and checked, the dies are ready for machining of the impression.

The machine tools for die sinking have changed dramatically over the years. The simple vertical milling machine has developed into a very sophisticated machine tool, with hydraulic movement of ram, table, and spindle, having the ability to trace from a template or tracing mold. The impression (cavity) is sunk to within a few thousandths of an inch of its finished part size.

The cutting tools used are fabricated from high-speed tool steel and have two, three, or four flutes (straight or spiral). They may also have angles to produce drafts of 3°, 5°, 7°, and so forth. For heavy flat cutting, a carbide insert cutter is used. As the die sinking begins, the deepest section is cut first with the largest cutter, working progressively to the shallowest section, until all vertical walls are machined. The webs and radii are machined last. The X and Y dimensions are machined according to the scribed lines on the face, with control of the Z dimensions or depth by means of a depth gage or profile template. If the design calls for more than one impression, only the first impression is made until it has been benched and a cast has been submitted for approval. Regardless of when the rest of the operations are completed, the same procedure is used. Flashing and guttering of the dies can be done at either time.

The complexity of some forgings may dictate that a die be fabricated using a wooden pattern of the forging. The pattern is then used to construct a plaster mold that is used to trace the impression into the die. This method requires minimal layout. The dimensions of the impression are determined by the mold.

Finishing of impressions is primarily done by hand with the aid of power hand grinders. All tool marks and sharp corners must be removed, and all vertical and horizontal radii made according to specifications. The surfaces are then polished. Most of the surfaces have been machined within a few thousandths of the finish dimensions; subsequent benching is not done to remove an appreciable amount of stock, but only to polish the surfaces to ensure that they are true in every dimension and free of tool marks, blemishes, and sharp corners. These hand operations help ensure filling of the impression with the least resistance to metal flow during forging. Likewise they minimize abrasive wear on the impressions.

When the bench work on the finishing impression is completed, a parting agent is applied to the surface of the impression to prepare for proofing of the impression. The pair of dies is clamped together in exact alignment, using the matched edges as guides, and the cavity formed by the finishing impression is filled with molten lead, plaster, or special nonshrinking compounds to obtain a die proof. The die proof is then checked for dimensional accuracy. When all dimensions are correct, the die proof is submitted to the customer for approval, if requested.

Other die impressions may then be sunk (to perform edging, fullering, and bending operations), depending on the complexity of the forging. These impressions for preliminary forging operations may also be sunk in a separate set of dies. The arrangement and sequence of preliminary operations differ widely according to variations in practice throughout the forging industry.

Ordinarily, the final machining operations on the faces of a set of dies are performed on the flash gutter. After guttering of dies, dowel pockets are usually milled into one side of the shank of each die block. The dowel pocket accommodates the dowel key, which is inserted by the hammer or press operator to maintain die alignment in the equipment from front to back.

Another close inspection of the dies is generally scheduled as a final precaution. All dimensions of blocking, as well as finishing impressions, are again carefully compared with the blueprint dimensions and specifications.

Extreme care is required in bringing the dies into exact alignment as they are placed in the forging equipment so that forgings will be on match and there will be a minimum of strain on the equipment and wear on the dies. Dies correctly and properly handled are normally capable of producing thousands of uniform forgings of identical shape and size.

An alternative method for sinking dies uses electrodischarge machining (EDM) in place of a vertical mill. This method is used when minimal draft angles and very narrow ribs are required, and it has the ability to produce dies accurately. Also, if several of the same cavities are to be sunk in one die, use of EDM ensures reproducibility.

The machine tool for this method of die fabrication has a hydraulic-powered ram and table. The table is a large tank that is open at the top. All metal removal is done with the die block submerged in a dielectric solution, which is used as a flushing agent to keep the burning area clean. The solution also acts as the carrier for electric current between the electrode and the die block. The solution is constantly circulated through a separate filter system to keep it clean and free of contaminants from the burning operation. A clean solution is necessary for an efficient burn. The electrode never makes contact with the die block as the electric current passes through the dielectric solution to the die block and erodes the die steel to create the impression.

Resinking

Solid dies must be resunk after they have worn out of tolerance. The number of resinkings that can be made in a set of dies is a function of block thickness less maximum depth of impression. For a block of a given thickness, the number of resinkings depends mainly on the depth of the impression. Shallow impressions such as those used for making open-end wrenches or adjustable wrench handles may be resunk as many as six times before the blocks are too thin for further use. With deeper impressions, the number of possible resinkings decreases to one or, in extreme cases, none. In general, the thickness of the block remaining beneath (or above) the impression should be at least three times the depth of the impression. That is, if the impression is 51 mm (2 in.) deep, the total thickness of the block should be at least 203 mm (8 in.). These figures are only approximate, and the thickness required will depend somewhat on the severity of the impression (radii and draft angles) as well as on the depth. For extremely shallow forgings such as thin open-end wrenches, the block thickness should be more than three times the depth of the impression; otherwise, the block might not have enough thickness to provide adequate backing.

For long production runs, some shops resink the dies by small amounts (for example, 1.6 mm, or $\frac{1}{16}$ in.) at shorter intervals instead of waiting until the impression is worn completely out of tolerance and needs a deeper resink.

Cast Dies

Most forging dies are fabricated by machining the impressions in wrought steel (die sinking; see the section "Fabrication of Impression Dies" in this article). For some applications, however, cast dies have proved to be economical alternatives.

Advantages. The principal advantage of cast dies is the savings in diemaking costs that can be effected by minimizing the amount of machining necessary for die fabrication. Usually, only a polishing operation is necessary to finish cast dies. Another advantage of cast dies is improved microstructure over wrought dies, with smaller, more evenly dispersed carbides and less grain-boundary segregation of carbides. Nonuniform carbide distribution in some wrought tool steels can lead to early wear (in areas lean in carbides) and premature heat checking (in areas rich in carbides). A further advantage provided by cast dies is more equiaxed grain structure than wrought products formed by rolling or forging. Grain direction in wrought alloys improves properties in some directions (parallel to the grain) but results in reduced properties transverse to the grain direction. Castings have no grain directionality and therefore display more uniform properties.

Disadvantages. There are also some disadvantages in using cast dies. Sections around the die cavity must be of a fairly uniform thickness to avoid excessive residual stresses in the casting of the die. Also, because of the lower strength of cast dies, the sections around the die cavity must be relatively thick; the dies can therefore become rather massive. Finally, inspection can be difficult; radiographic inspection is virtually the only method available to test for soundness.

Where Cast Dies Are Used. Large cast dies are used when it is not convenient to make the die as a forging either because of its mass or because of a lack of capacity to produce a forging of the required size. Cast dies can be used as inserts when intricate detail is required in the die cavity. Cast dies also are sometimes used for isothermal forging because the alloys used for these dies (for example, nickel-base alloys and TZM molybdenum alloy) are difficult to machine.

Heat Treating

Nominal compositions of chromium- and tungsten-base AISI hot-work tool steels are given in Table 1. The group of steels denoted low-alloy proprietary steels in Table 1 is included here in the discussion of hot-work tool steels because they are also used extensively for hot-work applications. Table 2 summarizes the heat-treating practices commonly employed for this composite group of tool steels.

Note: A, air; O, oil; S, salt.

(a) Holding time, after uniform through heating, varies from about 15 min, for small sections, to about 1 h, for large sections. Work is cooled from temperature in still air.

(b) Lower limit of range should be used for small sections, upper limit should be used for large sections. Holding time varies from about 1 h for light sections and small furnace charges to about 4 h for heavy sections and large charges; for pack annealing, hold for 1 h per inch of pack cross section.

(c) Maximum rate, to 425 °C (800 °F) unless footnoted to indicate otherwise.

(d) For open-furnace heat treatment. For pack hardening, hold for $\frac{1}{2}$ h per inch of pack cross section.

(e) Temper to precipitation harden.

(f) To 370 °C (700 °F).

(g) To 205 to 175 °C (400 to 350 °F), then air cool.

(h) Temper immediately.

(i) For isothermal annealing, furnace cool to 650 °C (1200 °F), hold for 4 h, furnace cool to 425 °C (800 °F), then air cool.

(j) For isothermal annealing, furnace cool to 670 °C (1240 °F), hold for 4 h, furnace cool to 425 °C (800 °F), then air cool.

(k) Cool with forced-air blast to 205 to 175 °C (400 to 350 °F), then cool in still air.

Normalizing. Because these steels as a group are either partially or completely airhardening, normalizing is not recommended.

Annealing. Recommended annealing temperatures, cooling practice, and expected hardness values are given in Table 2. Heating for annealing should be slow and uniform to prevent cracking, especially when annealing hardened tools. Heat losses from the furnace usually determine the rate of cooling; large furnace loads will cool at a slower rate than light loads. For most of these steels, furnace cooling to 425 °C (800 °F), at 22 °C max (40 °F max) per hour, and then air cooling, will suffice.

For types 6F2 and 6F3, an isothermal anneal (Table 2) may be employed to advantage for small tools that can be handled in salt or lead baths or for small loads in batch-type furnaces; however, isothermal annealing has no advantage over conventional annealing for large die blocks or large furnace loads of these steels.

In controlled-atmosphere furnaces, the work should be supported so that it does not touch the bottom of the furnace. This will ensure uniform heating and permit free circulation of the atmosphere around the work. Workpieces should be supported in such a way that they will not sag or distort under their own weight.

Stress Relieving. It is sometimes advantageous to stress relieve tools made of hot-work steel after rough machining but before final machining, by heating them to 650 to 730 °C (1200 to 1350 °F). This treatment minimizes distortion during hardening, particularly for dies or tools that have major changes in configuration or deep cavities. However, closer dimensional control can be obtained by hardening and tempering after rough machining and before final machining, provided that the final hardness obtained by this method is within the machinable range.

Preheating before austenitizing is nearly always recommended for all hot-work steels, with the exception of 6G, 6F2, and 6F3. These steels may or may not require preheating, depending on size and configuration of the workpieces. Recommended preheating temperatures for all the other types are given in Table 2.

Die blocks or other tools for open-furnace treatment should be placed in a furnace that is not over 260 °C (500 °F). Work that is packed in containers may be safely placed in furnaces at 370 to 540 °C (700 to 1000 °F). Once the workpieces (or containers) have attained furnace temperature, they are heated slowly and uniformly, at 85 to 110 °C (150 to 200 °F) per hour, to the preheating temperature (Table 2) and held for 1 h per inch of thickness (or per inch of container thickness, if packed). Thermocouples should be placed adjacent to the pieces in containers. Controlled atmospheres or other protective means must be used above 650 °C (1200 °F) to minimize scaling and decarburization.

Austenitizing temperatures recommended for the hardening of hot-work tool steels are given in Table 2. Rapid heating from the preheating temperature to the austenitizing temperature is preferred for types H19 through H26.

Except for steels H10 through H14 (see Table 2), time at the austenitizing temperature should only be sufficient to heat the work completely through; prolonged soaking is not recommended.

The equipment and method employed for austenitizing are frequently determined by the size of the workpiece. For tools weighing less than about 227 kg (500 lb), any of the methods would be suitable. However, larger tools or dies would be difficult to handle in either a salt bath or a pack.

Tools or dies made of hot-work steel must be protected against carburization and decarburization when being heated for austenitizing. Carburized surfaces are highly susceptible to heat checking. Decarburization causes decreased strength, which may result in fatigue failures. However, the principal detrimental effect of decarburization is to mislead the heat treater as to the actual hardness of the die. To obtain specified hardness of the decarburized surface, the die is tempered at too low a temperature. The die then goes into operation at excessive internal hardness and breaks at the first application of load.

An endothermic atmosphere produced by a gas generator is probably the most widely used protective medium. The dew point is normally held from 2 to 7 °C (35 to 45 °F) in the furnace, depending on the carbon content of the steel and the operating temperature. A dew point of 3 to 4 °C (38 to 40 °F) is ideal for most steels of type H11 or H13 when austenitized at 1010 °C (1850 °F).

Quenching. Hot-work steels range from high to extremely high in hardenability. Most of them will achieve full hardness by cooling in still air; however, even with those types having the highest hardenability, sections of die blocks may be so large that insufficient hardening results. In such instances, an air blast or an oil quench is required to achieve full hardness. Hot-work steels are never water quenched. Recommended quenching media are listed in Table 2.

If blast cooling is used, dry air should be blasted uniformly on the surface to be hardened. Dies or other tools should not be placed on concrete floors or in locations where water vapor may strike them during air quenching.

Some of the hot-work steels will scale considerably during cooling to room temperature in air. An interrupted quench reduces this scaling by eliminating the long period of contact with air at elevated temperature, but it also increases distortion. The best procedure is to quench from the austenitizing temperature in a salt bath held at 595 to 650 °C (1100 to 1200 °F), holding the workpiece in the quench until it reaches the temperature of the bath, and then with-drawing it and allowing it to cool in air. An alternative, but less precise, procedure is to quench in oil at room temperature or slightly above and judge by color (faint red) when the workpiece has reached 595 to 650 °C (1100 to 1200 °F); the piece is then quickly withdrawn and permitted to cool to room temperature in air. While cooling, the piece should be placed in a suitable rack, or be supported by wires, in such a manner as to allow air to come in contact with all surfaces.

Steel H23 requires a different type of interrupted quench, because ferrite precipitates rapidly in this steel at 595 °C (1100 °F), and M_S is below room temperature. This steel should be quenched in molten salt at 165 to 190 °C (325 to 375 °F) and the air cooled to room temperature. This steel will not harden in quenching but will do so by secondary hardening during the tempering cycle.

Parts quenched in oil should be completely immersed in the oil bath, held until they have reached bath temperature, and then transferred immediately to the tempering furnace. Oil bath temperatures may range from 55 to 150 °C (130 to 300 °F), but should always be below the flash point of the oil. Oil baths should be circulated and kept free of water.

Tempering. Hot-work tool steels should be tempered immediately after quenching, even though sensitivity to cracking in this stage varies considerably among the various types. These steels are usually tempered in air furnaces of the forced-convection type. Salt baths are used successfully for smaller parts, but for large, complex parts, salt bath tempering may induce too severe a thermal shock and cause cracking. The effect of tempering temperature on the hardness of chromium-base AISI hot-work tool steels is shown in Fig. 19; the effect of tempering temperature on the hardness of tungsten-base AISI hot-work tool steels is shown in Fig. 20.

Fig. 19 Effect of tempering temperature on hardness of chromium-base AISI hot-work tool steels. See also Fig. 20.

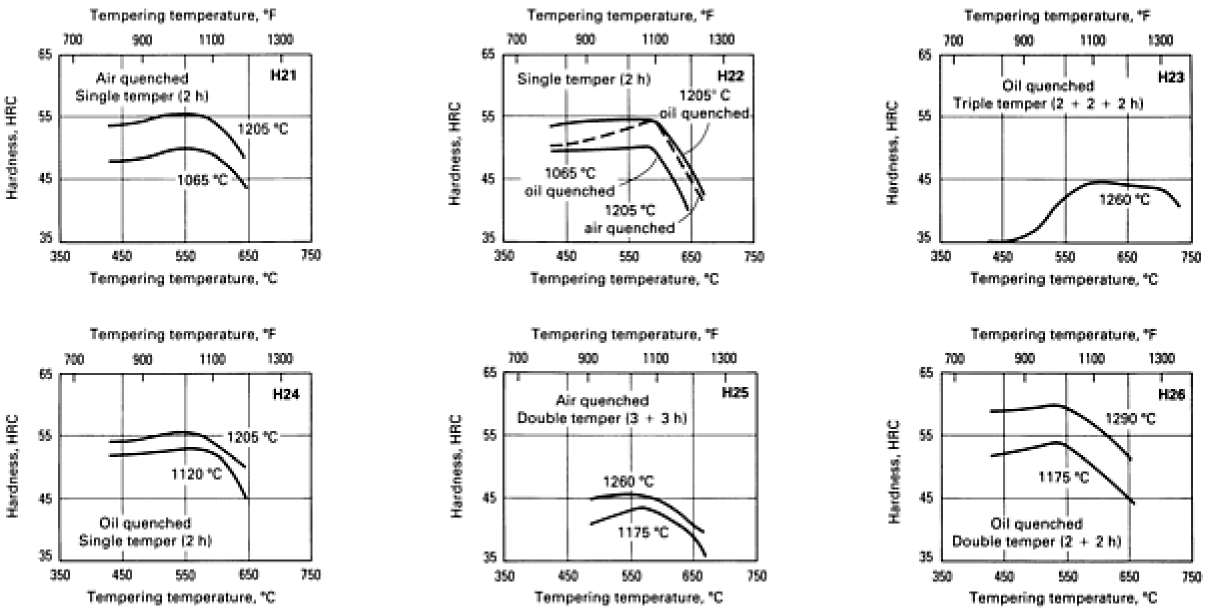

Fig. 20 Effect of tempering temperature on hardness of tungsten-base AISI hot-work tool steels. See also Fig. 19.

Multiple tempering ensures that any retained austenite that transforms to martensite during the first tempering cycle is tempered before a tool is placed in service. Multiple tempering also minimizes cracks due to stress originating from the hardening operation.

Multiple tempering has proved to be particularly advantageous for large or sharp-cornered die blocks that are not permitted to reach room temperature before the first tempering operation.

Trimming and Punching Dies

Trimming is the removal of flash that is produced on the part during the forging operation. Trimming may also be used to remove some of the draft material, thereby producing straight sidewalls on the part. It is usually performed by a top die and bottom die that are shaped to the contour of the part. The top die acts as a punch to push the part through the lower die containing the cutting edge. If the top die does not follow the contour of the part, the part may be deformed during the trimming operation.

An operation similar to trimming is punching, in which excess material on an internal surface is removed. To ensure accurate cuts, punching and trimming operations are often performed simultaneously.

Selection of materials for trimming and punching dies is based on the type of material to be trimmed and whether the part is to be trimmed while hot or cold. Punches are normally made from proprietary tool steels when carbon and stainless steels are to be trimmed, and from 1020 steel that has been hard faced when nonferrous alloys are to be trimmed. The trimming die, or bottom die, can be made from D2 tool steel or from cold-rolled steel that has a high-strength alloy hard facing applied to the cutting edge (see Table 3).

Table 3 Typical materials for trimming and punching dies

Material to be trimmed	**Cold trimming**				Hot trimming[a]	
	Normal trim		**Close trim**			
	Punch	**Blade**	**Punch**	**Blade**	**Punch**	Blade
Carbon and alloy steels	6F2 or 6G at 341 to 375 HB	D2 at 54 to 56 HRC	Generally hot trim		6F2 or 6G at 341 to 375 HB	**Hard facing alloy 4A on 1035 steel[b]; or D2 at 58 to 60 HRC**
Stainless steels and heat-resisting alloys	Generally hot trim		Generally hot trim		6F2 to 6G at 388 to 429 HB	**D2 at 58 to 60 HRC**
Aluminum, magnesium, and	**6150 at 461 to 477 HB**	**Hard facing alloy 4A on 1020 steel[b]; or O1**	**D2 at 58 to 60**	**D2 at 58 to 60**	**1020 soft**	**Hard facing alloy 4A on 1020 steel[b]**

(a) Both normal and close trimming.

(b) Hard facing alloy 4A has nominal composition of Co-1C-30Cr-4.5W-3Ni-1.5Fe.

Dies and Die Materials for Hot Forging

Causes of Die Failure

The three basic causes of premature die failure are overloading of the die, abrasive action, and overheating.

Overloading. Although fewer die failures can be ascribed to overloading than to abrasion or overheating, an overloaded die wears rapidly and may break. Overloading can be avoided by careful selection of die steel and hardness, use of blocks and inserts of adequate size, proper application of working pressures, proper die design to ensure correct metal flow, and proper seating of the dies in the hammer or press. Overloading from inadequate hammer or press capacity should not be compensated for by overheating the work metal.

Abrasive action is inherent in the flow and spreading of hot metal in the impression of a forging die. Abrasion is particularly severe if the design of the forging is complex or in other respects difficult to forge, if the metal being forged has a high hot strength, or if there is scale on the work metal.

Although abrasion cannot be eliminated, its effects can be minimized by good die design (including provision for a smooth progression in the shape of the forging from one die impression to the next, with work in the finisher at the minimum that is practical), careful selection of die composition and hardness, and a forging technique that includes proper heating, any necessary descaling, and correct die lubrication.

Overheating. As a die becomes hotter, its resistance to wear decreases. Overheating causes most of the premature die wear that occurs in forging.

Overheating is likely to occur in areas of the die impression that project into the cavity. In addition, overheating may result from continuous production. If an internal die-cooling system that is adequate to prevent overheating cannot be provided economically, dies, or portions of dies, that are susceptible to overheating should be constructed of steels with high heat resistance.

Cold dies may break in a brittle manner; for this reason, preheating to 260 to 315 °C (500 to 600 °F) is recommended. Preheating may be accomplished by installing heating devices to maintain temperature during idle periods. Inadequate preheating of dies has often resulted in die failure.

Die Life

Die life depends on several factors, including die material and hardness, work metal composition, forging temperature, condition of the work metal at forging surfaces, type of equipment used, workpiece design, and a variety of other factors. Changing one factor almost always changes the influence of another, and the effects are not constant throughout the life of the die.

Die material and hardness have a great influence on die life. A die made of well-chosen material at the proper hardness can withstand the severe strains imposed by both high pressure and heavy shock loads, and can resist abrasive wear, cracking, and heat checking.

Work Metal. Each material being forged has a different resistance to plastic deformation and, therefore, a different abrasive action against the die surfaces. The resistance of hot steel to plastic deformation increases as the carbon or alloy content increases. Other factors being constant, the higher the carbon or alloy content of the steel being forged, the shorter the life expectancy of the forging die.

Of all the work metal factors influencing die life, the temperature of the metal being forged is one of the most difficult to analyze. The surface temperature of the metal as it leaves the furnace can be determined, but unless the proper heating technique has been used, ensuring that the temperature is the same throughout the cross section, the measured temperature will not be an accurate indication of metal temperature. In addition, the time used for performing all the operations involved in forging works against maintenance of the optimum forging temperature. The metal loses heat during transfer from the heating source to the forging machine. Cooling of the metal during forging is accompanied by an increase in its resistance to plastic deformation and, correspondingly, in its abrasiveness.

The life of the finisher impression can be increased by reheating the preform before finish forging. Even though the metal may be hot enough to forge satisfactorily without reheating, forging of cooled metal in the finisher impression may cause premature flash cooling and premature wear of the flash land.

When the temperature of the flash is reduced several hundred degrees and forging is continued, the cushioning effect that otherwise would be provided by freely flowing flash is either greatly reduced or lost completely. If the dies do not crack, they suffer a peening effect on the flash land, which may cause a bulge in the die impression.

Scale is a hard, abrasive substance formed by the combining of iron and atmospheric oxygen on the surface of heated steel, particularly at the high temperatures of hot forging. The amount of scale formed varies with the grade of steel, type of furnace, and the atmosphere, or air-to-fuel ratio, in which the metal is heated. Lifting the forging and blowing the scale away after every blow or every two blows in the hammer or press helps reduce die wear due to scale. Hydraulic descaling, scraping, or using a preforming impression in which the scale is broken reduces die wear.

Workpiece Design. The shape and design of the workpiece often have a greater influence on die life than any other factor. For instance, records in one plant showed that in hammer forging of simple, round parts (near minimum severity), using dies made of 6G tool steel at 341 to 375 HB, the life of five dies ranged from 6000 to 10,000 forgings. In contrast, with all conditions essentially the same except that the workpiece had a series of narrow fibs about 25 mm (1 in.) deep (near maximum severity), the life of five dies ranged from 1000 to 2000 forgings.

In thin sections of a forging, the metal cools relatively rapidly. Upon cooling, it becomes resistant to flow and causes greater wear on the die. Thin sections, therefore, should be forged in the shortest time possible.

Pads or surfaces on the forging designated as tooling points, or those used for locating purposes during machining, should be as far from the parting line as practicable to increase die life. Draft angles in the die cavity and, correspondingly, draft on the part increase as more forgings are made in the die. This is because wear on the die wall is greatest at the parting line, and least on the sidewall at the bottom of the cavity. Maximum wear near the parting line is caused by metal being forced to flow into the cavity and then along the flash land.

Deep, narrow depressions in a forging must be formed by high, thin sections in the die. The life of thin die sections usually is less than that of other die sections, because the thin sections may become upset after repeated use.

Workpiece tolerance also has an influence on die life. Its effect on die life can be demonstrated by assuming a constant amount of die wear for a given number of forgings, assigning different tolerances to a single hypothetical forging dimension, and then comparing the number of forgings that can be made before the tolerances are exceeded. For instance, if a dimension on a forging increased 0.025 mm (0.001 in.) during the production of 1000 forgings and the dimension had a total tolerance of 0.76 mm (0.030 in.), die life would be no greater than 30,000 forgings, assuming a uniform rate of die wear. If the tolerance on the dimension were reduced to 0.5 mm (0.020 in.), all other factors being the same, die life would be reduced to no more than 20,000 forgings.

In assuming a constant rate of die wear, this calculation does not give an accurate reflection of the relation between number of forgings made and amount of die wear. In particular, experience has shown that die wear is not constant during the forging of carbon and alloy steels. The first few hundred forgings cause more wear on the die than an intermediate group of a larger number of forgings. Near the end of the die life, a small number of forgings cause a large amount of die wear. The actual effect of a change in dimensional tolerance on die life therefore depends on the slope of the curve that shows the relationship of die wear to the number of forgings made.

Rapidity and Intensity of Blow. The best die life is obtained when the forging energy is applied rapidly, uniformly, and without excessive pressure. A single high-energy blow does not necessarily result in maximum die life: A blow that is too hard causes the metal to flow too fast and high pressures to develop on the die surfaces. Therefore, if all the energy needed to make a forging is applied in one blow, the dies may split. If the blows are softened, die wear due to pressure may decrease; on the other hand, the increase in number of blows will add to forging time, and the additional time the hot metal is in contact with the lower die can decrease die life. The amount of heat transferred to the dies also can be reduced by stroking the hammer or press as rapidly as practicable.

Computer Applications

Computer-aided design and manufacturing (CAD/CAM) techniques are being increasingly applied in forging technology. Use of the three-dimensional description of a machined part, which may have been computer designed, makes it possible to generate the geometry of the associated forging. For this purpose, it is best to use a CAD/CAM system with software for handling geometry, drafting, dimensioning, and numerical control (NC) machining. Thus, the forging sections can be obtained from a common database.

Using well-proved analyses based on the slab method or other techniques, the forging load and stresses can be obtained and flash dimensions can be selected for each section, permitting metal flow to be regarded as approximately two-dimensional (plane strain or axisymmetric). In some relatively simple section geometries, a computer simulation can be used to evaluate initial estimates on blocker or preform sections. Once the blocker and finisher sections are obtained to the designer's satisfaction, this geometric database can be used to write NC part programs and thereby obtain NC tapes or disks for cutting the forging die (or the die used for EDM of the forging die).

This CAD/CAM procedure is still developing. In the near future, this technology can be expected to evolve in two main directions: handling the geometry of complex forgings, for example, three-dimensional description, automatic drafting and sectioning, and NC machining; and use of design analysis, for example, calculation of stresses in the forging and stress concentrations in the dies, prediction of elastic deflections in the dies, metal flow analysis, and blocker/preform design.

More information on computer applications for forging design, die design, and process modeling is available in the Section "Computer-Aided Process Design for Bulk Forming" in this Volume.

Safety

Flying flash may be a result of faults in die design, including inadequate gutters, incorrect flash land, or incorrect flash clearance. It is a hazard in forging and requires the use of protective equipment. Flash guards on the die and protective clothing are needed to minimize the danger to the operator; movable shields placed in back of the hammer will protect the passerby. Although such devices help to provide protection should flying flash occur, the problem can best be met by careful die construction and, if necessary, by correction in the die.

A hazard in the production of dies for closed-die forging involves the practice of making lead casts (proofs) of die impressions to check die dimensions. Personnel handling the lead must take precautions against lead absorption. Aprons, face shields, goggles, and gloves should be worn. Workers should be trained in personal hygiene precautions specific to the use of lead. Dies should be dry when the molten lead is poured into them, to prevent the formation of steam and the accompanying expulsion of hot metal. Overheating of the lead pot can be avoided by close temperature control. An exhaust system should be installed over the lead pot, and skimmings kept in a container.

References containing information on die safety are included in the list of Selected References on safety at the end of the article "Hammers and Presses for Forging" in this Volume.

Open-Die Forging

Revised by the ASM Committee on Open-Die Forging*; Chairman: Ashok K. Khare, National Forge Company

Introduction

OPEN-DIE FORGING, also referred to as hand, smith, hammer, and flat-die forging, can be distinguished from most other types of deformation processes in that it provides discontinuous material flow as opposed to continuous flow. Forgings are made by this process when:

- The forging is too large to be produced in closed dies
- The required mechanical properties of the worked metal that can be developed by open-die forging cannot be obtained by other deformation processes
- The quantity required is too small to justify the cost of closed dies
- The delivery date is too close to permit the fabrication of dies for closed-die forging

All forgeable metals can be forged in open dies.

Open-Die Forging

Revised by the ASM Committee on Open-Die Forging*; Chairman: Ashok K. Khare, National Forge Company

Size and Weight

The size of a forging that can be produced in open dies is limited only by the capacity of the equipment available for heating, handling, and forging. Items such as marine propeller shafts, which may be several meters in diameter and as long as 23 m (75 ft), are forged by open-die methods. Similarly, forgings no more than a few inches in maximum dimension are also produced in open dies. An open-die forging may weigh as little as a few kilograms or as much as 540 Mg (600 tons).

Open-Die Forging

Revised by the ASM Committee on Open-Die Forging*; Chairman: Ashok K. Khare, National Forge Company

Shapes

Highly skilled hammer and press operators, with the use of various auxiliary tools, can produce relatively complex shapes in open dies. However, the forging of complex shapes is time consuming and expensive, and such forgings are produced only under unusual circumstances. Generally, most open-die forgings can be grouped into four categories: cylindrical (shaft-type forgings symmetrical about the longitudinal axis), upset or pancake forgings, hollow (including mandrel and shell-type forgings), and contour-type forgings. Some examples of the various shapes generated are:

- Rounds, squares, rectangles, hexagons, and octagons forged from ingots, concast material, or billet stock (Example 1), in order to develop mechanical properties that are superior to those of rolled bars or to provide these shapes in compositions for which the shapes are not readily available as as-rolled products. These shapes are usually forged in lengths of 3 to 5 m (10 to 16 ft) and then sawed to obtain desired multiple lengths
- Hub forgings that have a small diameter adjacent to a large diameter (Example 2). Hub forgings are machined into gears, pulleys, and similar components of machinery
- Spindle, pinion gear, and rotor forgings (Examples 3 and 4). These forgings are for shaftlike parts and have their major or functional diameters either in the center or at one end, with one or more smaller diameters extending from one or both sides of the major diameter in shaftlike extensions
- Simple pancake forgings, made by upsetting a length of stock. Finished parts made from these forgings include gears, wheels, and milling cutter and tubesheet blanks
- Forged and pierced blanks, for subsequent conversion to rolled or saddle-forged rings (see Examples 5 and 6). When saddle forging is used to produce symmetrical forgings, the forging process includes expanding in the tangential direction by working on a loose-fitting mandrel bar
- Mandrel forgings to produce symmetrical, long, hollow forgings. The forging process includes expanding in the longitudinal (axial) direction by working on a tight-fitting mandrel (Example 7)
- Various basic shapes that are developed between open dies with the aid of loose tooling. Depending on the design of the tooling, these forgings may be of the open-die type, or they may be closed-die blocker-type forgings. Such forgings are discussed in the article "Dies and Die Materials for Hot Forging" in this Volume
- Contour forgings, such as turbine wheels and pressure vessel components with extruded nozzles and bottleneck-shaped forgings (see the section "Contour Forging" in this article)

Hammers and Presses

Because the length of the hammer ram stroke and the magnitude of the force must be controllable over a wide range throughout the forging cycle, gravity-drop hammers and most mechanical presses are not suitable for open-die forging. Power forging hammers (air or steam driven) and hydraulic presses are most commonly used for the production of open-die forgings that weigh up to 4.5 Mg (5 tons). Larger forgings are usually made in hydraulic presses. Further information on hammers and presses is available in the article "Hammers and Presses for Forging" in this Volume.

Open-Die Forging

Revised by the ASM Committee on Open-Die Forging*; Chairman: Ashok K. Khare, National Forge Company

Dies

Most open-die forgings are produced in a pair of flat dies--one attached to the hammer or to the press ram, and the other to the anvil. Swage dies (curved), V-dies, V-die and flat-die combinations, FM (free from Mannesmann Effect) dies and FML (free from Mannesmann Effect with low load) dies are also used. The Mannesmann Effect refers to a tensile stress state as a result of compressive stresses in a perpendicular orientation. These die sets are shown in Fig. 1. In some applications, forging is done with a combination of a flat die and a swage die. The dies are attached to platens and rams by either of the methods shown in Fig. 1(a) and (b). Figure 1 also shows several types of dies that are held on the anvil manually by means of handles similar to those on the cutting and fullering bars shown in Fig. 4. Information on die materials, die parallelism, and die life for open-die forging is presented in the article "Dies and Die Materials for Hot Forging" in this Volume.

Auxiliary Tools

Mandrels, saddle supports, sizing blocks (spacers), ring tools, bolsters, fullers, punches, drifts (expansion tools), and a wide variety of special tools (for producing shapes) are used as auxiliary tools in forging production. Because most auxiliary tools are exposed to heat, they are usually made from the same steels as the dies.

Saddle Supports. An open-die forging can be made with an upper die that is flat, while the lower die utilizes another type of tool. Two or more hammers or presses and die setups are often needed to complete a shape (or operations are done at different times in the same hammer or press by changing the tooling). For example, large rings are made by upsetting the stock between two flat dies, punching out the center, and then saddle forging (Examples 5 and 6). As shown in Fig. 2, the lower die is replaced by a saddle arrangement that supports a mandrel inserted through the hollow workpiece.

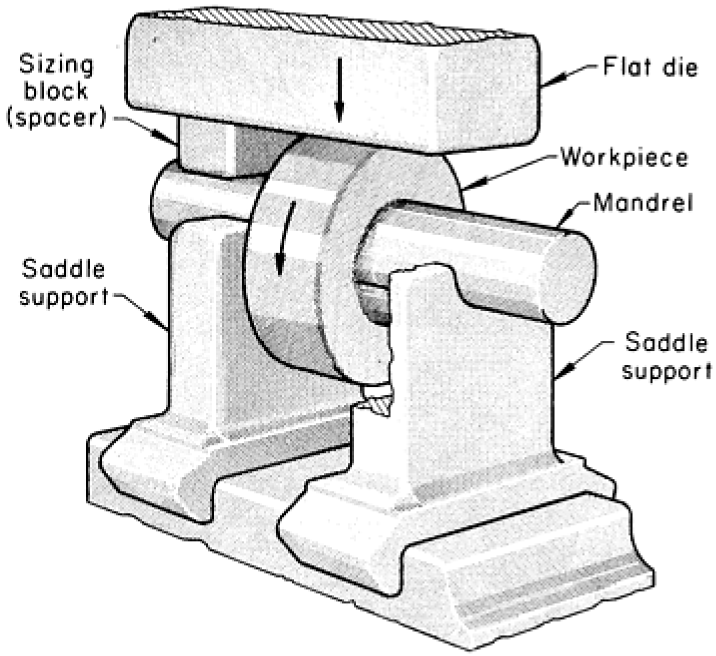

Fig. 2 Setup for saddle forging a ring

Sizing Blocks. A sizing block can be used between the mandrel and the ram to prevent the cross section of the workpiece from being forged too thin. Most state-of-the-art presses have automatic sizing or thickness controls.

Bolsters. The open-die forging of hubs requires a bolster (Example 2). Hub forgings are forged to the shape shown in Fig. 13, Operation 2. A bolster is then placed on the lower die, the smaller diameter of the workpiece is inserted into the bolster, and the larger diameter is upset. Depending on the size and shape of the workpiece, it may be necessary to remove the lower die and to use the anvil to support the bolster.

Ring Tools. A tonghold can be retained on a forging so that the forging can be more easily handled after upsetting, as shown in Fig. 3. A ring tool with a center opening is placed on the workpiece. During the upsetting, the hot work metal at the ring tool opening is protected from being upset, and it is back extruded to a tonghold with a length equal to the thickness of the ring tool. Alternatively, the tonghold can be forged on one end of the workpiece prior to upsetting; a hole in the lower die protects the tonghold during the upsetting operation.

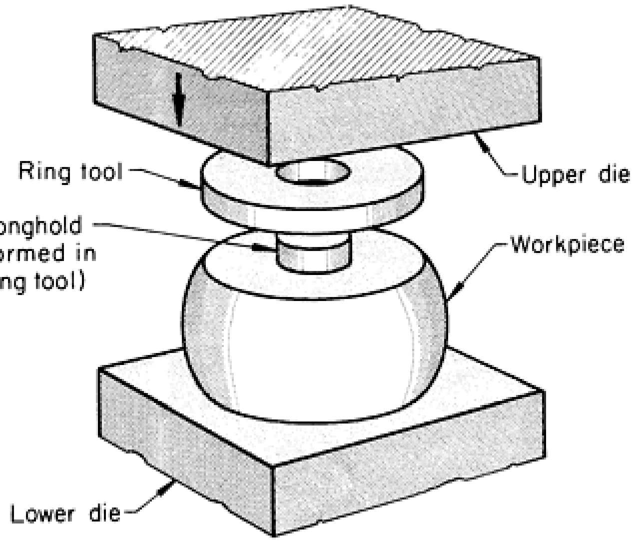

Fig. 3 Setup showing use of a ring tool for forming and retaining a tonghold in the workpiece during upsetting

Fullers are required for starting stepped-down diameters on workpieces such as spindle forgings. They are often used in pairs (see Example 3). Figure 4 illustrates some of the commonly used cutting and fullering bars.

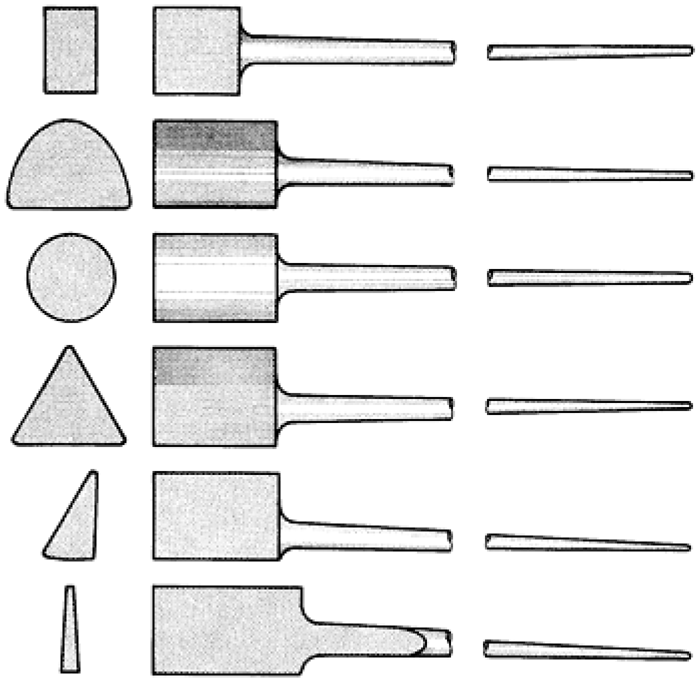

Fig. 4 Cutting and fullering bars

Mandrels are used to produce long, symmetrical, hollow forgings. The workpiece is elongated in the longitudinal (axial) direction while positioned on the mandrel and is worked between the top flat die and bottom V-die combination (Example 7). The mandrel has a slight taper on the outside diameter in order to facilitate removal of the finished hollow forging. In addition, a 25 to 50 mm (1 to 2 in.) hole in the center helps to provide water cooling of the mandrel inside diameter in order to avoid the hot forge welding of the workpiece onto the mandrel. The length and outside diameter of the mandrel bar is governed by the inside diameter and the length of the hollow forging.

Punches. To make holes, punches are placed on the hot workpiece and are driven through, or partly through, by a ram. A hole can also be made by punching from both sides (Example 5). Relatively deep holes can be produced by punching from both sides until only a thin center section remains.

Hot trepanning is done to produce a hole through the center of a large cross section, large-mass workpiece. A circular cutter having an outside diameter of the same size as the desired hole and measuring about 25 mm (1 in.) in wall thickness and about 203 mm (8 in.) in height is initially positioned and pushed into the hot workpiece by the top die while the workpiece is sitting on a lower die with a hole in it. The hot-trepanning operation is continued by pushing the followers through the workpiece.

These followers have the same inside diameter as the cutter, but a slightly smaller outside diameter (~13 mm, or $\frac{1}{2}$ in. smaller). The followers are locked into position prior to being pushed into the hot workpiece. The length of the followers varies and is based on the length of hot trepanning desired. This hot-trepanning length could be made up by using one or more multiple followers.

Open-Die Forging

Revised by the ASM Committee on Open-Die Forging*; Chairman: Ashok K. Khare, National Forge Company

Handling Equipment

The handling of workpieces is often more difficult in open-die forging than in closed-die forging. Usually, the workpieces are heavier, and they must be repositioned many times during the forging cycle.

In practice, small forgings weighing up to about 45 kg (100 lb) are handled with tongs by the forging crew, or a small floor manipulator can be used. Larger forgings weighing up to about 910 kg (2000 lb) are usually handled by floor manipulators and, less frequently, by special tongs or porter bars. Forgings weighing more than 910 kg (2000 lb) are handled by large mobile manipulators, by manipulators on tracks, or by porter bars in conjunction with overhead cranes. Ingots that are forged into bars or billets are usually handled by a balancing porter bar and an overhead crane.

Electric overhead traveling cranes with special lifting devices are used to transport billets and semifinished forgings to and from the heating furnaces and to and from the forging machines. At the forging machine, several different types of equipment are available for moving the workpiece. One is an electric crane that carries a turning gear suspended from the main hoist. The turning gear consists of a frame carrying a drum that can be rotated by an electric motor through gearing. An endless chain, called a sling, constructed of flat links and pins, passes over the drum and moves with it. This device is also called a rotator.

Porter Bars. Another handling device is the porter bar. It has a hollow end that is shaped to fit the sinkhead of the billet being forged or some portion of the workpiece. The load, represented by the workpiece and porter bar, is balanced on the sling at the center of gravity of the combined load. The sling is occasionally moved to preserve the balance as the dimensions of the forging change. Figure 5 shows a porter bar and a sling used for handling a large forging.

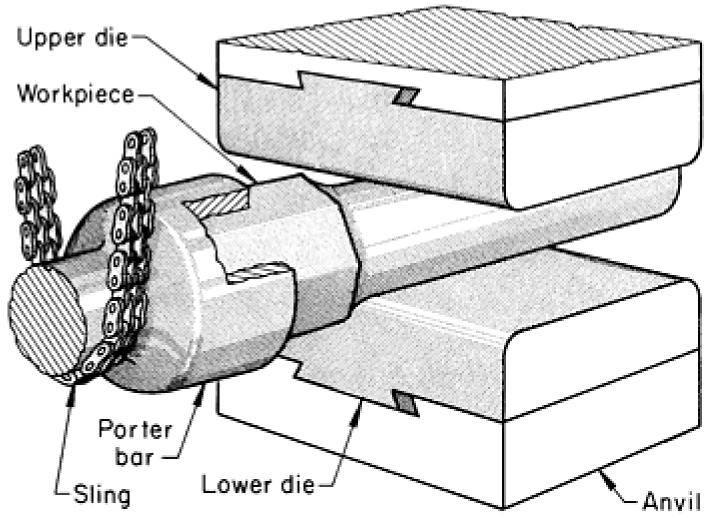

Fig. 5 Handling a forging by means of a porter bar and a sling.

Manipulators. Faster and more accurate handling of hot workpieces is accomplished by manipulators. These machines are equipped with powerful tongs at the end of a horizontal arm that can be moved from side to side, raised or lowered, tilted, and rotated about its longitudinal axis. Large manipulators travel on tracks (track-bound) between the furnace and the forging hammer or press, and they can handle workpieces weighing up to 68 Mg (75 tons). Small manipulators move on rubber-tired wheels. State-of-the-art manipulators include both manned and unmanned operations. Unmanned operations are frequently controlled by the press operator and incorporate programmable positioning and manipulating sequences.

Open-Die Forging

Revised by the ASM Committee on Open-Die Forging*; Chairman: Ashok K. Khare, National Forge Company

Production and Practice

Stock for smaller open-die forgings is usually prepared by cold sawing to a length that is computed to contain the required weight and volume of material. Allowance is made for dimensional variations in the cross section of the billet stock. Stock is sometimes sheared to length, but the upper limit that can be sheared is about 152 mm (6 in.) square or round. Large open-die forgings are commonly forged from ingots. Large ingots are sometimes used to produce two or more forgings in which the individual forgings are parted by cutting (cold or hot), burning, or machining. When ingots are used, an additional weight allowance is usually provided for the removal of end defects, such as shrinkage, porosity, and pipe.

Blocking and Upsetting. The first step in the forging process usually consists of elongating the ingot along its longitudinal axis. This process has been referred to as blocking, cogging, solid forging, elongation forging, or drawing out. However, some forging ingots--particularly small electroslag remelted and vacuum arc remelted ingots, which are usually free from solidification porosity--are direct upset forged. Upsetting is a hot-working process done with the ingot axis in a vertical position under the press. This operation decreases the axial length of the ingot and increases its cross section. As discussed later in this article, both blocking and upsetting are sometimes used to produce certain forging shapes.

Heating practice for the forging stock is the same in open-die and closed-die forging (see the article "Closed-Die Forging in Hammers and Presses" in this Volume). Large ingots, blooms, or billets of alloy steels such as AISI 4340 should be heated carefully in order to minimize decarburization and to avoid cracking due to rapid heating. Preheating can be used to minimize cracking.

Die temperature is usually less critical in open-die than in closed-die forging. Flat dies are usually not preheated (forgings composed of aluminum and nonferrous alloys are the exception). Swage or V-dies, if they have become completely cold (as from a weekend shutdown), are sometimes warmed, particularly for hammer operations. Die heating or warming can be accomplished by closing the dies on slabs of heated steel (warmers). Any cooling of the open dies is incidental and results from the compressed air or high-pressure water spray used in descaling the forging in process or from the ambient temperature of the forge shop.

Lubrication is usually not required for open-die forging except in those loose tooling applications in which metal flow is problematic. Lubrication is sometimes used for the upsetting operation in order to eliminate the dead zone (undeformed material) directly under the dies. This is especially critical for materials that cannot be refined through phase transformation, such as austenitic stainless steels, aluminum alloys, and nickel-base alloys. Lubrication is also used in mandrel forging and in contour forming to improve metal flow (such as for nozzle extrusion and certain pressure vessel components that are contour formed).

Descaling of the workpiece is done by busting and blowoff, as in some closed-die operations (see the article "Closed-Die Forging in Hammer and Presses" in this Volume). Best practice includes the use of compressed air to blow away the scale as it breaks off. High-pressure water is also sometimes used to loosen scale, especially at hard-to-reach locations, such as the inside diameter of a mandrel forging. Failure to remove the scale causes it to be forged in, resulting in pits and pockets on the forged surfaces. The total amount of scale formed in open-die forging is usually greater than in closed-die forging because the hot metal is exposed to the atmosphere for a longer time; that is, open-die forgings usually require more forging strokes and sometimes require reheating. Metal loss through scaling usually ranges from 3 to 5%. For certain types of forgings, such as back extrusions, the descaling time is critical in terms of forgeability because the temperature of the forging can drop dramatically during prolonged descaling, resulting in a loss in forgeability.

Hammer/Press Practice. Unlike closed-die forging, in which the metal in the entire forging is worked at the same time, open-die forging involves the working of only a portion of the forging. Therefore, a given hammer or press can produce open-die forgings of greater weight and size than a hammer or press of equivalent rating in closed-die work, but at a lower production rate.

Hammer and press practice vary considerably from one open-die shop to another. For example, in one shop, a hammer may make three times as many blows per hour as a similar hammer in another shop, yet each shop may be using the equipment efficiently in terms of the nature of the work, the capacity of the furnaces and other equipment, and the size of the crew. In addition, different shops may make the same shape in different steps. For instance, in Example 5, a square billet was pancaked, shingled to an octagonal shape, and then rounded. Another shop might make this disk by breaking the corners of the square billet to obtain an octagonal shape, which would then be pancaked to a disk.

Revised by the ASM Committee on Open-Die Forging*; Chairman: Ashok K. Khare, National Forge Company

Ingot Structure and Its Elimination

Ingots are extensively used as forging stock in the open-die forging of large components, such as the turbine rotor described in Example 4. Whenever ingots are used, it is desirable (and often mandatory) to adopt a forging procedure that will remove the cast structure (ingotism) in the finished forging. Figure 6 shows a schematic cross section of a large ferrous forging ingot. Because of the large diameter of heavy forging ingots (up to 4.1 m, or 160 in.), the solidification process is extremely slow, often taking as long as 2 to 3 days. Unfortunately, the slow cooling rate causes considerable macrosegregation, especially in the ingot center toward the top of the ingot. Consequently, the center of the ingot must be mechanically worked during the forging operation to redistribute the segregated elements and to heal internal porosity (Ref 2).

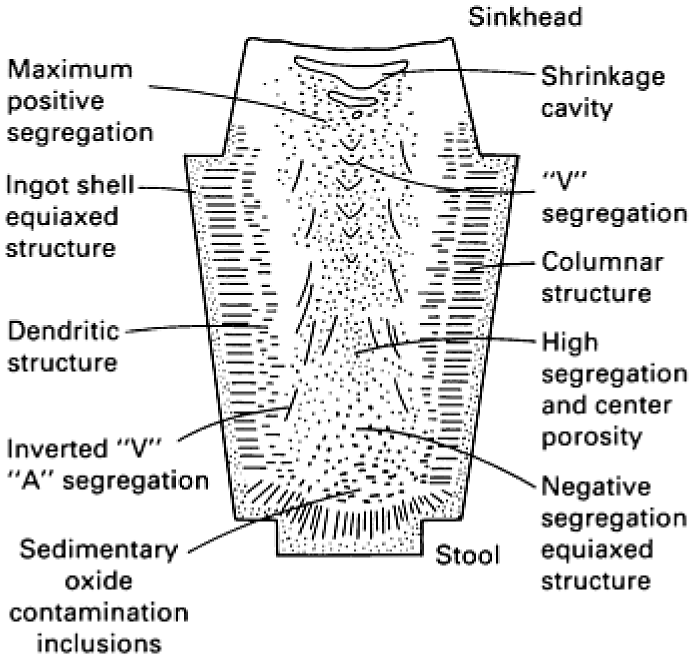

Fig. 6 Schematic illustrating macrosegregation in a large steel ingot. Source: Ref 1.

The segregated regions are usually associated with a coarse dendritic structure; therefore, breaking up these regions by using hot deformation leads to refined microstructures. Compression of the dendritic arms reduces the local diffusion distance, which can enhance homogenization during subsequent heat treatment. Repeated hot deformation also causes grain refinement through static and/or dynamic recrystallization of the austenite. Finer austenitic grain sizes promote finer microstructures during subsequent transformation to ferrite, pearlite, and bainite or martensite or both. Finer microstructures lead to more uniform mechanical properties and, in general, improved tensile properties coupled with greater toughness. However, nonuniform hot deformation can lead to undesirable duplex microstructures, that is, mixed fine and coarse grain size/transformation products. Segregated regions containing higher alloy concentrations can also lead to nonuniform recrystallization and grain growth.

Various approaches are available for minimizing the undesirable effects of segregation. In some forgings, the centerline is actually removed from the finished product in the form of a core bar by machine trepanning. This is permissible for some symmetrical rotating machinery; however, many forgings are not symmetrical, and the center region cannot be removed. In these cases, the thermal and thermomechanical treatments must be optimized in order to redistribute the solute elements. Long homogenization treatments at temperatures approaching 1290 °C (2350 °F) are frequently conducted to allow some diffusion of alloying elements. However, redistribution (homogenization) of the substitutional solid-solution elements, such as manganese, silicon, nickel, chromium, molybdenum, and vanadium, would require several weeks at temperature, which is far too long to be economically feasible. The other alternative is to put as much hot work as possible into the segregated regions.

Hot deformation in the center of the ingot is enhanced when there is a temperature gradient from the surface to the center of the ingot (Ref 3, 4, 5). Under certain circumstances in production, ingots are deliberately air cooled from the soaking temperature before forging. The cooler surface regions, having a higher flow stress, translate the forces of the draft (percentage of reduction) to the center of the ingot, thus increasing centerline consolidation.

Transformation of the initial cast structure into a fully wrought structure requires extensive hot working in the form of successive reduction of cross section, enlargement of cross section by upsetting, and an additional reduction of cross section. Therefore, in Example 4, the principal section of the rotor forging was enlarged by upsetting in Operation 3, Position 1, and was then reduced by almost 30% in Operation 3, Position 2. This seemingly circuitous procedure helps to break up the cast structure and to eliminate ingotism throughout the section.

The development of substantial deformation at the center of the ingot, bloom, or billet to break up the cast structure and to heal any porosity depends on the press capacity and on the relationship between die width and stock height (*w*/*h*). If the press capacity is small and if die width is narrow, the penetration, or depth of deformation, will be small. The width of the draw-out dies should be at least 60% of the stock height in order to ensure adequate centerline deformation (Ref 6). The die width and depth of penetration (percentage of the reduction, or draft size) have a significant influence on the size of the press used for open-die forging. Although billets cut from wrought bars are normally free of ingotism, they can be given additional hot working (more than the minimum required to develop contour) in order to refine the structure and to impose a more desirable flow pattern than that inherent in the original billet or in the wrought product.

Open-Die Forging

Revised by the ASM Committee on Open-Die Forging*; Chairman: Ashok K. Khare, National Forge Company

Forgeability

Metals and alloys vary in forgeability from highly forgeable to relatively brittle. Relative forgeability is indicated below for metals and alloys used in open-die forging:

Most forgeable
Aluminum alloys
Magnesium alloys
Copper alloys
Carbon and low-alloy steels
Martensitic stainless steels
Maraging steels

Austenitic stainless steels
Nickel alloys
Semiaustenitic PH stainless steels
Titanium alloys
Iron-base superalloys
Cobalt-base superalloys
Niobium alloys
Tantalum alloys
Molybdenum alloys
Nickel-base superalloys
Tungsten alloys
Beryllium alloys
Least forgeable

Open-Die Forging

Revised by the ASM Committee on Open-Die Forging*; Chairman: Ashok K. Khare, National Forge Company

Deformation Modeling

The ability to predict material flow, energy requirements, and forming loads is very helpful in facilitating design or operations in open-die forging. The maximum force developed in forging will determine the size of the hammer or press required and will set the limits for the elastic distortion permissible for the forging equipment to be used. The energy requirement will determine whether a given forging can be made on an available hammer or press. The design of a forging practice for an open-die forging involves the selection of certain parameters to be used, such as die dimensions and shapes, amount of reduction, ingot shape, temperature gradient, ram velocity, and pass sequence. The development of forging practices through full-scale production trials is expensive and time consuming. In addition, only minimal internal strain data can be collected. Therefore, both mathematical and physical modeling are applied to provide design criteria and to gain a better understanding of open-die forging operations.

Mathematical Modeling. The forging process can be understood with the aid of a series of theoretical approaches in the field of metalworking. Elementary plasticity theory (Ref 7, 8) is used to provide a series of relationships that can yield an estimation of the force and energy requirements for such forging operations as upsetting and blocking. If the correct coefficient of friction can be selected, such relationships permit an accurate estimation of the force and energy requirements (Ref 9).

Slip-line theory is used to obtain deformation information relating to localized stress states. This permits precise statements to be made concerning stress states in the center of the forged ingots (Ref 10). The disadvantage of this theoretical method lies in its assumption that the metal used in hot forging behaves as an ideal rigid-plastic material, which is usually not the case. Therefore, this technique is incapable of describing such an effect as the influence of bite displacement on stress state. On the other hand, the upper bound method seeks to compensate for the lack of information on the actual material flow by assuming a velocity field and by optimizing the performance without stress consideration (Ref 11, 12). The disadvantage of this method is that the assumed velocity field becomes extremely complex if all of the kinematic parameters are to be satisfied.

Because precise knowledge of the stress and deformation history of a workpiece is necessary to determine its real formability during forging, the computational procedure of the finite-element method appears to have the best prospects for simulating forging processes. The use of the finite-element method as a numerical analysis tool has dominated this field and remains the most popular method for deformation modeling. In two dimensions, a variety of problems can be explained and simulated, such as the progress of centerline penetration or comparisons between two forging processes (Ref 13), the design of upsetting and ring compression tests (Ref 14, 15, 16, 17), and the influence of selected forging parameters on the final quality of the forge products (Ref 18, 19).

In general, the theoretical methods used to predict forces and other performance variables are based on certain assumptions (ideal conditions) that deviate to some degree from the actual forging process. In addition, their reliability and effectiveness are strictly dependent on how smoothly a forging process proceeds. However, as soon as the workpiece is of any complexity (that is, any deviation from the ideal), this method fails. Therefore, calculated values are usually considerably higher or (depending on the conditions and forging process) lower than the measured values. One reason for this discrepancy is related to the temperature gradients developed during forging. In addition, strain rates vary during various parts of the forging stroke, and it is difficult to choose a true representative strain rate and corresponding yield stress at the estimated average temperature. For all of these reasons, calculation of the force and energy requirements on a theoretical basis is still in its infancy.

Both private and government-sponsored research efforts are making progress toward the goal of providing modeling techniques that are useful to the open-die forging industry. In addition, heuristic or artificial-intelligence expert systems are being developed to apply new open-die technology processes and designs. More detailed information can be found in the Section "Computer-Aided Process Design for Bulk Forming" in this Volume.

Physical Modeling. Because of the above disadvantages associated with the use of theoretical modeling methods, physical modeling is often employed. Physical modeling can often provide deformation information that would otherwise be inaccessible or too expensive to obtain by other techniques; this makes physical modeling a powerful tool for the study of forging practices. As its name implies, physical modeling involves changing some physical aspect of the process being studied, such as the size or the material being deformed. In doing so, however, some properties of the original material or the process or both are sacrificed in order to bring the relevant properties more clearly into focus. Nonetheless, if the modeling material employed is homogeneous, isotropic, and obeys the laws of similitude and if the boundary conditions, especially friction and tool geometry, are met in the physical modeling experiment, then excellent qualitative and sometimes quantitative results can be achieved (Ref 20).

Among the various metallic (steel, aluminum, and lead) and nonmetallic (wax and plasticine) modeling materials, plasticine, a particular type of modeling clay, is probably the most widely used for studying open-die press processes (Ref 21, 22, 23, 24, 25, 26, 27, 28, 29). There are several advantages to using plasticine as a modeling material. First, plasticine is readily available, inexpensive, and nontoxic. Second, plasticine deforms under low forces at room temperature, thus considerably simplifying the experimentation and allowing the use of low-cost tooling and equipment. Third, two-color models are feasible for studying internal material flow. Fourth, plasticine exhibits dynamic deformation properties that are similar to those of steel at high temperature. Lastly, plasticine is able to provide quantitative information with respect to the deformation distribution by means of specially designed layered specimens.

Physical modeling with plasticine and lead is extensively used to develop processes for new products and to improve existing manufacturing techniques for better economical processes in various types of open-die forgings. In blocking, such parameters as die width, die configuration, die overlapping, die staggering ingot shape, temperature gradient, and draft design can be optimized to maximize the internal deformation for better structural homogeneity and soundness of material in the core of the ingot (Ref 26, 27). Figures 7 and 8 show the effects of temperature gradient and draft design, respectively, on the centerline deformation distribution for square cross-sectional ingots subjected to multiple-stroke blocking (Ref 27).

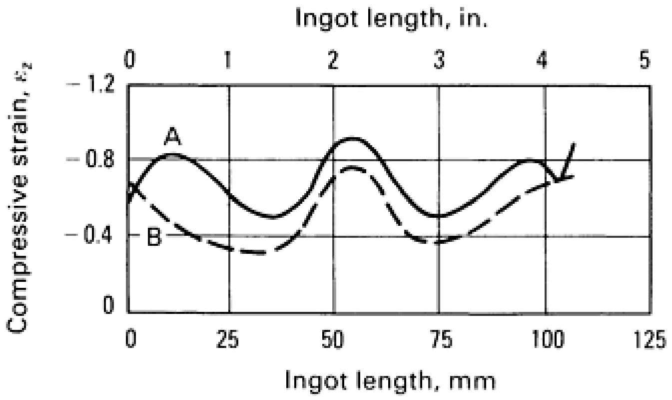

Fig. 7 Effect of temperature gradient using scaled 2.79 × 2.79 × 3.86 m (110 × 110 × 152 in.) ingots, 1.52 × 1.83 m (60 × 72 in.) flat conventional dies, and a 24% reduction. A, with temperature gradient; B, without temperature gradient

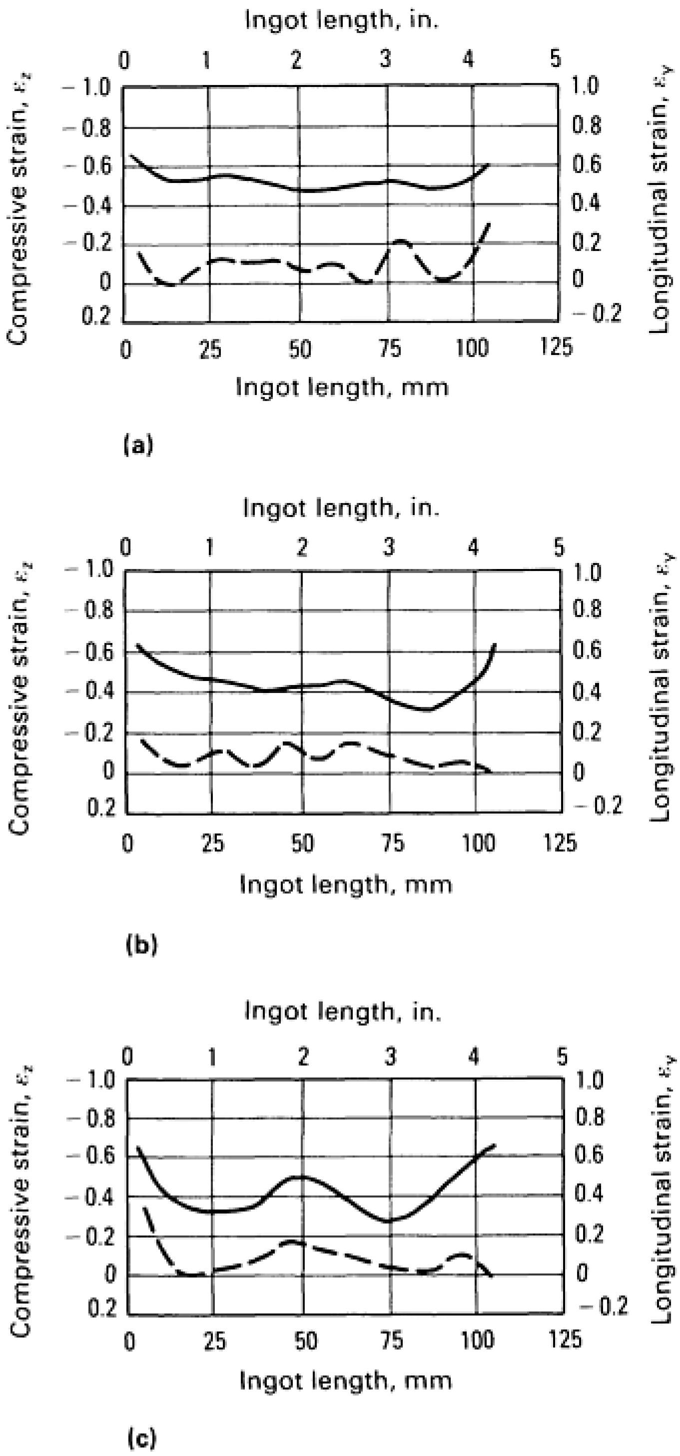

Fig. 8 Effect of draft design on the compressive strain distribution. Solid line indicates compressive strain; broken line, longitudinal strain. (a) 5% reduction increments. (b) 8% reduction increments. (c) 10% reduction increments

In upsetting, the influence of selected parameters such as aspect ratio, crosshead speed, ingot chuck, spreading, indenting, and dished dies versus upsetting dies on the internal deformation distribution can be effectively studied through physical modeling (Ref 28). Figure 9 shows the influence of various aspect ratios on the compressive strain distribution from the top to the bottom of the upset-forged ingot (Ref 28). The influence of these blocking and upsetting parameters on void closure can be determined by providing artificial holes inside plasticine or lead ingots (Ref 29, 30).

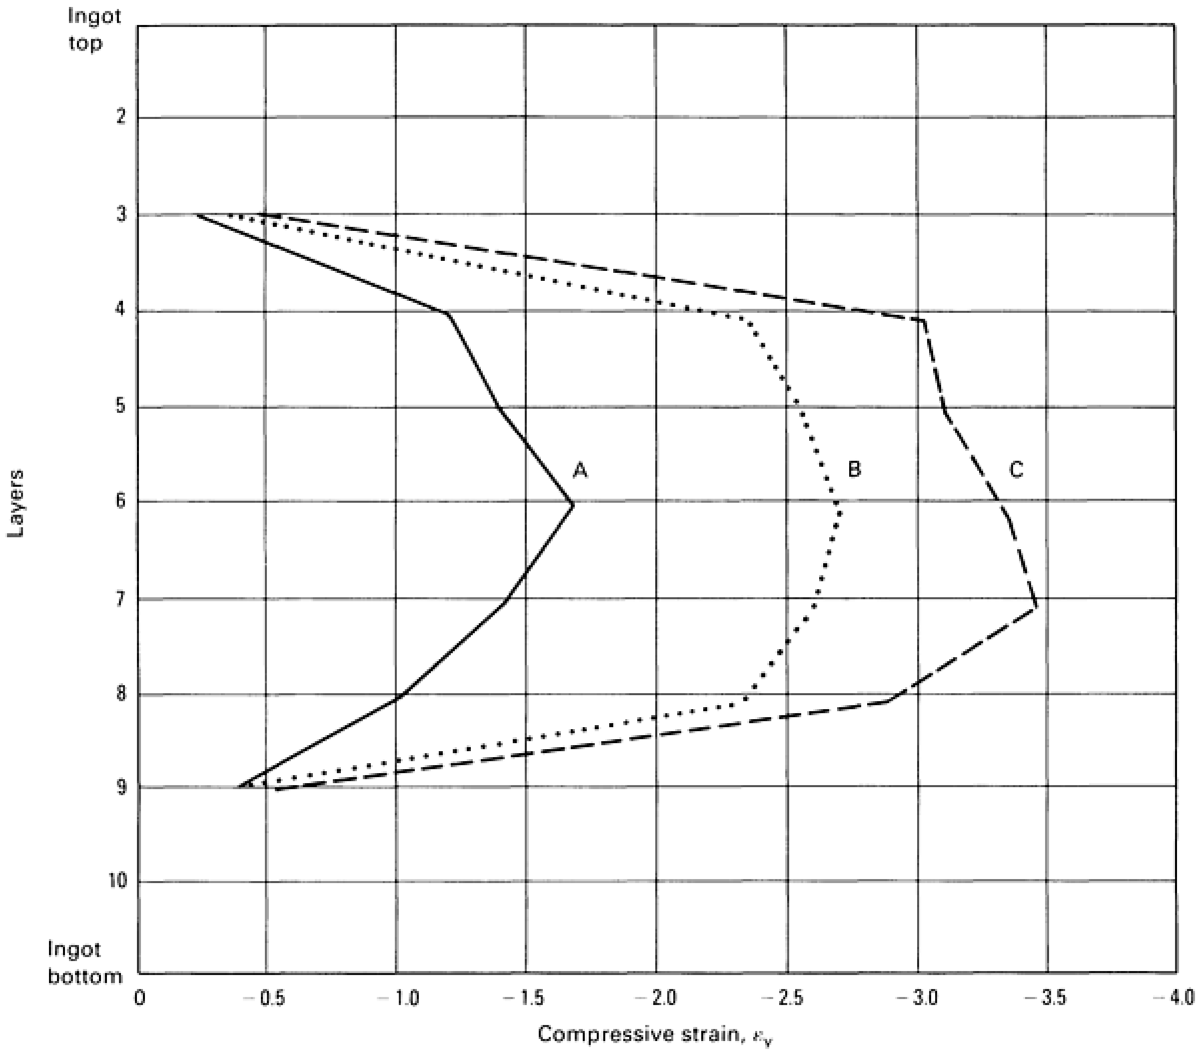

Fig. 9 Effect of aspect ratio (H/D) on compressive strain distribution in plasticine ingots. A, 1.0 ratio; B, 1.5 ratio; C, 2.0 ratio

The application of physical modeling to forged products has led to improvements in yield and quality and cost savings. Additional information is available in the Section "Computer-Aided Process Design for Bulk Forming" in this Volume.

Open-Die Forging

Revised by the ASM Committee on Open-Die Forging*; Chairman: Ashok K. Khare, National Forge Company

Examples of Production Practice

Because of differences in equipment and operator skill, procedures for open-die forging vary considerably from plant to plant. Figure 10 shows typical steps in the drawing and forging of stock and in the fabrication of common shapes from billets of square, rectangular, and round cross sections. The procedures described in the following examples are typical of those used for the production of some common open-die forgings.

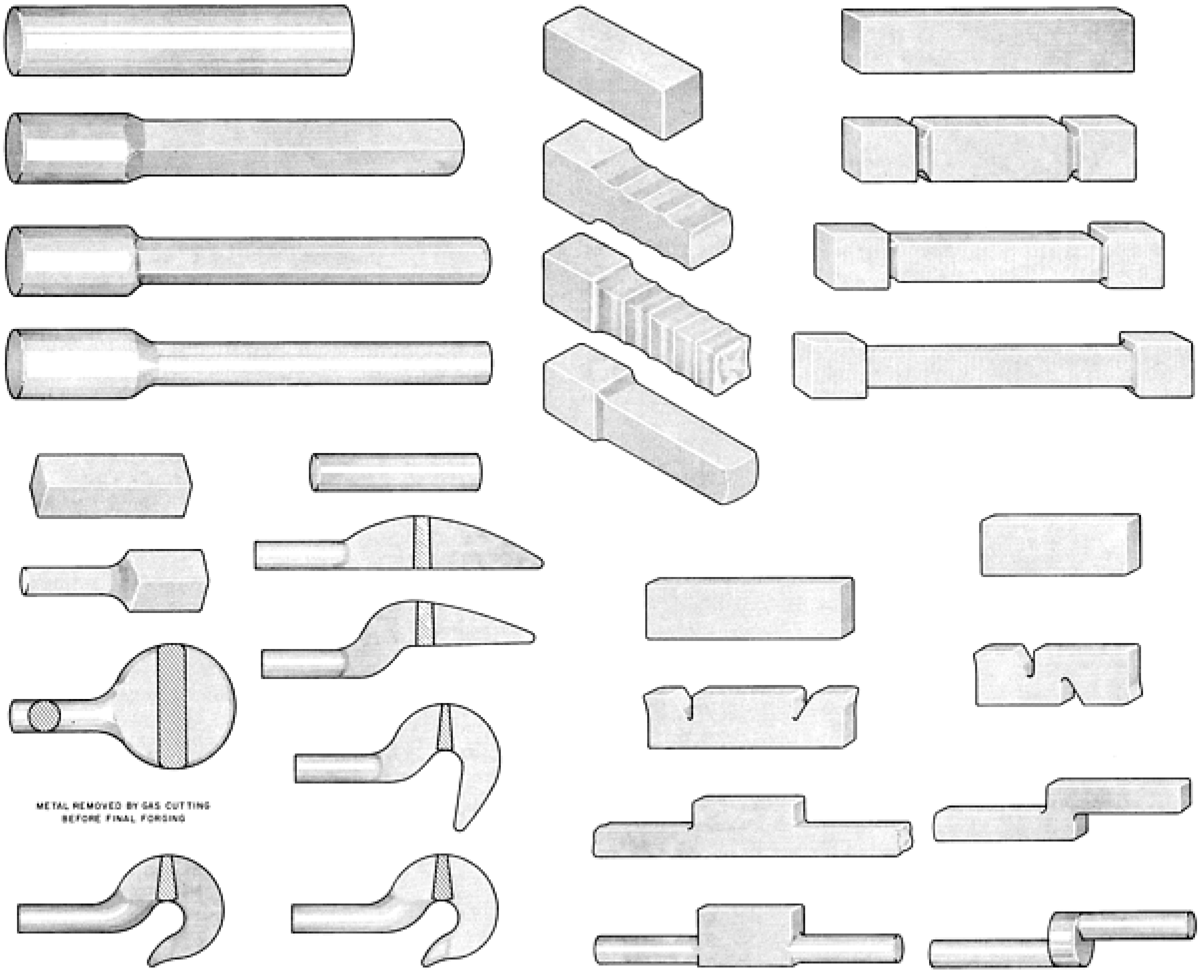

Fig. 10 Typical steps in drawing out forging stock and in producing common shapes in open dies

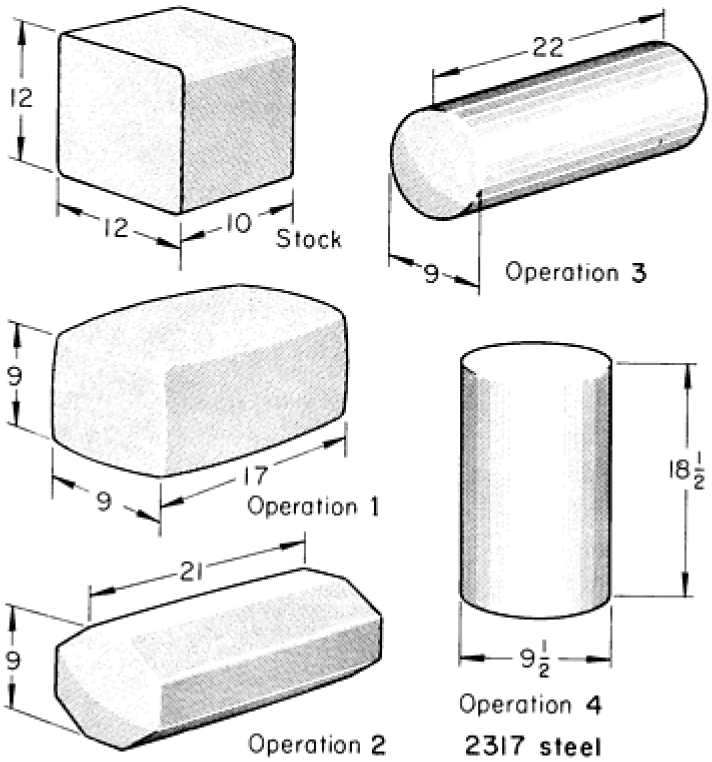
Example 1: Forging a 170-kg (375-lb) Solid Cylinder in Flat Dies.

A cylinder, 241 mm ($9\frac{1}{2}$ in.) in diameter by 470 mm ($18\frac{1}{2}$ in.) in length, was forged in flat dies from 305 × 305 × 254 mm (12 × 12 × 10 in.) stock in four operations without reheating the billet (Fig. 11). The following sequence of operations was used.



Stock preparation	**Cold sawing**
Stock size	**305 × 305 × 254 mm (12 × 12 × 10 in.)**
Stock weight	**179 kg (395 lb)**
Finished weight	**170 kg (375 lb)**
Heating furnace	**Gas-fired, automatic temperature control**
Heating temperature	**1230 °C (2250 °F)[(a)]**
Forging machine	**18 kN (4000 lb) steam hammer**

(a) Forging was completed in one heat.

Fig. 11 Sequence of operations in the forging of a cylindrical workpiece from square stock. Dimensions in figure given in inches

Operation 1. The 305 mm (12 in.) square section was hammered to a 229 mm (9 in.) square section, which increased the length to 432 mm (17 in.).

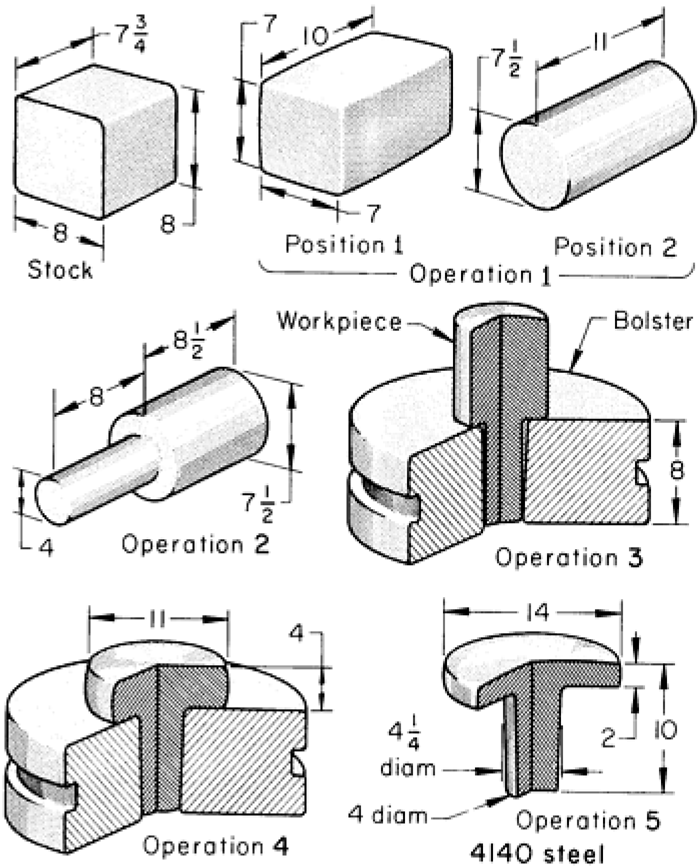
Operation 2. The corners of the square were hammered to produce an octagonal shape approximately 229 mm (9 in.) across flats and 533 mm (21 in.) long.

Operation 3. The octagon was rounded by successive hammer blows as the workpiece was rotated. The cylindrical forging was then approximately 559 mm (22 in.) long.

Operation 4. The forging was upended and hammered lightly on both ends to flatten the bulge on the ends. This decreased the length to 470 mm ($18\frac{1}{2}$ in.) and increased the diameter to 241 mm ($9\frac{1}{2}$ in.). Additional processing details are given in the table in Fig. 11.

Example 2: Forging a Combined Gear Blank and Hub in Flat Dies Using a Bolster.

The combined gear blank and hub forging shown in Fig. 12 was forged from 203 × 203 × 175 mm (8 × 8 × $7\frac{3}{4}$ in.) stock in five operations, as follows.



Stock preparation	**Cold sawing**
Stock size	**203 × 203 × 197 mm (8 × 8 × $7\frac{3}{4}$ in.)**

Stock weight	**64 kg (140 lb)**
Forging weight (after rough machining)	**54 kg (120 lb)**
Heating furnace	**Gas-fired, automatic temperature control**
Heating temperature	**1230 °C (2250 °F)[(a)]**
Forging machine	**18 kN (4000 lb) steam hammer**
Crew size	**Four men**

(a) Forging was completed in one heat.

Fig. 12 Typical procedure for the forging of a gear blank and hub in open dies, featuring the use of a bolster. Dimensions in figure given in inches.

Operation 1. The stock was forged to 178 × 178 × 254 mm (7 × 7 × 10 in.). This oblong was then forged into a bellied-end cylinder about 191 mm ($7\frac{1}{2}$ in.) in diameter and 279 mm (11 in.) in length, by being rotated and struck with successive hammer blows.

Operation 2. A stem approximately 102 mm (4 in.) in diameter and 203 mm (8 in.) in length was drawn from 64 mm ($2\frac{1}{2}$ in.) of the 279 mm (11 in.) length.

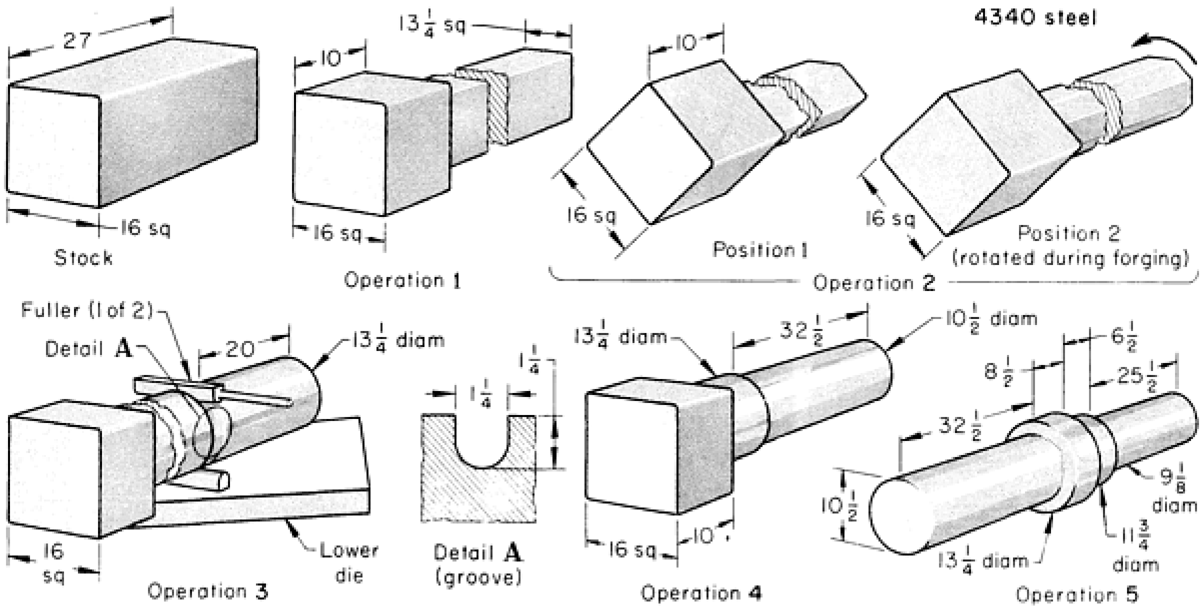
Operation 3. The workpiece was placed vertically in a bolster, as shown in Fig. 12, Operation 3.

Operation 4. The head was flattened (upset) until it was approximately 102 mm (4 in.) thick. The forging was then removed from the bolster and rounded up in flat dies.

Operation 5. The workpiece was placed in the bolster again and forged to the dimensions shown in Fig. 12, Operation 5. The forging was fully annealed and rough machined. Additional processing details are given in the table with Fig. 12.

Example 3: Forging a Four-Diameter Spindle in Flat Dies.

The four-diameter spindle forging shown in Fig. 13 was forged from 686 × 406 × 406 mm (27 × 16 × 16 in.) stock with one reheat in the following sequence of operations.



Stock preparation	**Cold sawing**
Stock size	**686 × 406 × 406 mm (27 × 16 × 16 in.)**
Stock weight	**878 kg (1935 lb)**
Forging weight (after rough machining)	**796 kg (1755 lb)**
Heating furnace	**Gas-fired, automatic temperature control**
Heating temperature	**1230 °C (2250 °F)[(a)]**
Forging machine	**22 kN (5000 lb) steam hammer**
Crew size	**Five men**

(a) Forging was reheated for operation 5.

Fig. 13 Sequence of operations in the forging of a four-diameter spindle in open dies, featuring the use of fullers. Dimensions in figures given in inches.

Operation 1. All but 254 mm (10 in.) of the hot stock was forged to a 337 mm ($13\frac{1}{4}$ in.) square section, using a sizing block on the lower die to gage size.

Operation 2. The workpiece was turned 45°, and the 337 mm ($13\frac{1}{4}$ in.) square section was flattened as shown in Position 1, Operation 2 (Fig. 13). The workpiece was rotated as the reduced portion was forged to an octagonal shape, as shown in Position 2, Operation 2. The octagon was then hammered into a round approximately 337 mm ($13\frac{1}{4}$ in.) in diameter (final shape in Position 2 not shown).

Operation 3. The workpiece was placed diagonally across the lower die; 508 mm (20 in.) from the end, a 267 mm ($10\frac{1}{2}$ in.) diam section was started by top and bottom fullers. The workpiece was rotated as the fullers were pressed into the hot steel, and a deep groove was formed around the workpiece (Fig. 13, Operation 3).

Operation 4. The 337 mm ($13\frac{1}{4}$ in.) sizing block was replaced by 267 mm ($10\frac{1}{2}$ in.) sizing block. The 508 mm (20 in.) long section was hammered first to a square, then to an octagon, and finally to a round (similar to procedures for Operations 1 and 2), with the length of this section increasing to 826 mm ($32\frac{1}{2}$ in.). The workpiece was then reheated.

Operation 5. The reheated workpiece was grasped on the 267 mm ($10\frac{1}{2}$ in.) diameter by 254 mm (10 in.) tongs. The 406 mm (16 in.) square section (unforged stock) was converted to a 337 mm ($13\frac{1}{4}$ in.) diam round section. At a distance of 216 mm ($8\frac{1}{2}$ in.) along the 337 mm ($13\frac{1}{4}$ in.) diameter, a back shoulder was started, using fullers as in Operation 3. After the groove was formed, the 337 mm ($13\frac{1}{4}$ in.) sizing block was replaced with a 298 mm ($11\frac{3}{4}$ in.) sizing block, and the 298 mm ($11\frac{3}{4}$ in.) diam by 165 mm ($6\frac{1}{2}$ in.) long section was forged in the same manner as described in Operations 1 and 2. The final section 232 mm, or $9\frac{1}{8}$ in., in diameter by 648 mm, or $25\frac{1}{2}$ in., in length, as shown in Fig. 13, Operation 5, was formed by similar procedures.

After forging, the workpiece was immediately placed in the furnace for full annealing. Additional processing details are given in the table with Fig. 13.

Example 4: Five-Operation Forging of a Large Seven-Diameter Turbine Rotor.

A seven-diameter turbine rotor (bottom right, Fig. 14) was forged from a 1.78 m (70 in.) diam, 2.79 m (110 in.) long, 64,900 kg (143,000 lb) corrugated ingot of low-alloy (Ni-Cr-Mo-V) steel. The steel was melted in basic electric furnaces and was vacuum stream degassed at the ingot mold to prevent flaking from entrapped hydrogen. The forging operations (Fig. 14) were as follows.

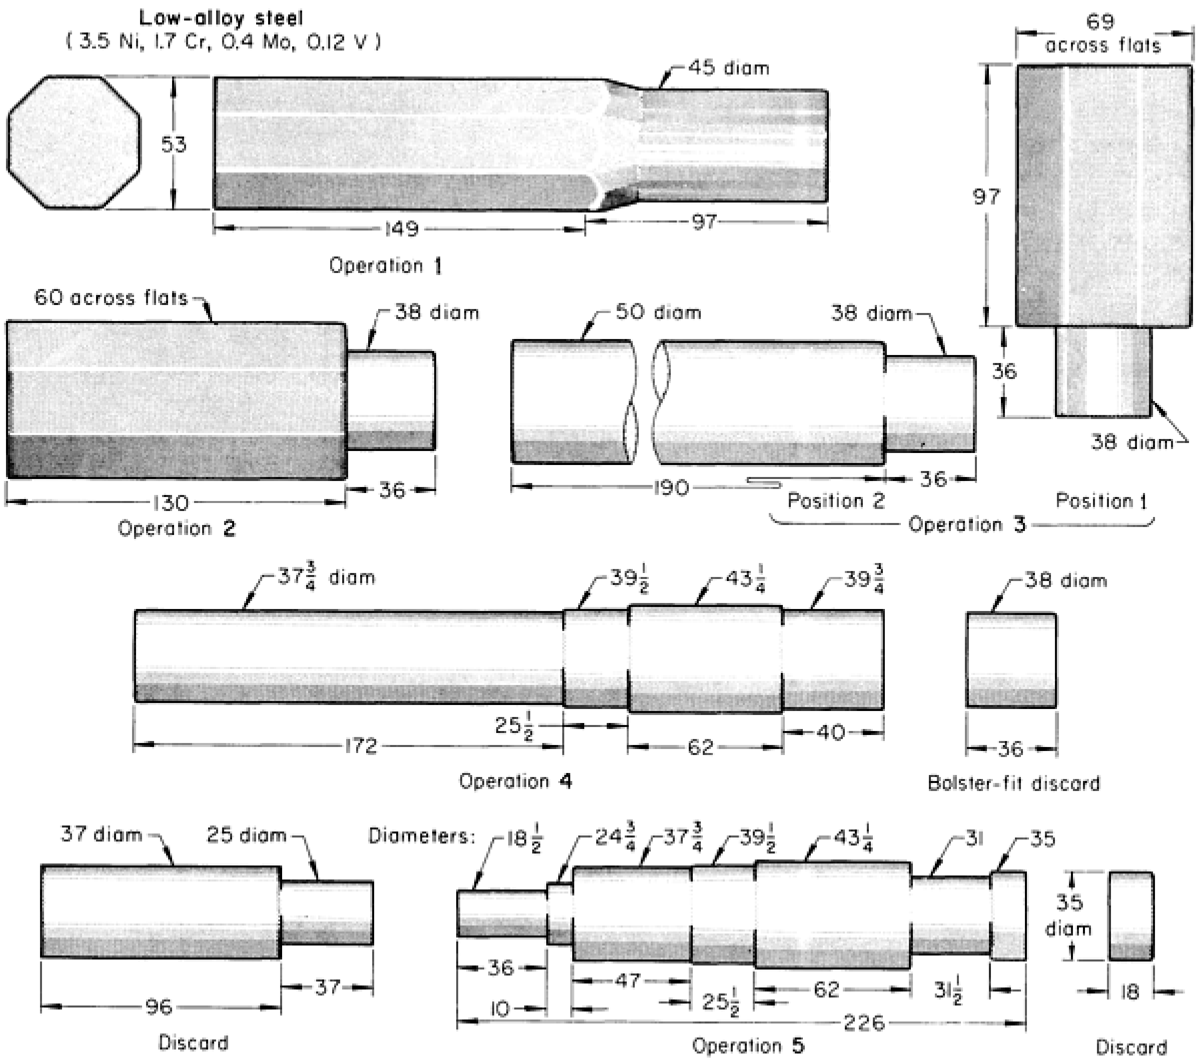


Fig. 14 Sequence of operations in the forging of a large turbine rotor in open dies. Dimensions given in inches.

Operation 1. The ingot was edged between flat dies to develop a bottle shape 6.25 m (246 in.) long, along with an octagonal section 1.35 m (53 in.) across flats and a round section 1.15 m (45 in.) in diameter.

Operation 2. The bottle-shaped workpiece was further developed by forging the 1.15 m (45 in.) diameter and the adjacent shoulder in V-dies, thus eliminating the shoulder and reducing the 1.15 m (45 in.) section to a 965 mm (38 in.) bolster fit. The bolster section was then cropped to remove part of the sinkhead, reducing the length of this section to 914 mm (36 in.). In addition, the octagonal section was upset to a width of 1.52 m (60 in.) across flats and a length of 3.30 m (130 in.).

Operation 3. In Position 1 of this operation (Fig. 14), the heavy section of the piece was upset, expanding the 1.52 m (60 in.) section to 1.75 m (69 in.), with the bolster in a position at the stem end, which rested on the lower die. The upset reduced the length of the heavy octagonal section from 3.30 to 2.46 m (130 to 97 in.). In Position 2 of this operation, the bloom was returned to the horizontal position, and the octagonal section was rounded between a flat top die and a bottom V-die, reducing its diameter to 1.27 m (50 in.) and extending its length to 4.83 m (190 in.).

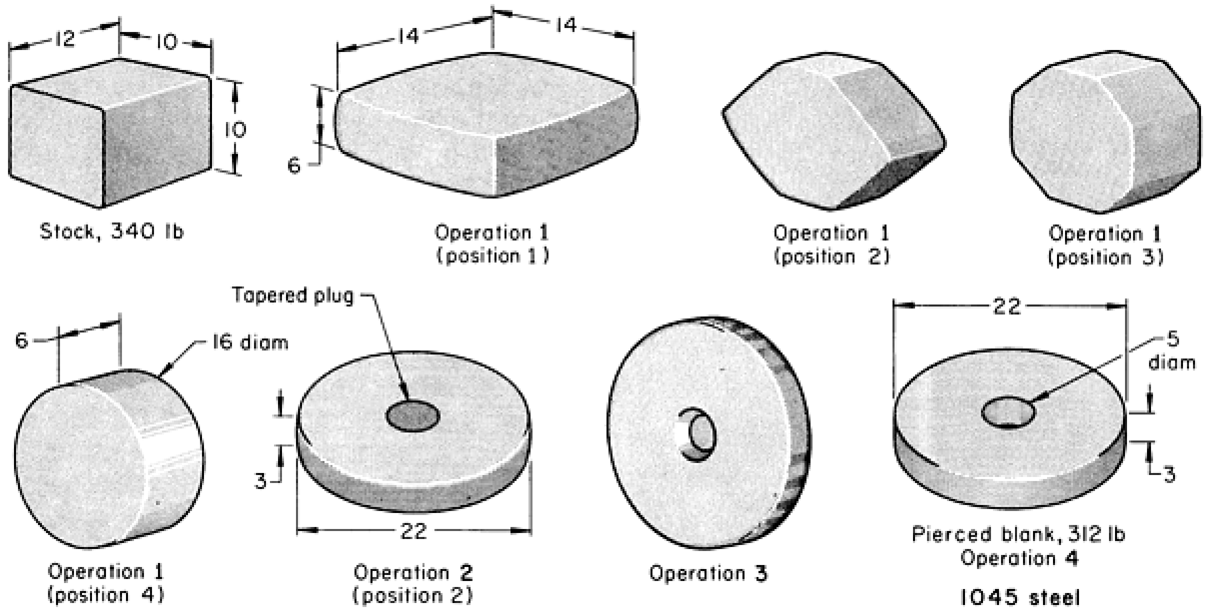
Operation 4. The main body of the forging was developed between a flat top die and a bottom V-die. The ends of the forging were set down to 959 mm and 1.01 m ($37\frac{3}{4}$ and $39\frac{3}{4}$ in.) diameters, respectively, and two additional diameters were forged between these sections. The bolster section (965 mm, or 38 in., in diameter by 914 mm, or 36 in., in length) was cut away at the conclusion of this operation.

Operation 5. Finish forging developed two additional stepped sections, ranging from 470 to 889 mm ($18\frac{1}{2}$ to 35 in.) in diameter, at each end of the forging. Following this operation, discard sections were cut from both ends of the forging. A large discard section was removed from the end of the forging (corresponding to the bottom of the ingot) that had not been cropped during the previous operations.

The finished forging was heat treated to develop optimal mechanical properties. Extensive mechanical tests were performed on specimens taken from the discard sections.

Example 5: Forging and Piercing a Blank for Forming a Ring.

The forged and pierced blank shown in Fig. 15 was forged from 305 × 254 × 254 mm (12 × 10 × 10 in.) stock. The sequence of operations was as follows.



Stock preparation	**Cold sawing**
Stock size	**305 × 254 × 254 mm (12 × 10 × 10 in.)**
Stock weight	**154 kg (340 lb)**
Shipping weight	**142 kg (312 lb)**
Heating furnace	**Gas-fired, automatic temperature control**
Heating temperature	**1230 °C (2250 °F)[(a)]**
Forging equipment	**18 kN (4000 lb) steam hammer**

Size of ring saddle forged from pierced blank	**1020 mm (40 in.) OD × 762 mm (30 in.) ID × 50 mm (2 in.)**

(a) Blank was completed in one heat.

Fig. 15 Sequence of operations in the forging and piercing of a circular blank. Dimensions in figure given in inches.

Operation 1. Heated stock was placed vertically on a flat die. The 305 mm (12 in.) height was reduced to 152 mm (6 in.) and the 254 mm (10 in.) square cross section was increased to 356 mm (14 in.) square. The workpiece was repositioned and hammered, first to a hexagonal, next to an octagonal, and then to a round section 406 mm (16 in.) in diameter by 152 mm (6 in.) in length.

Operation 2. The workpiece was flattened to a 75 mm (3 in.) thick, 559 mm (22 in.) round, and a tapered plug was centered and hammered in.

Operation 3. The hot workpiece was rotated and hammered on its circumference to flatten the edge, which bulged from previous hammering, and to loosen the plug.

Operation 4. The workpiece was positioned as shown in Fig. 15, Operation 4, and the 127 mm (5 in.) diam hole was completed by piercing from the opposite side. The pierced blank was saddle forged to a ring on a mandrel, following the technique shown in Fig. 2 (see also Example 6).

Forging of Rings. Rings are often rolled from forged and pierced blanks (see the article "Ring Rolling" in this Volume); however, when rolling is precluded (because of small quantities, short delivery time, or other reasons), saddle forging (Fig. 2) is often used. Typical procedures for producing rings by this method are described in the following example.

Example 6: Saddle Forging a 1.02 m (40 in.) OD Ring From a 559 mm (22 in.) OD Blank.

A 1.02 in (40 in.) OD ring was saddle forged in a 6670 N (1500 lbf) steam hammer from a 559 mm (22 in.) OD blank produced as described in Example 5 and shown in Fig. 15. Flattening operations were done at suitable intervals to reduce the ring to a 50 mm (2 in.) thickness. Saddle forging was done as follows (Fig. 16).

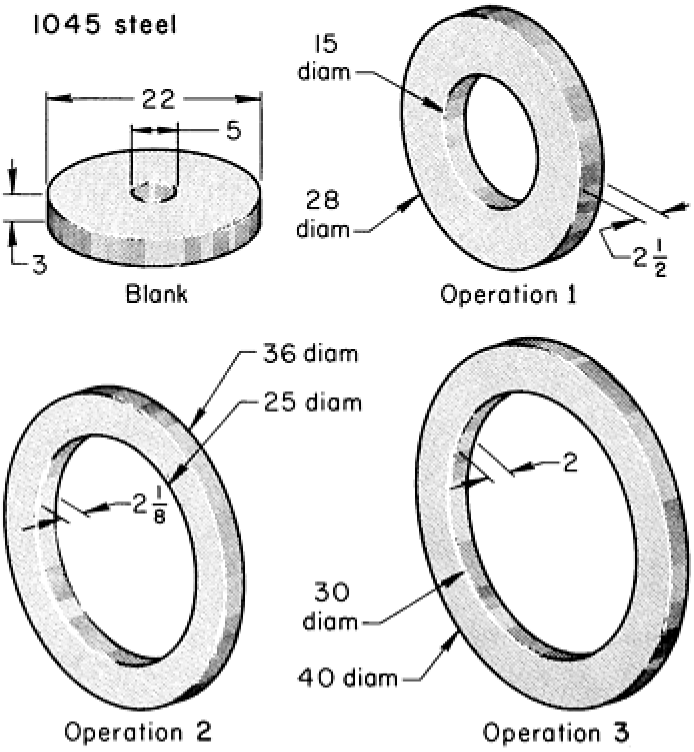


Fig. 16 Shapes produced in the three-operation saddle forging of a ring from a forged and pierced blank. Dimensions given in inches.

Operation 1. The blank was heated to 1230 °C (2250 °F) and forged to the dimensions shown in Fig. 16, Operation 1, by alternate saddle forging and flattening.

Operation 2. The 711 mm (28 in.) OD ring was reheated to 1230 °C (2250 °F) and forged by the same technique used in Operation 1 to produce a 914 mm (36 in.) diam ring.

Operation 3. The 914 mm (36 in.) OD ring was reheated to 1230 °C (2250 °F) and saddle forged and flattened as needed to obtain a 50 mm (2 in.) thickness, a 1.02 m (40 in.) outside diameter, and a 762 mm (30 in.) inside diameter.

Example 7: Mandrel Forging a Long Hollow Piece on a 40.9 MN (4600 tonf) Hydraulic Press.

Mandrel-forging technique is utilized to produce a long, hollow, cylindrically symmetrical piece. The outside diameter of the production piece was 1.32 m (52.0 in.). The average inside diameter was 914 mm (36.0 in.). The total overall length was 7.0 m (23.0 ft) with a 1.59 m (62.75 in.) diam by 482 mm (19.0 in.) long flange included on one end of the piece. The flange drops to a 1.45 m (57.0 in.) diameter, which tapers to the 1.32 m (52.0 in.) body diameter over a 229 mm (9.0 in.) length.

Operation 1. The 2.11 m (83 in.) diam, 78,900 kg (174,000 lb) ingot of AISI 4130 grade steel was used as the starting stock. It as heated to the forging temperature and straight forged (saddened) to 1.57 m (62.0 in.) diam size.

Operation 2. Top and bottom ingot discards were taken by flame cutting to yield a slug of 1.57 m (62.0 in.) in diameter and 3.20 m (126.0 in.) in length.

Operation 3. The slug was upset forged by positioning it vertically under the press. The 3.20 m (126.0 in.) dimension was reduced to 3.15 m (80.0 in.).

Operation 4. The upset slug was hot trepanned using 559 mm (22.0 in.) cutters to remove the core.

Operation 5. The slug was saddle forged to increase the inside diameter to 991 mm (39.0 in.).

Operation 6. The piece was mandrel forged on a tapered mandrel (0.8 to 1 m, or 33 to 39 in., in diameter) using the top flat die and bottom V-die. Mandrel forging caused the metal to move in the longitudinal (axial) direction, thus producing the desired part.

Open-Die Forging

Revised by the ASM Committee on Open-Die Forging*; Chairman: Ashok K. Khare, National Forge Company

Examples of Production Practice

Because of differences in equipment and operator skill, procedures for open-die forging vary considerably from plant to plant. Figure 10 shows typical steps in the drawing and forging of stock and in the fabrication of common shapes from billets of square, rectangular, and round cross sections. The procedures described in the following examples are typical of those used for the production of some common open-die forgings.

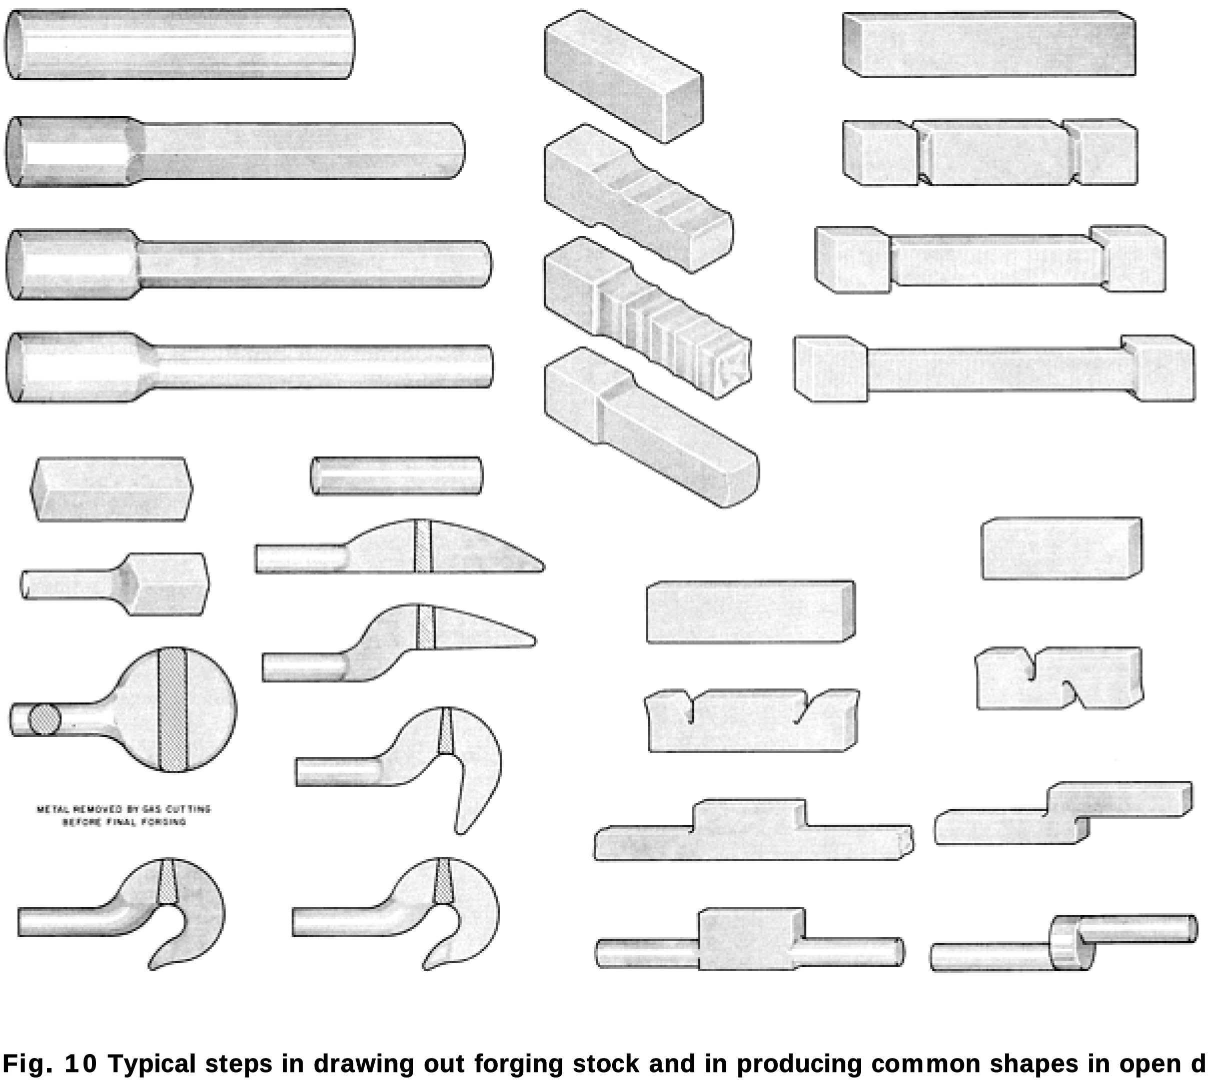

Fig. 10 Typical steps in drawing out forging stock and in producing common shapes in open dies

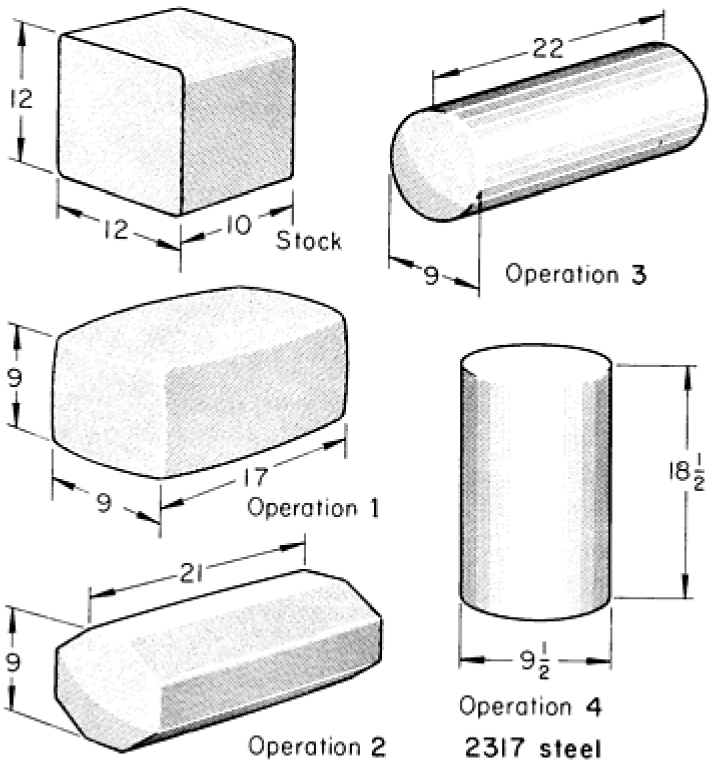
Example 1: Forging a 170-kg (375-lb) Solid Cylinder in Flat Dies.

A cylinder, 241 mm ($9\frac{1}{2}$ in.) in diameter by 470 mm ($18\frac{1}{2}$ in.) in length, was forged in flat dies from 305 × 305 × 254 mm (12 × 12 × 10 in.) stock in four operations without reheating the billet (Fig. 11). The following sequence of operations was used.



Stock preparation	**Cold sawing**
Stock size	**305 × 305 × 254 mm (12 × 12 × 10 in.)**
Stock weight	**179 kg (395 lb)**
Finished weight	**170 kg (375 lb)**
Heating furnace	**Gas-fired, automatic temperature control**
Heating temperature	**1230 °C (2250 °F)[(a)]**
Forging machine	**18 kN (4000 lb) steam hammer**

(a) Forging was completed in one heat.

Fig. 11 Sequence of operations in the forging of a cylindrical workpiece from square stock. Dimensions in figure

given in inches

Operation 1. The 305 mm (12 in.) square section was hammered to a 229 mm (9 in.) square section, which increased the length to 432 mm (17 in.).

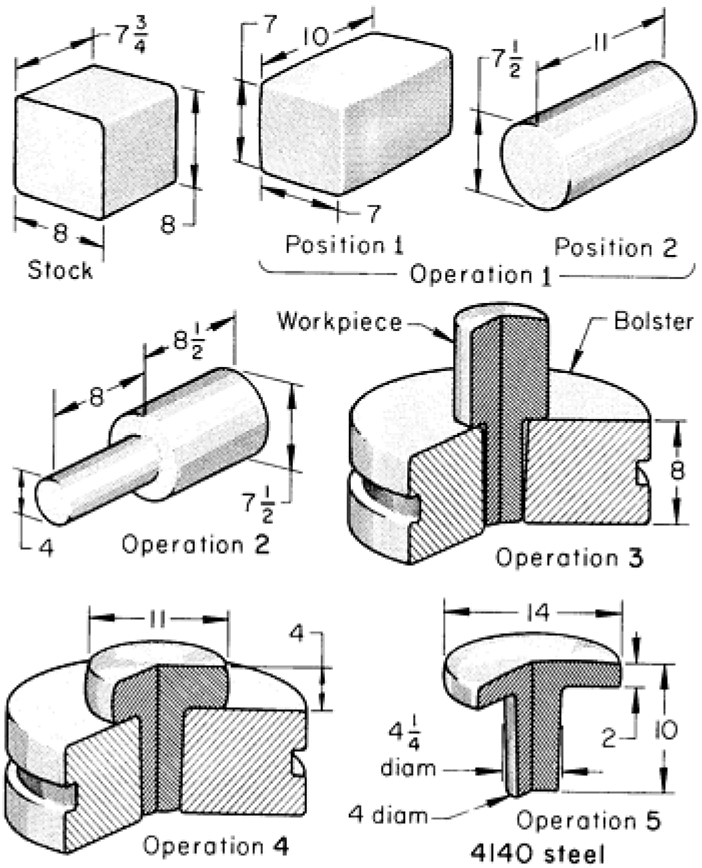
Operation 2. The corners of the square were hammered to produce an octagonal shape approximately 229 mm (9 in.) across flats and 533 mm (21 in.) long.

Operation 3. The octagon was rounded by successive hammer blows as the workpiece was rotated. The cylindrical forging was then approximately 559 mm (22 in.) long.

Operation 4. The forging was upended and hammered lightly on both ends to flatten the bulge on the ends. This decreased the length to 470 mm ($18\frac{1}{2}$ in.) and increased the diameter to 241 mm ($9\frac{1}{2}$ in.). Additional processing details are given in the table in Fig. 11.

Example 2: Forging a Combined Gear Blank and Hub in Flat Dies Using a Bolster.

The combined gear blank and hub forging shown in Fig. 12 was forged from 203 × 203 × 175 mm (8 × 8 × $7\frac{3}{4}$ in.) stock in five operations, as follows.



Stock preparation	**Cold sawing**

Stock size	**203 × 203 × 197 mm (8 × 8 × 7$\frac{3}{4}$ in.)**
Stock weight	**64 kg (140 lb)**
Forging weight (after rough machining)	**54 kg (120 lb)**
Heating furnace	**Gas-fired, automatic temperature control**
Heating temperature	**1230 °C (2250 °F)[a]**
Forging machine	**18 kN (4000 lb) steam hammer**
Crew size	**Four men**

(a) Forging was completed in one heat.

Fig. 12 Typical procedure for the forging of a gear blank and hub in open dies, featuring the use of a bolster. Dimensions in figure given in inches.

Operation 1. The stock was forged to 178 × 178 × 254 mm (7 × 7 × 10 in.). This oblong was then forged into a bellied-end cylinder about 191 mm (7$\frac{1}{2}$ in.) in diameter and 279 mm (11 in.) in length, by being rotated and struck with successive hammer blows.

Operation 2. A stem approximately 102 mm (4 in.) in diameter and 203 mm (8 in.) in length was drawn from 64 mm (2$\frac{1}{2}$ in.) of the 279 mm (11 in.) length.

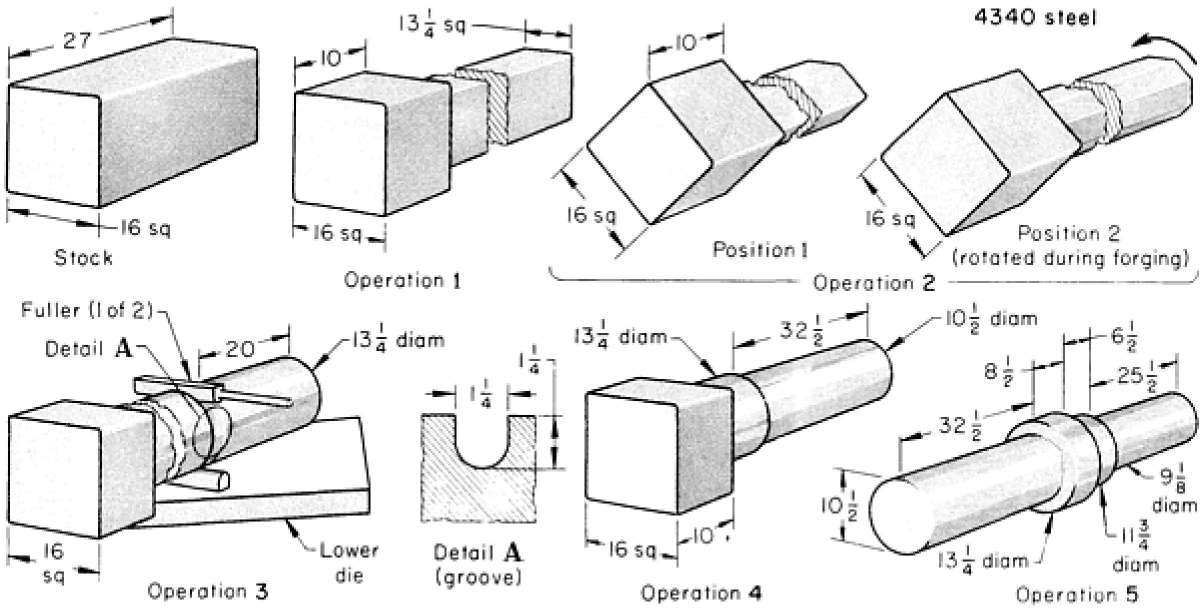
Operation 3. The workpiece was placed vertically in a bolster, as shown in Fig. 12, Operation 3.

Operation 4. The head was flattened (upset) until it was approximately 102 mm (4 in.) thick. The forging was then removed from the bolster and rounded up in flat dies.

Operation 5. The workpiece was placed in the bolster again and forged to the dimensions shown in Fig. 12, Operation 5. The forging was fully annealed and rough machined. Additional processing details are given in the table with Fig. 12.

Example 3: Forging a Four-Diameter Spindle in Flat Dies.

The four-diameter spindle forging shown in Fig. 13 was forged from 686 × 406 × 406 mm (27 × 16 × 16 in.) stock with one reheat in the following sequence of operations.



Stock preparation	**Cold sawing**
Stock size	**686 × 406 × 406 mm (27 × 16 × 16 in.)**
Stock weight	**878 kg (1935 lb)**
Forging weight (after rough machining)	**796 kg (1755 lb)**
Heating furnace	**Gas-fired, automatic temperature control**
Heating temperature	**1230 °C (2250 °F)[(a)]**
Forging machine	**22 kN (5000 lb) steam hammer**
Crew size	**Five men**

(a) Forging was reheated for operation 5.

Fig. 13 Sequence of operations in the forging of a four-diameter spindle in open dies, featuring the use of fullers. Dimensions in figures given in inches.

Operation 1. All but 254 mm (10 in.) of the hot stock was forged to a 337 mm ($13\frac{1}{4}$ in.) square section, using a sizing block on the lower die to gage size.

Operation 2. The workpiece was turned 45°, and the 337 mm ($13\frac{1}{4}$ in.) square section was flattened as shown in Position 1, Operation 2 (Fig. 13). The workpiece was rotated as the reduced portion was forged to an octagonal shape, as shown in Position 2, Operation 2. The octagon was then hammered into a round approximately 337 mm ($13\frac{1}{4}$ in.) in diameter (final shape in Position 2 not shown).

Operation 3. The workpiece was placed diagonally across the lower die; 508 mm (20 in.) from the end, a 267 mm ($10\frac{1}{2}$ in.) diam section was started by top and bottom fullers. The workpiece was rotated as the fullers were pressed into the hot steel, and a deep groove was formed around the workpiece (Fig. 13, Operation 3).

Operation 4. The 337 mm ($13\frac{1}{4}$ in.) sizing block was replaced by 267 mm ($10\frac{1}{2}$ in.) sizing block. The 508 mm (20 in.) long section was hammered first to a square, then to an octagon, and finally to a round (similar to procedures for Operations 1 and 2), with the length of this section increasing to 826 mm ($32\frac{1}{2}$ in.). The workpiece was then reheated.

Operation 5. The reheated workpiece was grasped on the 267 mm ($10\frac{1}{2}$ in.) diameter by 254 mm (10 in.) tongs. The 406 mm (16 in.) square section (unforged stock) was converted to a 337 mm ($13\frac{1}{4}$ in.) diam round section. At a distance of 216 mm ($8\frac{1}{2}$ in.) along the 337 mm ($13\frac{1}{4}$ in.) diameter, a back shoulder was started, using fullers as in Operation 3. After the groove was formed, the 337 mm ($13\frac{1}{4}$ in.) sizing block was replaced with a 298 mm ($11\frac{3}{4}$ in.) sizing block, and the 298 mm ($11\frac{3}{4}$ in.) diam by 165 mm ($6\frac{1}{2}$ in.) long section was forged in the same manner as described in Operations 1 and 2. The final section 232 mm, or $9\frac{1}{8}$ in., in diameter by 648 mm, or $25\frac{1}{2}$ in., in length, as shown in Fig. 13, Operation 5, was formed by similar procedures.

After forging, the workpiece was immediately placed in the furnace for full annealing. Additional processing details are given in the table with Fig. 13.

Example 4: Five-Operation Forging of a Large Seven-Diameter Turbine Rotor.

A seven-diameter turbine rotor (bottom right, Fig. 14) was forged from a 1.78 m (70 in.) diam, 2.79 m (110 in.) long, 64,900 kg (143,000 lb) corrugated ingot of low-alloy (Ni-Cr-Mo-V) steel. The steel was melted in basic electric furnaces and was vacuum stream degassed at the ingot mold to prevent flaking from entrapped hydrogen. The forging operations (Fig. 14) were as follows.

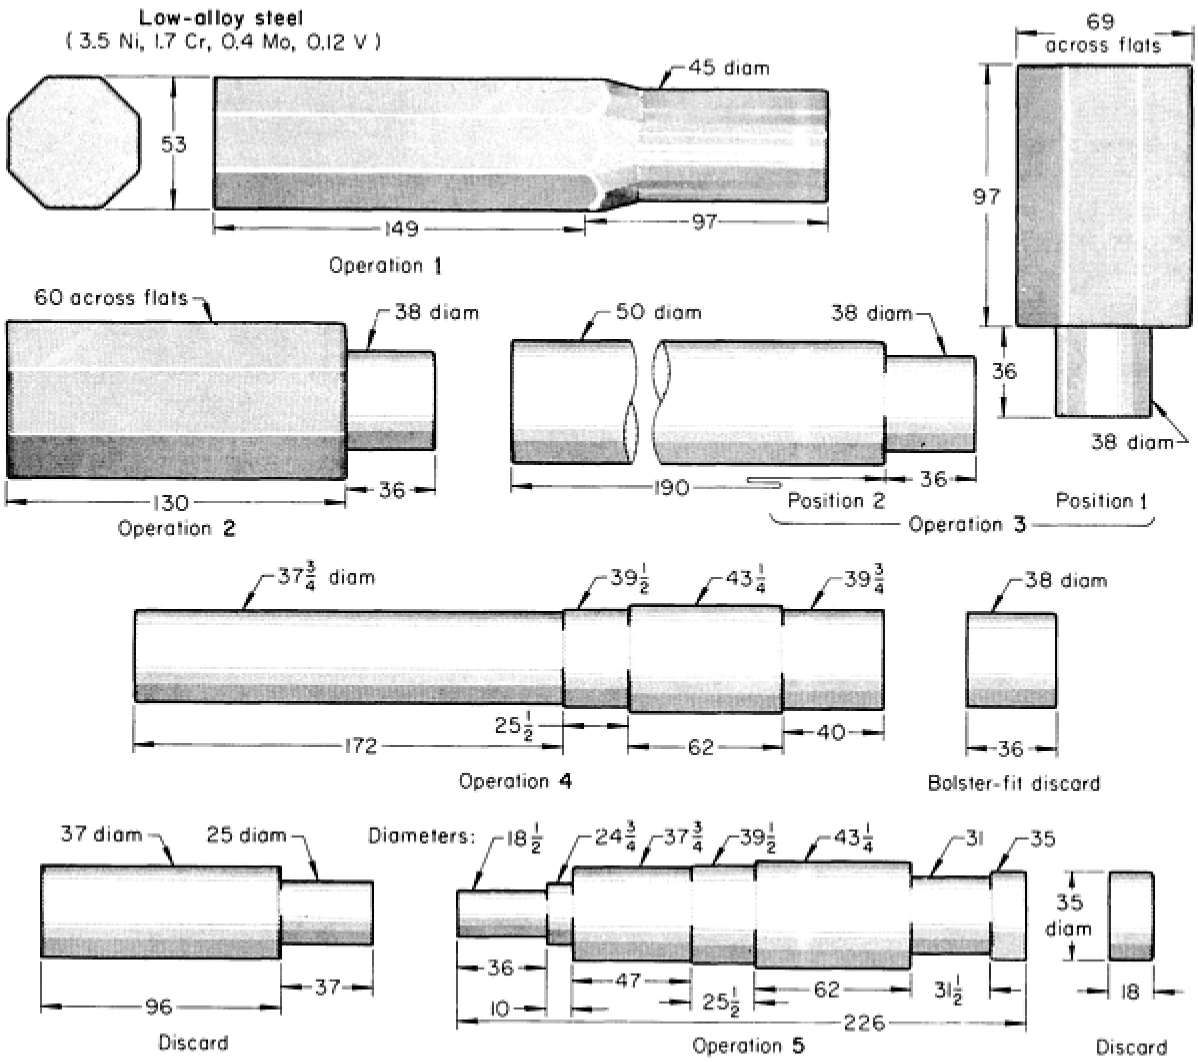


Fig. 14 Sequence of operations in the forging of a large turbine rotor in open dies. Dimensions given in inches.

Operation 1. The ingot was edged between flat dies to develop a bottle shape 6.25 m (246 in.) long, along with an octagonal section 1.35 m (53 in.) across flats and a round section 1.15 m (45 in.) in diameter.

Operation 2. The bottle-shaped workpiece was further developed by forging the 1.15 m (45 in.) diameter and the adjacent shoulder in V-dies, thus eliminating the shoulder and reducing the 1.15 m (45 in.) section to a 965 mm (38 in.) bolster fit. The bolster section was then cropped to remove part of the sinkhead, reducing the length of this section to 914 mm (36 in.). In addition, the octagonal section was upset to a width of 1.52 m (60 in.) across flats and a length of 3.30 m (130 in.).

Operation 3. In Position 1 of this operation (Fig. 14), the heavy section of the piece was upset, expanding the 1.52 m (60 in.) section to 1.75 m (69 in.), with the bolster in a position at the stem end, which rested on the lower die. The upset reduced the length of the heavy octagonal section from 3.30 to 2.46 m (130 to 97 in.). In Position 2 of this operation, the bloom was returned to the horizontal position, and the octagonal section was rounded between a flat top die and a bottom V-die, reducing its diameter to 1.27 m (50 in.) and extending its length to 4.83 m (190 in.).

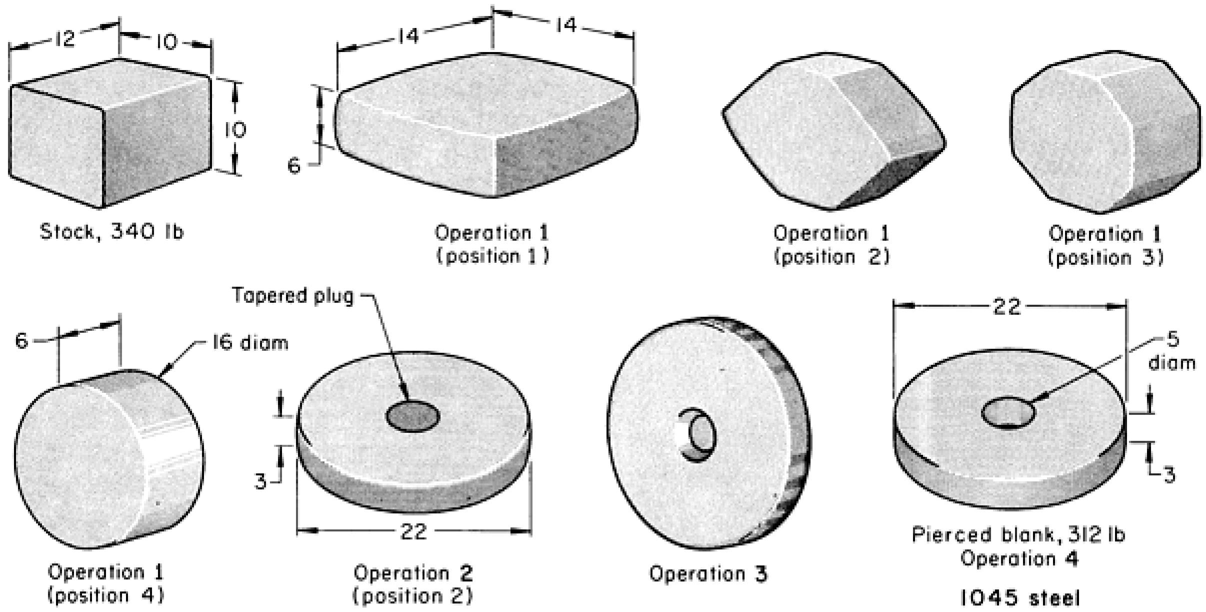
Operation 4. The main body of the forging was developed between a flat top die and a bottom V-die. The ends of the forging were set down to 959 mm and 1.01 m ($37\frac{3}{4}$ and $39\frac{3}{4}$ in.) diameters, respectively, and two additional diameters were forged between these sections. The bolster section (965 mm, or 38 in., in diameter by 914 mm, or 36 in., in length) was cut away at the conclusion of this operation.

Operation 5. Finish forging developed two additional stepped sections, ranging from 470 to 889 mm ($18\frac{1}{2}$ to 35 in.) in diameter, at each end of the forging. Following this operation, discard sections were cut from both ends of the forging. A large discard section was removed from the end of the forging (corresponding to the bottom of the ingot) that had not been cropped during the previous operations.

The finished forging was heat treated to develop optimal mechanical properties. Extensive mechanical tests were performed on specimens taken from the discard sections.

Example 5: Forging and Piercing a Blank for Forming a Ring.

The forged and pierced blank shown in Fig. 15 was forged from 305 × 254 × 254 mm (12 × 10 × 10 in.) stock. The sequence of operations was as follows.



Stock preparation	**Cold sawing**
Stock size	**305 × 254 × 254 mm (12 × 10 × 10 in.)**
Stock weight	**154 kg (340 lb)**
Shipping weight	**142 kg (312 lb)**
Heating furnace	**Gas-fired, automatic temperature control**
Heating temperature	**1230 °C (2250 °F)[(a)]**
Forging equipment	**18 kN (4000 lb) steam hammer**

Size of ring saddle forged from pierced blank	**1020 mm (40 in.) OD × 762 mm (30 in.) ID × 50 mm (2 in.)**

(a) Blank was completed in one heat.

Fig. 15 Sequence of operations in the forging and piercing of a circular blank. Dimensions in figure given in inches.

Operation 1. Heated stock was placed vertically on a flat die. The 305 mm (12 in.) height was reduced to 152 mm (6 in.) and the 254 mm (10 in.) square cross section was increased to 356 mm (14 in.) square. The workpiece was repositioned and hammered, first to a hexagonal, next to an octagonal, and then to a round section 406 mm (16 in.) in diameter by 152 mm (6 in.) in length.

Operation 2. The workpiece was flattened to a 75 mm (3 in.) thick, 559 mm (22 in.) round, and a tapered plug was centered and hammered in.

Operation 3. The hot workpiece was rotated and hammered on its circumference to flatten the edge, which bulged from previous hammering, and to loosen the plug.

Operation 4. The workpiece was positioned as shown in Fig. 15, Operation 4, and the 127 mm (5 in.) diam hole was completed by piercing from the opposite side. The pierced blank was saddle forged to a ring on a mandrel, following the technique shown in Fig. 2 (see also Example 6).

Forging of Rings. Rings are often rolled from forged and pierced blanks (see the article "Ring Rolling" in this Volume); however, when rolling is precluded (because of small quantities, short delivery time, or other reasons), saddle forging (Fig. 2) is often used. Typical procedures for producing rings by this method are described in the following example.

Example 6: Saddle Forging a 1.02 m (40 in.) OD Ring From a 559 mm (22 in.) OD Blank.

A 1.02 in (40 in.) OD ring was saddle forged in a 6670 N (1500 lbf) steam hammer from a 559 mm (22 in.) OD blank produced as described in Example 5 and shown in Fig. 15. Flattening operations were done at suitable intervals to reduce the ring to a 50 mm (2 in.) thickness. Saddle forging was done as follows (Fig. 16).

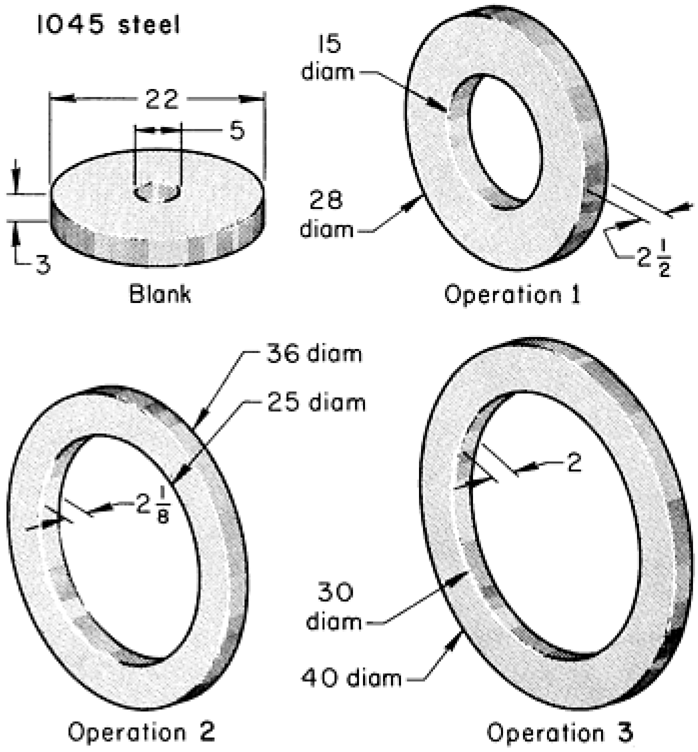


Fig. 16 Shapes produced in the three-operation saddle forging of a ring from a forged and pierced blank. Dimensions given in inches.

Operation 1. The blank was heated to 1230 °C (2250 °F) and forged to the dimensions shown in Fig. 16, Operation 1, by alternate saddle forging and flattening.

Operation 2. The 711 mm (28 in.) OD ring was reheated to 1230 °C (2250 °F) and forged by the same technique used in Operation 1 to produce a 914 mm (36 in.) diam ring.

Operation 3. The 914 mm (36 in.) OD ring was reheated to 1230 °C (2250 °F) and saddle forged and flattened as needed to obtain a 50 mm (2 in.) thickness, a 1.02 m (40 in.) outside diameter, and a 762 mm (30 in.) inside diameter.

Example 7: Mandrel Forging a Long Hollow Piece on a 40.9 MN (4600 tonf) Hydraulic Press.

Mandrel-forging technique is utilized to produce a long, hollow, cylindrically symmetrical piece. The outside diameter of the production piece was 1.32 m (52.0 in.). The average inside diameter was 914 mm (36.0 in.). The total overall length was 7.0 m (23.0 ft) with a 1.59 m (62.75 in.) diam by 482 mm (19.0 in.) long flange included on one end of the piece. The flange drops to a 1.45 m (57.0 in.) diameter, which tapers to the 1.32 m (52.0 in.) body diameter over a 229 mm (9.0 in.) length.

Operation 1. The 2.11 m (83 in.) diam, 78,900 kg (174,000 lb) ingot of AISI 4130 grade steel was used as the starting stock. It as heated to the forging temperature and straight forged (saddened) to 1.57 m (62.0 in.) diam size.

Operation 2. Top and bottom ingot discards were taken by flame cutting to yield a slug of 1.57 m (62.0 in.) in diameter and 3.20 m (126.0 in.) in length.

Operation 3. The slug was upset forged by positioning it vertically under the press. The 3.20 m (126.0 in.) dimension was reduced to 3.15 m (80.0 in.).

Operation 4. The upset slug was hot trepanned using 559 mm (22.0 in.) cutters to remove the core.

Operation 5. The slug was saddle forged to increase the inside diameter to 991 mm (39.0 in.).

Operation 6. The piece was mandrel forged on a tapered mandrel (0.8 to 1 m, or 33 to 39 in., in diameter) using the top flat die and bottom V-die. Mandrel forging caused the metal to move in the longitudinal (axial) direction, thus producing the desired part.

Open-Die Forging

Revised by the ASM Committee on Open-Die Forging*; Chairman: Ashok K. Khare, National Forge Company

---

Contour Forging

Open-die contour or form forging requiring the use of dedicated dies has been successfully accomplished for carbon, alloy, and stainless steels as well as for superalloys. Contour forging can be advantageous under such circumstances as the following:

- Enhancement of grain flow at specific locations, when demanded by product application
- Reduction of the quantity of starting material; this is especially critical when using expensive materials such as stainless steels and superalloys
- Reduction of machining costs; this is critical when machinability or excessive material removal are factors

Open-die contour forging may be a requirement, as in the case of grain flow, or it may be an option, as in the case of material and machining cost savings. The material and machining cost savings typically outweighs the forging tooling costs.

Die material is largely dependent on the forging hours required for the product run. Generally, when dealing with a small production run having total forging hours of 30 or fewer, in which tooling cost has a significant impact on product cost, H-13 would be an acceptable die material. However, larger forging runs would require the use of superalloy material.

Set Down. It may not be possible to calculate precisely the amount of material required for the contour forging of complex shapes. It is then recommended to run trials on low-cost material. The factors affecting the consideration would be the condition of the forge press, operator skill, forge preheat, and the extent of the net shape design affecting metal flow.

Turbine Wheel Forging. Turbine wheels, which are commonly 2.54 m (100 in.) in diameter, are forged by first upsetting a block of steel and then contour forging to provide the thick hub and thin rim sections (Fig. 17). This is done using a shaped (contoured) bottom die, which supports the entire workpiece, and a shaped partial top (contoured swing) die. Successive strokes are taken with the top die as it is indexed around the vertical centerline of the press. The partial top die minimizes the force required to deform the metal, yet produces the desired forge envelope.

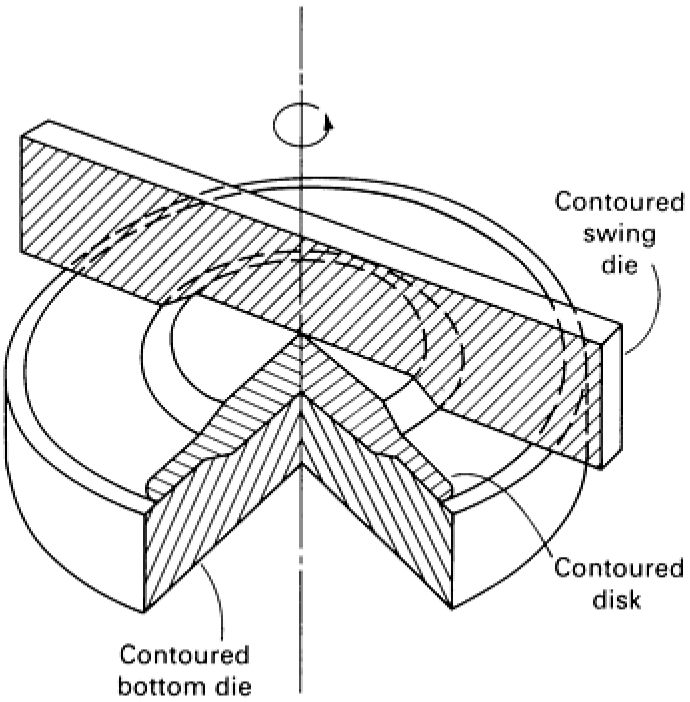

Fig. 17 Illustrations showing turbine wheel formed by using contour forging method.

Nozzle extrusion is a more complex contour-forging method (Fig. 18). Nozzle extrusions are commonly used for thick-wall vessels in cases in which the cost of extruding the nozzle shape offsets the cost and quality risk factors involved in producing the shell and the nozzle as a weldment. The tooling consists of a shaped bottom die and a punch. The punch is forced through a machined pilot hole in the workpiece. The material conforms to the shape of the bottom die and is extended forward to form the nozzle. Two possible methods of producing a shell section with a nozzle are shown in Fig. 19. Design engineers prefer the nozzle extrusion technique over the welded nozzle because of the superior grain flow characteristics, toughness, and favorable costs associated with the extrusion process.

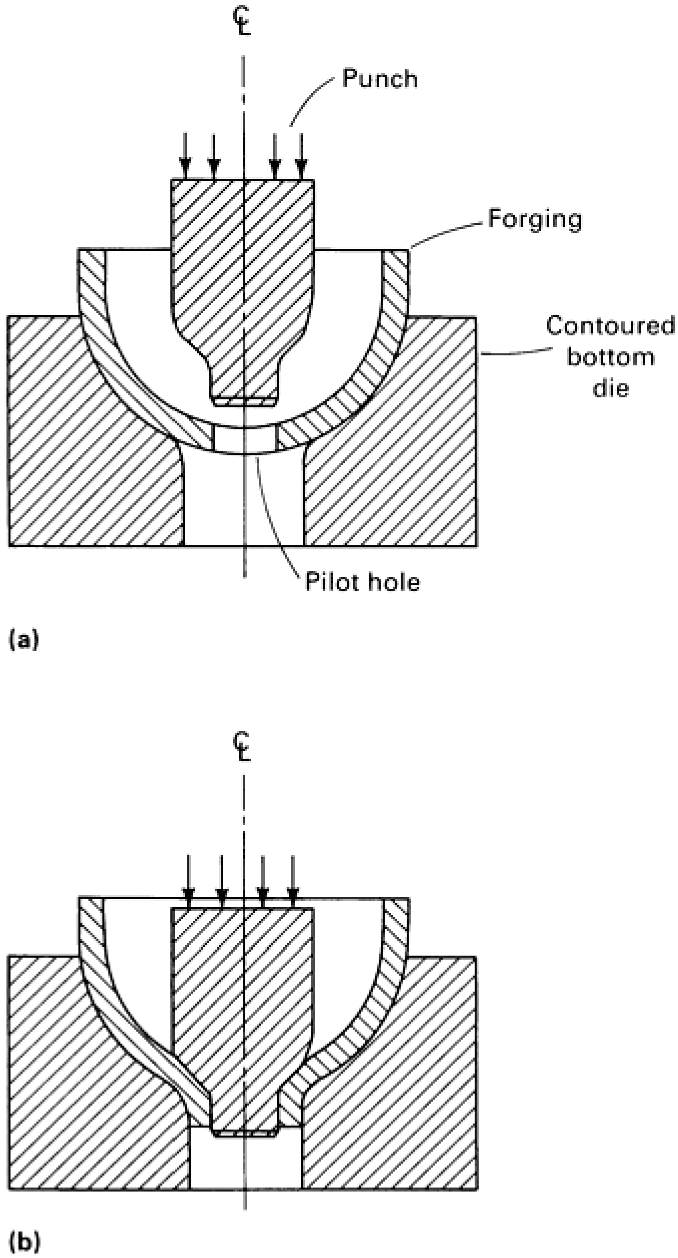

Fig. 18 Illustration of nozzle extrusion, a complex contour forging method. (a) Punch position before extrusion. (b) Punch position after extrusion.

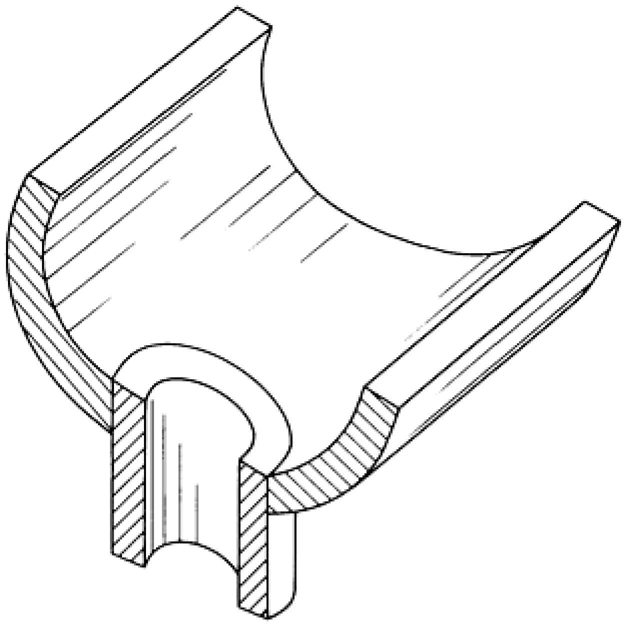
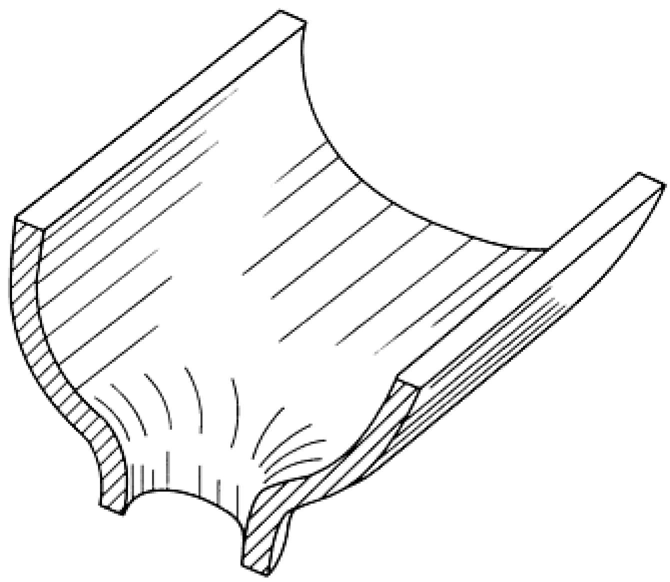


(a)



(b)

Fig. 19 Metal shells featuring nozzles formed by two different methods. (a) Welded nozzle. (b) Extruded nozzle.

Pressure vessel head forgings can be produced from either forged or rolled plate by either of two methods. In the first method, full male and female dies are used to develop a dome shape (Fig. 20a). In the second method, a partial male die and a full female die are used to produce a dome shape (Fig. 20b). The second method, although requiring more forging strokes than the first method (the top die is swung in incremental positions for each stroke), reduces the press load per stroke. Therefore, larger dome shapes can be made by this technique. In addition, if required, smaller presses can be used to make the dome shapes (press capacity will determine the appropriate swing die width that can be used).

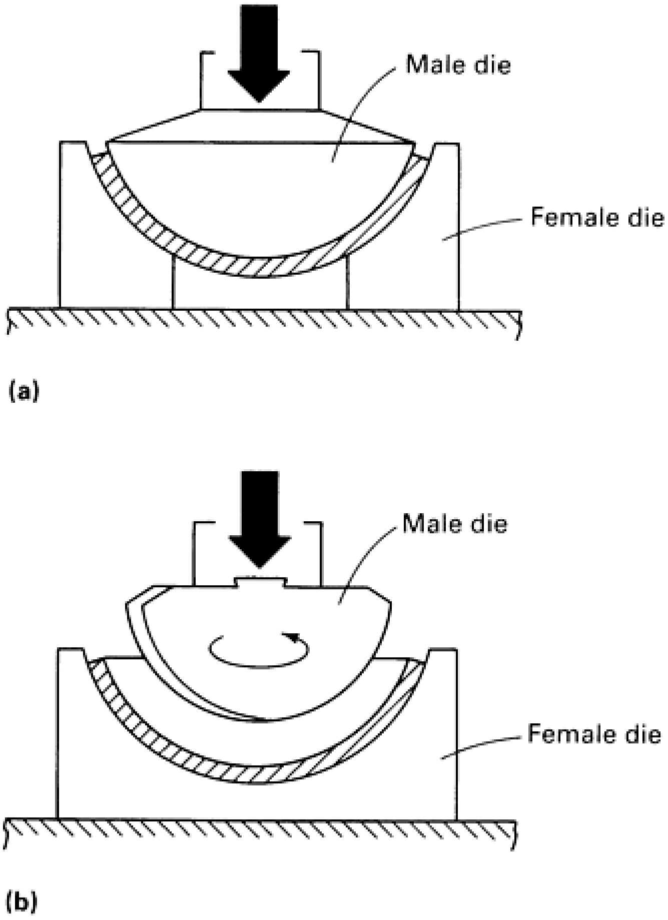


Fig. 20 Contour forming of a pressure vessel head using a (a) full male die and a (b) partial male die.

Bottleneck-shaped forgings are made as doubles from a straight forged bar (Fig. 21). For example, 292 mm (11.5 in.) radius contour dies are set down 165 mm (6.5 in.) to achieve the small diameter of 254 mm (10.0 in.) from the large diameter of 584 mm (23.0 in.). In order to generate axial movement during the forging process, the flat die width must be a minimum of 50 mm (2.0 in.) less than the set down dimension. In addition, the die radius adjacent to the flat and the contour should be a minimum of 38 mm (1.5 in.) to enhance axial metal flow and to minimize material lapping.

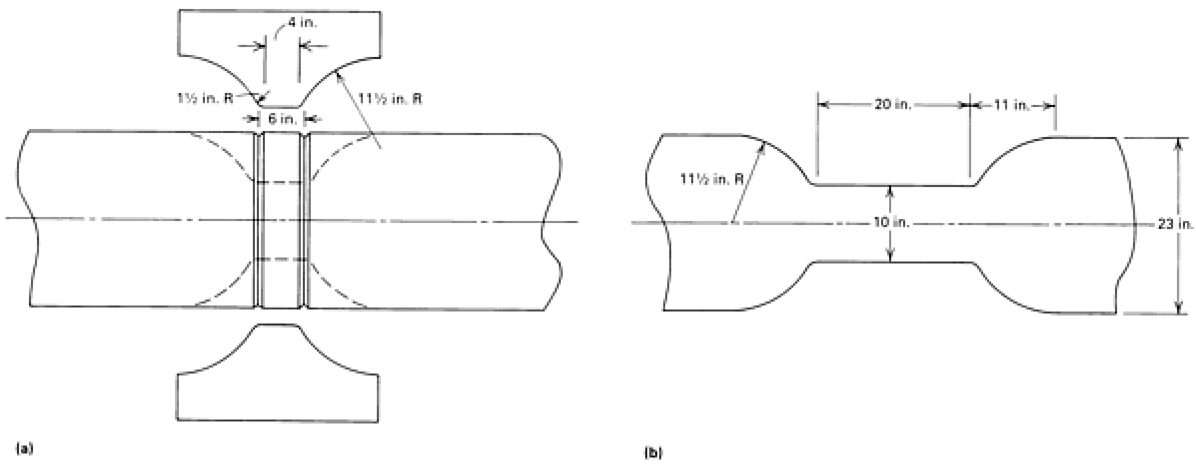

Fig. 21 Contour forging of a straight forged bar to form a double bottleneck-shaped workpiece. (a) Original 320 kg (700 lb) bar. (b) Contour-forged, 205 kg (450 lb) finished workpiece.

Forging quality is best achieved using a 17.8 MN (2000 tonf) hydraulic press by positioning the die to the set-down mark as shown in Fig. 21 and manually or mechanically rotating the workpiece in 10° to 15° increments using not greater than 25 mm (1 in.) drafts. The process is continued by working from side to side, keeping the die tight to the contour, while exercising caution to avoid lapping on the contour.

Open-Die Forging

Revised by the ASM Committee on Open-Die Forging[*]; Chairman: Ashok K. Khare, National Forge Company

Allowances and Tolerances

To make certain that forgings can be machined to correct final measurements, it is necessary at the forging stage to establish allowances, tolerances, and specifications for flatness and concentricity.

Allowance. In open-die forging, the allowance defines the amount by which a dimension is increased in order to determine its size at an earlier stage of manufacture. An allowance is added to a finish-machined size. Similarly, an additional allowance is added to a rough-machined dimension to determine the forged size. These allowances provide enough stock to permit machining to final dimensions.

The stock provided for machining increases the weight of the forging at earlier stages of manufacture. The weight of the additional metal and the machining operations necessary to remove it increase the cost of the finished part. Consequently, the allowances specified for each step of manufacture should be kept as small as practical while still maintaining enough metal so that all dimensions of the finished part can be readily achieved with normal production techniques.

Table 1 shows allowances added to rough-machined dimensions of straight round, square, rectangular, or octagonal bars of uniform cross section. The allowance increases as diameter (or section width) and length increase. Table 1 also explains how allowances are determined for open-die forgings with more than one cross-sectional dimension.

Table 1 Allowances and tolerances for as-forged shafts and bars

Allowance is added to rough-machined dimension to obtain forged dimension. Tolerances are the variations permitted on forged dimensions.

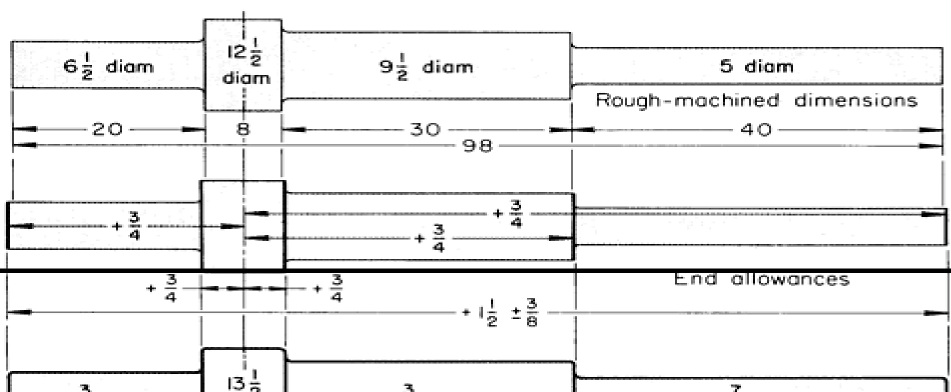
Allowances and tolerances for as-forged shoulder shafts

A shaft forging that has more than one cross-sectional dimension is illustrated at right. To compute allowances and tolerances for a forging of this type, use the following method:

For the largest diameter, take the allowance given in the table above, using the overall length of the forging.



For each smaller diameter, take allowance given in table above, using overall length of forging, and average this with allowance for largest diameter. Use next-larger allowance wherever calculated average is not found. Allowance on each end of the overall length is the value indicated in the first column for the largest diameter or the value indicated on the top line for the overall length, whichever is greater. Allowance on each end of intermediate lengths is same as allowance on each end of overall length. Tolerance is as indicated in the table above for the allowance that is applied.	
Applying the rules given above to the forging illustrated at right:	

Allowances and tolerances for diameters

Machined dimension, mm (in.)	**Allowance, mm (in.)**	**Forging dimension, mm (in.)**	Tolerance on forging, mm (in.)[a]
318 (12 $\frac{1}{2}$)	25.4 (1)	343 (13 $\frac{1}{2}$)	**±6.4 (± $\frac{1}{4}$)**
241 (9 $\frac{1}{2}$)	22.2 [(19.1 + 25.4) ÷ 2] ($\frac{7}{8}$ [($\frac{3}{4}$ + 1) ÷ 2])	264 (10 $\frac{3}{8}$)	**+6.4, -4.8 (+ $\frac{1}{4}$, - $\frac{3}{16}$)**
165 (6 $\frac{1}{2}$)	22.2 [(15.9 + 25.4) ÷ 2] ($\frac{7}{8}$ [($\frac{5}{8}$ + 1) ÷ 2])[b]	187 (7 $\frac{3}{8}$)	**+6.4, -4.8 (+ $\frac{1}{4}$, - $\frac{3}{16}$)**
127 (5)	**22.2 [(14.3 + 25.4) ÷ 2] ($\frac{7}{8}$ [($\frac{9}{16}$ + 1) ÷ 2])[b]**	**149 (5 $\frac{7}{8}$)**	**+6.4, -4.8 (+ $\frac{1}{4}$, - $\frac{3}{16}$)**

Allowances and tolerances for ends

Table allowance for 2490 mm (98 in.) length	**12.7 mm ($\frac{1}{2}$ in.)**
Table allowance for 318 mm (12 $\frac{1}{2}$ in.) diameter	**19.1 mm ($\frac{3}{4}$ in.)**
End allowance applicable (point 3 above)	**19.1 mm ($\frac{3}{4}$ in.) per end**
Tolerance on 19.1 mm ($\frac{3}{4}$ in.) end allowance	**4.8 mm ($\frac{3}{16}$ in.) per end; 9.5 mm ($\frac{3}{8}$ in.) on total length**

(a) From the table, for allowances of 25.4 and 22.2 mm (1 and $\frac{7}{8}$ in.).

(b) Because product is not in the table, the next-larger allowance is used (as noted in item 2 in the list of instructions at left above). Dimensions in figure given in inches

Under precisely controlled conditions and with state-of-the-art thickness-controlled presses manned by highly skilled operators, it may be possible to forge somewhat closer to rough-machined dimensions; however, such a decrease in allowances must be carefully controlled to avoid machining problems. For example, usual practice may consist of increasing the allowance for critical applications in which all decarburization must be removed during rough machining. Under these conditions, 6.4 mm ($\frac{1}{4}$ in.) on a diameter or cross section (3.2 mm, or $\frac{1}{8}$ in., per side) is usually added to the allowance given in Table 1.

Tolerance describes the permissible variation in a specific dimension. Tolerances on allowances are given in Table 1. Tolerance is approximately one-fourth (plus or minus) the allowance.

Flatness and concentricity for a forging are usually negotiated between the forge shop and the customer. However, some users of open-die forgings have established specifications. For example, one user specifies that for pancake forgings up to 610 mm (24 in.) in diameter eccentricity or out-of-roundness shall not exceed 6.4 mm ($\frac{1}{4}$ in.) and flatness shall be within 4.8 mm ($\frac{3}{16}$ in.). For pancake forgings somewhat larger than 610 mm (24 in.) in diameter, eccentricity or out-of-roundness shall be no more than 9.5 mm ($\frac{3}{8}$ in.), and flatness shall be within 6.4 mm ($\frac{1}{4}$ in.).

Safety

In open-die forging, as in other types of forging operations, safe practices must be observed when handling materials and operating equipment. More information on safety in a forging facility is available in the article "Hammers and Presses for Forging" in this Volume.

Closed-Die Forging in Hammers and Presses

Introduction

CLOSED-DIE FORGING, or impression-die forging, is the shaping of hot metal completely within the walls or cavities of two dies that come together to enclose the workpiece on all sides. The impression for the forging can be entirely in either die or can be divided between the top and bottom dies.

The forging stock, generally round or square bar, is cut to length to provide the volume of metal needed to fill the die cavities, in addition to an allowance for flash and sometimes for a projection for holding the forging. The flash allowance is, in effect, a relief valve for the extreme pressure produced in closed dies. Flash also acts as a brake to slow the outward flow of metal in order to permit complete filling of the desired configuration.

Capabilities of the Process

With the use of closed dies, complex shapes and heavy reductions can be made in hot metal within closer dimensional tolerances than are usually feasible with open dies. Open dies are primarily used for the forging of simple shapes or for making forgings that are too large to be contained in closed dies. Closed-die forgings are usually designed to require minimal subsequent machining.

Closed-die forging is adaptable to low-volume or high-volume production. In addition to producing final, or nearly final, metal shapes, closed-die forging allows control of grain flow direction, and it often improves mechanical properties in the longitudinal direction of the workpiece.

Size. The forgings produced in closed dies can range from a few ounces to several tons. The maximum size that can be produced is limited only by the available handling and forging equipment. Forgings weighing as much as 25,400 kg (56,000 lb) have been successfully forged in closed dies, although more than 70% of the closed-die forgings produced weigh 0.9 kg (2 lb) or less.

Shape. Complex nonsymmetrical shapes that require a minimum number of operations for completion can be produced by closed-die forging. In addition, the process can be used in combination with other processes to produce parts having greater complexity or closer tolerances than are possible by forging alone. Cold coining and the assembly of two or more closed-die forgings by welding are examples of other processes that can extend the useful range of closed-die forging.

Forging Materials

In closed-die forging, a material must satisfy two basic requirements. First, the material strength (or flow stress) must be low so that die pressures are kept within the capabilities of practical die materials and constructions, and, second, the forgeability of the material must allow the required amount of deformation without failure. By convention, closed-die forging refers to hot working. Table 1 lists various alloy groups and their respective forging temperature ranges in order of increasing forging difficulty. The forging material influences the design of the forging itself as well as the details of the entire forging process. For example, Fig. 1 shows that, owing to difficulties in forging, nickel alloys allow for less shape definition than aluminum alloys. For a given metal, both the flow stress and the forgeability are influenced by the metallurgical characteristics of the billet material and by the temperatures, strains, strain rates, and stresses that occur in the deforming material.

Table 1 Classification of alloys in order of increasing forging difficulty

Alloy group	Approximate forging temperature range	
	°C	°F
Least difficult		
Aluminum alloys	400-550	**750-1020**
Magnesium alloys	250-350	**480-660**
Copper alloys	600-900	**1110-1650**

Carbon and low-alloy steels	850-1150	**1560-2100**
Martensitic stainless steels	1100-1250	**2010-2280**
Maraging steels	1100-1250	**2010-2280**
Austenitic stainless steels	1100-1250	**2010-2280**
Nickel alloys	1000-1150	**1830-2100**
Semiaustenitic PH stainless steels	1100-1250	**2010-2280**
Titanium alloys	700-950	**1290-1740**
Iron-base superalloys	1050-1180	**1920-2160**
Cobalt-base superalloys	1180-1250	**2160-2280**
Niobium alloys	950-1150	**1740-2100**
Tantalum alloys	1050-1350	**1920-2460**
Molybdenum alloys	1150-1350	**2100-2460**
Nickel-base superalloys	1050-1200	**1920-2190**
Tungsten alloys	1200-1300	**2190-2370**
Most difficult		

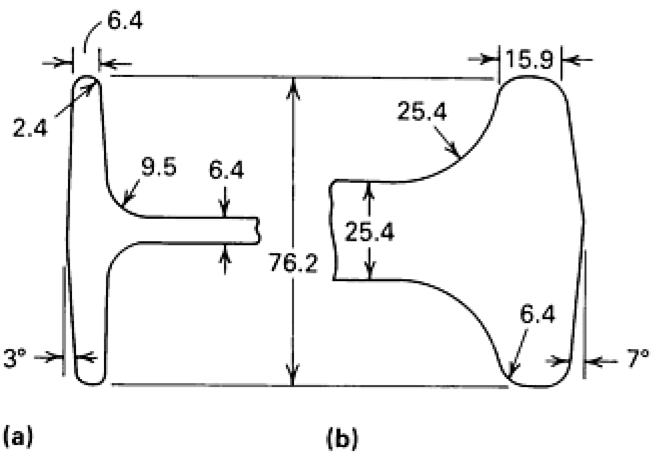

Fig. 1 Comparison of typical design limits for rib-web structural forgings of aluminum alloys (a) and nickel-base alloys (b). Dimensions given in millimeters.

In most practical hot-forging operations, the temperature of the workpiece material is higher than that of the dies. Metal flow and die filling are largely determined by the resistance and the ability of the forging material to flow, that is, flow stress and forgeability; by the friction and cooling effects at the die/material interface; and by the complexity of the forging shape. Of the two basic material characteristics, flow stress represents the resistance of a metal to plastic deformation, and forgeability represents the ability of a metal to deform without failure, regardless of the magnitude of load and stresses required for deformation.

The concept of forgeability has been used vaguely to denote a combination of resistance to deformation and the ability to deform without fracture. A diagram illustrating this type of information is presented in Fig. 2. Because the resistance of a metal to plastic deformation is essentially determined by the flow stress of the material at given temperature and strain rate conditions, it is more appropriate to define forgeability as the capability of the material to deform without failure, regardless of pressure and load requirements.

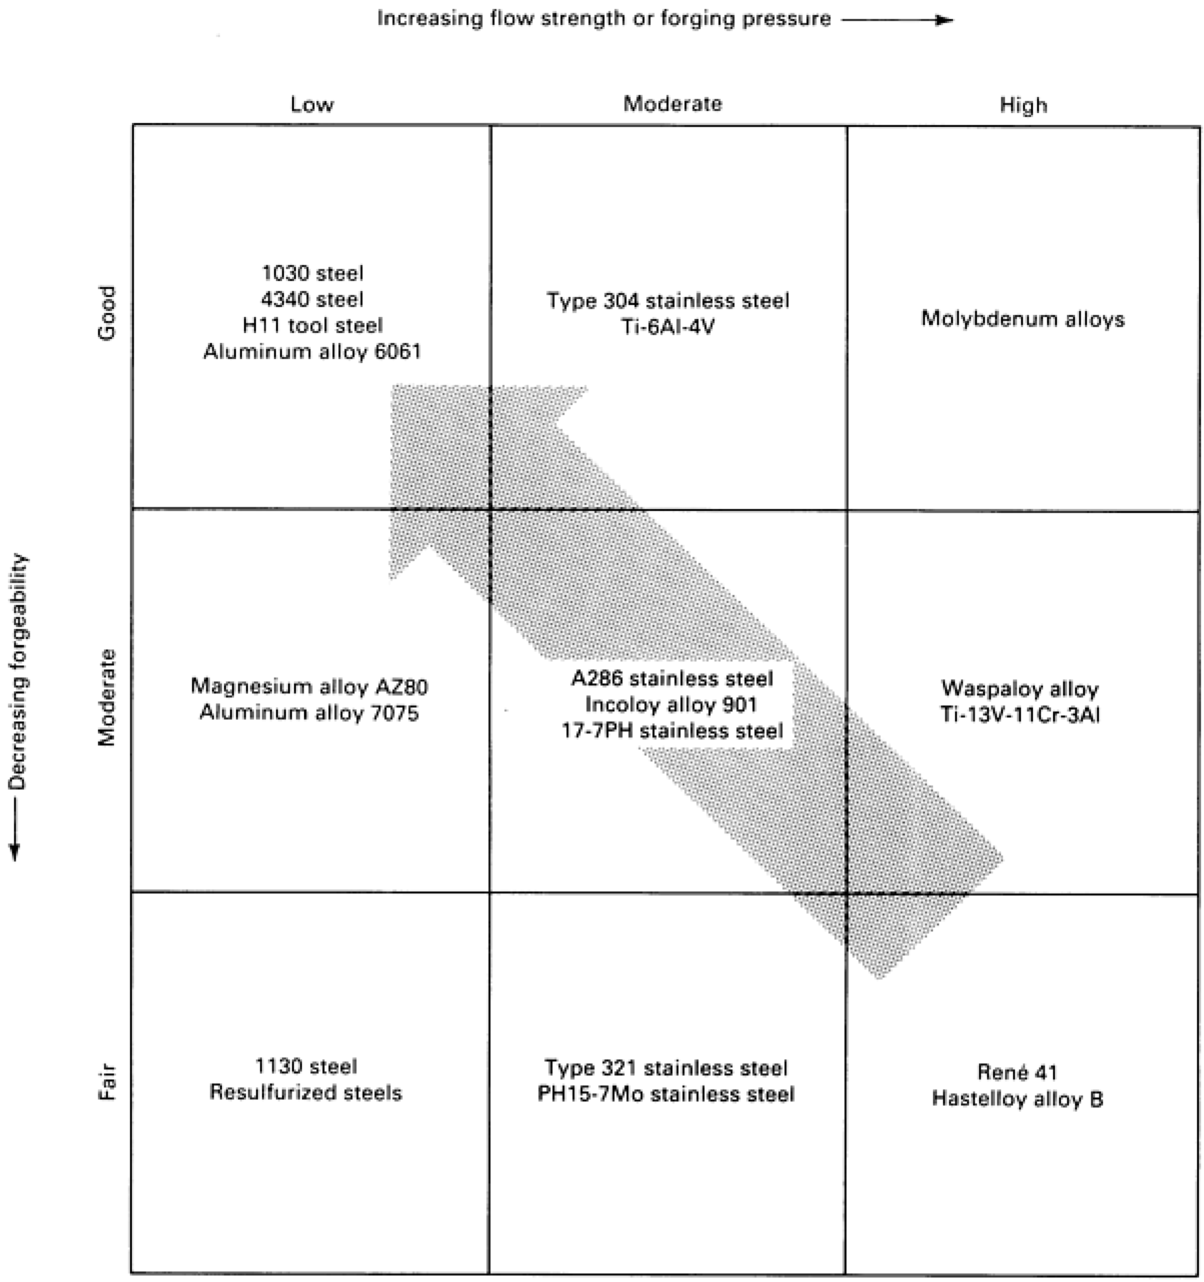

Fig. 2 Influence of forgeability and flow strength in die filling. Arrow indicates increasing ease of die filling.

In general, the forgeability of metals increases with temperature. However, as temperature increases, grain growth occurs, and in some alloy systems, forgeability decreases with increasing grain size. In other alloys, forgeability is greatly influenced by the characteristics of second-phase compounds. The state of stress in a given deformation process significantly influences forgeability. In upset forging at large reductions, for example, cracking may occur at the outside fibers of the billet, where excessive barreling occurs and tensile stresses develop. In certain extrusion-type forging operations, axial tensile stresses may be present in the deformation zone and may cause centerburst cracking. As a general and practical rule, it is important to provide compressive support to those portions of a less forgeable material that are normally exposed to the tensile and shear stresses.

The forgeability of metals at various deformation rates and temperatures can be evaluated by using such tests as torsion, tension, and compression tests. In all of these tests, the amount of deformation prior to failure of the specimen is an indication of forgeability at the temperature and deformation rate used during that particular test.

Closed-Die Forging in Hammers and Presses

Friction and Lubrication in Forging

In forging, friction greatly influences metal flow, pressure distribution, and load and energy requirements. In addition to lubrication effects, the effects of die chilling or heat transfer from the hot material to colder dies must be considered. For example, for a given lubricant, friction data obtained from hydraulic press forging cannot be used for mechanical press or hammer forging even if die and billet temperatures are comparable.

In forging, the ideal lubricant is expected to:

- Reduce sliding friction between the dies and the forging in order to reduce pressure requirements, to fill the die cavity, and to control metal flow
- Act as a parting agent and prevent local welding and subsequent damage to the die and workpiece surfaces
- Possess insulating properties so as to reduce heat losses from the workpiece and to minimize temperature fluctuations on the die surface
- Cover the die surface uniformly so that local lubricant breakdown and uneven metal flow are prevented
- Be nonabrasive and noncorrosive so as to prevent erosion of the die surface
- Be free of residues that would accumulate in deep impressions
- Develop a balanced gas pressure to assist quick release of the forging from the die cavity; this characteristic is particularly important in hammer forging, in which ejectors are not used
- Be free of polluting or poisonous components and not produce smoke upon application to the dies.

No single lubricant can fulfill all of the requirements listed above; therefore, a compromise must be made for each specific application.

Various types of lubricants are used, and they can be applied by swabbing or spraying. The simplest is a high flash point oil swabbed onto the dies. Colloidal graphite suspensions in either oil or water are frequently used. Synthetic lubricants can be employed for light forging operations. The water-base and synthetic lubricants are extensively used primarily because of cleanliness.

Closed-Die Forging in Hammers and Presses

Classification of Closed-Die Forgings

Closed-die forgings are generally classified as blocker-type, conventional, and close-tolerance.

Blocker-type forgings are produced in relatively inexpensive dies, but their weight and dimensions are somewhat greater than those of corresponding conventional closed-die forgings. A blocker-type forging approximates the general shape of the final part, with relatively generous finish allowance and radii. Such forgings are sometimes specified when only a small number of forgings are required and the cost of machining parts to final shape is not excessive.

Conventional closed-die forgings are the most common type and are produced to comply with commercial tolerances. These forgings are characterized by design complexity and tolerances that fall within the broad range of general forging practice. They are made closer to the shape and dimensions of the final part than are blocker-type forgings; therefore, they are lighter and have more detail.

Close-tolerance forgings are usually held to smaller dimensional tolerances than conventional forgings. Little or no machining is required after forging, because close-tolerance forgings are made with less draft, less material, and thinner walls, webs, and ribs. These forgings cost more and require higher forging pressures per unit of plan area than conventional forgings. However, the higher forging cost is sometimes justified by a reduction in machining cost.

Shape Complexity in Forging

Metal flow in forging is greatly influenced by part or die geometry. Several operations (preforming or blocking) are often needed to achieve gradual flow of the metal from an initially simple shape (cylinder or round-cornered square billet) into the more complex shape of the final forging. In general, spherical and blocklike shapes are the easiest to forge in impression or closed dies. Parts with long, thin sections or projections (webs and ribs) are more difficult to forge because they have more surface area per unit volume. Such variations in shape maximize the effects of friction and temperature changes and therefore influence the final pressure required to fill the die cavities. There is a direct relationship between the surface-to-volume ratio of a forging and the difficulty in producing that forging.

The ease of forging more complex shapes depends on the relative proportions of vertical and horizontal projections on the part. Figure 3 shows a schematic of the effects of shape on forging difficulties. The parts illustrated in Fig. 3(c) and 3(d) would require not only higher forging loads but also at least one more forging operation than the parts illustrated in Fig. 3(a) and 3(b) in order to ensure die filling.

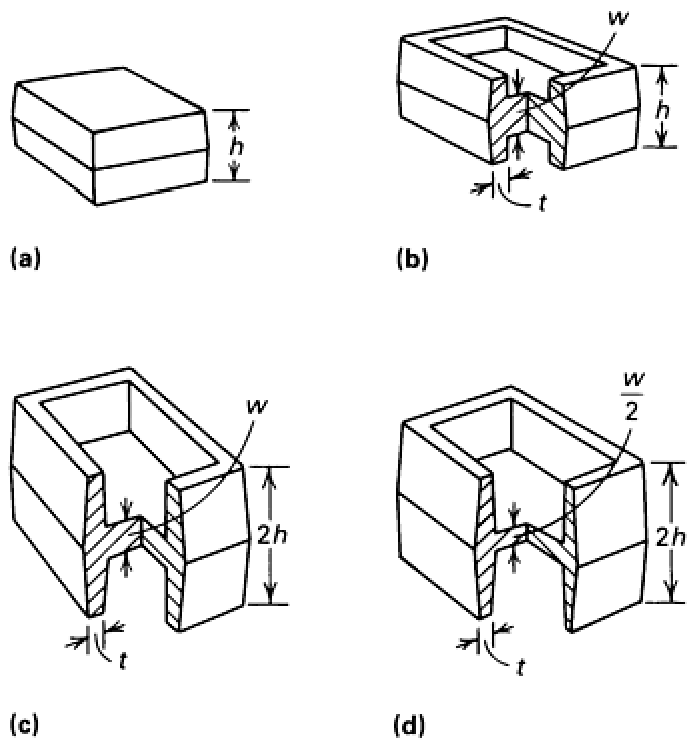

Fig. 3 Forging difficulty as a function of part geometry. Difficulty in forging increases from (a) to (d). (a)

Rectangular shape. (b) Rib-web part. (c) Part with higher rib. (d) Part with higher rib and thinner web.

As shown in Fig. 4, most forgings can be classified into three main groups. The first group consists of the so-called compact shapes, whose three major dimensions (length, l; width, w; and height, h) are approximately equal. The number of parts that fall into this group is rather small. The second group consists of disk shapes for which two of the three dimensions (l and w) are approximately equal and are greater than the height h. All round forgings belong in this group, which includes approximately 30% of all commonly used forgings. The third group consists of long shapes that have one major dimension significantly greater than the other two ($l > w \cdot h$). These three basic groups are further divided into subgroups depending on the presence and type of elements subsidiary to the basic shape.

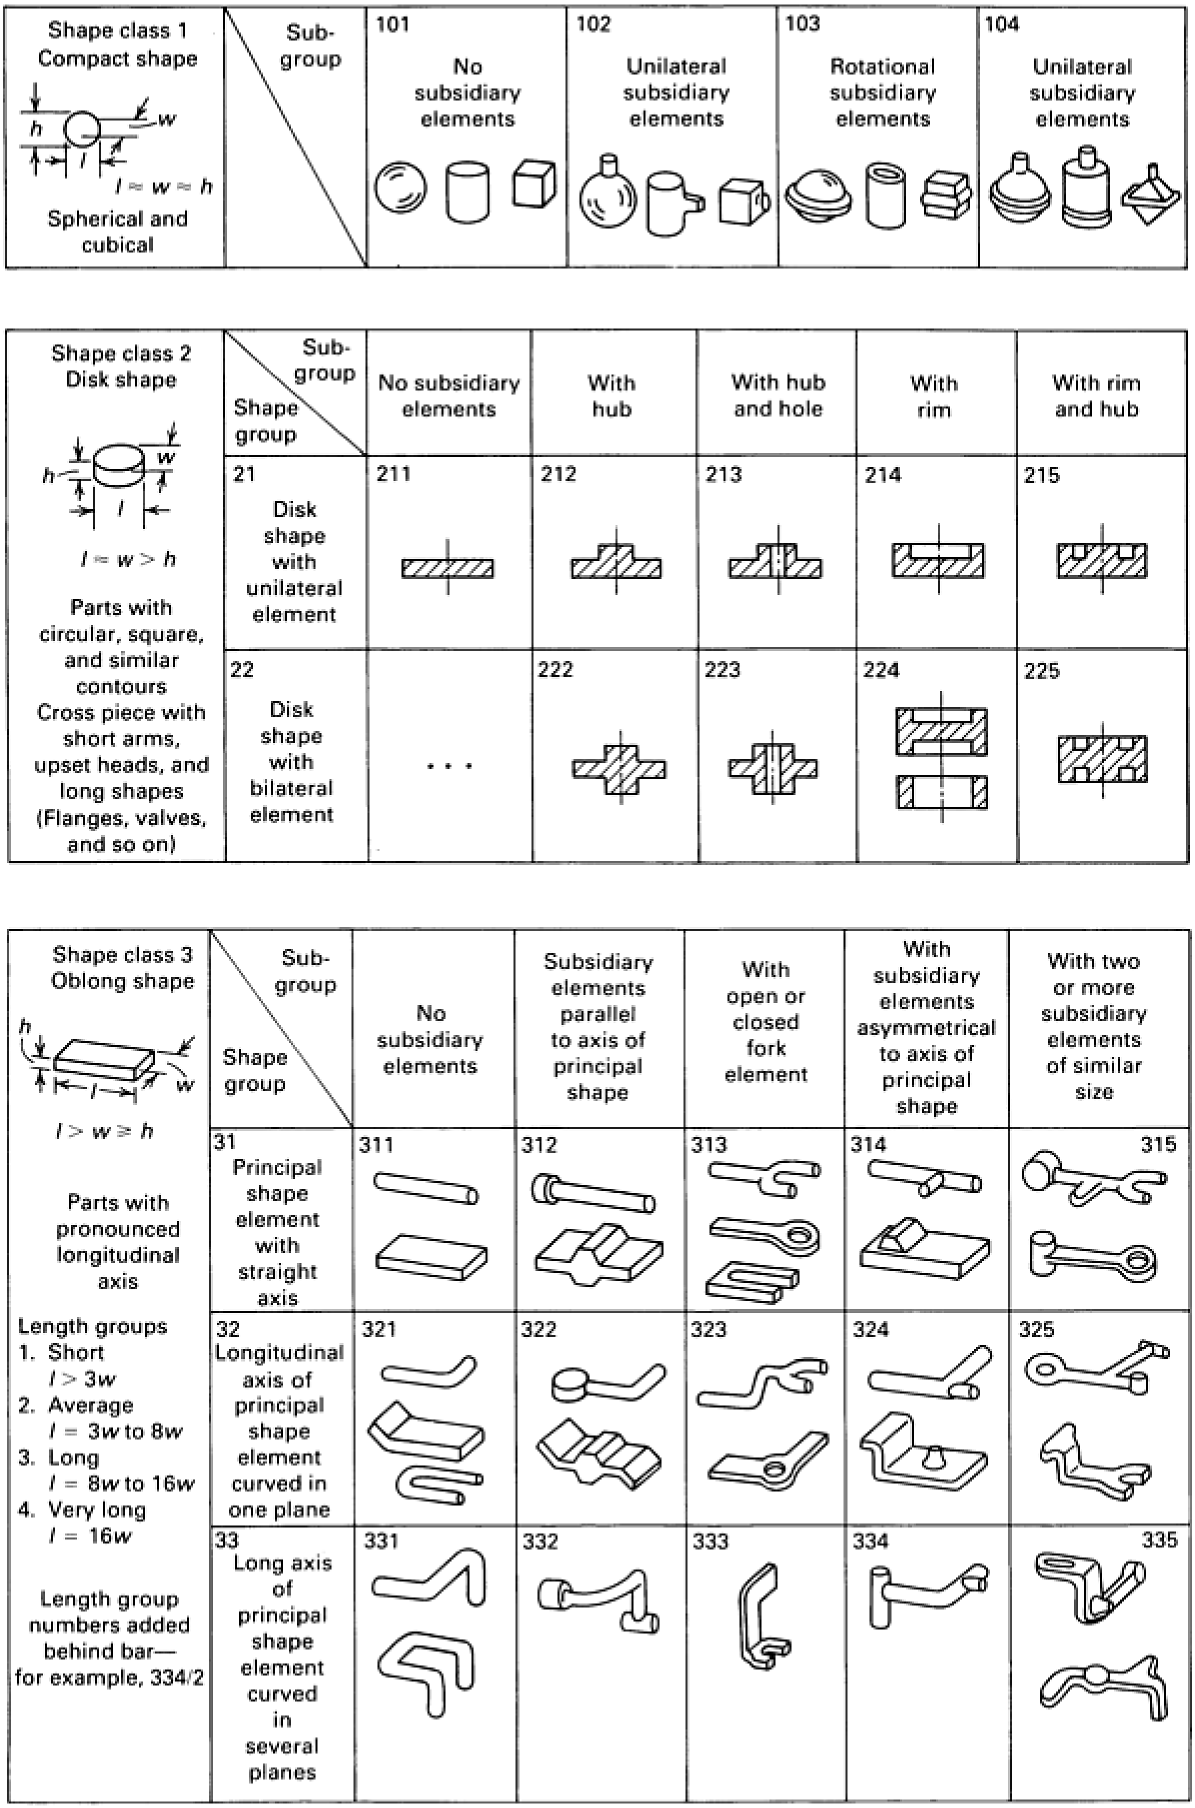

Fig. 4 Classification of forging shapes. See text for details.

This shape classification can be useful for practical purposes, such as estimating costs and predicting preforming steps. However, this method is not entirely quantitative and requires some subjective evaluation based on past experience.

Design of Blocker (Preform) Dies

One of the most important aspects of closed-die forging is proper design of preforming operations and of blocker dies to achieve adequate metal distribution. Therefore, in the finish-forging operation, defect-free metal flow and complete die filling can be achieved, and metal losses into the flash can be minimized. In preforming, round or round-cornered square stock with constant cross section is deformed such that a desirable volume distribution is achieved prior to the final closed-die forging operation. In blocking, the preform is die forged in a blocker cavity before finish forging.

The primary objective of preforming is to distribute the metal in the preform in order to:

- Ensure defect-free metal flow and adequate die filling
- Minimize the amount of material lost into flash
- Minimize die wear in the finish-forging cavity by reducing metal movement in this direction
- Achieve desired grain flow and control mechanical properties

Common practice in preform design is to consider planes of metal flow--that is, selected cross sections of the forging--as shown in Fig. 5. Several preforming operations may be required before a part can be successfully finish forged. In determining the various forging steps, it is first necessary to obtain the volume of the forging, based on the areas of successive cross sections throughout the forging. A volume distribution can be obtained by using the following procedure:

- Lay out a dimensioned drawing of the finish configuration, complete with flash
- Construct a baseline for area determination parallel to the centerline of the part
- Determine maximum and minimum cross-sectional areas perpendicular to the centerline of the part
- Plot these areas at proportional distances from the baseline
- Connect these points with a smooth curve. In cases in which it is not clear how the curve would best show the changing cross-sectional areas, plot additional points to assist in determining a smooth representative curve
- Above this curve, add the approximate area of the flash at each cross section, giving consideration to those sections where the flash should be widest. The flash will generally be of a constant thickness, but will be widest at the narrower sections and smallest at the wider sections
- Convert the maximum and minimum area values to round or rectangular shapes having the same cross-sectional areas

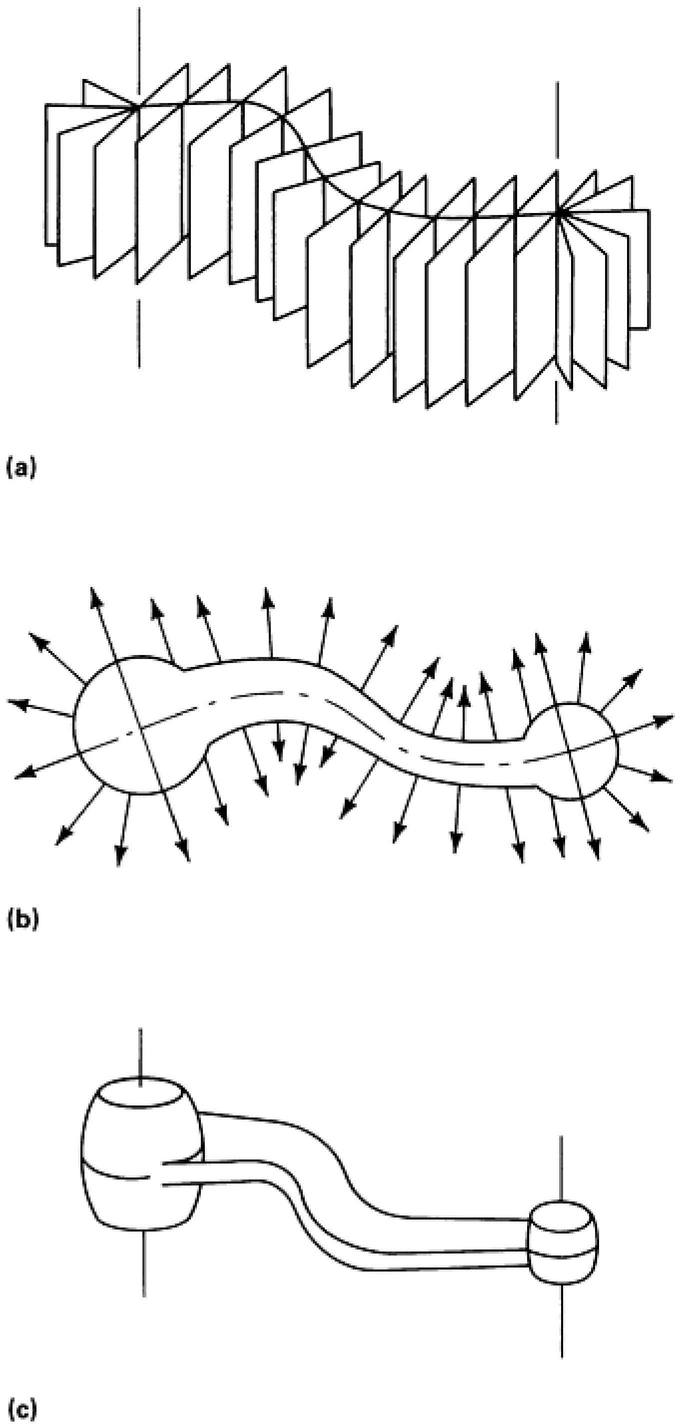

Fig. 5 Planes (a) and directions (b) of metal flow during the forging of a relatively complex shape. The finished forging is shown in (c).

In designing the cross sections of a blocker (preform) die impression, three basic rules must be followed:

- The area of each cross section along the length of the preform must be equal to the area of the finish cross section augmented by the area necessary for flash. Therefore, the initial stock distribution is obtained by determining the areas of cross sections along the main axis of the forging
- All the concave radii (including fillet radii) of the preform should be larger than the radii of the forged part
- When practical, the dimensions of the preform should be greater than those of the finished part in the forging direction so that metal flow is mostly of the upsetting type rather than the extrusion type. During

the finishing operation, the material will then be squeezed laterally toward the die cavity without additional shear at the die/material interface. Such conditions minimize friction and forging load and reduce wear along the die surfaces

Application of these three principles to steel forgings is illustrated in Fig. 6 for some solid cross sections. The qualitative principles of preform design are well known, but quantitative information is rarely available.

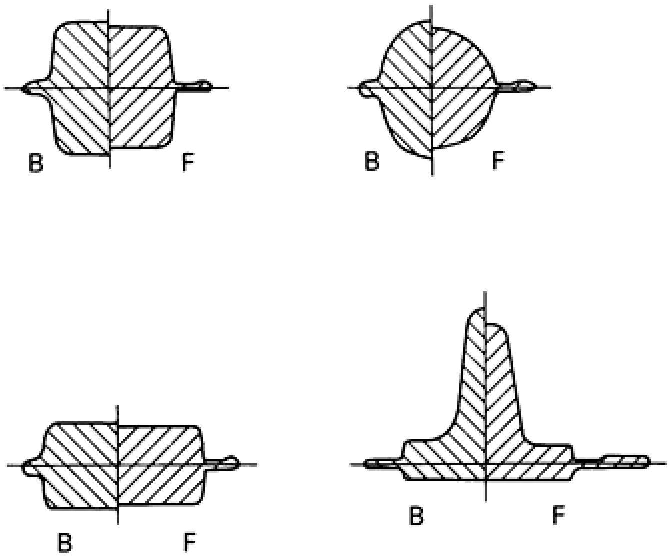

Fig. 6 Suggested blocker cross sections for steel forgings. B, blocker; F, finished forging.

For the forging of complex parts, empirical guidelines may not be sufficient, and trial-and-error procedures may be time consuming and costly. A more systematic and well-proven method for developing preform shapes is physical modeling, using a soft material such as lead, plasticine, or wax as a model forging material and hard plastic or low-carbon steel dies as tooling. Therefore, with relatively low-cost tooling and with some experimentation, preform shapes can be determined. Detailed information on physical modeling and the use of computer-aided design and manufacturing (CAD/CAM) for forging design is available in the Section "Computer-Aided Process Design for Bulk Forming" in this Volume. The use of CAD/CAM in die design is also discussed in the section "CAD/CAM of Forging Dies" in this article.

Flash Design

The influences of flash thickness and flash land width on forging pressure are reasonably well understood from a qualitative viewpoint (Fig. 7). Essentially, forging pressure increases with decreasing flash thickness and with increasing flash land width because of combinations of increasing restriction, increasing frictional forces, and decreasing metal temperatures at the flash gap.

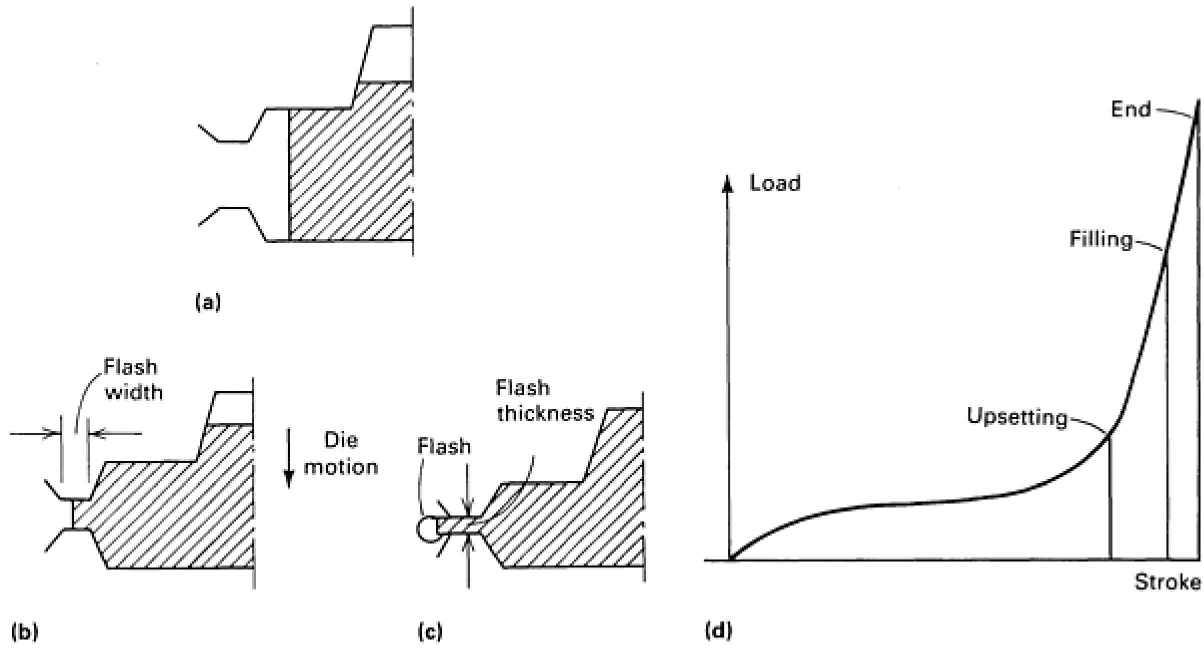

Fig. 7 Metal flow (a to c) and load-stroke curve (d) in closed-die forging. (a) Upsetting. (b) Filling. (c) End.

A typical load-versus-stroke curve for a closed-die forging is shown in Fig. 8. Loads are relatively low until the more difficult details are partly filled and the metal reaches the flash opening (Fig. 7). This stage corresponds to point P_1 in Fig. 8. For successful forging, two conditions must be fulfilled when this point is reached. First, a sufficient volume of metal must be trapped within the confines of the die to fill the remaining cavities, and second, extrusion of metal through the narrowing gap of the flash opening must be more difficult than filling the more intricate detail in the die.

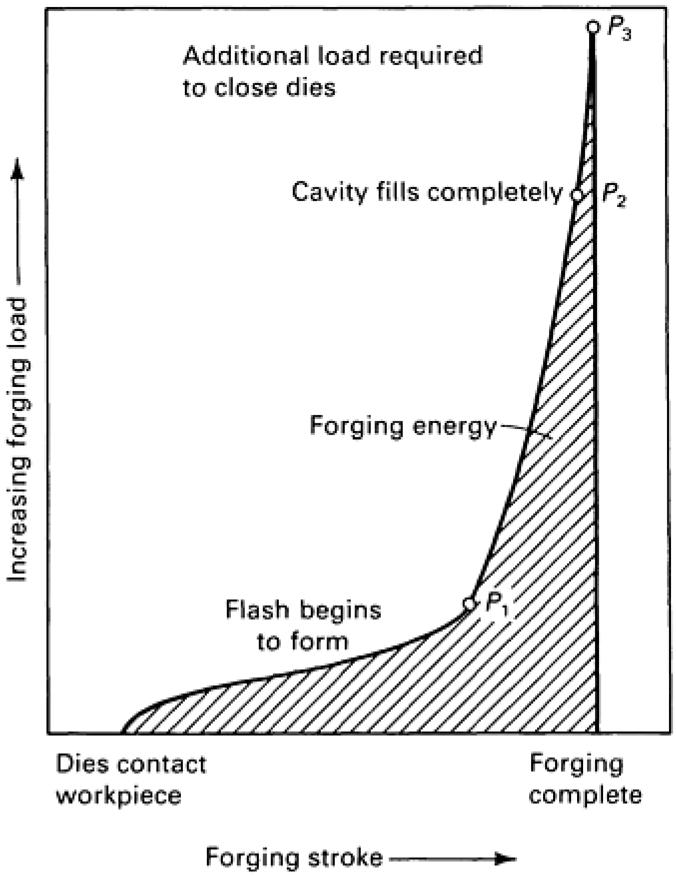

Fig. 8 Typical load-stroke curve for a closed-die forging showing three distinct stages.

As the dies continue to close, the load increases sharply to a point P_2, the stage at which the die cavity is filled completely. Ideally, at this point, the cavity pressure provided by the flash geometry should be just sufficient to fill the entire cavity, and the forging should be completed. However, P_3 represents the final load reached in normal practice for ensuring that the cavity is completely filled and that the forging has the proper dimensions. During the stroke from P_2 to P_3, all metal flow occurs near or in the flash gap, which in turn becomes more restrictive as the dies close. In this respect, the detail most difficult to fill determines the minimum load for producing a fully filled forging. Therefore, the dimensions of the flash determine the final load required for closing the dies. Formation of the flash, however, is greatly influenced by the amount of excess material available in the cavity, because this amount determines the instantaneous height of the extruded flash and therefore the die stresses.

A cavity can be filled with various flash geometries if there is always sufficient material in the die. Therefore, is it possible to fill the same cavity by using a less restrictive (thicker) flash and to do this at a lower total forging load if the necessary excess material is available (in this case, the advantages of lower forging load and lower cavity stress are offset by increased scrap loss) or if the workpiece is properly preformed (in which case low stresses and material losses are obtained by additional preforming).

The shape classification (Fig. 4) has been used in the systematic evaluation of flash dimensions in steel forgings. The results for shape group 224 are presented in Fig. 9 as an example. In general, the flash thickness is shown to increase with forging weight, while the ratio of flash land width to flash thickness decreases to a limiting value.

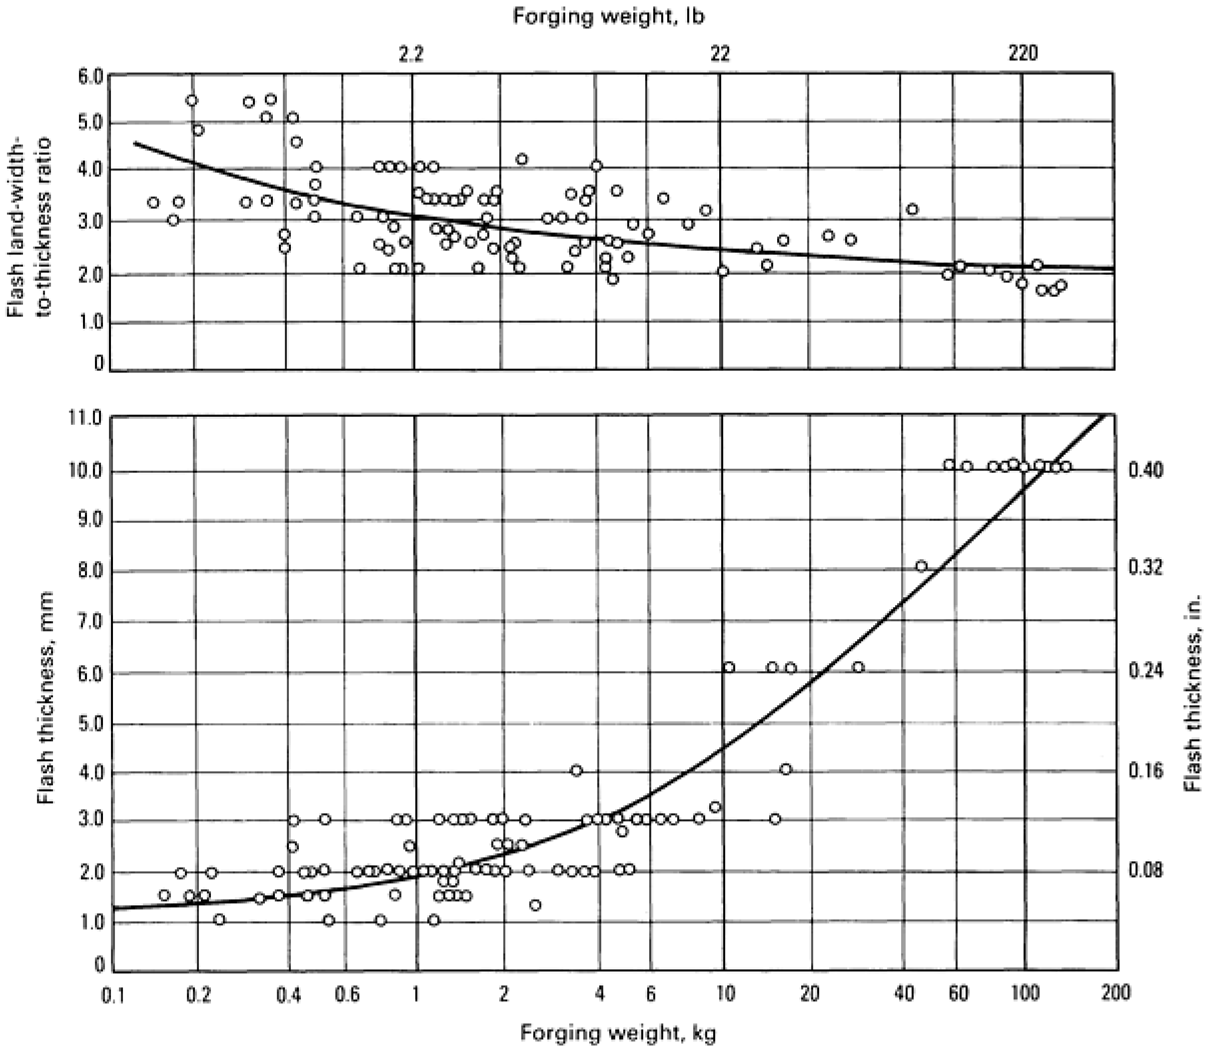

Fig. 9 Variations in flash land-width-to-thickness ratio (top) and in flash thickness (bottom) with forging weight for carbon and alloy steel forgings in shape group 224 (see Fig. 4).

Prediction of Forging Pressure

It is often necessary to predict forging pressure so that a suitable press can be selected and so that die stresses can be prevented from exceeding allowable limits. In estimating the forging load empirically, the surface area of the forging, including the flash zone, is multiplied by an average forging pressure known from experience. The forging pressures encountered in practice vary from 56 to 98 kg/mm^2 (80 to 140 ksi), depending on the material and the geometrical configuration of the part. Figure 10 shows forging pressures for parts made of various carbon (up to 0.6% C) and low-alloy steels. In these trials, flash land-width-to-thickness ratios from 2 to 4 were used. The variable that most influences forging pressure is the average height of the forging. The lower curve in Fig. 10 relates to relatively simple parts, and the upper curve to more difficult-to-forge parts.

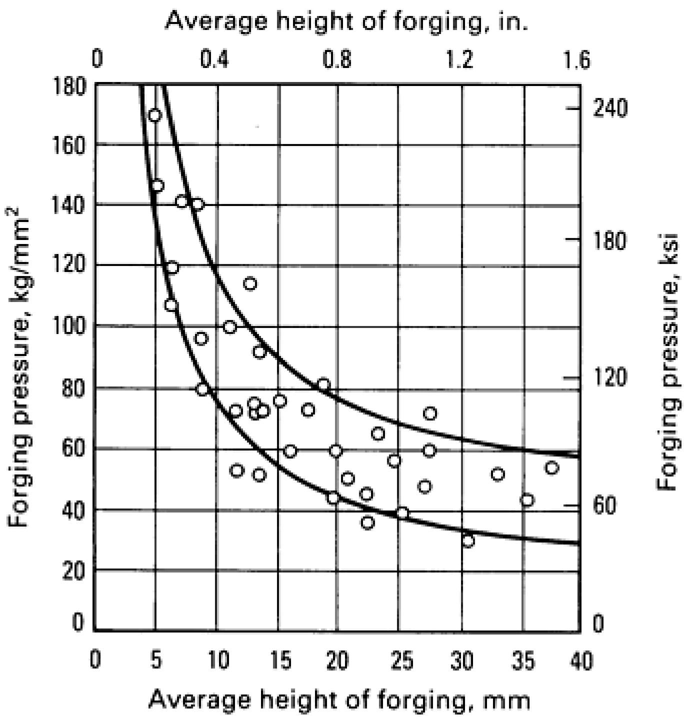

Fig. 10 Forging pressure versus average height of forging for carbon and low-alloy steel forgings. Lower curve is for relatively simple parts; upper curve relates to more difficult-to-forge part geometries. Data are for flash land-to-thickness ratios from 2 to 4.

Most empirical methods, summarized in terms of simple formulas or nomograms, are not sufficiently general for predicting forging loads for a variety of parts and materials. Lacking a suitable empirical formula, one may use analytical or computer-aided techniques for calculating forging loads and stresses.

CAD/CAM of Forging Dies

During the last decade, computers have been used to an increasing extent for forging applications. The initial developments focused on the numerically controlled (NC) machining of forging dies. In the mid-1970s, computer-aided drafting and NC machining were also introduced for structural forgings and for forging steam turbine blades. During the early 1980s several companies began to use stand-alone CAD/CAM systems--normally used for mechanical designs, drafting, and NC machining--for the design and manufacture of forging dies.

Stand-alone CAD/CAM systems are commercially available and have the necessary software for computer-aided drafting and NC machining. A typical CAD/CAM system consists of a microcomputer or minicomputer, a graphics display terminal, a keyboard, a digitizer with menu for data entry, an automatic drafting machine, and hardware for information storage and NC tape punching or floppy disk preparation. Such systems also allow, at various levels of automation, three-dimensional representation of the forging and the possibility of zooming and rotating the forging-geometry display on the graphics terminal screen for the purpose of visual inspection. These systems also allow sectioning of a given forging, that is, the description, drawing, and display of desired forging cross sections for the purpose of die stress and metal flow analyses. Therefore, the results can be displayed for easy interaction between the designer and the computer system, modifications to die design can be easily made, and alternatives can be explored.

The ultimate advantage to computer-aided design in forging is achieved when reasonably accurate and inexpensive computer software is available for simulating metal flow throughout a forging operation (Fig. 11). In this case, forging experiments can be conducted on a computer by simulating the finish forging that would result from an assumed or selected blocker design, and the results can be displayed on a graphics terminal. If the simulation indicates that the selected blocker design would not fill the finisher die or that too much material would be wasted, another blocker design can be selected and the computer simulation, or trial, can be repeated. Such computer-aided simulations reduce the required number of expensive die tryouts. More information on CAD/CAM in forging design is available in the Section "Computer-Aided Process Design for Bulk Forming" in this Volume.

Equipment for Closed-Die Forging

Hammers and Presses. The various types of hammers and presses used to provide the force for closed-die forging are described in the article "Hammers and Presses for Forging" in this Volume. Capacities and ratings of each major type of press or hammer are discussed in the article "Selection of Forging Equipment" in this Volume.

Dies for closed-die forging are discussed in detail in the article "Dies and Die Materials for Hot Forging" in this Volume.

Cutting of bar stock can be accomplished by cold or hot shearing, sawing, abrasive cutting, and thermal or electric arc cutting. These operations, as well as equipment used for cutting, are described in the Section "Shearing, Slitting, and Cutting" in this Volume.

Heating Equipment. There are wide variations in the forging temperature ranges for various materials (Table 1). These differences, along with differences in stock and the availability of various fuels, have resulted in a wide variety of heating equipment. Various types of electric and fuel-fired furnaces are used, as well as resistance and induction heating. Regardless of the heating method used, temperature and atmospheric conditions within the heating unit must be controlled to ensure that the forgings subsequently produced will develop the optimal microstructure and properties.

Forging Temperatures for Steels

Maximum safe forging temperatures for carbon and alloy steels are given in Table 2, which indicates that forging temperature decreases as carbon content increases. The higher the forging temperature, the greater the plasticity of the steel, which results in easier forging and less die wear; however, the danger of overheating and excessive grain coarsening is increased. If a steel that has been heated to its maximum safe temperature is forged rapidly and with large reduction, the energy transferred to the steel during forging can substantially increase its temperature, thus causing overheating.

Table 2 Maximum safe forging temperatures for carbon and alloy stools of various carbon contents

Carbon content, %	Maximum safe forging temperature			
	Carbon steels		Alloy steels	
	°C	**°F**	**°C**	°F
0.10	1290	2350	1260	**2300**
0.20	1275	2325	1245	**2275**
0.30	1260	2300	1230	**2250**
0.40	1245	2275	1230	**2250**
0.50	1230	2250	1230	**2250**
0.60	1205	2200	1205	**2200**

0.70	1190	2175	1175	**2150**
0.90	1150	2100	. . .	**. . .**
1.10	**1110**	**2025**	**. . .**	**. . .**

The effect of carbon content on forging temperature is the same for most tool steels as for carbon and alloy steels. However, the complex alloy compositions of some tool steels have different effects on forging temperature. Forging temperatures for tool steels are listed in Table 3.

Table 3 Recommended forging temperature ranges for tool steels

Steels	Forging temperatures					
	Preheat slowly to:		**Begin forging at[(a)]:**		Do not forge below:	
	°C	**°F**	**°C**	**°F**	**°C**	°F

P20	**815**	**1500**	**1065-1230**	**1950-2250**	**815**	**1500**

(a) The temperature at which to begin forging is given as a range; the higher side of the range should be used for large sections and heavy or rapid reductions, and the lower side for smaller sections and lighter reductions. As the alloy content of the steel increases, the time of soaking at forging temperature increases proportionately. Similarly, as the alloy content increases, it becomes more necessary to cool slowly from the forging temperature. With very high alloy steels, such as high-speed steels and air-hardening steels, this slow cooling is imperative in order to prevent cracking and to leave the steel in a semisoft condition. Either furnace cooling of the steel or burying it in an insulating medium (such as lime, mica, or diatomaceous earth) is satisfactory.

(b) Forging temperatures for water-hardening tool steels vary with carbon content. The following temperatures are recommended: for 0.60-1.25% C, the range given; for 1.25 to 1.40% C, the low side of the range given.

Heating Time. For any steel, the heating time must be sufficient to bring the center of the forging stock to the forging temperature. A longer heating time than necessary results in excessive decarburization, scale, and grain growth. For stock measuring up to 75 mm (3 in.) in diameter, the heating time per inch of section thickness should be no more than 5 min for low-carbon and medium-carbon steels or no more than 6 min for low-alloy steel. For stock 75 to 230 mm (3 to 9 in.) in diameter, the heating time should be no more than 15 min per inch of thickness. For high-carbon steels (0.50% C and higher) and for highly alloyed steels, slower heating rates are required, and preheating at temperatures from 650 to 760 °C (1200 to 1400 °F) is sometimes necessary to prevent cracking.

Finishing temperature should always be well above the transformation temperature of the steel being forged in order to prevent cracking of the steel and excessive wear of the dies, but should be low enough to prevent excessive grain growth. For most carbon and alloy steels, 980 to 1095 °C (1800 to 2000 °F) is a suitable range for finish forging. More information on forging parameters for ferrous alloys is available in the articles "Forging of Carbon and Alloy Steels" and "Forging of Stainless Steel" in this Volume.

Forging Temperatures for Steels

Maximum safe forging temperatures for carbon and alloy steels are given in Table 2, which indicates that forging temperature decreases as carbon content increases. The higher the forging temperature, the greater the plasticity of the steel, which results in easier forging and less die wear; however, the danger of overheating and excessive grain coarsening is increased. If a steel that has been heated to its maximum safe temperature is forged rapidly and with large reduction, the energy transferred to the steel during forging can substantially increase its temperature, thus causing overheating.

Table 2 Maximum safe forging temperatures for carbon and alloy stools of various carbon contents

Carbon content, %	Maximum safe forging temperature			
	Carbon steels		Alloy steels	
	°C	°F	°C	°F
0.10	1290	2350	1260	2300
0.20	1275	2325	1245	2275
0.30	1260	2300	1230	2250
0.40	1245	2275	1230	2250
0.50	1230	2250	1230	2250
0.60	1205	2200	1205	2200
0.70	1190	2175	1175	2150
0.90	1150	2100	. . .	. . .
1.10	1110	2025	. . .	. . .

The effect of carbon content on forging temperature is the same for most tool steels as for carbon and alloy steels. However, the complex alloy compositions of some tool steels have different effects on forging temperature. Forging temperatures for tool steels are listed in Table 3.

(a) The temperature at which to begin forging is given as a range; the higher side of the range should be used for large sections and heavy or rapid reductions, and the lower side for smaller sections and lighter reductions. As the alloy content of the steel increases, the time of soaking at forging temperature increases proportionately. Similarly, as the alloy content increases, it becomes more necessary to cool slowly from the forging temperature. With very high alloy steels, such as high-speed steels and air-hardening steels, this slow cooling is imperative in order to prevent cracking and to leave the steel in a semisoft condition. Either furnace cooling of the steel or burying it in an insulating medium (such as lime, mica, or diatomaceous earth) is satisfactory.

(b) Forging temperatures for water-hardening tool steels vary with carbon content. The following temperatures are recommended: for 0.60-1.25% C, the range given; for 1.25 to 1.40% C, the low side of the range given.

Heating Time. For any steel, the heating time must be sufficient to bring the center of the forging stock to the forging temperature. A longer heating time than necessary results in excessive decarburization, scale, and grain growth. For stock measuring up to 75 mm (3 in.) in diameter, the heating time per inch of section thickness should be no more than 5 min for low-carbon and medium-carbon steels or no more than 6 min for low-alloy steel. For stock 75 to 230 mm (3 to 9 in.) in diameter, the heating time should be no more than 15 min per inch of thickness. For high-carbon steels (0.50% C and higher) and for highly alloyed steels, slower heating rates are required, and preheating at temperatures from 650 to 760 °C (1200 to 1400 °F) is sometimes necessary to prevent cracking.

Finishing temperature should always be well above the transformation temperature of the steel being forged in order to prevent cracking of the steel and excessive wear of the dies, but should be low enough to prevent excessive grain growth. For most carbon and alloy steels, 980 to 1095 °C (1800 to 2000 °F) is a suitable range for finish forging. More information on forging parameters for ferrous alloys is available in the articles "Forging of Carbon and Alloy Steels" and "Forging of Stainless Steel" in this Volume.

Control of Die Temperature

Dies should be heated to at least 120 °C (250 °F), and preferably to 205 to 315 °C (400 to 600 °F), before forging begins. Dies are sometimes heated in ovens before being placed in the hammer or press. Temperature-indicating crayons can be used to measure surface temperature. Failure to warm the dies is likely to result in die breakage.

Operating Temperature. Normal hammer-forging and press-forging practices do not include special methods for cooling the dies; their mass and the lubricant usually provide cooling and keep them within a safe operating range (typically 315 °C, or 600 °F, maximum). However, the maximum operating temperature depends greatly on the die-steel composition. Higher temperatures may be permitted for the higher-alloy die steels, such as H11. In no event should any portion of the die be operated at a temperature higher than that at which it was tempered. Most dies are tempered at 540 to 595 °C (1000 to 1100 °F), and sometimes higher; therefore, the danger of exceeding the temperature is not great. However, the hardness at working temperature varies a great deal for different steels.

Trimming

The trimming method used for closed-die forgings depends mainly on the quantity of forgings to be trimmed, the size of the forgings, and the equipment available. A specific trimming procedure can sometimes eliminate a machining operation.

For small quantities or for large forgings, sawing or other machining operations are frequently used to remove the flash. For large quantities, the cost of trimming dies can usually be justified. Most closed-die forgings are die trimmed.

With respect to die trimming, forging materials can be divided into two groups: those that can be trimmed cold and those that should be trimmed hot. Almost all materials can be cold trimmed, but some must have special treatment after forging and prior to cold trimming. Generally, a forging can be cold trimmed satisfactorily if the work metal to be trimmed has a tensile strength of not more than 690 MPa (100 ksi) or a hardness of not more than 207 HB.

Cold trimming usually refers to the trimming of metal flash at a temperature below 150 °C (300 °F). This method is extensively used, especially for small forgings. An advantage of cold trimming is that it can be done at any time; it need not be a part of the forging sequence, and no reheating of the forgings is needed.

Hot trimming is done at temperatures as low as 150 °C (300 °F) for nonferrous alloys and as high as 980 °C (1800 °F) or above for steels and other ferrous alloys.

Cooling Practice

Cooling in still air or in factory tote boxes is common practice and is usually satisfactory for carbon steel or low-alloy steel forgings when cross sections are no greater than approximately 64 mm ($2\frac{1}{2}$ in.). Flaking may occur on larger forgings when they are air cooled. Flakes (also called shatter cracks or snowflakes) are short, discontinuous internal fissures attributed to stresses produced by localized transformation and decreased solubility of hydrogen during cooling. In a fractured surface, flakes appear as bright silvery areas; on an etched surface, they appear as short cracks. Flaking indicates the need for cooling to at least 175 °C (350 °F) in a furnace or cooling by burying the piece in sand or slag. An alternative method of treating large forgings made of alloy steels such as 4340 consists of cooling in air to about 540 °C (1000 °F), followed by isothermal annealing at 650 °C (1200 °F). Forgings of alloy tool steel should always be cooled slowly, as is recommended above for larger forgings of carbon and alloy steels.

Closed-Die Forging in Hammers and Presses

Typical Forging Sequence

The forging of automotive connecting rods is a good example of the various steps taken to produce a closed-die forging. As shown in Fig. 12, the sequence begins with round bar stock. The bar stock is heated to the proper temperature, then delivered to the hammer. Preliminary hot working proportions the metal for forming of the connecting rod and improves grain structure.

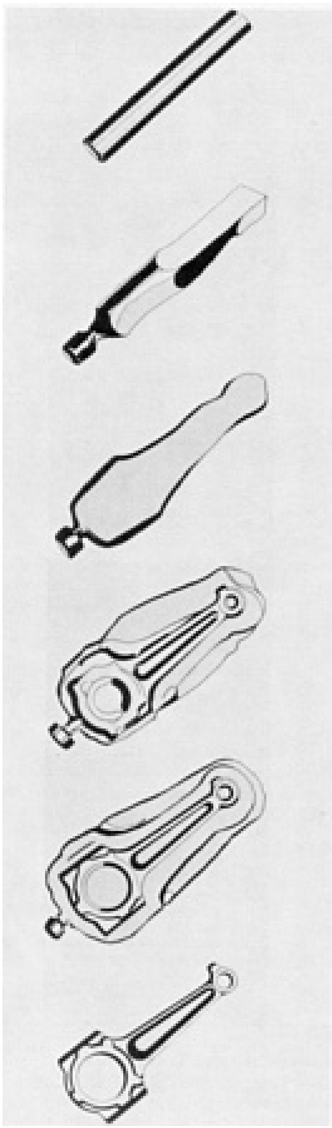

Fig. 12 Steps involved in the closed-die forging of automotive connecting rods. See text for details.

Blocking then forms the connecting rod into its first definite shape. This may necessitate several blows from the hammer. Flash is produced in the blocking operation and appears as flat, unformed metal around the edges of the connecting rod. The final shape of the connecting rod is obtained by the impact of several additional blows from the hammer to ensure that the dies are completely filled by the hot metal. The completed part may be trimmed either hot or cold to remove flash.

Hot Upset Forging

Revised by Wilfred L. Mehling, Ajax Manufacturing Company

Introduction

HOT UPSET FORGING (also called hot heading, hot upsetting, or machine forging) is essentially a process for enlarging and reshaping some of the cross-sectional area of a bar, tube, or other product form of uniform (usually round) section. In its simplest form, hot upset forging is accomplished by holding the heated forging stock between grooved dies and applying pressure to the end of the stock, in the direction of its axis, by the use of a heading tool, which spreads (upsets) the end by metal displacement.

Hot Upset Forging

Revised by Wilfred L. Mehling, Ajax Manufacturing Company

Applicability

Although hot upsetting was originally restricted to the single-blow heading of parts such as bolts, current machines and tooling permit the use of multiple-pass dies that can produce complex shapes accurately and economically. The process is widely used for producing finished forgings ranging in complexity from simple bolts or flanged shafts to wrench sockets that require simultaneous upsetting and piercing. Forgings that require center (not at bar end) or offset upsets can also be completed.

In many cases, hot upsetting is used as a means of preparing stock for forging on a hammer or in a press. Hot upsetting is also occasionally used as a finishing operation following hammer or press forging, such as in making crankshafts.

Because the transverse action of the moving die and the longitudinal action of the heading tool are available for forging in both directions, either separately or simultaneously, hot upset forging is not limited to simple gripping and heading operations. The die motion can be used for swaging, bending, shearing, slitting, and trimming. In addition to upsetting, the heading tools are used for punching, internal displacement, extrusion, trimming, and bending.

In the upset forging process, the working stock is frequently confined in the die cavities during forging. The upsetting action creates pressure, similar to hydrostatic pressure, that causes the stock to fill the die impressions completely. Thus, a wide variety of shapes can be forged and removed from the dies by this process.

Work Material and Size. Although most forgings produced by hot upsetting are made of carbon or alloy steel, the process can be used for shaping any other forgeable metal. The size or weight of a workpiece that can be hot upset is limited only by the capabilities of available equipment; forgings ranging in weight from less than an ounce to several hundred pounds can be produced by this method.

Hot Upset Forging

Revised by Wilfred L. Mehling, Ajax Manufacturing Company

Forging Machines

The essential components of a typical machine for hot upset forging are illustrated in Fig. 1. These machines are mechanically operated from a main shaft with an eccentric drive that operates a main slide, or header slide, horizontally. Cams drive a die slide, or grip slide, which moves horizontally at right angles to the header slide, usually through a toggle mechanism. The action of the header slide is similar to that of the ram in a mechanical press. Power is supplied to a machine flywheel by an electric motor. A flywheel clutch provides for stop-motion operation, placing movement of the slides under operator control.

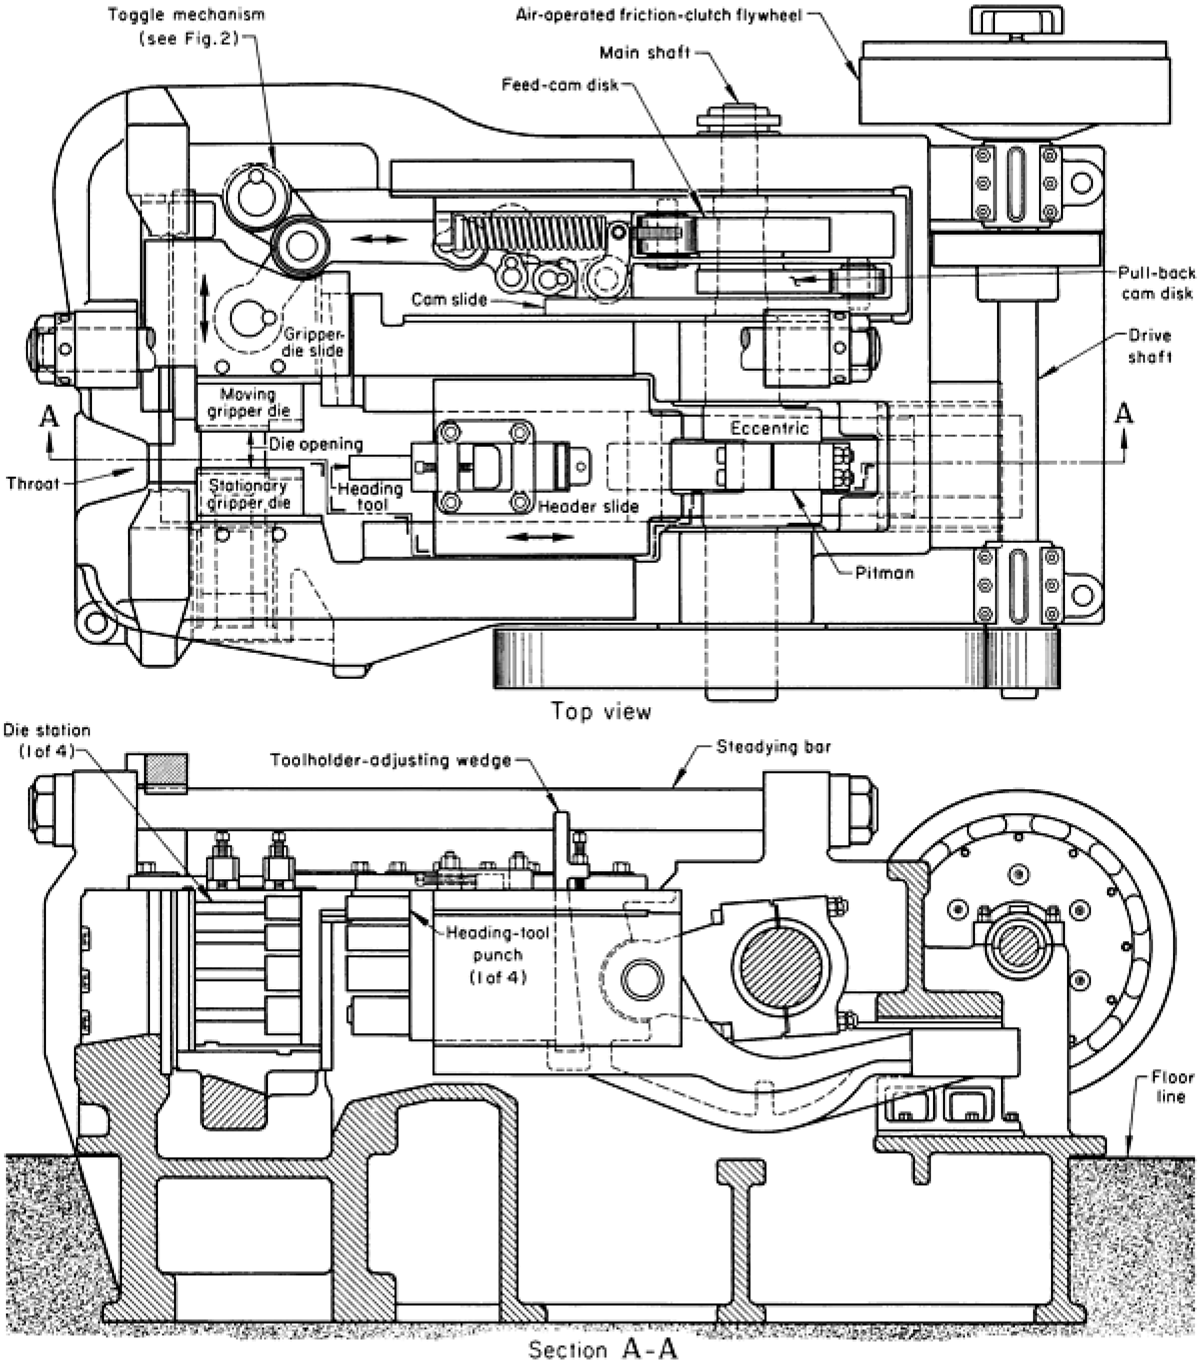

Fig. 1 Principal components of a typical machine for hot upset forging with a vertical four-station die. See text for description of operation.

Forging takes place in three die elements. There are two gripper dies (one stationary and one moved by the die slide), which have matching faces with horizontal grooves to grip the forging stock and hold it by friction, and there is a heading tool, or header, which is carried by the header slide in the plane of the work faces of the gripper dies and aligns with the grooves in these dies (Fig. 2). The travel of the moving die is designated as the die opening, and its timed relationship to the movement of the header slide is such that the dies close during the early part of the header-slide stroke. The part of the forward header-slide stroke that takes place after the dies are closed is known as the stock gather, and the amount that the returning header slide travels before the moving die starts to open is called the hold-on, or the hold.

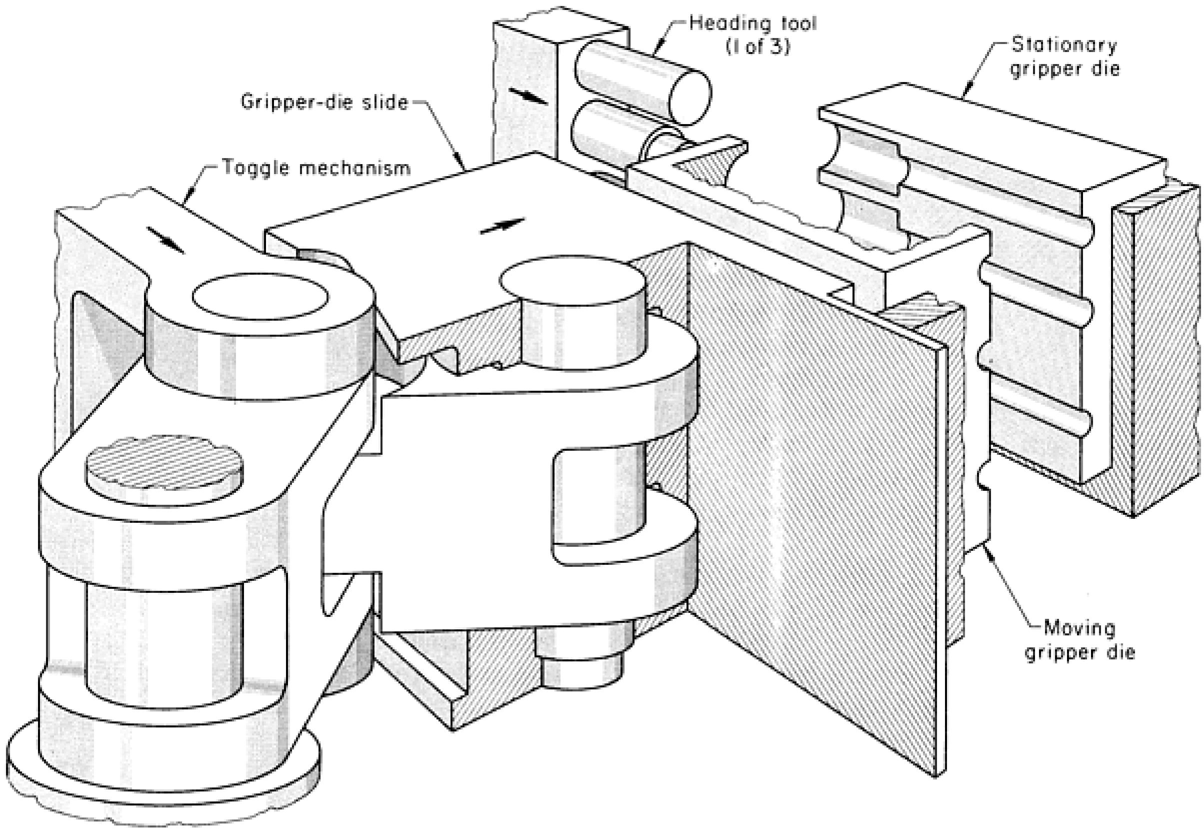

Fig. 2 Basic actions of the gripper dies and heading tools of an upsetter

The die opening determines the maximum diameter of upset that can be transferred between the dies and withdrawn through the throat, without pushing the workpiece forward and lifting it out over the top. The diameter of the stock, rather than the stock gather, determines the amount of stock that can be upset; the stock gather, however, has an important bearing on the depth to which internal displacement can be carried. The height of the die determines the number of progressive operations that can be accommodated in one set of dies.

Operation. The basic actions of the gripper dies and the header tools of an upsetter can be demonstrated by the three-station setup shown in Fig. 2. The stock is positioned in the first (topmost) station of the stationary die of the machine.

During the upset forging cycle, the movable die slides against the stationary die to grip the stock. The header tool, fastened in the header slide, advances toward and against the forging stock to spread it into the die cavity. When the header punch retracts to its back position, the movable dies slide to open position to release the forging. This permits the operator to place the partly forged piece into the next station, where the cycle of the movable die and header tool is repeated. Many forgings can be produced to final shape in a single pass of the machine. Others may require multiple passes for completion.

Revised by Wilfred L. Mehling, Ajax Manufacturing Company

Selection of Machine Size

The rated sizes for upsetters are listed in Table 1, which also provides data on typical rated tonnage capacities, working strokes per minute, and motor ratings. Pressure capacities required for the upset forging of carbon and low-alloy steels are about 345 MPa (25 tons per square inch, or tsi) for simple shapes, but more complex shapes may require pressures of about 510 MPa (37 tsi). Tonnage calculations must include the area of flash produced. The effects of alloy composition on the capacity requirements for upsetters are approximately the same as those for other types of forging equipment. These effects are discussed in the article "Hammers and Presses for Forging" in this Volume. The choice of machine size is also affected by one or more of the following factors: gripper-die stroke, die space, throat clearance, header-slide stroke, header-slide gather, header-slide hold-on, available energy, and cost.

Table 1 Size and operating data for upset forging machines

Rated size, in.[(a)]	**Nominal rated capacity, tonf**[(b)]	**Average strokes per minute**	Average motor rating, hp
1	200	90	**7.5**
$1\frac{1}{4}$	225	75	**10**
$1\frac{1}{2}$	300	65	**10-15**

$2\frac{1}{2}$	500	55	**20-25**
3	600	45	**30**
4	800	35	**40-60**
5	1000	30	**60-75**
6	1200	27	**75**
7	1500	25	**125**
9	1800	23	**150**

10	**2250**	**20**	**200**

(a) 1 in. = 25.4 mm.

(b) 1 tonf = 8.896 kN

Gripper-die stroke is one of the simplest indicators of the maximum diameter of upset (assuming that the stock is a readily forgeable carbon or alloy steel) that can be safely produced on a given size of machining. This stroke must permit a forging having a maximum-diameter upset to drop freely between the dies into the discharge chute below the dies. In using this criterion, allowance must be made for the fact that, unless brake adjustment is perfect, there will be some override (failure of the brake to stop the movement in the extreme open condition), which will reduce the effective clearance between the dies. Therefore, the maximum diameter of upset on forgings that are to drop between the dies should be 12.5 to 25 mm ($\frac{1}{2}$ to 1 in.) less than the gripperdie stroke, depending on machine size. This is a general rule that is applicable to simple upsets in readily forgeable steels and adjustments must be made to accommodate varying conditions. For example, the maximum diameter of upset on forging from more difficult materials, such as stainless steel or heat-resistant alloys, must be reduced in proportion to the reduced forgeability of the material. Similarly, on extremely thin flanges or on upsets having difficult-to-fill contours, maximum diameters must be reduced in proportion to the increase in force required to finish the upset; otherwise, the part will not be completely filled.

Under some circumstances, with special consideration to die design to avoid overloading the machine, it is possible to produce forgings with larger-diameter upsets than the above rule would indicate. When this is done, forgings must be moved forward ahead of the dies if they are to be dropped into the chute, or if long bars are being upset, they are moved forward to clear the dies and then raised and brought back over the top of the dies and out the rear of the machine, where they are unloaded by the operator. The following three techniques can be employed to extend the maximum diameter of upset that can be produced in a machine of a given size.

The first technique involves the use of a blocking pass that finishes the center portion of the upset, followed by a final pass that finishes the outer portion. By this procedure, the effective area of the metal being worked is lessened in each pass. To be effective, however, the face of the finished upset should be slightly concave, so that the finishing punch does not contact the center area finished by the blocking pass.

Second, flange diameters that are in excess of the normal machine capacity can be forged if no attempt is made to confine the outside diameter of the flange. This requires some additional stock removal by machining or trimming, but is an effective means of producing a larger-than-normal upset on an available machine without damage to the machine.

Lastly, the maximum diameter of upset that can be produced in a given size of machine can sometimes be increased by slightly modifying the shape of the upset to facilitate metal flow. Upset shapes that restrict metal flow should be avoided in favor of those that encourage the metal to flow in the desired direction. Small corner or fillet radii and thin flanges should be avoided when the size of a forging makes it borderline for machine capacity.

Die Space. For some applications, a larger machine must be selected because more die space is needed. Die blocks must be high enough to accommodate all passes, and the dies should be long enough to contain all impressions and to allow for gripping or for tong or porter-bar backup. Dies are normally thick enough for any forging that can be produced in the machine in which they fit.

Throat clearance through the machine may become a limiting factor, particularly in upsetting long bars or tubes that extend through the machine throat during operation. The extension of the stationary die beyond the throat is one-half of the maximum diameter of stock that can be cleared.

Header-slide stroke is normally adequate for any forging that can be produced on a given size of machine. However, in some applications, unusually long punches will be retracted insufficiently when the machine is open, thus inhibiting installation and removal of the dies without interference. Under these circumstances, a larger machine may be required.

Header-Slide (Stock) Gather. The forward movement of the header slide and the closing movement of the gripper dies begin simultaneously. That portion of the forward stroke of the header slide remaining after the gripper dies are fully closed is known as the stock gather, and it is the maximum portion of the stroke that can be used for forging. Die layout, particularly in applications involving long upsets or deep piercing operations, should be checked to determine the position of all punches in relation to the work at the start of the stock gather in each pass. Occasionally, this will dictate the selection of a larger machine than would otherwise be required.

Header-slide hold-on, the short distance the header slide travels back on the return stroke before the gripper die starts to open, is important in such operations as deep piercing, in which the tools must be stripped from the work. In these operations, the punch designs should be checked to determine that they will strip free from the work before the gripper die starts to open.

Available Energy. When using the general rule that upsets should be 12.5 to 25 mm ($\frac{1}{2}$ to 1 in.) less in diameter than the gripper-die stroke, it usually follows that the energy input of the machine is sufficient. However, it is sometimes helpful--particularly in applications involving thin flanges, difficult-to-fill shapes, difficult-to-forge materials, or other special upsetting problems--to consider machine capacity in terms of equivalent static pressure, measured in tonnage. This is especially practical when facilities are available to determine experimentally, using hydraulic press equipment, the unit force (MPa or tsi) required to upset a specific workpiece.

If the tonnage rating of machine is not known, it can be obtained from the manufacturer. This tonnage rating will be the load that can be imposed close to the end of the forward stroke without damaging the machine or without causing slip of the friction relief overload protection. As with any crank-operated machine, the available force decreases as the distance from the end of the stroke increases. In a typical upsetter, the available force at the start of the gather will be approximately 80% of the safe rating at the end of the stroke. This is a factor that must be considered in selecting the proper size of machine for upsetting long lengths of stock in one pass.

Cost is often a primary factor in the selection of machine size. If an undersize machine is used, the cost of machine maintenance and tool replacement will be excessive. For production runs, an oversize machine is usually not economical, because burden rate increases with equipment size, and the higher rate increases cost per piece excessively. However, there are exceptions in which the increase in burden cost accompanying the use of a machine larger than required is outweighed by increased productivity.

Hot Upset Forging

10	**2250**	**20**	**200**

(a) 1 in. = 25.4 mm.

(b) 1 tonf = 8.896 kN

Gripper-die stroke is one of the simplest indicators of the maximum diameter of upset (assuming that the stock is a readily forgeable carbon or alloy steel) that can be safely produced on a given size of machining. This stroke must permit a forging having a maximum-diameter upset to drop freely between the dies into the discharge chute below the dies. In using this criterion, allowance must be made for the fact that, unless brake adjustment is perfect, there will be some override (failure of the brake to stop the movement in the extreme open condition), which will reduce the effective clearance between the dies. Therefore, the maximum diameter of upset on forgings that are to drop between the dies should be 12.5 to 25 mm ($\frac{1}{2}$ to 1 in.) less than the gripperdie stroke, depending on machine size. This is a general rule that is applicable to simple upsets in readily forgeable steels and adjustments must be made to accommodate varying conditions. For example, the maximum diameter of upset on forging from more difficult materials, such as stainless steel or heat-resistant alloys, must be reduced in proportion to the reduced forgeability of the material. Similarly, on extremely thin flanges or on upsets having difficult-to-fill contours, maximum diameters must be reduced in proportion to the increase in force required to finish the upset; otherwise, the part will not be completely filled.

Under some circumstances, with special consideration to die design to avoid overloading the machine, it is possible to produce forgings with larger-diameter upsets than the above rule would indicate. When this is done, forgings must be moved forward ahead of the dies if they are to be dropped into the chute, or if long bars are being upset, they are moved forward to clear the dies and then raised and brought back over the top of the dies and out the rear of the machine, where they are unloaded by the operator. The following three techniques can be employed to extend the maximum diameter of upset that can be produced in a machine of a given size.

The first technique involves the use of a blocking pass that finishes the center portion of the upset, followed by a final pass that finishes the outer portion. By this procedure, the effective area of the metal being worked is lessened in each pass. To be effective, however, the face of the finished upset should be slightly concave, so that the finishing punch does not contact the center area finished by the blocking pass.

Second, flange diameters that are in excess of the normal machine capacity can be forged if no attempt is made to confine the outside diameter of the flange. This requires some additional stock removal by machining or trimming, but is an effective means of producing a larger-than-normal upset on an available machine without damage to the machine.

Lastly, the maximum diameter of upset that can be produced in a given size of machine can sometimes be increased by slightly modifying the shape of the upset to facilitate metal flow. Upset shapes that restrict metal flow should be avoided in favor of those that encourage the metal to flow in the desired direction. Small corner or fillet radii and thin flanges should be avoided when the size of a forging makes it borderline for machine capacity.

Die Space. For some applications, a larger machine must be selected because more die space is needed. Die blocks must be high enough to accommodate all passes, and the dies should be long enough to contain all impressions and to allow for gripping or for tong or porter-bar backup. Dies are normally thick enough for any forging that can be produced in the machine in which they fit.

Throat clearance through the machine may become a limiting factor, particularly in upsetting long bars or tubes that extend through the machine throat during operation. The extension of the stationary die beyond the throat is one-half of the maximum diameter of stock that can be cleared.

Header-slide stroke is normally adequate for any forging that can be produced on a given size of machine. However, in some applications, unusually long punches will be retracted insufficiently when the machine is open, thus inhibiting installation and removal of the dies without interference. Under these circumstances, a larger machine may be required.

Header-Slide (Stock) Gather. The forward movement of the header slide and the closing movement of the gripper dies begin simultaneously. That portion of the forward stroke of the header slide remaining after the gripper dies are fully closed is known as the stock gather, and it is the maximum portion of the stroke that can be used for forging. Die layout, particularly in applications involving long upsets or deep piercing operations, should be checked to determine the position of all punches in relation to the work at the start of the stock gather in each pass. Occasionally, this will dictate the selection of a larger machine than would otherwise be required.

Header-slide hold-on, the short distance the header slide travels back on the return stroke before the gripper die starts to open, is important in such operations as deep piercing, in which the tools must be stripped from the work. In these operations, the punch designs should be checked to determine that they will strip free from the work before the gripper die starts to open.

Available Energy. When using the general rule that upsets should be 12.5 to 25 mm ($\frac{1}{2}$ to 1 in.) less in diameter than the gripper-die stroke, it usually follows that the energy input of the machine is sufficient. However, it is sometimes helpful--particularly in applications involving thin flanges, difficult-to-fill shapes, difficult-to-forge materials, or other special upsetting problems--to consider machine capacity in terms of equivalent static pressure, measured in tonnage. This is especially practical when facilities are available to determine experimentally, using hydraulic press equipment, the unit force (MPa or tsi) required to upset a specific workpiece.

If the tonnage rating of machine is not known, it can be obtained from the manufacturer. This tonnage rating will be the load that can be imposed close to the end of the forward stroke without damaging the machine or without causing slip of the friction relief overload protection. As with any crank-operated machine, the available force decreases as the distance from the end of the stroke increases. In a typical upsetter, the available force at the start of the gather will be approximately 80% of the safe rating at the end of the stroke. This is a factor that must be considered in selecting the proper size of machine for upsetting long lengths of stock in one pass.

Cost is often a primary factor in the selection of machine size. If an undersize machine is used, the cost of machine maintenance and tool replacement will be excessive. For production runs, an oversize machine is usually not economical, because burden rate increases with equipment size, and the higher rate increases cost per piece excessively. However, there are exceptions in which the increase in burden cost accompanying the use of a machine larger than required is outweighed by increased productivity.

Hot Upset Forging

Revised by Wilfred L. Mehling, Ajax Manufacturing Company

Tools

The four basic types of upsetter heading tools and dies, shown schematically in Fig. 3, differ in operating principle as follows:

- Tooling does not support exposed working stock (Fig. 3a). Stock is held by the gripper dies, and the heading tool advances to upset the exposed stock
- Stock is supported in the gripper-die impression (Fig. 3b). Great lengths of stock can be upset with this method by using repeated blows. The diameter of the preceding upset becomes the diameter of the working stock for the next pass
- Stock is supported in a recess in the heading tool, which is shaped like the frustum of a cone (Fig. 3c). Stock is gathered in the recessed heading tool. This method is widely used when large amounts of stock must be gathered, as in the forging of transmission shafts
- Stock is supported in the frustum-shaped recess of the heading tool and in the recesses of the gripper dies (Fig. 3d). This method is widely used to achieve a better balance of metal displacement, especially in the development of intricate, difficult-to-forge shapes

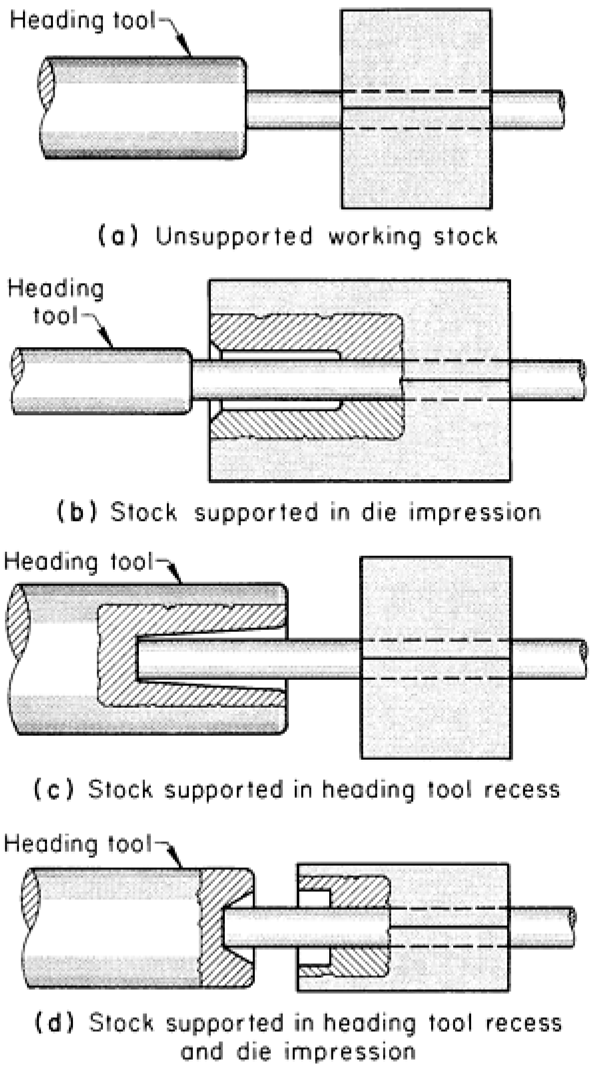

Fig. 3 Basic type of upsetter heading tools and dies showing the extent to which stock is supported

Although some forgings are produced by a single stroke of the ram, most shapes require more than one pass. The upsetter dies may incorporate several different impressions, or stations. The stock is moved from one impression to the next in sequence to give the forging a final shape. Each move constitutes a pass. Three or more passes are commonly used to complete the upset, and if flash removal (trimming) is a part of the forging operation, another pass is added.

Piercing and shearing passes can also be incorporated into the dies. In single-blow solid-die machines, the gripper dies are replaced by a shear arm and a shear blade. A long, heated bar of forging stock is placed in a slot and pushed against a stop. As the foot pedal is depressed, a motion similar to that of a conventional upsetter occurs except that, instead of the die closing, a section of the bar is sheared off. While the shear slide is moving, a cam actuates a transfer arm, which moves until it contacts the stock. The stock, now positioned between the shear blade and the transfer arm, is moved into the proper position between the punch and the die. As the punch advances and contacts the stock, the shear blade and the transfer arm move apart. The punch continues its advance, and the forging is produced in a single blow. Ejector pins push the forging from the die, and the forging drops onto an underground conveyor. The operator pushes another heated bar of forging stock against the stop, and the cycle is repeated.

Tool Materials. Hot-work tool steels are commonly used for hot upsetting dies. Alloy steels such as 4150 and 4340 are also used, especially for gripper dies.

For short runs, it is common practice to use solid dies made of alloy steels such as 4340, 6G, or 6F3. For runs of about 1000 pieces, higher-alloy hot-work tool steels such as H11, H13, 6H1, or 6H2 are commonly used for dies or for die inserts. Detailed information on the factors that govern the selection of tool materials for hot upsetting, recommendations for specific applications, and tool life is provided in the article "Dies and Die Materials for Hot Forging" in this Volume.

Using inserts in master blocks may be less costly than making the entire heading tool or the gripper dies from an expensive steel. However, the two more important advantages of using punch and die inserts are that they can be replaced when worn out and that, in many applications, two or more different parts can be forged with a master block by changing inserts. Additional information is provided in the section "Inserts versus Solid Dies" in the article "Dies and Die Materials for Hot Forging" in this Volume.

Hot Upset Forging

Revised by Wilfred L. Mehling, Ajax Manufacturing Company

Preparation of Forging Stock

Cold and hot shearing are the most commonly used methods of preparing blanks for hot upset forging. Sawing, cutting with abrasive wheels, and flame cutting are also used, but less frequently. The use of machined or previously forged blanks for hot upsetting is usually confined to applications involving special requirements.

Cold shearing blanks from mill-length hot-rolled bar stock is the most common method of preparing stock for hot upsetting. Cold shearing is the most rapid method of producing blanks, and it involves no waste of metal. One shear can accommodate a wide range of sizes, and equipment is adaptable to mass production when used in conjunction with tables and transfer mechanisms. Magnetic feed tools and proper bar hold-down devices are usually required for efficient operation.

With the types of shearing equipment available, it is not uncommon to cold shear medium-carbon alloy steels in diameters to 125 mm (5 in). If section thickness and hardness of material permit, it is usually economical to shear as many bars in one cut as possible, using multiple-groove shear blades. It is common practice to use multiple shearing on low-carbon steel up to 50 mm (2 in.) in diameter.

For medium-diameter bar stock, it is common practice to forge from the bar progressively, cutting off each forging on the last upsetter pass. This method produces a short length of bar scrap, which can be held to a minimum by careful selection of bar length in relation to blank length. This method is widely used for producing small, simple forgings that can be upset in one blow. A secondary cold trimming operation may be necessary to remove flash.

For small-diameter blanks, it is often advantageous to use coiled cold-drawn wire. This wire is straightened and cut off, and the blanks are stacked by means of high-speed machines. The use of blanks made from wire is especially beneficial when shank diameter on the upset forging must be held to closer tolerances than can be obtained with hot-rolled bars. A more detailed discussion of the equipment and techniques used in the cold shearing of bars is provided in the article "Shearing of Bars and Bar Sections" in this Volume.

Hot shearing is recommended for cutting bars more than 125 mm (5 in.) in diameter, and it can be used for smaller-diameter bars in semiautomatic operations. For diameters up to about 28.6 mm ($1\frac{1}{8}$ in.) and when the upset can be made in one blow, the preliminary preparation of individual blanks can be avoided. Mill-length bars are heated and fed into a semiautomatic header. The blank is cut off at the same time the upset is made. A stock gage between the gripper dies and the header die locates the stock before it is held by the gripper dies. The gage, mounted on a slide that is actuated by the header slide, retracts as the header tool advances. A typical tooling arrangement is shown in Fig. 4.

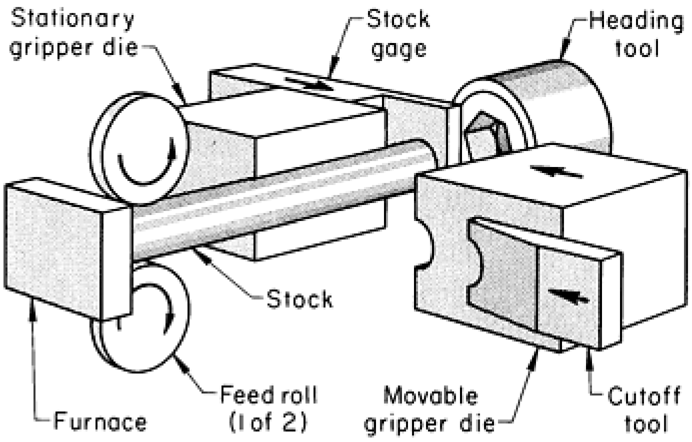

Fig. 4 Setup for simultaneous upsetting and cutoff of continuously fed, heated mill lengths of stock in a semiautomatic header.

Cold sawing is used in conjunction with or as an alternative to shearing. The saw is power fed and may have an automatic clamping device to hold the stock. It has a pump and supply tank to feed coolant to the cutting edge of the blade. Stock gages are used to set cutting lengths.

Sawing is useful for those sizes or materials that cannot be readily sheared. It produces a uniform edge and can be used for sampling and where distortion is a problem. Sawing is a comparatively slow operation and wastes a significant amount of metal. Maintenance costs are also higher in sawing than in shearing. In sawing, however, set-ups can be made quickly; therefore, sawing is often preferred for preparing small quantities of blanks.

Abrasive cutoff wheels are sometimes used for preparing blanks from high-alloy or extremely hard metals. This method must be used with extreme care if the material being cut is susceptible to grinding cracks. Except for this warning, the advantages and disadvantages of abrasive cutting are essentially the same as those of cold sawing.

Gas cutting is generally used only for the preparation of large-diameter blanks. In this operation, the cost of the fuel gases and the resulting melted metal on the ends of the cut stock must be considered.

Special Methods. Some forgings require an unusual distribution of metal, which necessitates some preliminary gathering of material before the final upset forging operation. This can be accomplished in several ways, such as using rolled sections, machining the blank, or preshaping the blank on a hammer or press.

Hot Upset Forging

Revised by Wilfred L. Mehling, Ajax Manufacturing Company

Metal-Saving Techniques

In high-production upsetting, even the most minute saving of metal on a single forging can result in substantial overall savings. Metal can be saved by observing the following practices, when applicable:

- The least wasteful method of stock preparation should be used
- The part and the procedure should be designed to avoid or minimize flash
- Stock should be calculated in order to obtain the most economical length for the specific forging, thus minimizing loss from cropped ends
- Procedures that eliminate or minimize machining, such as combined upsetting and piercing, should be used

- Backstop tongs should be used to avoid loss in cropped ends
- Welded-on or embedded tongholds should be used to obtain additional forgings from a bar

Use of Backstop Tongs. In the production of forgings from precut lengths of stock, when the dies are longer than the forging, the stock is cut to a length that allows one end to protrude from the dies (Fig. 5) so that it can be held by the operator during the forging operation. After the opposite end has been upset, the extra stock for holding is cut off to bring the forging within specified length. The waste of metal involved in this practice can be eliminated by the use of backstop tongs as shown in Fig. 5(b), which also eliminates the additional operation of cutting to length after forging.

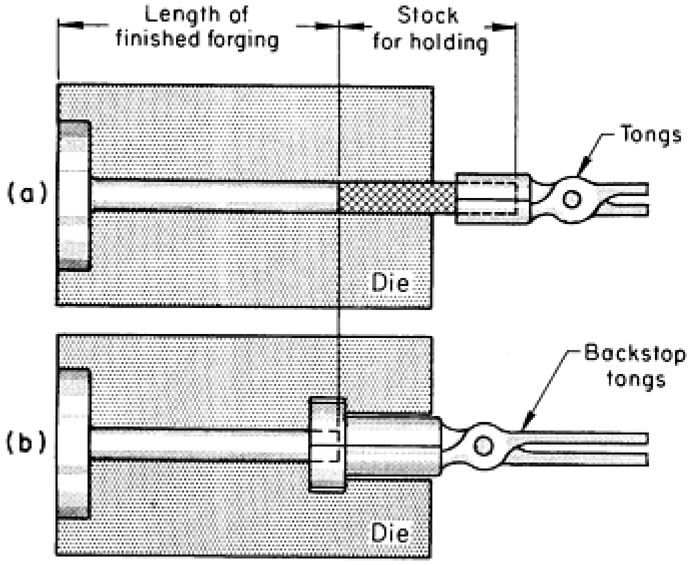

Fig. 5 One method of eliminating the need for overlength stock for holding during forging. (a) Dies exceed length of finished forging. (b) Backstop tongs reduce amount of stock required for holding and eliminate separate operation for trimming of excess stock

Use of Tongholds. In the production of forgings from bar stock that is continuously upset and cut off within the machine, a portion of the stock used in handling and gripping becomes too short to yield additional forgings. One method of obtaining several more forgings from the crop ends is to attach a tonghold to the end of the bar. This can be done by embedding a pin into the heated end of the bar or by welding a stud to the bar, as in one application in which 54 and 75 mm ($2\frac{1}{8}$ and 3 in.) diam bars were forged in 102, 127, and 152 mm (4, 5, and 6 in.) upsetters. The crop ends were about 305 mm (12 in.) long, and loss was appreciable. By welding studs 16 mm ($\frac{5}{8}$ in.) in diameter and 70 mm ($2\frac{3}{4}$ in.) long onto bar ends (Fig. 6) additional forgings were produced, and crop-end loss was reduced by approximately 50%.

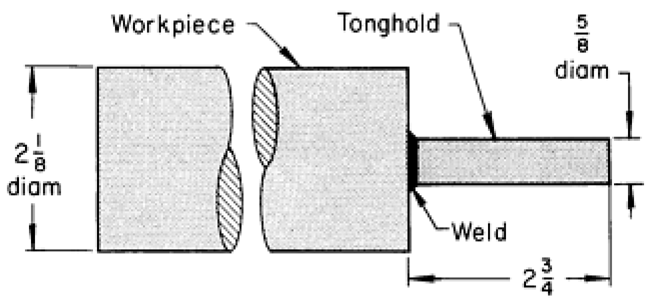

Fig. 6 Welded-on tonghold that substantially reduced crop-end loss. Dimensions given in inches

Hot Upset Forging

Revised by Wilfred L. Mehling, Ajax Manufacturing Company

Heating

The variations in upsetting temperature for different materials, the differences in stock, and the availability of various fuels have produced a substantial variety of equipment and procedures that can be used to heat stock for upsetting. Heating for upsetting can be accomplished in electric or fuel-fired furnaces, by electrical induction or resistance processes, or by special gas burner techniques. Whatever the method of heating, care should be taken to prevent excessive scaling, decarburization, burning, overheating, or rupturing of the forging stock. Heating of specific metals and alloys for forging is discussed in the Sections "Forging of Carbon, Alloy, and Stainless Steels and Heat-Resistant Alloys" and "Forging of Nonferrous Metals" in this Volume.

Hot Upset Forging

Revised by Wilfred L. Mehling, Ajax Manufacturing Company

Descaling

Preventing the formation of scale during heating or removing the scale between heating and upsetting will result in longer die life, smoother surfaces on the forging, and improved dimensional control. The presence of scale on forgings also makes hot inspection unreliable and increases cleaning cost. When controlled heating methods for minimizing scale formation are not available, scale can be removed from the heated metal before forging, either by mechanical methods or by the use of high-pressure jets of water.

Mechanical Methods. One effective method of descaling is to brush the heated bar with rotating wire brushes. In another method, knifelike tools are shaped to the periphery of the heated bar, and the bar is scraped across the knife-edge to dislodge and remove scale. For example, for descaling a round bar, a curved knife section having the shape of a half circle is used. The heated round bar is placed in the half-circle knife section and drawn through the knife to remove the scale from half of the surface of the bar. The bar is then rotated 180°, and the operation is repeated to remove scale from the remaining surface of the bar length. Although economical, this method is less effective than wire brushing.

High-Pressure Water Jets. The use of high-pressure water jets is the most effective method of descaling. Four or more high-pressure nozzles are used; they are positioned equidistantly from one another to impinge simultaneously on all sides of the workpiece. These nozzles are usually placed inside a cabinet that is shielded at the opening into which the hot bar is inserted. Water is supplied to the nozzles at 8 to 12 MPa (1200 to 1800 psi). Nozzle openings vary with stock diameter, but an opening of 0.75 × 1.3 mm (0.030 × 0.05 in.) is common for stock diameters from 38 to 75 mm ($1\frac{1}{2}$ to 3 in.). A 35° angle of the water stream relative to the workpiece provides optimal efficiency. The water spurts are only a fraction of a second in duration in order to prevent excessive lowering of the workpiece temperature.

Hot Upset Forging

Revised by Wilfred L. Mehling, Ajax Manufacturing Company

Die Cooling and Lubrication

Normal practice is to keep dies below 205 °C (400 °F) during operation. In some low-production operations, no coolant is required for keeping dies below this temperature. In most applications, however, a water spray (sometimes containing a small amount of salt) is used as a coolant.

Die lubrication slows production and is not widely used in the upsetting of steel. Because of the die action in upsetting, parts are less likely to stick than in hammer or press forging. In deep punching and piercing, however, sticking may be encountered, necessitating the use of a lubricant. An oil-graphite spray is an effective lubricant and may also provide adequate cooling. A recirculated suspension of alumina in water is used in some high-production operations.

Hot Upset Forging

Revised by Wilfred L. Mehling, Ajax Manufacturing Company

Simple Upsetting

In simple upsetting, the severity limitation is directly related to the length of unsupported stock beyond the gripper dies.

In the single-blow upsetting of low-carbon, medium-carbon, or alloy steels, the maximum unsupported length is about $2\frac{1}{2}$ times the diameter. Beyond this length, the unsupported stock may buckle or bend, forcing metal to one side and preventing the formation of a concentric forging. Exceeding this limitation also causes grain flow to be erratic and nonuniform around the axis of the forging and encourages splitting of the upset on its outside edges.

Location of Upset Cavities. Upset cavities may be located entirely within the heading tool, entirely within the gripper dies, or divided between the heading tool and gripper dies. The location depends largely on the severity of the upset and the preferred location of flash--either for convenience in trimming or for satisfying dimensional requirements in the trimmed area.

Simple forgings, requiring an upset of minimum or near-minimum severity, are often upset with the entire cavity within the heading tool. Conversely, forgings requiring an upset of greater severity are often forged with the entire cavity within the gripper dies.

Preventing Laps and Cold Shuts. Laps and cold shuts are forging defects that arise from the partial separation of some hot metal from the main body of the forging. The defects are formed when the partly separated metal, in the course of the forging cycle, is folded back against, and forged into, the main body of the forging. An oxide film, formed on the underside of the fold, creates a barrier that prevents satisfactory welding of the fold with the parent metal, thus accounting for the defect.

In hot upsetting, the displacement of too much metal in a single pass is a common cause of laps and cold shuts. When the size or shape of the upset is such that these defects occur, one or more stock-gathering passes must be added to the forging cycle in advance of the finishing pass.

The volume of upset on a forging similar to that shown in Fig. 7 could be increased slightly without the need for additional finishing passes, but additional stock-gathering passes would be required. Alternatively, with no increase in upset volume but with a more severe upset shape, an additional pass would be required to ensure complete filling of the upset impression.

Hot Upset Forging

Revised by Wilfred L. Mehling, Ajax Manufacturing Company

Upsetting and Piercing

In addition to providing upset shapes with a central recess or bore, upsetting and piercing are frequently combined to promote die filling, to lessen material use, and to eliminate one or more machining operations. The maximum depth that can be pierced is limited only by the equipment available. In the following example, upsetting and piercing were combined for the production of gear blanks.

Example 1: Combined Upsetting and Piercing of 8622 Steel Gear Blank.

The gear blank shown in Fig. 8 was produced more satisfactorily by upsetting and piercing than if a conventional hammer or press had been used. Less material was used, and external flash was eliminated. It was also possible to hold dimensional tolerances of +1.6, -0 mm (+$\frac{1}{16}$, -0 in.).

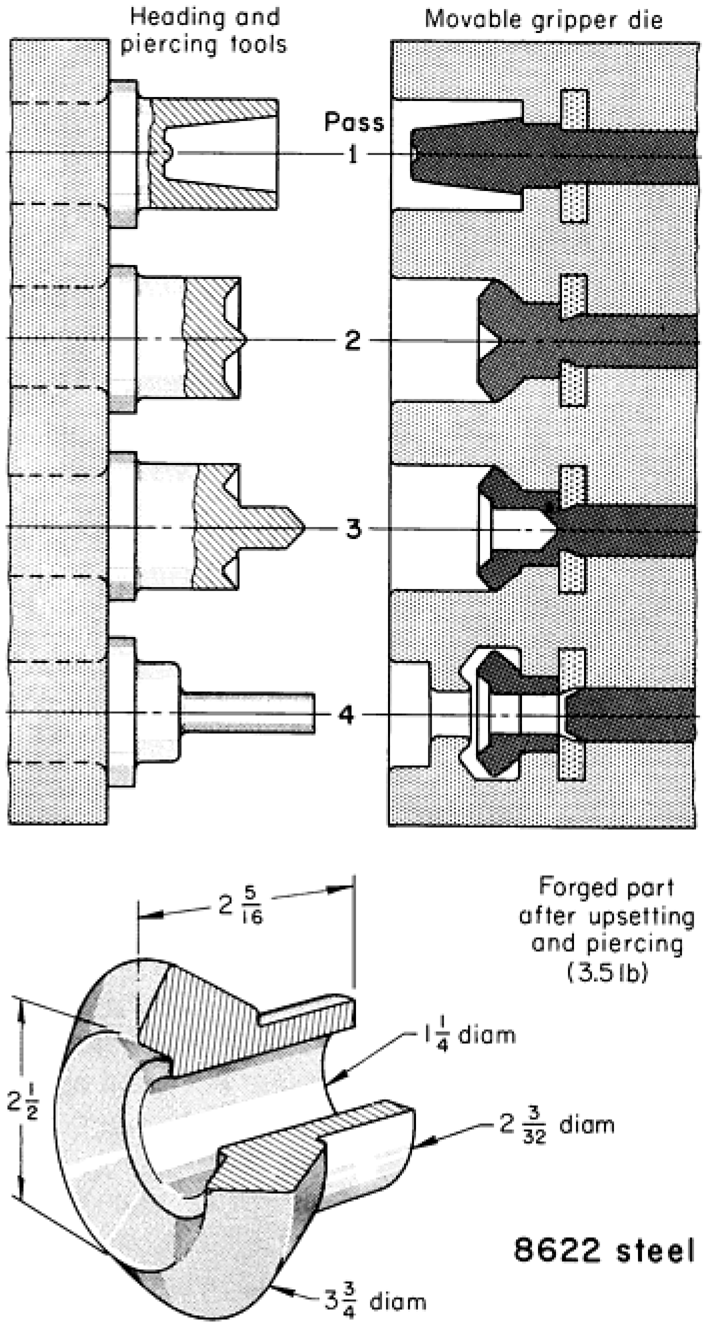

Fig. 8 Gear blank produced by four-pass hot upsetting and piercing in the tooling arrangement shown, with almost no metal loss and no trimming required. Dimensions given in inches

Forging stock consisted of 41 mm ($1\frac{5}{8}$ in.) diam 8622 steel bars, cold sheared to 1.5 m (60 in.) lengths, each of which produced ten gear blanks. The steel was heated to 1260 °C (2300 °F) in an oil-fired batch furnace, then upset and pierced in four passes (Fig. 8) in a 102 mm (4 in.) machine. Production rate was 90 forgings per hour.

The solid dies were made of H11 tool steel and were heat treated to 37 HRC. Approximately 8000 pieces were produced before the dies required resinking.

Ringlike shapes can sometimes be more economically produced from a bar by combined upsetting and piercing than from machining of tubing, as in the following example.

Example 2: Use of Upsetting and Piercing to Produce Bearing Races Without Flash.

The bearing race shown in Fig. 9 was upset, pierced, and cut off in two passes without flash. A 127 mm (5 in.) upsetter was used to forge the part from 3 m (10 ft) lengths of 64 mm ($2\frac{1}{2}$ in.) diam bar stock of 4720 steel in the tooling setup shown in Fig. 9. Long bars were used to minimize loss of material from cropping; however, although 68 forgings were obtained from each 3 in (10 ft) bar, only enough bar for forging three parts was heated at a time. This method was more economical than machining the bearing races from tubing.

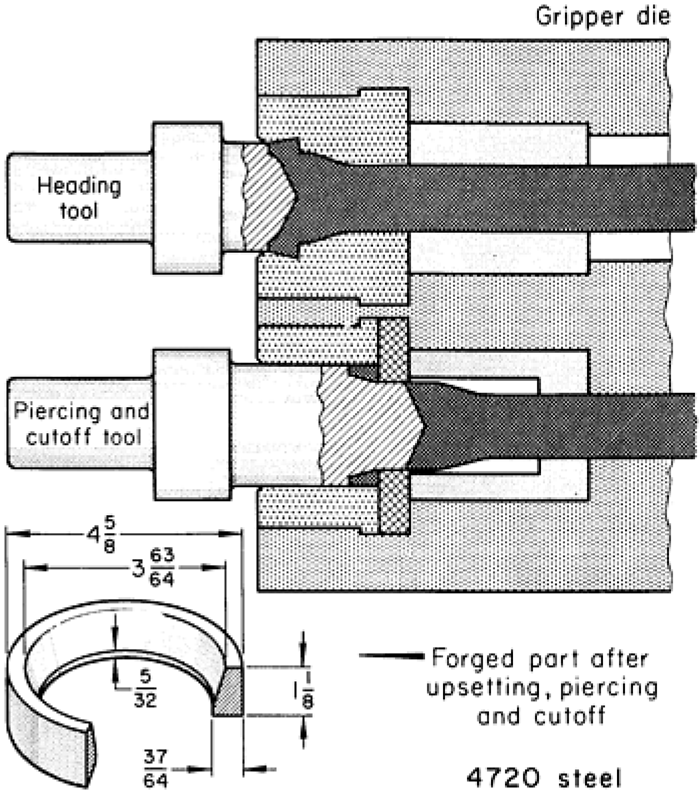

Fig. 9 Tooling setup for producing bearing races from 3-m (10-ft) lengths of 64-mm ($2\frac{1}{2}$-in.) diam bar by upsetting, piercing, and cutoff in two passes. Dimensions given in inches.

Heating (to 1205 °C, or 2200 °F, in an oil-fired batch furnace) and upsetting were done by a two-man crew at a production rate of 150 pieces per hour. Because there were no provisions for atmosphere control in the furnace, a descaler was used to minimize carryover of scale into the upsetter. Die inserts (made solid from H11 tool steel and heat treated to 37 HRC) produced about 8000 pieces before requiring resinking to maintain the tolerances of +1.6, -0 mm (+$\frac{1}{16}$, -0 in.) specified for the forging.

Double upsetting and piercing can often be used to produce complicated shapes, such as the cluster gear discussed in the following example.

Example 3: Two Upsetting and Piercing Passes in the Production of Cluster Gears.

Two separate operations, each involving two upsetting and piercing passes and one trimming pass, were used for producing 152 mm (6 in.) OD cluster gear blanks from 373 mm ($14\frac{11}{16}$ in.) lengths of 75 mm (3 in.) diam 4320 steel. These operations were performed in a 127 mm (5 in.) upsetter; the tooling setup used is illustrated in Fig. 10. The initial forging blank, which weighed 13.4 kg (29.5 lb) was cold sawed to length and heated to 1230 °C (2250 °F) in a box furnace. After upsetting one end, blanks were reheated to the same temperature before upsetting the other end.

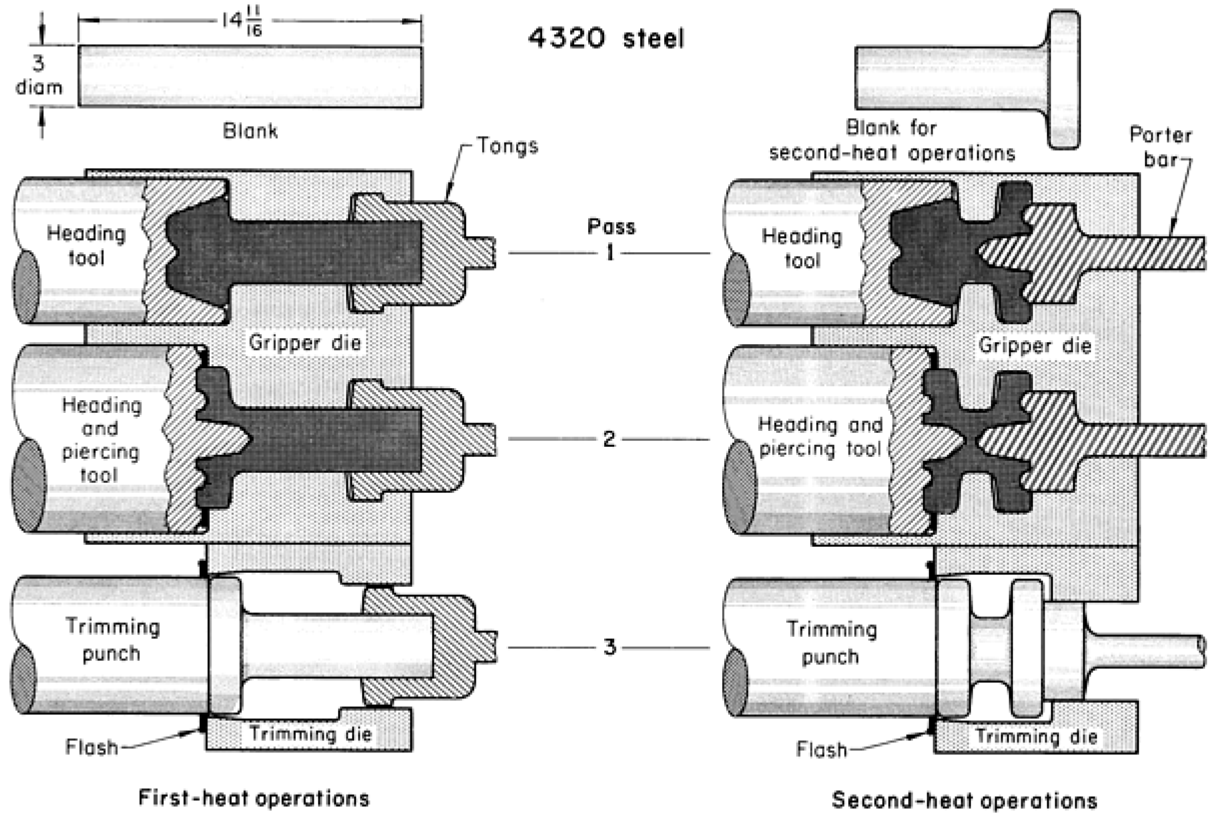

Fig. 10 Tooling setup for producing a cluster gear blank in two separate operations involving upsetting and piercing, then trimming. Dimensions given in inches

The die inserts used were made of 6F2 alloy steel at a hardness of 341 to 375 HB. Dies for forging each end produced an average of 5000 pieces (and occasionally as many as 6000) before requiring resinking to maintain specified tolerances of +3.2, -0 mm (+1.8, -0 in.) on the outside diameter and of +0, -3.2 mm (+0, -$\frac{1}{8}$ in.) on the inside diameter. Each end of the gear blank was produced at the rate of 70 pieces per hour.

Recesses for Flash. Depending on the shape of the upset, a recess may be required in the gripper die to take care of the flash that forms as a collar on the workpiece. The shape of the workpiece often provides natural clearance. In other applications, as in the following example, a recess must be provided.

Example 4: Shape of Upset That Necessitated a Recess for Flash in the Gripper Dies.

Five passes were required to upset, pierce, and trim the wrench socket shown in Fig. 11 Because of the required shape of the upset, a recess was necessary in the gripper dies to allow space for the flash, as shown in Fig. 11.

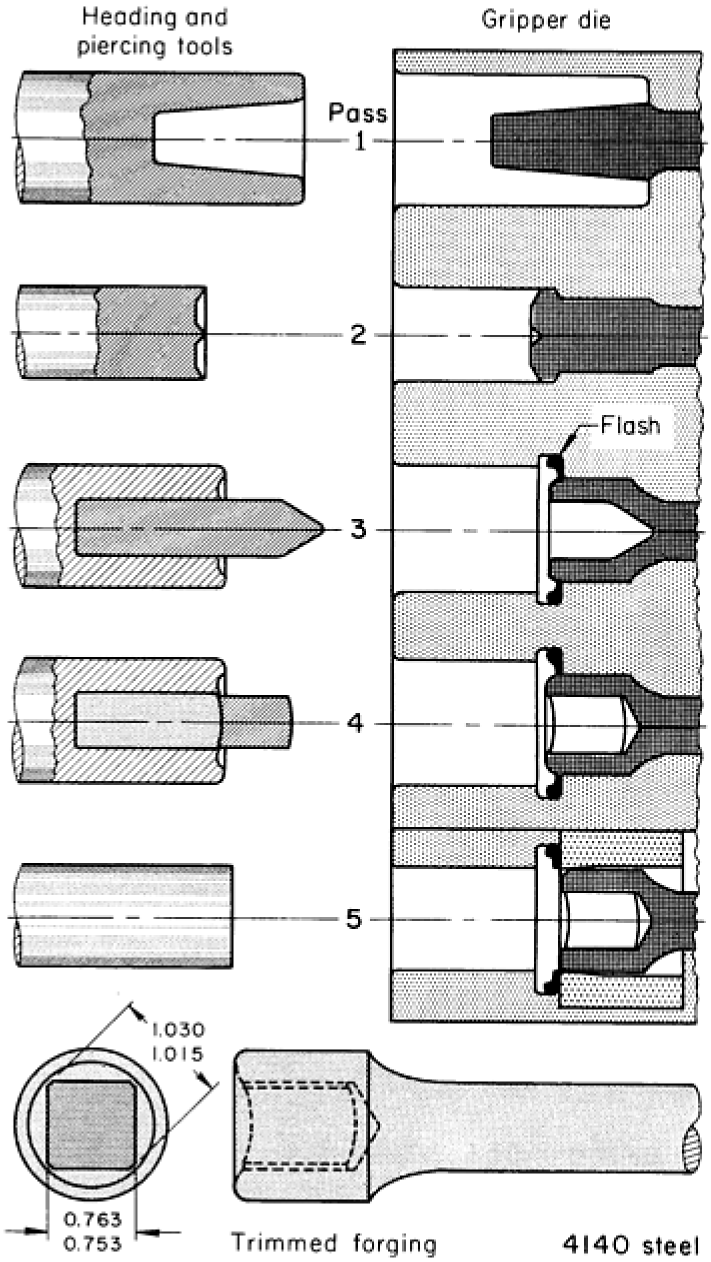

Fig. 11 Tooling arrangement in which a recess for flash was incorporated into the gripper die for five-pass upsetting, piercing, and trimming of a wrench socket. Dimensions given in inches

The forgings were produced from 0.63 kg (1.38 lb) blanks of 19 mm ($\frac{3}{4}$ in.) diam 4140 steel sheared to lengths of 280 mm (11.04 in.). Blanks were induction heated to 1150 °C (2100 °F) and forged in a 50 mm (2 in.) upsetter using solid dies. Gripper dies and trimming guides were made of H12 tool steel, punches of H21, and trimming cutters of T1. Because of the square pierce and the close dimensional requirements (Fig. 11), die life between reworkings was short (500 to 600 pieces).

Irregular Shapes. Different methods of forging can be combined advantageously to produce irregular shapes, such as that of the hand-tool component discussed in the following example. Because the direction of the blind hole prevented the use of drop forging, the main body was hammer forged, and the blind hole was pierced in an upsetter. The closing of the gripper dies was used to advantage in hot sizing the flat portion of the forging.

Example 5: Upsetting and Piercing an Irregularly Shaped Hammer-Forged Blank.

The component (used on hand tools such as spades and root-cutters to serve as a junction between tool and handle) shown in Fig. 12 was originally produced as a casting. For production as a forging, this part was first blanked by hammer forging from 4142 steel. The hammer-forged blank was then heated to 1205 °C (2200 °F) and upset and pierced in a 102 mm (4 in.) upsetter using the tooling setup shown in Fig. 12. The gripper dies were also used to hot size the flat portion of the forging during upsetting. Dies for the upsetter were made solid from 6F2 alloy steel at 341 to 373 HB and produced an average of 12,000 pieces (at a rate of 175 per hour) before requiring resinking to maintain dimensional requirements.

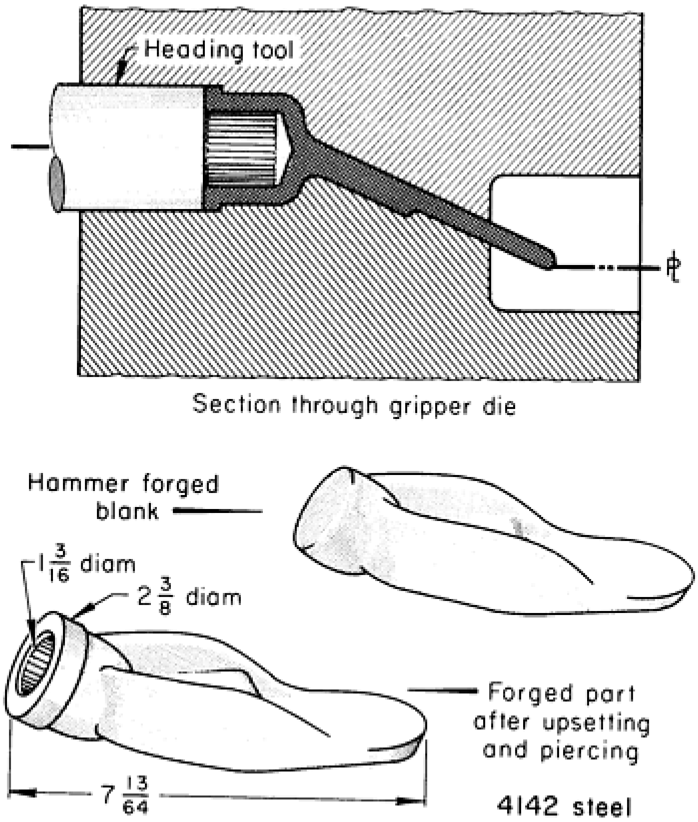

Fig. 12 Irregularly shaped hand-tool component that was upset and pierced from a hammer-forged blank in the tooling setup shown. Dimensions given in inches.

Hot Upset Forging

Revised by Wilfred L. Mehling, Ajax Manufacturing Company

Offset Upsetting

In most of the forgings produced in upsetters, the upset portions are symmetrical and concentric with the axis of the initial forging stock. However, upsetters are not limited to the production of this type of forging. With proper die design and techniques, parts having eccentric, or offset, upsets can be produced. Such upsets are usually, but not necessarily, symmetrical to the plane through the axis of the stock in the direction of the offset. Dies for offset upsetting must be designed so that the metal for the upset is directed eccentrically but is sufficiently restricted in movement to prevent folding or buckling that will cause cold shuts in the finished forging.

In some applications, particularly when the eccentric upset is directly at the end of the forging, the stock is bent in the first operation so that the axis of the bent-over portion is perpendicular to the direction of travel of the header slide. In such applications, the forging techniques used in the subsequent passes (blocking, finishing, and trimming) are basically the same as those used in producing symmetrical upsets. Forgings of this type can be produced with or without flash. When they are forged with flash, the flash can be removed in a final trimming operation.

When the eccentric upset is some distance removed from the end of the forging, it is impossible to position the stock in an initial bending operation. In such parts, the metal must be forced to upset eccentrically into cavities in the punches, dies, or both by the axial movement of the punches. The degree of eccentricity of such upsets is more limited, because of the problem of preventing the stock from initially buckling in the direction of the upset and thus producing cold shuts on the opposite side.

Double-End Upsetting

For many forgings, the use of double-end upsetting--that is, two separate upsetting operations performed on opposite ends of the stock--is required for producing the desired shape. In double-end upsetting, the passes for the operation at each end are based on the same design considerations as in producing an upset on only one end of a straight bar. Double-end upsetting, however, often presents handling and heating problems not encountered in single-end upsetting.

One of the first decisions that must be made in planning the processing for double-end upset forgings is which end is to be forged in the first heat. If there is a difference in the upset diameters, it is almost always preferable to forge the smaller diameter first. This usually simplifies handling in the second heat. It also permits closer spacing in the furnace for the reheating, which results in more efficient use of furnace capacity.

The cut blank for the first-heat operations is handled by tongs or porter bars, as in single-end upsetting. Handling in second-heat operations is done by similar means, except that the design of the handling tools is influenced by the shape of the first upset.

If the finished part produced from the forging will have a drilled or bored hole central with the axis of the forging, it is often desirable, as a first-heat operation, to pierce a hole of suitable diameter and depth to facilitate handling in the second operation with a porter bar made to fit the pierced hole. When pierced holes are not permitted, some other means must be used to handle the forging during the second upsetting operation.

When a double-upset forging requires a pierced through hole, part of the hole is pierced in each upset end, and the connecting metal is removed by trimming, either in an additional pass in the upsetter or in a separate operation. Forgings to be produced by double-end upsetting must be provided with enough draft to facilitate insertion and removal from the second operation without pinching or sticking. To prevent distortion of the first-heat upset during the second-heat operations, the workpiece should be reheated such that the upset portion is kept as cool as possible. The difference in diameters, together with proper placement in the furnace, usually provides a satisfactory temperature differential. A greater differential may be provided by the use of a water-cooled furnace front designed to shield the first-heat upset from furnace heat during reheating.

Hot Upset Forging

Revised by Wilfred L. Mehling, Ajax Manufacturing Company

Upsetting With Sliding Dies

The hot upset forging process is not limited to forging heads or upsets at the ends of bars; it can also gather material for the upset at any point along the length of a bar. This special type of upsetting, which can be performed on round or rectangular bars, requires special tooling in the form of sliding dies. These sliding dies are inserted into the gripper-die frames.

A typical sliding-die arrangement is shown in Fig. 13. With this method, one of the sliding dies moves in the same direction as the moving gripper die to hold the workpiece firmly against a second sliding die and a stationary gripper die.

The ram stroke then pushes both sliding dies inward against the end of the stock to form the upset. The sliding action is facilitated by backing the sliding dies with brass liners. The sliding dies can be retracted by springs or by loading a new workpiece into the upsetter.

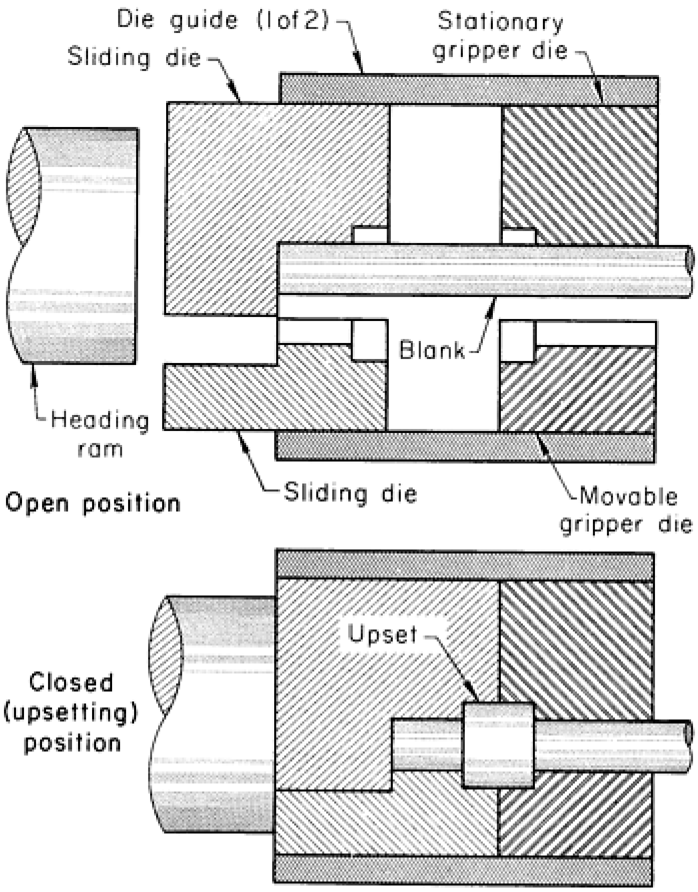

Fig. 13 Typical arrangement of sliding dies used for forging an upset at some point along the length of a bar

Recessed Heading Tools. The use of sliding dies requires a greater-than-normal amount of die maintenance and often presents operating problems. Forging scale becomes entrapped between the sliding members, causing scoring, excessive wear, and sticking. Springs that return the dies to the open position often become weakened because of the softening effect of heat, or they become loaded with scale, which interferes with their action.

Because of these undesirable features, the use of recessed heading tools (or hollow punches), as described in the following example, is a common alternative to sliding dies. When this method is used, however, a slight draft, or taper, must be added to the portion of the stock contained in the heading-tool cavity to facilitate removal after upsetting.

Example 6: Use of Two-Piece Recessed Heading Tools for Center Upset.

The forging shown in Fig. 14 was center upset in two passes in a 152 mm (6 in.) machine using recessed heading tools. As the tooling arrangement in Fig. 14 indicates, two-piece recessed heading tools were used to facilitate machining of the deep cavities.

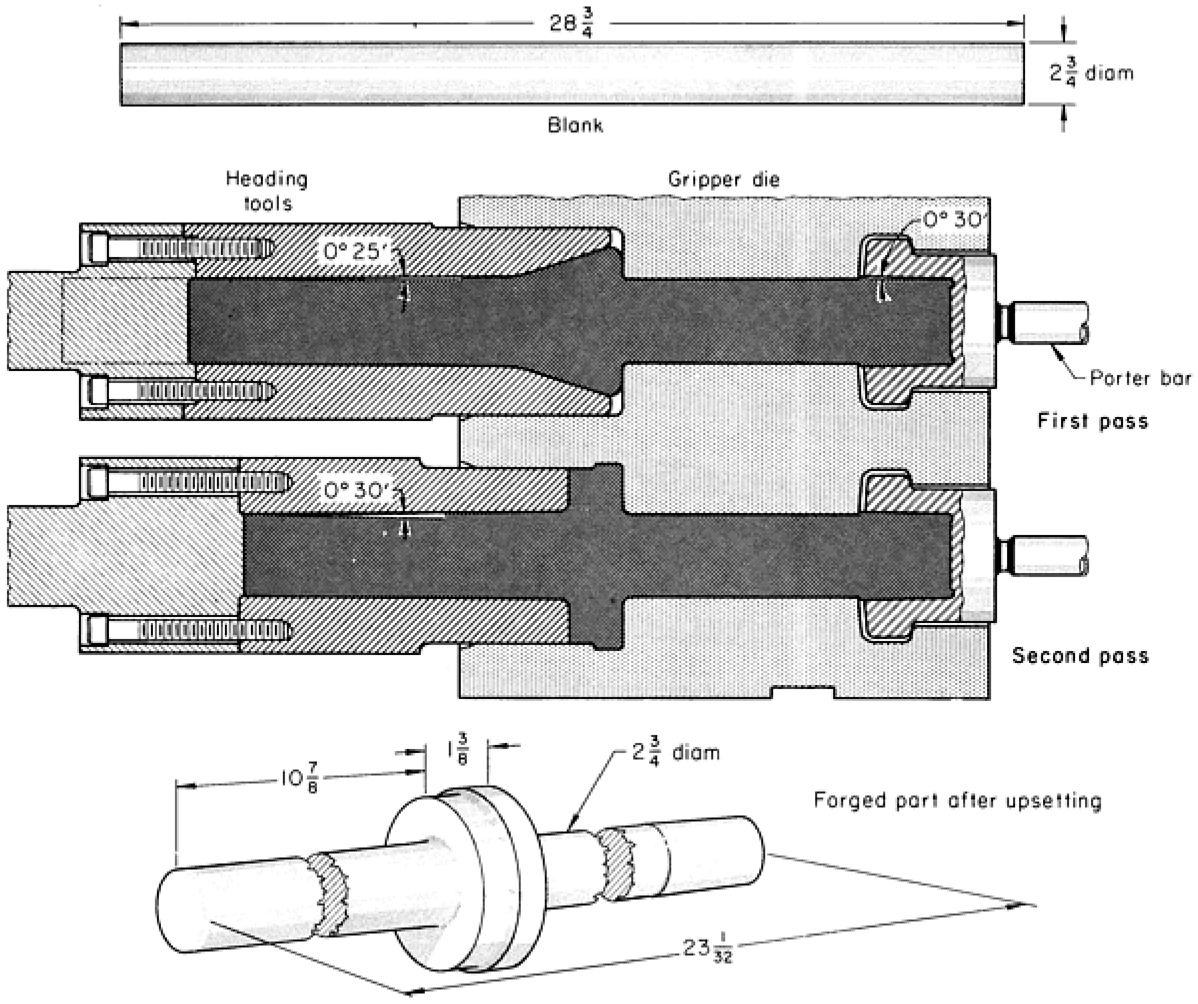

Fig. 14 Tooling setup for two-pass center upsetting using two-piece recessed heading tools. Dimensions given in inches

The bore in the first-pass heading tool had a 0° 25' taper, and the bore in the second-pass tool had a 0° 30' taper to assist in removal of the forging. A backstop porter bar was used in addition to the gripper dies to locate the upset portion.

The first pass gathered the stock into a conical shape; the second pass finish-upset the flange. Both header tools were piloted in the gripper die to ensure alignment.

Hot Upset Forging

Revised by Wilfred L. Mehling, Ajax Manufacturing Company

Upsetting Pipe and Tubing

In many applications, it is desirable and practical to use seamless pipe or mechanical tubing as the stock for upset forgings, particularly for long forgings requiring a through hole. The use of tubular stock for such forgings reduces weight and eliminates the need for gun drilling.

Many forge shops are reluctant to use pipe or tubing as raw material for upset forgings because these product forms present forging problems not encountered when upsetting bar stock. However, most of these problems can be eliminated or minimized by fully understanding the dimensional tolerances applicable to pipe or tubing and making compensating allowances for those tolerances in both the forging design and the die design; by employing heating techniques that will provide close control of temperature and of length heated; and by observing the following rules, which relate wall thickness to the extent to which tubing can be upset in a single blow without injurious folds or buckling:

- To prevent buckling in single-blow flanging, the length of working stock to be upset without support should not exceed $2\frac{1}{2}$ times the wall thickness of the stock
- In single-blow external upsetting (increasing the outside diameter of the tubing while confining the inside diameter), the wall thickness of working stock can be increased to a maximum of $1\frac{1}{2}$ times its original thickness. When greater wall thickness is required, successive outside upsets can be made, using the minimum wall thickness of the preceding upset as the limiting thickness
- In single-blow internal upsetting (decreasing the inside diameter of the tubing while confining the outside diameter), the wall thickness of working stock can be increased to a maximum of twice its original thickness. When greater wall thickness is required, successive inside upsets can be made, using the minimum wall thickness of the preceding upset as the limiting thickness
- In single-blow external and internal upsetting (simultaneously increasing the outside diameter and decreasing the inside diameter), the wall thickness of working stock can be increased to a maximum of $1\frac{1}{2}$ times its original thickness

Tolerances. Pipe or tubing used for upset forgings is normally purchased to specified outside diameter and wall thickness dimensions. Both of these dimensions are subject to mill tolerances. For example, pipe having an outside diameter up to 38 mm ($1\frac{1}{2}$ in.) can vary +0.4, -0.8 mm ($+\frac{1}{64}$, $-\frac{1}{32}$ in.); pipe 50 mm (2 in.) and more can vary -1% from standard. Wall thickness can vary -12.5% from standard. No direct tolerances apply to the inside diameter or to concentricity between outside and inside diameters; these dimensions are controlled only as required to meet the tolerances on outside diameter and wall thickness. Consequently, there is almost always some eccentricity, within the allowable wall thickness variations, between the outside and inside diameters of pierced tubing or pipe. This condition must be recognized, and the necessary allowances made in the design of the forgings as well as the forging tools.

It is also important to understand that the eccentricity does not necessarily run in a straight line throughout the tube. Instead, the locus of the center of the inside diameter may spiral around the centerline, as established from the outside diameter, in a long-pitched helix. That is, if a line were scribed along the outside wall of the tube connecting all points where the wall is thinnest (or thickest), this line may spiral around the outside wall.

When the above condition is not understood, it is commonly assumed that the outside diameter can be made to run true by chucking on the inside diameter for the initial machining. Except on short lengths, however, this is not correct, and in some cases, the runout may even be increased by chucking on the inside diameter. Therefore, it is almost always preferable to design the tubular forging with the understanding that the chucking for the initial machining operations is to be done with reference to the outside diameter. This is important, because a tubular forging with adequate machining-stock allowance when chucked on the outside diameter will not necessarily clean up when chucked on the inside diameter.

Assuming that the initial machining of the forging is to be done from the outside diameter, the outside diameter of the tube, when minimum, should be sufficient to provide the minimum amount of machining. The wall thickness should be such that when it is minimum and the outside diameter is maximum, the minimum desired machining stock will be allowed on the inside diameter. Additional allowances must be made on both the outside diameter and the wall thickness to compensate for any camber that is expected to be present in the forging after processing. The forging limitations in some parts will dictate the selection of tubing with a large outside diameter, a greater wall thickness, or both. However, the above advice should be followed to determine the minimum outside diameter and wall thickness that will ensure that the forging will clean up when machined, regardless of how it is chucked.

Heating pipe and tubing for upsetting requires more critical control than is necessary for bar stock or other solid product forms. For almost all tubular forgings, it is important that the blank be heated so that there is a sharp break between the heated and unheated portions and that this break be at precisely the desired distance from the end of the blank.

Control of the length heated can best be accomplished by induction heating. However, when this method is not available, satisfactory results can be obtained by using water-cooled fronts, or jackets, that are fitted in the slot of ordinary oil-fired or gas-fired slot-type forging furnaces. These fronts are designed with a desired number of holes of proper size, through which the tubular blanks are inserted for heating. Inlet and exhaust water lines to the fronts are located such that the front is completely filled with water at all times. A continuous flow of water, sufficient to prevent boiling, is maintained. The blanks to be heated are gaged from the back, in some convenient manner, to ensure correct length of insertion into the furnace. The use of water-cooled fronts, together with careful control of furnace temperature and time in the furnace, will ensure uniformity of blank temperature and length heated.

When working with thin-wall tubing, it is sometimes difficult to maintain a proper forging temperature in the blank throughout several operations, because of the chilling influence of the dies. This can be partly offset by preheating the dies, but in some applications, it is necessary to reheat the blank one or more times.

Examples of Procedures. A variety of upsetting operations can be performed on pipe or tubing. The wall can be upset externally or internally or both. Tubes can be flared, flanged, pierced, expanded, or reduced (bottled). In many cases, achieving the desired upset shape requires a combination of several of these operations. This is demonstrated in the following examples, which describe the tooling and techniques employed in various production applications involving upsetting of tubing.

Example 7: Internal and External Double-End Upsetting in Three Passes.

A 102 mm (4 in.) upsetter was used for the double-end upsetting of 690 mm ($27\frac{3}{16}$ in.) long, 95 mm ($3\frac{3}{4}$ in.) OD tubes of 4340 steel having a wall thickness of 19 mm (0.750 in.). As shown in Fig. 15, an external collar was upset on one end of the tube in two passes, using the top and center stations in the die, and the opposite end was upset internally in one pass in the bottom station.

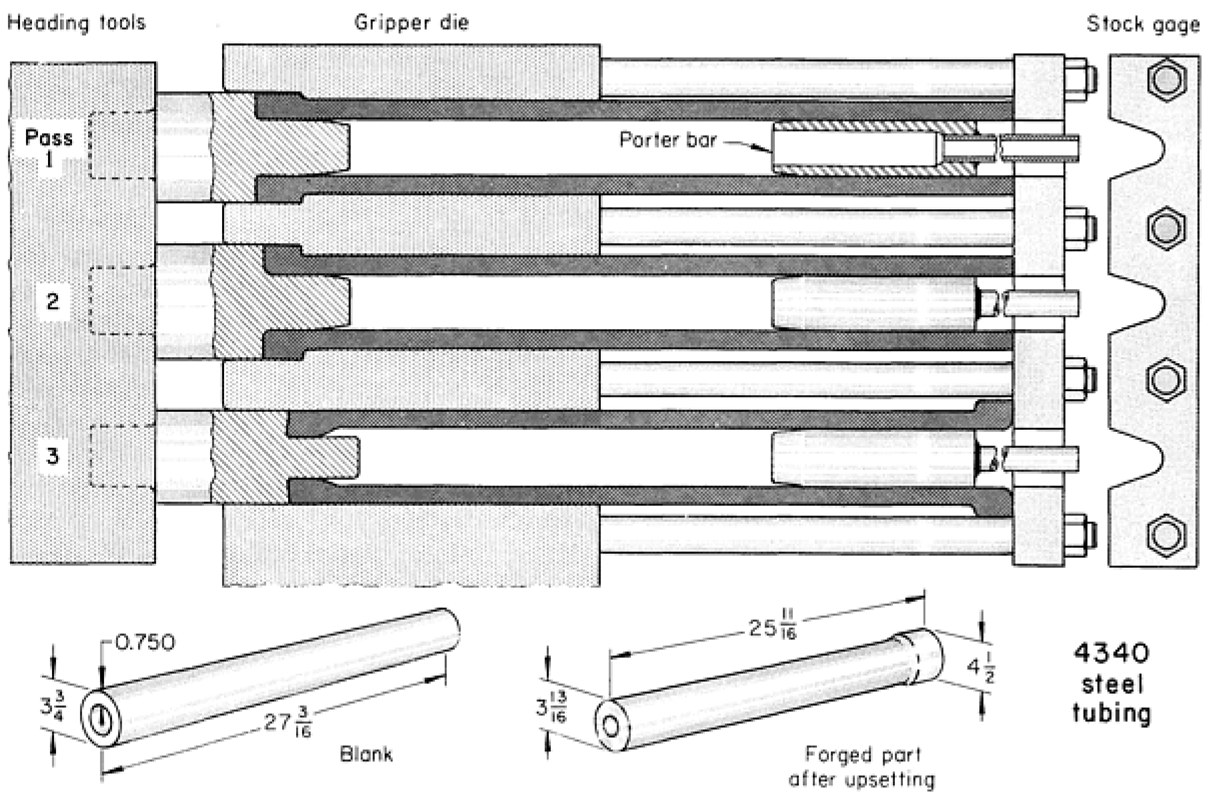

Fig. 15 Tooling setup for external (first and second passes) and internal (third pass) upsetting of opposite ends of a steel tube. Dimensions given in inches

For the external upset, the wall thickness was increased in both the first pass and the second pass by a total of about 50% over the original thickness. Only the amount of stock required for the upset was heated, and a sharp break was maintained between the heated and unheated portions of the stock. This prevented internal upsetting of the stock behind the upset portion.

Grip rings (not shown in Fig.15) designed to bite into the unheated tube were used in all passes in order to prevent slippage through the gripper dies. These rings were supplemented by a backstop secured to the stationary die with studs. The backstop also served as a stock gage and ensured close control of the length between upsets.

Blanks were prepared by sawing and were heated at 1205 °C (2200 °F) in a gas-fired slot-type furnace with a water-cooled front. Dies were made from H10 tool steel. Production rate was 32 pieces per heat. Die life was about 6000 pieces before reconditioning was required.

In this case, two passes were required for producing the external upset at one end of the forging, because the 50% increase in wall thickness was too great to be made in a single pass without risking forging defects. In upsets of this type, the metal barrels outward in one or more convolutions, depending on the length being forged, as the heading tool begins to work. If this outward barreling is contained quickly enough, the metal flows back in a smooth upset that is free from defects; if not, cold shuts may develop. Considering wall thickness variations and other factors, the practical maximum safe external upset in one pass is a 40% increase in wall thickness.

For internal upsets such as the one produced at the opposite end of the forging in Example 7, the only means of controlling the transition contour between the inside diameter of the upset and the inside diameter of the stock is by control of the length heated. This is less precise than control by tools, and tolerances must be established accordingly; however, if good control of the length heated is maintained, transitional contours can be consistently reproduced.

An unusual feature of the procedure described in the next example is the use of a combination flaring and upsetting operation in the first pass. When forging design permits the use of this type of operation, greater lengths of stock can be gathered in a single pass than in a straight external upsetting operation of the type described in Example 7.

Example 8: Upsetting and Flaring One End in Two Passes.

A 175 mm ($6\frac{7}{8}$ in.) flange was upset on the end of a 4340 steel tube, 114 mm ($4\frac{1}{2}$ in.) outside diameter and 22.2 mm (0.875 in.) wall thickness, in two passes in a 152 mm (6 in.) machine, using the tooling setup shown in Fig. 16. The heading tool for the first pass was unique in that it first flared and then upset the end of the stock in a continuous movement. The initial flaring produced a shape that hugged the heading tool as the tool traveled inward. When the stock became seated in the deepest section of the heading tool, it remained there, and the continuing forward movement of the tool upset the stock and filled the cavity. Forward movement was controlled so that no flash was formed. Because of the inherent variation in tubing wall thickness, however, the degree of filling varied around the periphery of the upsetting tool.

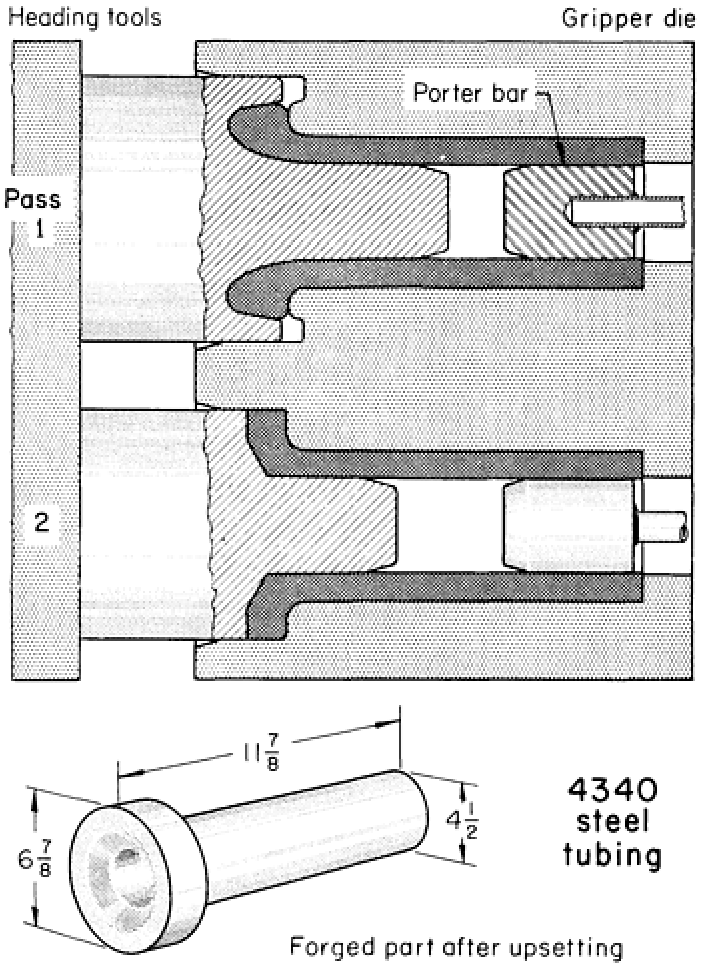

Fig. 16 Tooling setup for producing a flange on one end of a steel tube in two passes in a 152-mm (6-in.) upsetter. The first pass, a combination flaring-upsetting action, permitted gathering of a greater amount of stock than would have been possible by upsetting alone. Dimensions given in inches

The 360 mm ($14\frac{3}{16}$ in.) long blanks were prepared by sawing. Heating was done in a gas-fired, slot-type, water-cooled-front furnace at 1205 °C (2200 °F). Dies were made from H10 tool steel. Production rate was 55 pieces per hour, and die life was about 6000 pieces before reconditioning.

Upsetting Away From the Tube End. For some forgings, an upset must be produced at a distance from the end of the tube. A successful upset of this kind is described in the following example.

Example 9: Forming a Flange a Short Distance From the End in Three Passes.

The flange on the 4340 steel tube shown in Fig. 17 was produced in three passes in a 102 mm (4 in.) upsetter. Blanks were 718 mm ($28\frac{1}{4}$ in.) lengths of 64 mm ($2\frac{1}{2}$ in.) OD seamless mechanical tubing with a wall thickness of 18.2 mm (0.718 in.). The problem of upsetting the flange a short distance back from the end of the tube was solved by the use of the tooling setup illustrated in Fig. 17. In the first pass, the stock was upset into a cavity in the die, increasing the wall thickness by about 33%. In the second and third passes, the wall thickness through the upset was increased 39 and 23%, respectively, using heading tools that were designed to support the unforged section ahead of the flange.

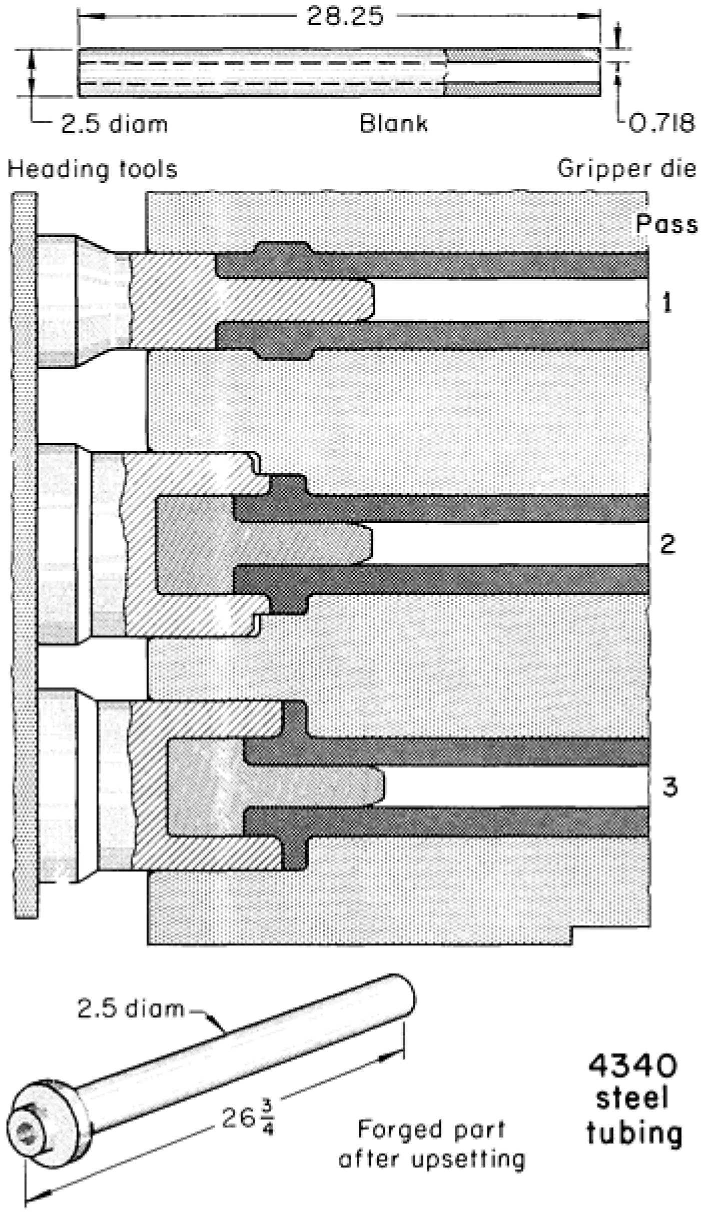

Fig. 17 Tooling setup for upsetting a flange a short distance in from the end of a tube. Dimensions given in inches

Blanks were prepared by sawing and were heated at 1205 °C (2200 °F) in a gas-fired, slot-type, water-cooled-front furnace. Dies were made from H10 tool steel. The production rate was 55 pieces per hour, and about 6000 pieces were produced before dies required reconditioning.

The die design and technique described in this example could be used for producing a flange still farther from the end of a tube. However, if the flange were considerably removed from the end, it would be necessary that only a band of the tube of proper length and location for the upset be heated, leaving both ends cool.

Large Workpieces. The upsetting of unusually large tubes may present tooling problems and may require the use of more heating operations or an increased number of passes or both, as indicated in the following example.

Example 10: Double-End Upsetting (Flanging and Bottling) of Large-Diameter Tubing in Three Heats and Six Passes.

The tooling used for producing a particularly difficult tubular forging by double-end upsetting in six passes and three heats is shown in Fig. 18. A 229 mm (9 in.) upsetter was used. The forging blanks were 1.14 m ($44\frac{7}{8}$ in.) lengths of 238 mm ($9\frac{3}{8}$ in.) OD 8620 steel seamless mechanical tubing with 19 mm (0.750 in.) wall thickness.

Fig. 18 Tooling setup for double-end upsetting of a large-diameter steel tube in six passes and three heats. Dimensions given in inches.

The unusually large outside diameter of the stock posed a problem because, following normal design procedures, there would have been interference between the tube and the stationary-die side of the machine. To prevent this interference, the die parting line was moved 16 mm ($\frac{5}{8}$ in.) from the vertical centerline of the header slide, toward the moving-die side of the machine. Heading tools were eccentrically shanked and keyed to the main toolholder to maintain alignment with the dies.

As shown in Fig. 18, in the first heat, one end of the tube was flanged in two operations. In the second heat, the opposite end was internally upset in two operations. In the third heat, the internally upset end was bottled, or reduced, in two operations. Controlled heating was an important factor in the production of acceptable forgings, and it was particularly critical for the second-heat and third-heat operations because production of the inside contour of the bottled section depended entirely on the maintenance of uniform blank temperature and length heated.

Blanks were prepared by sawing and were heated at 1205 °C (2200 °F) in a gas-fired, slot-type, water-cooled-front furnace. Dies were made from H10 tool steel. The production rate was 16 pieces per hour, and about 6000 pieces were produced before dies required reconditioning.

Hot Upset Forging

Revised by Wilfred L. Mehling, Ajax Manufacturing Company

Assignment of Tolerances

Any forging, regardless of its simplicity, may become a severe production problem if the forging tolerances assigned to it are unduly restrictive. Therefore, the tolerances specified for any new forging should be critically reviewed to determine whether or not they will result in the lowest cost for the finished part. This will not be accomplished by assigning tolerances that are so loose that all control of forging quality is lost. On the other hand, it is also possible to be too restrictive in an effort to avoid some subsequent cost, so that the end cost is actually increased because of the excessive die replacement and the high percentage of rejected forgings that result from the attempt to maintain close tolerances.

The establishment of optimal tolerances is based largely on consideration of all operations required to make the finished part. For example, if holding an abnormally tight tolerance in upsetting eliminates a subsequent machining operation, it is likely to prove economical to hold the close tolerance. However, if the machining operation cannot be completely eliminated, it will probably be less costly to use loose tolerances, thus lowering forging cost, and to make the corrections in machining.

Tolerances for upset forging are not completely standardized and are usually negotiated between the forger and the user. The most common tolerance for upset diameters is +1.6, -0 mm (+$\frac{1}{16}$, -0 in.). For thin sections of flanges and for upsets relatively large in ratio to the stock sizes used, the tolerance is +2.4, -0 mm (+$\frac{3}{32}$, -0 in.). An increase over these values is often necessary because of variations in the size of the hot-rolled bars, extreme die wear, or complexity of the part. Tolerances that are tighter than those mentioned above are arbitrarily identified as close tolerances. Individual tolerance specifications cited in the examples in this article vary widely, from 0.2 mm (0.008 in.) total tolerance to ±3.2 mm (±$\frac{1}{8}$ in.). For an upset forged part that requires several operations or passes, the dimensioning of lengths is determined on the basis of the design of each individual pass or operation.

Effect of Tolerances on Cost

As tolerances are tightened, cost generally is increased, mainly because of the decreased number of parts that can be obtained before dies require reworking to maintain the tolerances. Cost is increased through die resinking as well as increased setup time and machine downtime. Die life between reworkings may vary several hundred percent, depending on workpiece shape. However, for any given shape, tool life decreases rapidly as tolerances are tightened.

If close-tolerance upsetting is required, costs can be minimized by observing the following practices during die design and die maintenance:

- Tool materials and methods of heat treatment should be selected with care. Some experimentation may be required to determine the tool materials that are best suited to a specific job. A detailed discussion of the selection of tool materials for hot upset forging is provided in the article "Dies and Die Materials for Hot Forging" in this Volume
- Welding should be used for the repair of areas in die inserts where wear is most severe
- Sidewise mismatch should be reduced by restricting clearance between the heading tool and heading-tool guides in the gripper dies to 0.4 mm ($\frac{1}{64}$ in.) or less
- All practical steps should be taken to minimize the introduction of scale into the tooling, either by preventing the formation of scale (by heating under atmosphere protection, or rapidly as by induction) or by removing it. Effective methods are discussed in the section "Descaling" in this article
- Endwise mismatch should be reduced by the use of die locks to secure the gripper dies in the closed position

Probably the most efffective die lock is the bar lock, which consists of a key inserted in the face of the moving die and a mating keyway in the face of the stationary die. Wide master dies or die blocks are required for this type of lock. A typical bar lock for a 152 mm (6 in.) upsetter would be about 75 mm (3 in.) wide, protruding out of the moving die about 50 mm (2 in.) and locking into the stationary die.

Other types of die locks can be substituted; they are less expensive but are also less effective than bar locks. For example, a lock consisting of two or four round dowels pressed in at the faces of the dies can be used, or the top and bottom of the dies can be milled to accommodate a rectangular, tapered lock (about 25 × 75 × 152 mm, or 1 × 3 × 6 in.) that is bolted in position.

Die locks must be reworked after each resinking of the inserts. This can be done by hardfacing the locking surfaces.

Hot Upsetting Versus Alternative Processes

Hammer and press forging, hot extrusion, cold heading, and cold extrusion may, under specific conditions, be alternative processes for hot upsetting. In many cases, two or more of the above processes are combined with each other or with hot upsetting to achieve optimal results. The choice of method depends largely on the size and shape of the upset, the work metal composition, and the available forging equipment.

Hot Upsetting Versus Hammer or Press Forging. In comparing hot upsetting and hammer or press forging, the most important advantage of hot upsetting is that forging can be done in two directions 90° apart, a capability that is built into an upsetter and is common for any tooling. Accomplishing this in a conventional vertical hammer or press requires complex tooling for each part.

Other advantages of hot upsetting over hammer or press forging include:

- Less material is required, because flash is minimized or eliminated by the two-direction forging principle, in which just the right amount of metal is trapped in the dies
- Less draft is required, because upset forging dies open in both directions
- Production efficiency is higher for upsetting when piercing, because final piercing and cutoff can generally be accomplished in one pass from long bars
- Grain flow can be more easily controlled
- Large parts, such as automotive axle shafts, cannot fit into the die space (shut height) of a hammer or forging press

The primary disadvantage of hot upsetting is that it is limited to the production of reasonably symmetrical forgings, while hammers or presses can produce a greater variety of shapes. There are applications in which hammer or press forging can be advantageously combined with hot upsetting, as in Example 5.

Hot upsetting and hot extrusion are closely related. In many applications, some extrusion takes place during upsetting, or some upsetting during extrusion. When an upset is required that is much larger in diameter than the starting blank (six times, for example), hot upsetting or hot extrusion can be used, but this extreme severity may present difficulty with either process used alone. However, hot upsetting of a preform made by hot extrusion is often the best procedure for producing a part that requires a severe upset.

Hot Upsetting Versus Cold Heading. Size is the major factor in determining whether hot upsetting or cold heading will be used for a specific application. When cold heading can meet all requirements, it is less expensive than hot upsetting, because heating the blanks and cleaning the headed parts are eliminated.

Cold heading is generally restricted to blanks no more than 38 to 50 mm ($1\frac{1}{2}$ to 2 in.) in diameter, and most cold heading is done on starting diameters less than 32 mm ($1\frac{1}{4}$ in.). Up to about 19 mm ($\frac{3}{4}$ in.) of stock diameter almost any upsetting that can be done hot can also be done cold on ductile metals. This applies to center as well as end upsetting. Exceptions can be work metals that are harder than annealed steels, or extremely severe shapes.

Hot Upsetting Versus Cold Extrusion. Hot upsetting and cold extrusion are often used in sequence to produce a specific shape; hot upsetting is used to produce a preform. Automotive axle shafts are notable examples of parts produced by hot upsetting followed by cold extrusion. Hot upsetting and piercing is sometimes interchangeable with cold extrusion.

Large presses are required for cold extrusion. Thus, the availability of equipment often determines a choice between hot upsetting and piercing, and cold extrusion. More detailed information on cold extrusion is available in the article "Cold Extrusion" in this Volume.

Revised by Wilfred L. Mehling, Ajax Manufacturing Company

Safety

A primary consideration in hot upsetting is the safety of the operator. Adequate training must be provided before operators are allowed to work with hot upsetting equipment, and protective clothing and equipment must be used. Ear protection may or may not be necessary, depending on the noise level in the shop. The need for aprons, spats, leggings, and sleeves depends on the hazards to which the operator is exposed.

With the exception of the feed area, the entire upsetter should be heavily guarded. Provision should be made such that the access doors to the upsetter must be closed before it can be operated. A guard over the operating pedal and a pedal lock will minimize accidental tripping of the upsetter. All loose articles should be removed from the top of the upsetter to prevent them from falling from or into the machine.

At no time should the operator put his hands or arms between the dies of the upsetter. Lubricating swabs or scale removers should have handles that are long enough to permit the operator to reach the full length of the dies without putting his hands between the dies. Before an operator makes an adjustment to any of the tools or dies, the power should be locked off, the flywheel should be completely stopped, and the air, water, and oil lines should be shut off. All power switches and valves should be identified and should be located where they can be easily reached by the operator. In handling heavy tools, lifting equipment is needed; the operator should use care to avoid injury when changing tools.

When gripper dies are used, it is important that the dies hold the forging in place. Although the use of backstops is recommended where practical, they should not be employed to offset insufficient gripping. Gages should locate the part with minimum hazard to the operator. For heavy forgings, properly maintained balancing equipment will reduce operator fatigue.

A preventive maintenance program is needed to keep upsetters in safe operating condition. In addition to making a daily check of tools, belts, pulleys, lines, gages, and valves, the operator should report any change in the performance of the upsetter when it is first observed. Handling equipment should be checked before it is used and should be thoroughly inspected on a regular basis. Daily lubrication is needed on machines that are not equipped with automatic lubrication. Air clutches and brakes should be checked daily, and moving parts should be checked and adjusted weekly.

An important consideration with regard to safety in hot upset forging is the selection of proper die material and die hardness. This is discussed in the article "Dies and Die Materials for Hot Forging" in this Volume.

Roll Forging

Introduction

ROLL FORGING (also known as hot forge rolling) is a process for reducing the cross-sectional area of heated bars or billets by passing them between two driven rolls that rotate in opposite directions and have one or more matching grooves in each roll. The principle involved in reducing the cross-sectional area of the work metal in roll forging is essentially the same as that employed in rolling mills to reduce billets to bars.

Applications

Any metal that can be forged by other methods can be roll forged. Heating times and temperatures are the same as those used in the forging of metals in open or closed dies. See the articles "Closed-Die Forging in Hammers and Presses" and "Hot Upset Forging," as well as the articles on the forging of specific metals, in this Volume.

Roll forging serves two general areas of application:

- As the sole operation, or as the main operation, in producing a shape
- As a preliminary operation to save material and number of hits in subsequent forging in closed dies

Applications in the first category above generally involve the shaping of long, thin, usually tapered parts. Typical examples are airplane propeller-blade half sections, tapered axle shafts, tapered leaf springs, table-knife blades, barge nails, hand shovels and spades, various agricultural tools (such as pitchforks), and tradesman's tools (such as chisels and trowels). Roll forging is sometimes followed by the upsetting of one end of the workpiece to form a flange, as in the forging of axle shafts.

Applications in the second category above include preliminary shaping of stock prior to forging in closed dies in either a press or hammer, thus eliminating a fullering or blocking operation. Crankshafts, connecting rods, and other automotive parts are typical products that are first roll forged from billets to preform stock, and then finish forged in a press.

Machines

Machines for roll forging (often called forge rolls, reducer rolls, back rolls, or gap rolls) are of two general types (Fig. 1 and 2). In both types, the driving motor is mounted at the top of the main housing. The motor drives a large flywheel by means of V-belts. In turn, the flywheel drives the roll shafts, to which the roll dies are attached, through a system of gears.

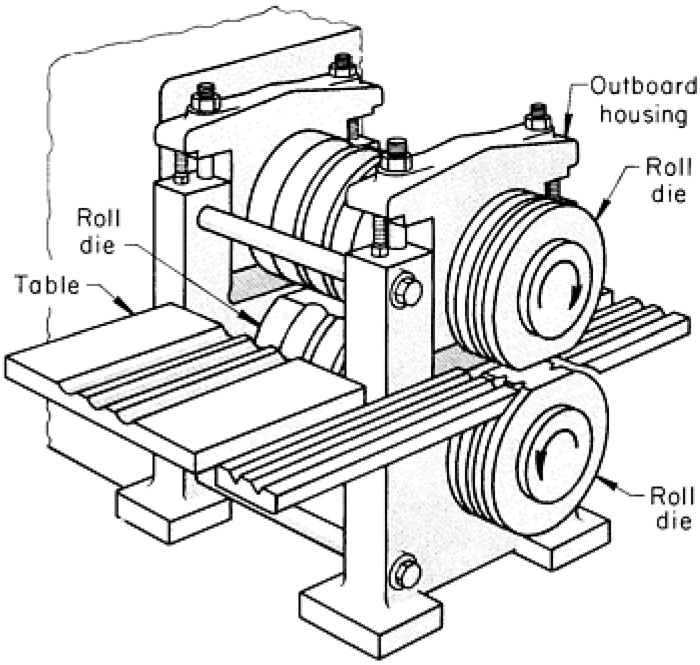

Fig. 1 Roll-forging machine with outboard housing.

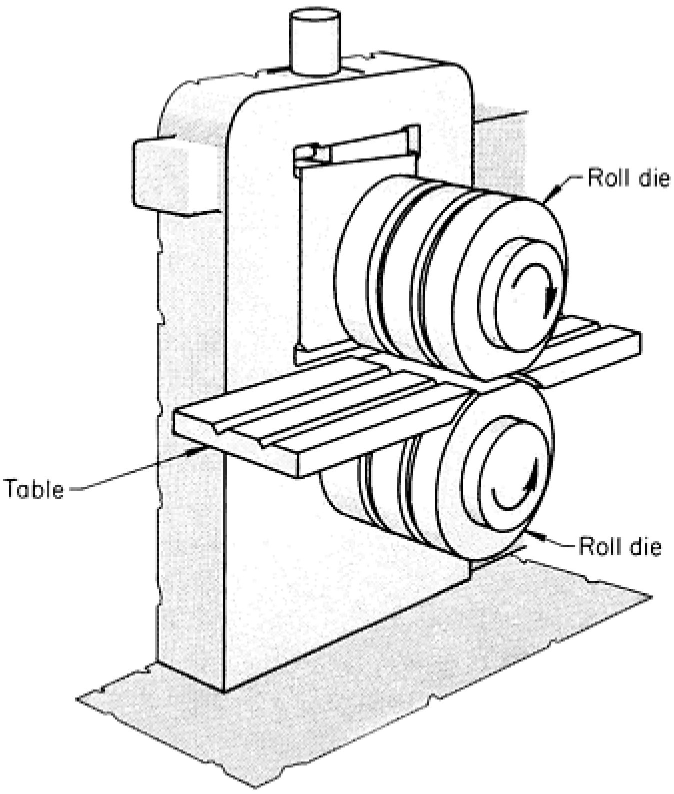

Fig. 2 Overhang-type roll-forging machine.

The machine shown in Fig. 1 has an outboard housing, which supports the roll shafts at both ends. On this machine, the shafts extend through the housing, thus permitting an additional pair of roll dies to be mounted on the shafts. On some machines of this type, the roll shafts extend only into the outboard housing; this permits the use of only one set of roll dies. Various sizes of this type of machine, ranging from 3.7 to 220 kW (5 to 300 hp), will accommodate roll dies 318 to 1120 mm ($12\frac{1}{2}$ to 44 in.) in diameter and 356 to 1520 mm (14 to 60 in.) wide.

The machine illustrated in Fig. 2 is generally known as the overhang type because it has no outboard housing to support the roll shafts. Otherwise, the significant components of this machine are similar to those of the machine illustrated in Fig. 1. Depending on size, these machines are equipped with 15 to 75 kW (20 to 100 hp) motors and will accommodate roll dies 305 to 559 mm (12 to 22 in.) in diameter and 178 to 457 mm (7 to 18 in.) wide.

Selection. The outboard-housing type of machine (Fig. 1) is ordinarily used when roll forging is the sole or the main operation for producing a shape and when close tolerances are required on the workpiece. The reason for the preference is that this class of work generally requires wide roll dies with many grooves (sometimes as many as 12 or more, but usually fewer than 8). If roll dies are extremely wide in relation to their diameter, lack of rigidity is a problem.

The overhang-type machine (Fig. 2) is most often used for the roll forging of stock in preparation for closed-die forging or up-setting. For this type of work, relatively narrow roll dies with two to four grooves are generally used. Therefore, lack of rigidity caused by excessive overhang is not a problem, and better accessibility is gained by the absence of the outboard housing. In addition, the fully cylindrical roll dies used in this type of machine offer more periphery for roll forging.

Selection of machine size depends mainly on the following considerations:

- Power must be adequate to reduce the forging stock
- Rigidity must be sufficient to maintain dimensional accuracy. Adequate rigidity is especially important when rolling to thin, wide wedge shapes
- Roll shafts must be long enough (overhang or distance between housings) to accommodate roll dies that

are wide enough to contain the entire series of grooves required to accomplish the cross-sectional reduction. The width of the roll dies can sometimes be reduced by using the first-reduction grooves for two or more passes or by inching the workpiece forward in the tapered grooves
- Distance between centers of roll shafts must be sufficient to accommodate roll dies large enough in diameter to roll the full length of the reduced section of the workpiece, so that the taper will not have to be overlapped in adjacent grooves of the roll dies

Forging rolls are available in numerous sizes and have the capacity to roll blanks up to 127 mm (5 in.) thick and 1020 mm (40 in.) tong.

Operation. Roll dies designed for forging the required shape are bolted to the roll shafts, which rotate in opposite directions during operation. Roll dies (or their effective forging portion) usually occupy about one-half the total circumference; therefore, at least some forging action takes place during half of the revolution.

Machines can be operated continuously or stopped between passes, as required. In the roll forging of long tapered workpieces, the more common practice is to operate the machine intermittently, using the following technique (Fig. 3):

- The operator lays the heated stock on the table of the machine, grasps the stock with tongs, and starts the machine (commonly controlled by a foot treadle)
- During the portion of the revolution when the roll dies are in the open position, the operator places the stock between them against a stock gage and in line with the first roll groove, retaining his tong hold on the workpiece. The tables are usually grooved to assist in aligning the stock
- As the roll dies rotate to the closed position, forging begins. The workpiece is forced back toward the operator, who moves it to the position of the next roll-die groove and again pushes it against the stop during the open position of the roll dies. This is repeated until the workpiece has been forged through the entire series of grooves

In a few mass-production applications, the roll-forging procedure described above has been automated, but manual operation is by far the most common practice.

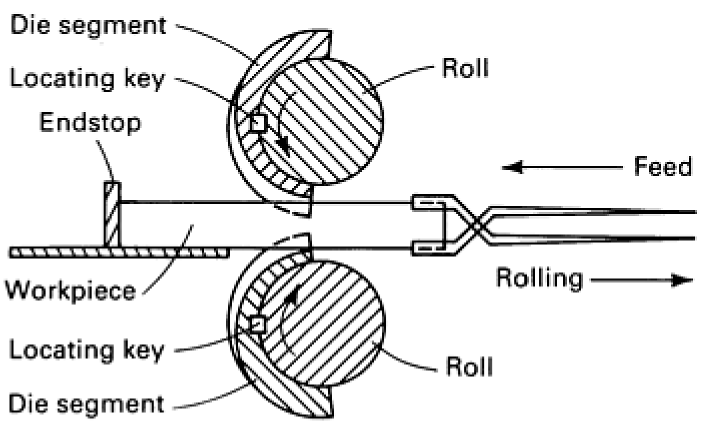

Fig. 3 Schematic of roll-forging operation using multiple passes.

When side squeezing between roll passes is desirable for such operations as the pointing of springs or the tapering of chisel blades, the machine can be designed to incorporate a horizontal front press close to the rolls. For shearing, trimming, straightening, and bending, a vertical side press can be built into the main housing. Both of these auxiliary presses are of the simple eccentric type, driven from a roll shaft.

When roll forging is used to preform stock prior to completing in dies, the machine is usually stopped after each roll pass, partly because fewer passes are used (often only one or two) and partly because continuous operation may be undesirable for the companion forging operations. Some automation is usually applied to this type of roll-forging application; therefore, little or no manual handling is required.

Roll Forging

Roll Dies

Roll dies are of three types: flat back, semicylindrical, and fully cylindrical (Fig. 4).

Fig. 4 Three types of dies used in roll forging.

Flat-back dies are primarily used for short-length reductions. They are bolted to the roll shafts and can be easily changed. Typical contours for a set of flat-back segmental dies are shown in Fig. 5.

Fig. 5 Contours in a typical set of flat-back segmental dies used to forge the workpiece illustrated.

Semicylindrical dies are well suited to the forging of medium-length workpieces. Most are true half-cylinders (180°), although some (particularly in large sizes) may encompass up to 220° of a circle to provide sufficient periphery for the specific application. When each die section is no more than 180°, the dies can be made by first machining the flat surfaces of the half-rounds for assembly, clamping the half-rounds together, and then boring and finishing.

Example 1: Forging of an Axle Shaft in Ten Passes Through Eight-Groove Semi-Cylindrical Roll Dies.

An axle shaft was roll forged from a 1037 steel blank in ten passes through eight-groove semicylindrical roll dies, as shown in Fig. 6. After each successive pass, the workpiece was rotated 90°. The shaft was forged in a 30 kW (40 hp) machine with an outboard housing; the eight-groove dies were 635 mm (24 in.) wide. The roll shafts were rotated at 40 rpm. In continuous operation, one operator rolled approximately 180 shafts per hour.

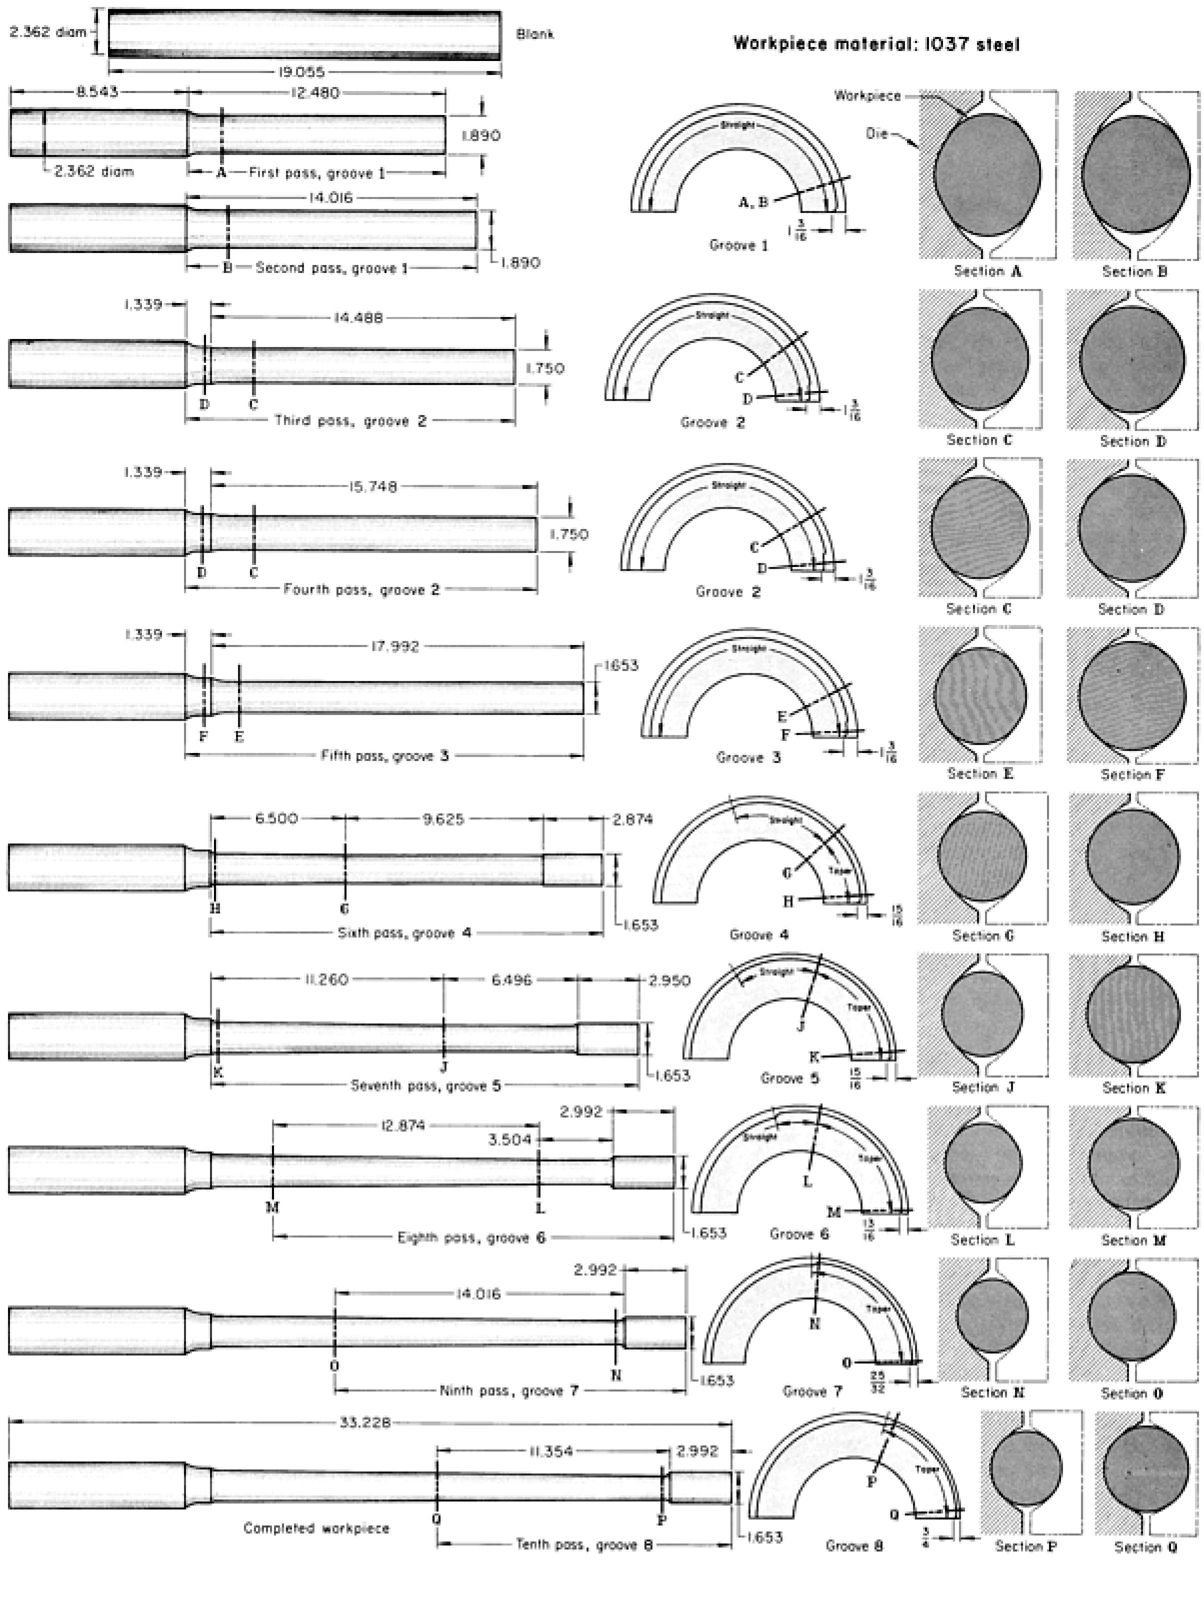

Fig. 6 Forging of an axle shaft in ten passes through eight-groove semicylindrical roll dies. Dimensions given in inches.

After it was roll forged, the shaft was straightened by hot coining and was sheared without being reheated. The large end was then reheated and was flanged in an upsetter.

Fully cylindrical dies are used for the forging of long members, sometimes in an overhang-type machine. They are made most economically by being built up with rings, with a cutaway portion just large enough to feed in the forging stock. Fully cylindrical dies are sometimes more efficient than semicylindrical or flat-back dies because of the larger periphery available for the forging action. However, one disadvantage of fully cylindrical dies is that the opening is too small to permit continuous operation; consequently, these dies require control of motion by a clutch and a brake.

Material. Steels used for roll dies do not differ greatly from those used for dies in hammer, press, and upset forging (see the articles "Closed-Die Forging in Hammers and Presses" and "Hot Upset Forging" in this Volume). However, because roll dies are subjected to less impact than dies in other types of forging, they can be made of die steels that are somewhat higher in carbon content--which is helpful in prolonging die life. The following composition is typical for roll dies:

Element	Composition, %
C	**0.70-0.80**
Mn	**0.60-0.80**
Si	**0.30-0.40**
Cr	**0.90-0.95**
Mo	**0.30-0.35**

Dies can be made from wrought material or from castings.

Hardness of roll dies is likely to vary considerably, depending largely on whether or not changes in die design are anticipated. When the die design is not subject to change, a hardness range of 50 to 55 HRC is common. Although this range is higher than can be tolerated in most hammer or press forging, it is permissible in roll forging because the dies are subjected to less impact, which helps to prolong die life.

When dies are subject to design changes, common practice is to keep hardness below the maximum that is practical to machine. Under these conditions, 45 HRC is the approximate maximum, and a range of 35 to 40 HRC is more common.

Die life depends mainly on die hardness, severity (depth of the grooves or other configurations in the dies), whether or not flash is permitted, and work metal composition. Die hardness has a major influence on die life. Dies hardened to 50 to 55 HRC have often had a total life of 190,000 to 200,000 pieces in the no-flash roll forging of low-carbon steel to simple shapes (severity no greater than that of the workpiece described in Example 1). In similar applications, however, dies of the same materials at 35 to 40 HRC have had a total life of only 30,000 pieces.

As severity increases, die life will decrease, to a degree generally parallel to that experienced with similar changes of severity in hammer and press forging (see the article "Dies and Die Materials for Hot Forging" in this Volume). If any flash is formed and not allowed for in die design, the dies will be overstressed and their life shortened. Although little significant difference in die life can be attributed to variations in composition among the carbon and alloy steels that are most commonly roll forged, die life does decrease as the hot strength of the work metal increases, as with other types of forging dies.

High-Energy-Rate Forging

Revised by Natraj C. Iyer, Westinghouse R&D Center

Introduction

HIGH-ENERGY-RATE FORGING (HERF), sometimes called high-velocity forging, is a closed-die hot- or cold-forging process in which the stored energy of high-pressure gas is used to accelerate a ram to unusually high velocities in order to effect deformation of the workpiece. Ideally, the final configuration of the forging is developed in one blow or, at most, a few blows. In high-energy-rate forging, the velocity of the ram, rather than its mass, generates the major forging force. Table 1 lists the die-closing speeds of forming machines, and it is apparent that the maximum impact velocity of HERF machines is about three to four times that of conventional drop hammers. Typically, the ram velocity at impact in the HERF machine is in the range of 5 to 22 m/s (16 to 72 ft/s); ram velocities range from 4.5 to 9.1 m/s (15 to 30 ft/s) for a power-drop hammer and from 3.6 to 5.5 m/s (12 to 18 ft/s) for a gravity-drop hammer.

Table 1 Forming machines and their die closing speeds

Press type	Impact speed	
	m/s	ft/s
Hydraulic press	0.27-0.456	**0.89-1.50**
Crank press	0.03-1.52	**0.10-4.99**
Toggle press	0.03-1.52	**0.10-4.99**
Friction screw press	0.30-1.21	**0.98-3.97**
Drop hammer	3.65-5.50	**12.0-18.0**
Power hammer	4.50-9.10	**14.8-29.9**

High-energy-rate machines can be used to hot forge parts of the same general shapes as those produced with conventional hammers and presses. However, the work metal must be capable of undergoing extremely rapid deformation rates as it fills the die cavity without rupturing it. In high-energy-rate forging, the high ram velocities permit the forging of parts with thin webs, high rib height-to-width ratios, and small draft angles to profiles sufficiently accurate that machining allowance can sometimes be as little as 0.500 mm (0.0197 in.). Even parts made of difficult-to-forge metals can be formed close to finished dimensions in a few blows and often without reheating.

When evaluating high-energy-rate forging in relation to conventional forging, both the machine advantages and process advantages, as a result of the high velocities, must be considered. The machine advantages are beyond dispute. For a given forming capacity, high-speed machines are much smaller than conventional forging machines, and they require much less installation/foundation and therefore a lower capital investment. These advantages arise because the principle utilized in these machines involves the conversion of the kinetic energy of a ram/platen into forming work. Kinetic energy is proportional to the square of the impact velocity; therefore, a threefold increase in impact speed produces a ninefold increase in forming energy. High-energy-rate forging machines are typically one-ninth the bulk and weight of equivalent slow-speed machines. Although the finished forging is generally made in one high-speed blow, some machines can be fired two or three times before the work metal has cooled below the forging temperature.

The process advantages are not as obvious as the machine advantages and depend on the particular application under consideration. In general, high-energy-rate forging offers the following advantages over conventional forging methods:

- Complex parts can be forged in one blow from a billet or a preform
- Many metals that have low forgeability or are difficult to forge by other methods can be successfully forged
- Dimensional accuracy, surface detail, and, often, surface finish are improved
- Draft allowances, both internal and external, can be reduced or, in some applications, eliminated
- Forgings are made to size or with a minimum of machining allowance. Reduced machining lowers the induced mechanical stress and minimizes the cutting of end grain, which improves the stress-corrosion resistance of some metals, notably aluminum
- Deep, thin sections can be forged because the rapidity of the blow provides little time for heat transfer to the die walls
- Substantial improvement in billet quality can be achieved when cropping/shearing at high speeds
- Severe deformation is possible, with the net result of greater grain refinement in some metals
- Less skill is required for the operating personnel

The process, however, does have the following limitations:

- Sharp corners and small radii cannot be forged without causing undue wear
- The process is generally limited to symmetrical parts, although some asymmetrical parts can be forged from preformed billets
- The production rate is about the same as in hammer or hydraulic press forging, but is slower than in mechanical press forging
- Part size is limited to about 11 to 12 kg (24 to 26 lb) for carbon steel forgings, and to lesser weights for forgings made of stainless steel or heat-resistant alloys
- Dies must be carefully designed and fabricated in order to withstand the high impact; compressive prestressing of the die inserts by a shrink ring is a common practice

Economics of High-Energy-Rate Forging. As mentioned earlier, HERF devices are only one-ninth the size and weight of conventional hammers and about two-fifths that of crank presses, and this accounts for the reduced capital investment associated with high-energy-rate forging. Furthermore, the installation costs are also lower because of the less expensive foundation requirements. Among the HERF machines, the combustion-pneumatic machines have a lower capital cost than the pneumatic-hydraulic devices.

Despite these advantages, HERF machines have not been found to be competitive in comparison with conventional forming machines for most of the components produced by the industry. This is partly attributed to the long cycle time of such devices, when loaded manually, and the high die and tooling costs. The production cycle time is typically 100% longer than the specified nominal cycle time (based on the ram speed) because of operator movement. With manually fed conventional presses, the operator does not need to change position during the forming operation; with a HERF hammer, the intensity of the blow would cause him to withdraw. Although robotic feeding of the workpiece has been tried with some success, most general-purpose feeding devices are slow. The introduction of innovative feeding mechanisms may drastically change these conditions.

Because of these limitations, the HERF process is better suited to special, rather than general, forging operations. The cost benefits associated with its application would have to be evaluated on a case-by-case basis for each part.

Revised by Natraj C. Iyer, Westinghouse R&D Center

Machines

There are three basic types of HERF machines:

- Ram-and-inner-frame machines
- Two-ram machines
- Controlled-energy-flow (counterblow) machines

These are illustrated and discussed in the article "Hammers and Presses for Forging" in this Volume. In all three types, the energy is derived from high-pressure gas (usually nitrogen) that is stored within the machine and released to accelerate the platens. The machines are designed to minimize shock transmission to the floor. Therefore, a special foundation is not needed, and the machine can be placed directly on the factory floor. Machine capacity ratings range from 17,000 to 544,000 J (12,500 to 400,000 ft · lb). Figure 1 shows a typical schematic of a HERF machine.

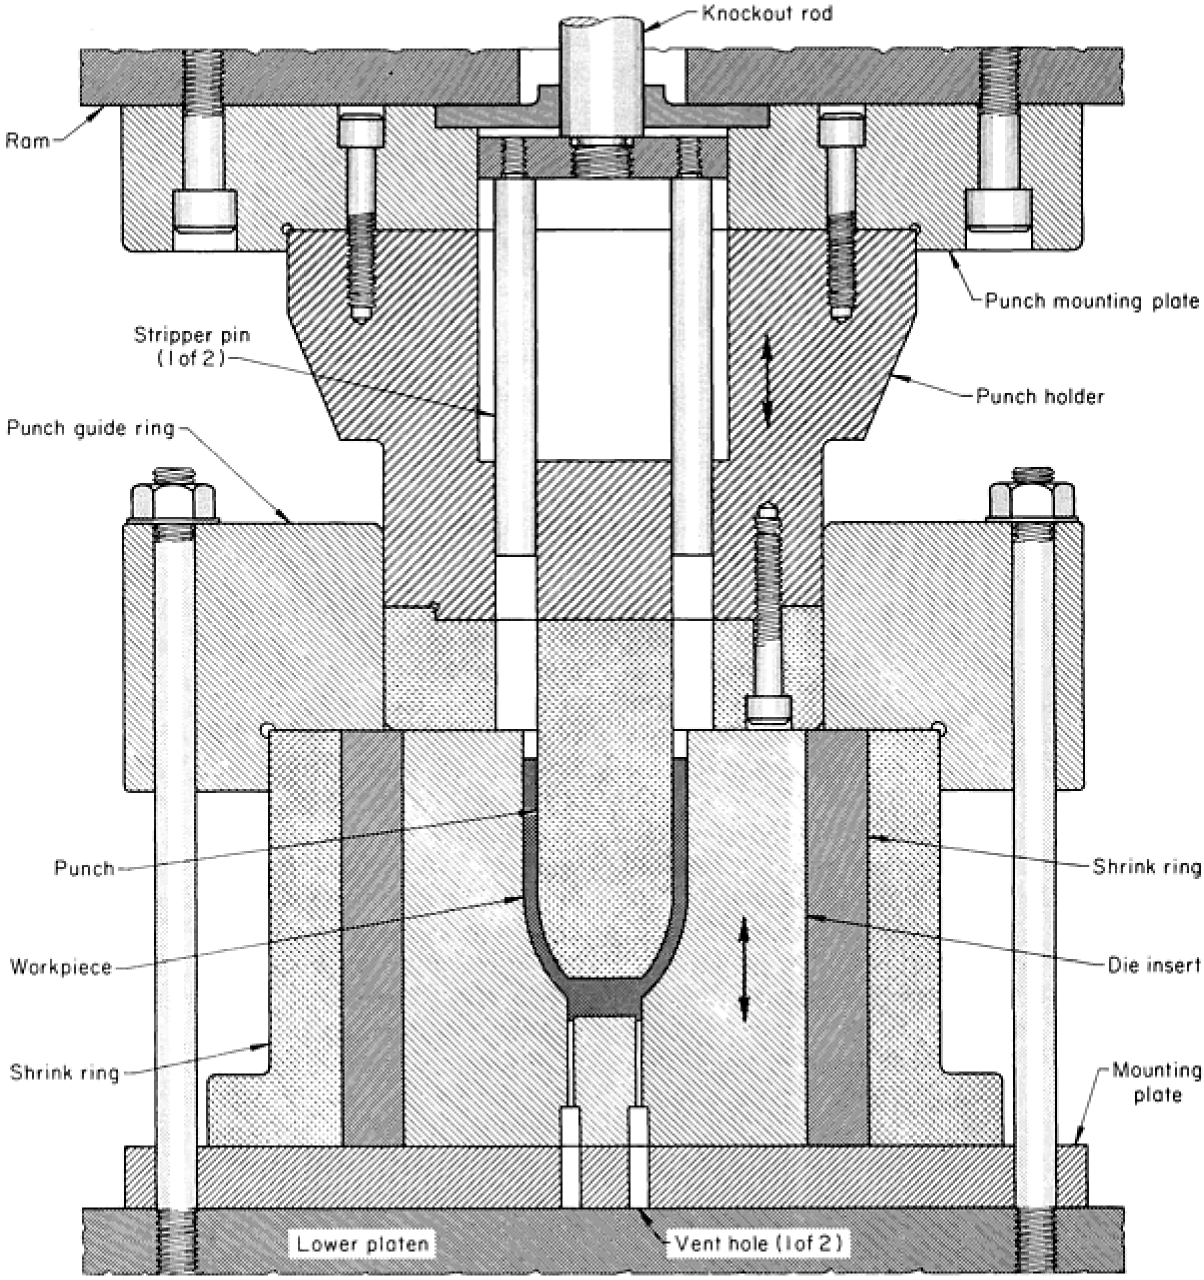

Fig. 1 Schematic of a HERF machine and details of the die used in making the mine nose shown as part D in Fig. 3.

Production Rate. The cycle time for a HERF machine is 12 to 20 s per piece, or a production rate of 180 to 300 parts per hour. Therefore, HERF machines can make parts to close profiles at production rates often comparable to those of drop-hammer and hydraulic presses. Adaptation of automatic transfer equipment to high-energy-rate forging would further increase the production rates to make it competitive with manually operated mechanical presses. The machines are readily adaptable to automatic loading and unloading equipment. However, high-production runs or multiple runs of similar parts are needed to justify the cost of automatic handling equipment.

Production Quantity. Table 2 compares HERF machines with hammer and press equipment on the basis of the production quantities for which each is typically used for forging a variety of parts. As this comparison shows, HERF machines are used for small and medium production quantities.

Table 2 Application of four basic types of machines for hot forging typical parts

L, large quantities: >10,000 parts; M, medium quantities: 500 to 10,000 parts; S, small quantities: <500 parts; N, not suitable for forging this type of part

Type of part	Hydraulic press	Mechanical press	Hammer	High-energy machine

High-Energy-Rate Forging

Revised by Natraj C. Iyer, Westinghouse R&D Center

Dies

Closed dies and flash-and-gutter impression dies are used in high-energy-rate forging. The closed dies restrict the flow of metal and force it to fill the cavity completely; they are recommended because they require less material in the billet and permit closer dimensional control of the forging. Flash-and-gutter impression dies are generally used for thicker parts with more liberal dimensional tolerances.

As in conventional hammer forging, the force of the ram should be completely expended in deforming the workpiece. Impact between the upper and lower tools is potentially destructive. It can be effectively avoided by controlling those processing conditions that significantly influence metal plasticity (such as temperature, volume, and die temperature and lubrication) and in some cases by selective placement of a protective ring around the upper die.

Die Design. The design of tooling for high-velocity pneumatic-mechanical forging is quite different from the methods used for designing dies for use in mechanical presses. This is especially true when the part to be forged is shaftlike or cuplike, requiring relatively deep dies. In these cases, the die assemblies should comply more closely with the design rules used by impact extruders. These involve interference-fit assemblies, undercut punches, rugged ejectors, and vertical flash movement. An important element in these design concepts is the lack of any contact between the tool on the ram and the tool on the bolster during the forging stroke. Unlike hammer-die forging, the stroke of a pneumatic-mechanical press is controlled entirely by stalling the ram movement when plastically deforming the workpiece. No contact is permitted between the die faces. Prestressed die inserts, carefully guided punches, and provisions for vertical flash are typical. Flash movement may be horizontal in the forging of flat parts.

Die inserts are often fitted into the heavy retainer rings to counteract the large horizontal forging forces. These rings put a compressive stress, sometimes as great as 690 MPa (100 ksi), on the metal in the die insert and therefore reduce die breakage.

Alignment of the upper and lower dies is maintained partly by the accuracy of the machine guides and partly by piloting the upper die in the lower die. Clearance between the punch and the die piloting surfaces is 0.025 to 0.102 mm (0.001 to 0.004 in.). In some dies, another clearance is provided below the piloting surfaces to allow for vertical flash movement. For example, in Fig. 2, the upper dies, which were located in a simple holder for ease of replacement, were guided by an extension of the lower die cavity. An auxiliary ring was used in the die shown in Fig. 1. Although smaller corner and fillet radii can be forged by the HERF method as compared to conventional forging methods, it should be anticipated that such radii will restrict metal flow and increase die wear.

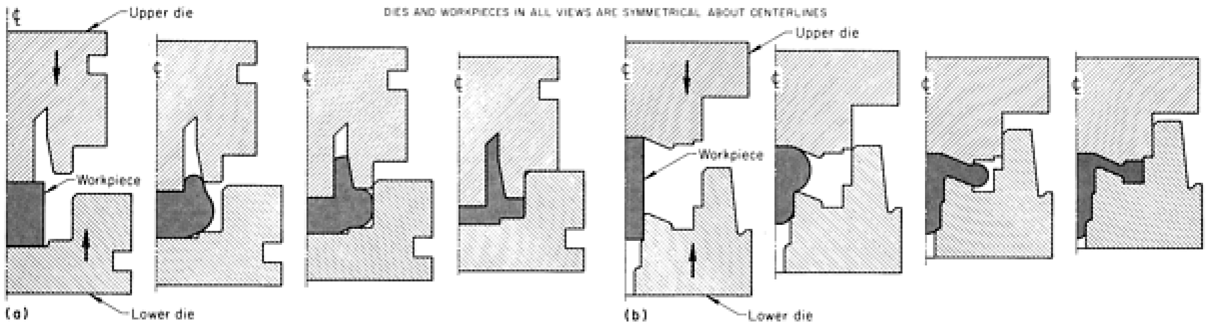

Fig. 2 Metal flow in high-energy-rate forging. (a) Upsetting and backward extruding a welding neck flange. (b) Upsetting and forward extruding a gear shaft.

As in conventional practice, the metal shrinkage allowance depends on the metal being forged. Draft is sometimes provided in the die cavity and on the upper die (or punch) for easy removal of the part. By using a positive punch stripper, it may be possible to eliminate the draft in the die cavity, allowing 1 to 3° draft on the punch. If depressions are formed in the bottom external surface of the part, knockouts are needed because of metal shrinkage around these areas.

Provision should be made in the lower die cavity for locating the hot billet. A shallow recess in the die is usually adequate. Die wear at locating points is greater than in other parts of the cavity, and an easy means of replacement should be designed into the die. The lower die cavity generally has a shorter die life than the punch or upper die, because of the longer time it is in contact with the billet.

Die fabrication practice for high-energy-rate forging is similar to that used for conventional forging dies. Dies have been made by casting and by electrical discharge machining the cavity in a rough-machined block. The use of electrical discharge machining in die fabrication is discussed in the article "Dies and Die Materials for Hot Forging" in this Volume.

Close-tolerance hubbing (die typing) is done in HERF machines. The hub, made of H11 or H13 steel and hardened to 48 to 52 HRC, is secured to a retainer fastened to the upper platen of the machine. The die blank, with a rough-machined cavity and heated to forging temperature, is placed into a retainer mounted on the lower platen. The hub is then driven at a high velocity into the blank to form the die cavity.

Die Materials. Prehardened tool steels such as 6F2 and 6F3 are used when forging stresses are low and production quantities are small. For larger quantities and severe forging requirements, tool steels such as H11 or H13 are used for the critical die components.

In high-production dies, 6F2 and 6F3 steels and alloy steels such as 4140 and 4340 are used for backup blocks, shrink rings, and retainers. A modified H13 tool steel containing 1.5% Ni is recommended for die inserts and punches for long production runs, close-tolerance forging, and hot-work applications in which exceptional toughness and resistance to abrasion and heat cracking are important.

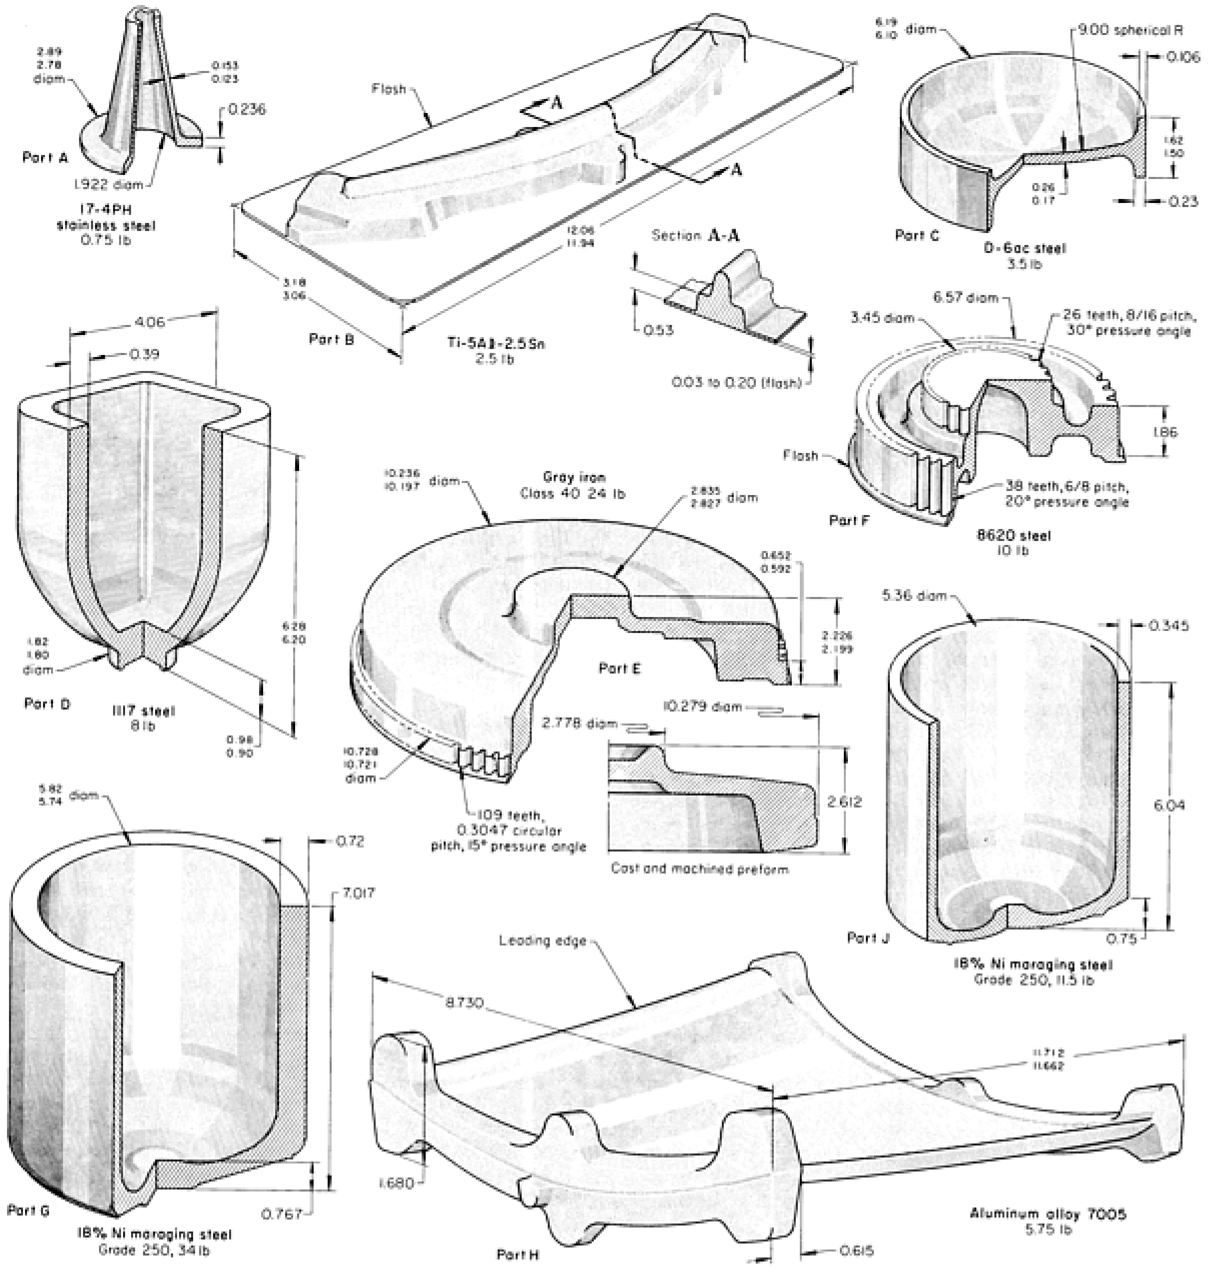
Hubbed die inserts are commonly made of H11 tool steel, but 4140 steel is sometimes used when production requirements are small or the operation is not severe. Almost any tool steel that will withstand hot working can be used for hubbed die blocks or inserts, although dies made of prehardened tool steel would soften during the hot-hubbing operation.

Die Life. The usual modes of failure of hot-forging dies, at both conventional and high forming speeds, are wear, heat checking, and fatigue. Early users of pneumatic-hydraulic HERF machines found die life to be considerably shorter than that encountered with conventional machines. This was subsequently attributed in part to the fact that the HERF machines tended to be used for the production of more complex and difficult components, which in many cases would not even have been attempted with conventional machinery.

Production tests carried out by the Drop Forging Research Association indicated that the service lives of dies used in a pneumatic-hydraulic HERF machine compare favorably with those of identical dies used in a conventional drop-stamping press. The forging of three different components using both methods established that neither method had the edge over the other in terms of die life. In general, no significant difference in the rate of change of salient component dimensions was noted in changing from the slow-speed process to the high-speed process. On both types of machines, the die life was limited by surface cracks. An exception to this has been observed in cases in which a corner adjacent to a flash gap of one die showed up to two to three times as much wear on the HERF machine as compared to the conventional machine.

Example 1: Die Specifications Needed to Produce Mine Nose by HERF.

The die shown in Fig. 1 was used to forge the mine nose shown in part D in Fig. 3. The die insert was made of H13 tool steel. The calculated prestress on this ring was 690 MPa (100 ksi). Small holes in the bottom of the die cavity vented the air during forging. The punch was made of H13 tool steel and hardened to 45 to 47 HRC. The punch holder and punch mounting plate were made of 4340 steel and hardened to 38 to 40 HRC. The punch guide ring on the die provided precise alignment of the punch as it entered the die. This die allowed production of concentric parts with uniform wall thickness. There was no draft on the side-walls of the die cavity or the punch. Because metal shrinkage caused the part to adhere to the punch, a stationary stripper ejected the forging from the punch on the upstroke of the ram.



Part	Name of part	Work metal	Blank size, mm (in.)		Weight		Forging temperature		Forging energy	
			Diameter	Length	kg	lb	°C	°F	J	ft · lbf[(a)]

High-Energy-Rate Forging

Revised by Natraj C. Iyer, Westinghouse R&D Center

Lubrication

Lubricants act as parting agents between the workpiece and the die. They also provide an insulating film on the die surface that reduces heat transfer between the hot billet and the die, thus lessening thermal cracking and increasing die life. Serviceable lubricants include high-temperature greases containing copper, molybdenum disulfide, or graphite and aqueous suspensions containing graphite. The spraying of water-base coolants containing soluble oil onto the surfaces of dies and punches prevents softening and extends die life.

Revised by Natraj C. Iyer, Westinghouse R&D Center

Preparation of Blanks

Blanks for symmetrical shapes are cut from bar stock that has been rough turned. The blank diameter is such that a hot blank will drop unimpeded into the die cavity and provide some degree of location. When a particular grain flow is specified, billets are pancaked or are progressively preformed by the multiple blows or by special preforming operations. The billet used in high-energy-rate forging is usually smaller than that used in conventional hammer forging methods for three reasons: Metal is not needed for a tonghold, the finished forging has little or no flash, and the machining allowance is small.

The volume of the blank is closely controlled so that the shape can be forged to relatively close tolerances. Close volume control helps reduce the cost of material; this is of particular importance in forging the more expensive metals, such as titanium alloys and maraging steel.

The tolerance on blank diameter and length varies with shop practice. One high-energy-rate forging shop purchases rough-turned bars manufactured to a diameter tolerance of +0.76 mm, -0.00 mm (+0.030 in., -0.000 in.), then saws blanks to length with the same tolerance. For some parts, tolerance is also specified on blank weight. For example, the forward motor case shown as part J in Fig. 3 was forged from a billet 114.3 + 0.8 mm, -0.0 mm (4.50 + 0.03 in., -0.00 in.) in diameter by 63.0 + 0.8 mm, -0.0 mm (2.48 + 0.03 in., -0.00 in.) in length with a specified weight of 5.22 kg ± 0.0285 kg (11 lb 8 oz ± 1 oz).

As-forged symmetrical parts often have little or no flash. However, when flash allowance is provided, it generally is less than 3% of the blank weight. Some of the flash is derived from the normal variation in blank weight. In sharp contrast, asymmetrical parts can develop considerable flash. For example, the fan stator vane shown as part H in Fig. 3 had a flash amounting to 10 to 15% of the blank weight.

High-Energy-Rate Forging

Revised by Natraj C. Iyer, Westinghouse R&D Center

HERF Processing

Like conventional forging, high-energy-rate forging can be accomplished over a broad range of temperatures, depending on the specific part, the material, and the design requirements.

Hot Forging. High forging speeds in hot forming result in reduced cooling of the material as it flows over the cooler die surfaces and in improved lubrication. The high strain rate increases the forming load, but this is partially offset by adiabatic heating of the workpiece, thus making it easier for the material to fill out the die cavity. However, in some materials, such as high nickel-base alloys, it can lead to incipient melting, which can in turn cause serious rupturing when large reductions are being forged.

Under the most favorable conditions, hot high-energy-rate forging allows the production of components that cannot be forged with conventional machines. Complex parts and components with thin sections have been produced; webs and ribs 3.18 mm (0.125 in.) thick and central ribs 4.76 mm (0.1875 in.) thick are technically feasible. However with pneumatic-hydraulic HERF machines, such results can often be obtained only at the expense of die life in view of their long dwell times.

The suitability of the hot-forming process depends on the component shape and the material formed. Although cylindrical, axisymmetric shapes are preferred, more complex shapes such as light alloy compressor blades have been successfully manufactured. Complex forging usually requires some preforming to ensure proper metal flow and to avoid such defects as laps, cracks, and unfavorable grain flow. Table 3 presents the suitability of a broad range of alloys for high-energy-rate forging. Most of the current applications are related to the first three alloys; namely, aluminum alloys, carbon and alloy steels, and stainless steels.

Table 3 Forgeability of various work metals by high-energy rate forging

Work metal	Forgeability
Aluminum alloys	**Excellent for alloys such as 2014, 2024, and others hardened basically with copper. For 7075 and 7079, forging temperatures and reductions must be adjusted downward to prevent rupturing. No improvements in shape detail obtained**
Carbon and low-alloy steels	**Excellent; greater shape detail possible than in hammers or hydraulic presses**
Stainless steels	**Excellent; greater shape detail possible than in hammers or hydraulic presses**
Iron-base heat-resistant alloys	**Good if forging temperatures are adjusted downward to prevent overheating. Greater shape detail possible than by conventional methods**
Nickel-base heat-resistant alloys	**Good if reduction per blow is limited to less than about 60% (depending on alloy).**
Magnesium alloys	**Poor for such alloys as AZ31B and AZ80A. Alloys HM21A and HM31A are as forgeable as in presses if temperatures are adjusted downward.**
Titanium alloys	**Good; care must be exercised to avoid β grain coarsening that can result from significant temperature increases.**

Cold Forging. High speeds in cold forging improve lubrication. Improved lubrication lowers the frictional forces, and this in turn results in improved metal flow and surface finish of the components. The process is practically adiabatic; therefore, with soft materials, such as aluminum and copper, some softening occurs. Forging forces and pressures are generally higher than those obtained at conventional speeds, although energy requirements may well be lower.

The research experience of high-speed cold forging is extensive, but production experience is very limited. There are two reasons for this. First, cold-formed components are generally small, and the available pneumatic-hydraulic HERF machines are too large in capacity and too slow to compete with the more automated high-production mechanical presses. Second, cold forming is carried out with presses or heading machines that have fixed stroke. With forward-extrusion hammers, adequate component length tolerance can be obtained only by the addition of clash faces, which generate unacceptably high levels of impact noise.

Cold forging, however, has been successfully used for the fabrication of blanks. Blanks for bevel gears, for example, have been cold forged from extruded preforms.

Warm Forging. In comparison to hot high-energy-rate forging, the principal advantage of warm forging is the absence of scale and therefore better surface quality, high precision, and improved tool life. In relation to cold high-energy-rate forging, the process leads to significant lowering of tool loads, permitting a wider range of both component sizes and available materials that can be formed without appreciable deterioration in component material properties.

For steels, the warm-forging temperatures range from 450 to 950 °C (840 to 1740 °F). Temperatures are most often between 600 and 815 °C (1100 and 1500 °F). The dies used resemble typical HERF dies.

Experience with high-speed warm forging is very limited. An example of a large warm-formed part is a transmission shaft, formed at 700 °C (1290 °F) with a single blow from a preform forged at conventional forging temperature on a horizontal upsetter.

Metals Forged. Current production by high-energy-rate forging involves a wide range of materials, such as aluminum, high-strength steel, stainless steel, alloy steels, and titanium. Low-carbon steel parts are being produced when the complexity of the part is such that the use of high-velocity impact equipment is required. Limited production work is being done with nickel-base heat-resistant alloys. The metals best suited to the process are those that withstand very high deformation rates without rupturing.

High-energy-rate forging is particularly suited to alloys that require high forging temperatures and pressures, especially when thin webs or unusual design features are required. Low-carbon steels, refractory metals, and nickel alloys that have broad forging temperature ranges can be forged. Metals with low ductility under rapid deformation rates, such as magnesium and beryllium alloys, cannot be forged by high-velocity methods.

Heating that is caused by rapid deformation, if excessive, may result in incipient melting and serious rupturing when forging to large reductions. The metals affected in this manner include high-carbon steels, high-strength aluminum alloys, and nickel-base heat-resistant alloys. Increased temperatures during forging can cause β embrittlement in some titanium alloys. Table 3 shows the forgeability of various work metals by HERF methods.

The range of metals and shapes forged by the HERF process is illustrated by the parts shown in Fig. 3. The aluminum alloy 7005 vane, shown as part H in Fig. 3, was forged in one die from an extruded and machined preform. The part was forged at a temperature of 425 °C (800 °F) to a closure tolerance of ±0.13 mm (±0.005 in.) and a contour tolerance within ±0.25 mm (±0.010 in.). The vane platform shown in part B in Fig. 3 was made of titanium alloy bar stock measuring 35 mm ($1\frac{3}{8}$ in.) in diameter by 267 mm ($10\frac{1}{2}$ in.) in length. Forging temperature was 1095 °C (2000 °F), and the forging energy was 190,000 J (140,000 ft · lbf). The bar stock was preformed into an arc having a radius about the same as that of the vane.

An example of a low-carbon steel part produced by high-energy-rate forging is an automobile front wheel hub that was forged from a 3.2 kg (7 lb) billet of 1020 steel. The part had a 102 mm (4 in.) diam flange and a 48 mm (1.9 in.) long hub. The outside surfaces were used as-forged; but the inside surfaces were machined, and bolt holes were drilled in the flange.

Metal Flow

In high-energy-rate forging, the metal can flow through small openings to fill large cavities and accurately produce intricate details. An experimental part having a thin web was forged using both a high-energy-rate machine and a drop hammer. The high-energy-rate machine forged a web thickness of 0.96 mm (0.038 in.) in one blow. By hammer forging, the minimum thickness obtained was 1.24 mm (0.049 in.) using three blows with a 910 kg (2000 lb) hammer and 1.52 mm (0.060 in.) when four blows with a 450 kg (1000 lb) hammer were used. The high-energy-rate machine used the lowest amount of energy available.

Metal spreads more in a high-speed blow. In one test on forging from a cylindrical billet, a measurement was made of the largest flange diameter that could be obtained before cracks appeared on its periphery. Larger diameter flanges could be produced in a HERF machine than by conventional forging. However, greater surface roughness was observed with the HERF method than with conventional forging.

Metal Flow During HERF Processing. When the clutch hub illustrated in Fig. 4 was forged from a 1038 steel billet 51 mm (2 in.) in diameter by 83 mm ($3\frac{1}{4}$ in.) in length, one high-velocity blow was sufficient to cause the metal to flow through the thin center web and into the thicker web and flange without cracking. Conventional hammer forging of the part would have used a blocking operation involving eight or nine blows and would have had a metal loss of about 0.34 kg ($\frac{3}{4}$ lb) from scale and flash.

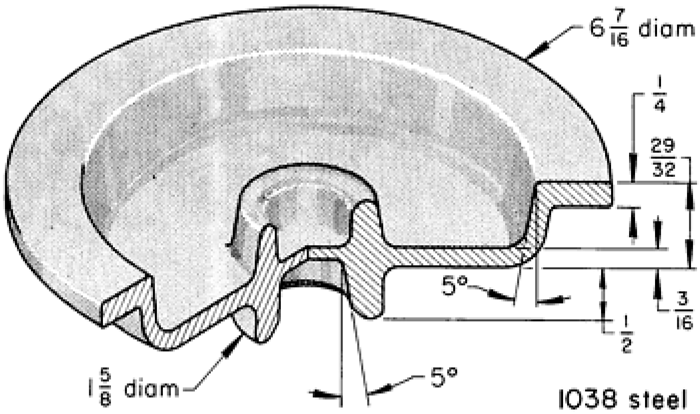

Fig. 4 Clutch hub with thin web and thick flange that was made in one blow by high-energy-rate forging. Dimensions given in inches.

The major diameter of a cluster gear (part F, Fig. 3) was 2.2 times the diameter of the blank. This gear was finish forged from the blank in one high-velocity blow consisting of 353,000 J (260,000 ft · lbf) of energy. The work metal was 8620 steel, and it was heated to a forging temperature of 1230 °C (2250 °F). In the hammer or press forging of this gear, the blank would have been flattened with one or more forging blows before being placed into the finisher impression. In addition, teeth are generally not formed on gear blanks during conventional forging.

The flow of metal by upsetting and backward extrusion during the high-energy-rate forging of a welding flange is shown in Fig. 2(a). Progressive metal flow during high-energy-rate upsetting and forward extrusion of a gear shaft is shown in Fig. 2(b). In the forging of both of these parts, the upper die was guided in the lower die, and die closure was controlled by the amount of metal in the workpiece and by a ring surrounding the upper die cavity that contacted the lower die. In each of these dies, the billet was located by a special recess in the lower part of the die cavity.

Dimensional Accuracy. Tolerances as small as ±0.05 mm (0.002 in.) have been held on parts produced by high-energy-rate forging. However, holding such close tolerances results in excessively greater die wear than when parts have more generous tolerances. This is true regardless of the type of forging process or equipment used. If the metal saved is expensive or if the machining that is eliminated or reduced involves costly three-dimensional profiling, forging to close dimensional tolerances may be justified. Forging with liberal tolerances may be more prudent if the metal is inexpensive and if machining operations are relatively simple.

Surface Finish. Surface finish on a forging, using any of the above processes, is only as good as the finish on the die or die cavity. Typically, any marks on the die will be reproduced on the surface of the forging. In general, the surface finish specified depends on the work metal, the amount of subsequent machining, and the end use of the forged product.

High-Energy-Rate Forging

Revised by Natraj C. Iyer, Westinghouse R&D Center

Applications

Nine typical parts that have been produced by high-energy-rate forging are shown in Fig. 3; the forging conditions are listed in the accompanying table. The weights of these parts range from 0.34 to 15 kg ($\frac{3}{4}$ to 34 lb). The 0.34 kg ($\frac{3}{4}$ lb) part A was forged in two separate blows with an intermediate reheat. It had a tolerance of ±0.38 mm (±0.015 in.) on the wall thickness and +2.8 mm, -0.0 mm (+0.11 in., -0.00 in.) on the flange diameter. The 15 kg (34 lb) part G was forged from the billet by two successive machine blows without being removed from the die.

The cup-shaped parts G and J in Fig. 3 were forged and backward extruded from billets of 18% Ni maraging steel, grade 250. Part G had a total tolerance on the inside diameter of 2.0 mm (0.08 in.); the draft angle on the punch was about $\frac{1}{2}$° per side. Permissible draft on the outside diameter was about 0.008 mm per mm (0.008 in. per in.). Part G had a wall thickness of 18.3 mm (0.72 in.) for a depth of about 171 mm (6.75 in.) and required two successive blows to finish forge. Part J had a total tolerance on the outside diameter of 3.8 mm (0.15 in.); the inside and the outside diameters were to be concentric within 1.02 mm (0.040 in.). The punch for part J had a draft angle of 1 to 3° per side. Part J had a wall thickness of 8.75 mm (0.345 in.) for a depth of about 135 mm (5.3 in.) and was forged in one machine blow. Both these parts had a 25 μm (1000 μin.) surface finish.

The double-flange bulkhead shown as part C in Fig. 3 was made of a D-6ac alloy steel billet that was heated to 1175 °C (2150 °F). Because of the spherical web, the draft allowance on the cavity for the outside diameter was 4° maximum per side. Total tolerance on the inside diameter was 2.3 mm (0.09 in.) on the convex side of the web and 1.02 mm (0.040 in.) on the opposite side. Tolerances on all three parts were unilateral, but were applied in order to allow wear on the punch and die cavity dimensions.

Another bulkhead with a flange extending from both sides of the web (an I-beam in cross section) was forged from D-6ac steel in one blow using 163,000 J (120,000 ft · lbf) of energy. The billet was 63.5 mm (2.50 in.) in diameter by 64.0 mm (2.52 in.) in length and was forged at 1150 °C (2100 °F). The web thickness was 0.267 mm ± 0.127 mm (0.0105 ± 0.005 in.). Maximum production rate was 120 pieces per hour for more than 20,000 bulkheads.

Forging a bulkhead by the high-energy-rate method can result in savings of material. For example, a bulkhead weighing 14 kg (30 lb) was forged from 18% Ni maraging steel, grade 250. When conventionally forged, the bulkhead weighed 41 kg (90 lb). The 14 kg (30 lb) part was made in a counterblow HERF machine by successive blows in the same die cavity without reheating the workpiece. The energy level was about 237,000 J (175,000 ft · lbf) per blow. The counterblow (controlled-energy-flow) machine is better suited for repetitive blows than the two other machines.

The 103 mm (4.06 in.) square mine nose shown as part D in Fig. 3 was made from a 1117 steel billet 99.6 mm (3.92 in.) in diameter by 61 mm (2.4 in.) in length that weighed about 4 kg (8 lb). The billet was heated to 1205 °C (2200 °F) and then forged with 214,000 J (158,000 ft · lbf) of energy. The draft angle on both the internal and external walls was 0°. The tolerance on the outside dimensions was +0.00 mm, -1.02 mm (+0.000 in., -0.040 in.); on the inside dimensions, +1.52 mm, -0.00 mm (+0.060 in., -0.000 in.). The zero draft angle and the close tolerances contributed to a substantial savings in machining compared to that required for a conventionally forged part.

The 12-point socket wrench shown in Fig. 5 is a precision forging that did not need machining of the internal spline section. This wrench was forged in one blow with 88,100 J (65,000 ft · lbf) of energy. The 4150 steel billet was 70 mm ($2\frac{3}{4}$ in.) in diameter by 83 mm ($3\frac{1}{4}$ in.) in length. The forging temperature was 1165 °C (2130 °F).

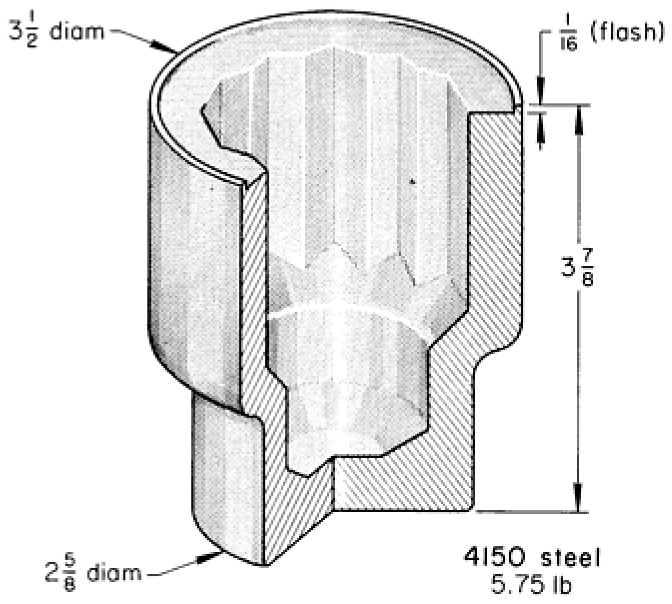

Fig. 5 Socket forged to final shape in one blow so that no machining was required for producing the 12-point spline. Dimensions given in inches.

Forging of Gears. It is possible to produce gears with a contoured grain flow that follows the configuration of the teeth using high-energy-rate forging. In the case of spur gears, this is achieved by pancaking to cause lateral flow of the metal in a die containing the desired tooth configuration at its periphery. Contoured grain increases the load-bearing capacity without increasing the tooth size. In addition, the process minimizes the machining required to produce the finished gear. Although spur gears are the easiest to forge, helical and spiral-bevel gears can also be forged if their configurations permit ejection of the gear from the die cavity. Gears have been forged from low-alloy steel, brass, aluminum alloys, stainless steel, titanium, and some of the heat-resistant alloys.

Gears with a diametral pitch of 5 to 20 are commonly forged with little or no machining allowance. The die life decreases significantly when forging finer-pitch gears.

The forging of 5-diametral-pitch gears with an involute tolerance of 0.013 mm (0.0005 in.) and total composite error of 0.08 mm (0.003 in.) has been reported. These gears were forged with a tooth-to-tooth spacing deviation of about 0.025 mm (0.001 in.) and a total accumulated deviation of 0.089 mm (0.0035 in.). Over-the-pins dimensions were held to ±0.05 mm (0.002 in.) on these gears, and the total composite error was about 0.20 mm (0.008 in.).

Holding gear dimensions to extremely close tolerances may eliminate finish machining, but the savings may be exceeded by higher die making/maintenance costs. Consequently, most forged gears have an allowance for machining.

A surface finish of 0.5 to 1.5 μm (20 to 60 μin.) on gear teeth is practical. However, even with a 0.5 μm (20 μin.) finish, local imperfections can increase the average to 1.5 μm (60 μin.) or greater. Therefore, it would be difficult to maintain a good surface finish on gear teeth without grinding.

Typical Gear Forgings. The 4.5 kg (10 lb) gear shown as part F in Fig. 3 was forged from 8620 steel billet 75 mm (3 in.) in diameter by 124 mm (4.9 in.) in length. An energy level of 353,000 J (260,000 ft · lbf) was needed to forge the gear in one blow at 1230 °C (2250 °F). The web on the gear was forged to final thickness; the teeth were forged with 0.51 mm (0.020 in.) of stock for finish machining.

The die inserts originally used to forge this gear were made of H11 or H13 tool steel. This steel typically softened after producing 20 gears because of its temperature rising above the 565 °C (1050 °F) tempering temperature of H13 steel. The use of Alloy 718 (UNS N07718) was found to improve the die insert life.

The automotive flywheel shown as part E in Fig. 3, 272.49 mm (10.728 in.) in diameter over the teeth and weighing 11 kg (24 lb), was forged from a machined blank cast from class 40 gray iron (generally considered unforgeable). The machined preform, a section of which is shown in Fig. 3, was heated to 955 °C (1750 °F) and forged at an energy level of 271,000 J (200,000 ft · lbf). This part had the smallest tolerance specification. The diameter over the teeth and the thickness of the body had a tolerance of +0.00 mm, -0.18 mm (+0.000 in., -0.007 in.). The largest tolerance on the part was ±1.02 mm (±0.040 in.) on the diameter of a recess. Tolerances on the other recesses were ±0.18 mm (±0.007 in.) and +0.48 mm, -0.00 mm (+0.019 in., -0.000 in.). This gear was forged to the finished dimensions.

Various gears with teeth as an integral part have been forged. These have ranged in outside diameter from 64 to 267 mm (2.5 to 10.5 in.) and in weight from 0.54 to 11 kg (1.2 to 24 lb). Most have been made with 0.13 to 0.51 mm (0.005 to 0.020 in.) of stock on the flank of each tooth for finish hobbing and grinding. Gears forged with integral teeth normally have longer fatigue and wear life than those made from a conventionally forged blank on which the teeth are hobbed, shaped, or milled.

Developmental Work. High-energy-rate forging is continually being extended to new applications. The rock drill bit shown in Fig. 6 is an example. Originally, the part was forged in a drop hammer as a conical forging, and the teeth were machined into the forging; hammer forging the part with integral teeth was considered impossible. The feasibility of forging the same part into near-net shape form has since been established using a HERF machine. The gray iron flywheel shown as part E in Fig. 3 was an experimental part used to determine the feasibility of forging teeth on a cast iron preform. Satisfactory parts have been made using the operating conditions listed.

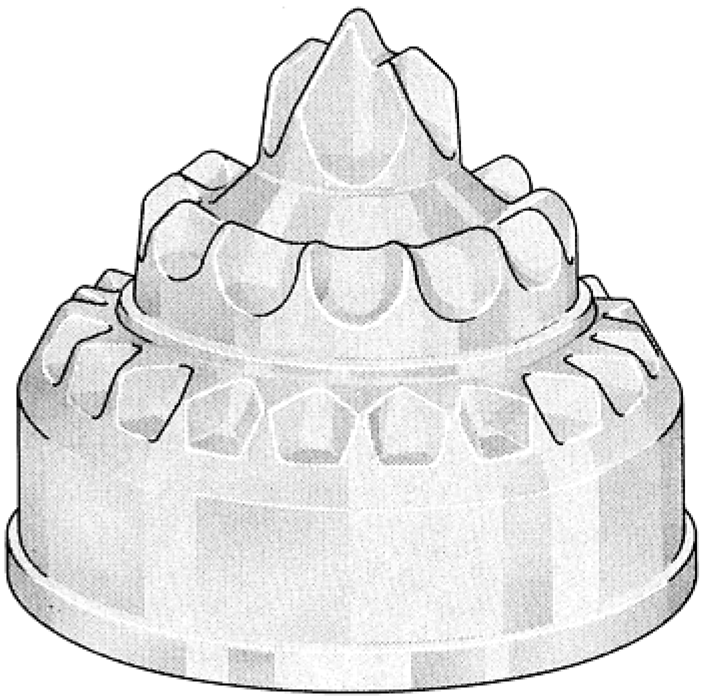

Fig. 6 Rock drill bit that was forged with three rows of teeth as shown.

Ring Rolling

C.R. Keeton, Ajax Rolled Ring Company

Introduction

RING ROLLING is a versatile metal-forming process for manufacturing seamless annular forgings that are accurately dimensioned and have circumferential grain flow. Ring rolling usually requires less input material than alternative forging methods, and it is applicable to production in any quantity.

In ring rolling, a heated doughnut-shaped blank, preformed on a press or forging hammer, is placed over a mandrel of slightly smaller diameter than the hole in the blank. The roll gap between the mandrel (undriven) and a larger-diameter driven main roll is progressively reduced. Friction between the main roll and the ring causes the ring to rotate, and the ring in turn rotates the bearing-mounted mandrel. As the radial cross section of the ring decreases, circumferential extrusion occurs in the direction of ring rotation, and the ring diameter grows. The work rolls may be plain, producing uniformly rectangular ring cross sections, or may have grooves or flanges to produce contoured ring cross sections. Ring height is controlled either by main roll shape or by the use of axial rolls set diametrically across the ring from the mandrel and main roll pass.

Ring Rolling

C.R. Keeton, Ajax Rolled Ring Company

Product and Application

Annular components can be ring rolled from any forgeable material. The configuration can range from very flat washer-shaped rings to long sleeve-type rings (Fig. 1). Typical materials include carbon and low-alloy steels, copper, brass, aluminum and titanium alloys, and high-strength nickel- and cobalt-base alloys, which are very difficult to form. Applications for seamless rolled rings include antifriction bearing races, gear rims, slewing rings, railroad wheel bearings, commutator rings, rotating and nonrotating rings for jet engines and other aerospace applications, nuclear reactor components, bevel ring gears, and flanges of all kinds (including weld-neck flanges), sheaves, wheels, valve bodies, food-processing dies, and chain master links.

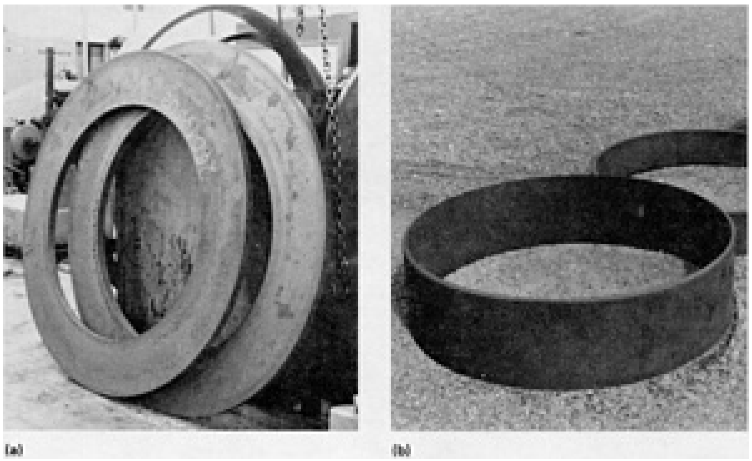

Fig. 1 Two possible rolled ring shapes. (a) Washerlike ring. (b) Sleeve-type ring. Rings with contoured cross sections can also be produced (see Fig. 2).

Sizes. About 90% of all rolled rings have outside diameters in the range from 240 to 980 mm (9.5 to 38.6 in.), heights (lengths) ranging from 70 to 210 mm (2.75 to 8.25 in.), and wall thicknesses between 16 and 48 mm (0.63 and 1.9 in.). A significant number of rings, however, are rolled outside the above parameters, and it is not unusual to find outside diameters ranging from 75 mm to 8 m (3 in. to 26.25 ft), heights from 15 mm to 2 m (0.6 in. to 6.5 ft), and weights from 0.4 to 82,000 kg (0.9 to 181,000 lb).

Shapes (Contours). Figure 2 shows a range of typical contoured/shaped cross sections that can be produced by ring rolling. In some cases, it is more economical and more practical to roll contoured rings as 2 in 1 multiples that are then slit. The two identical components are usually mirrored so as to place the thinnest wall section at the midheight of the rolled ring for ease of parting. Because the ring is then symmetrical about the line of midheight, such a ring can often be rolled from a simple blank, and it behaves more predictably during rolling than an asymmetrical ring would if rolled singly.

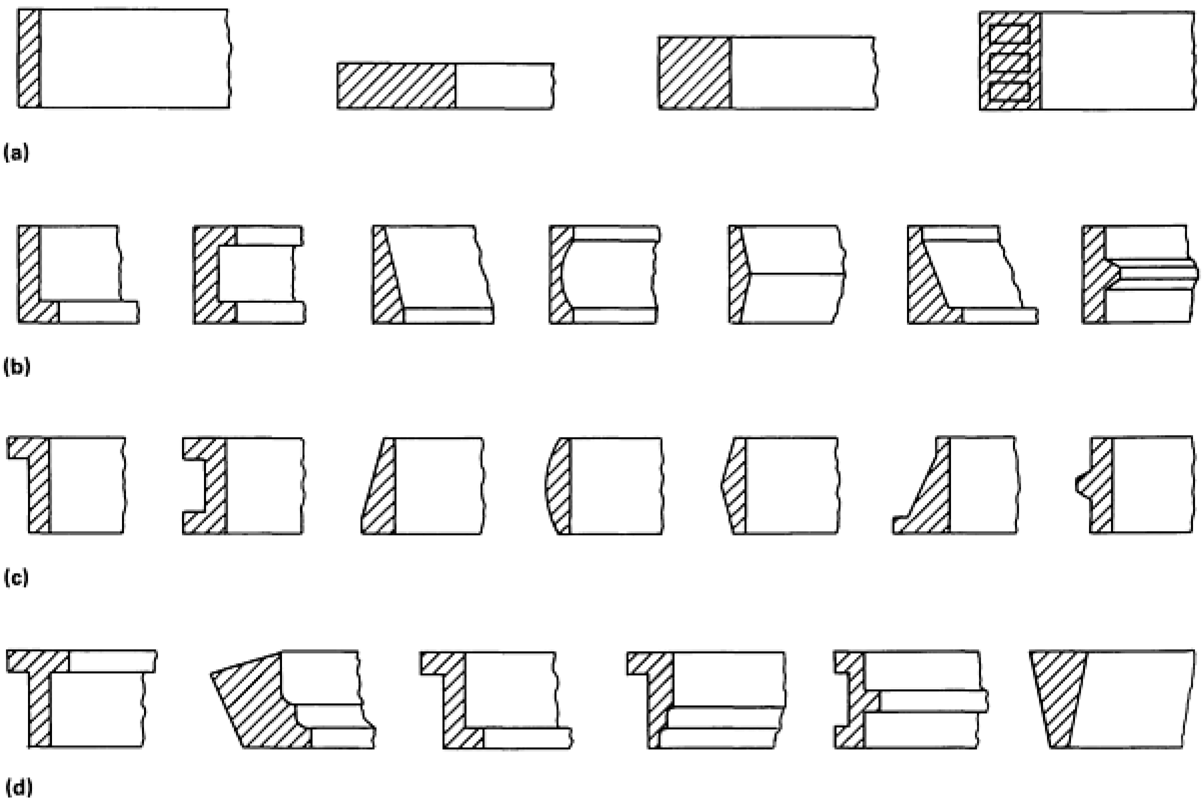

Fig. 2 Typical rolled ring cross sections. (a) Rectangular. (b) Rings with inside contours. (c) Rings with outside contours. (d) Rings with both inside and outside contours

Figure 3 shows the stages in producing a ring contoured on the inside diameter on a vertical mill, using a two-stage rolling technique. With improved ring mill design and construction and the introduction of computer control, the old rules concerning extremes of practically rollable ring-wall-to-ring-height ratios (1 to 4 for sleeves and 4 to 1 for flat, washer-like rings) are no longer applicable.

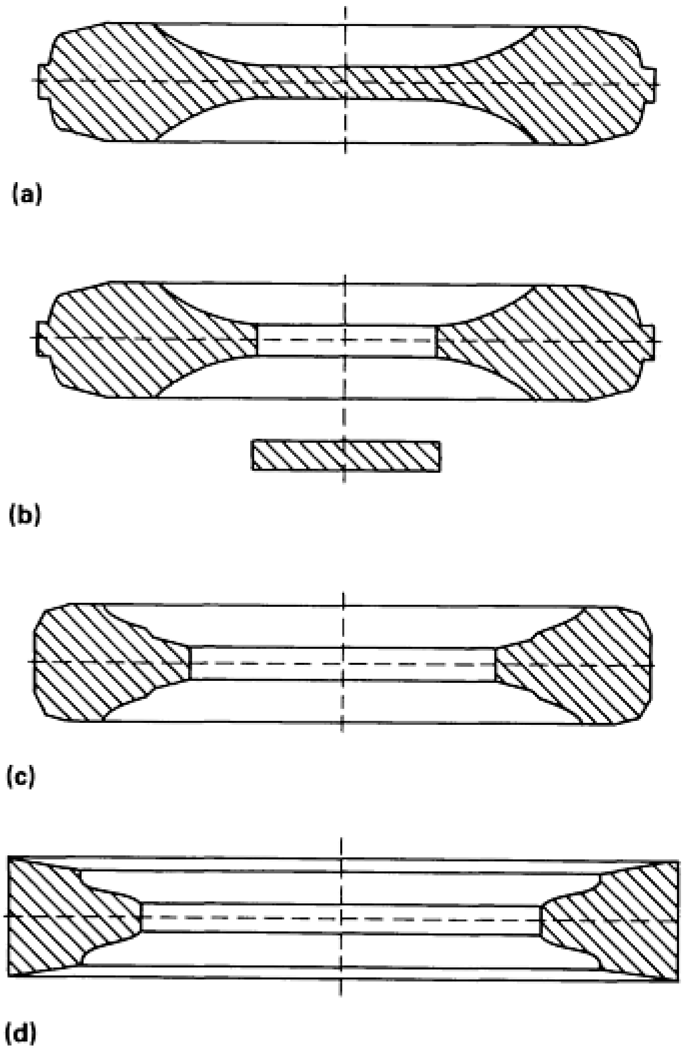

Fig. 3 Stages in the production of a contoured ring on a vertical mill. (a) Ring blank. (b) Pierced blank. (c) After first rolling operation. (d) After final rolling

Washers with a wall-to-height ratio of 16 to 1 and sleeves with wall-to-height ratios of 1 to 16 have been rolled on the same radial-axial ring mill. Using specially prepared tubular-shaped blanks, sleeves with wall-to-height ratios greater than 1 to 28 have been rolled in various materials.

Ring Rolling

C.R. Keeton, Ajax Rolled Ring Company

Machines

Historical Background. In the mid to late 19th century, the rapid expansion of rail-road systems created an increasing demand for railroad wheel-tires. Originally, these items were forged, laboriously, using hammers. As early as 1852, however, a tire rolling machine was built in England. The resulting increased productivity, improved product performance, and ability to put more shape into the tires before machining ensured the ring rolling technique a firm foothold in the forging industry.

Early machines were radial-pass units only (Fig. 4); that is, they used a single roll-pair and controlled height by containing the ring in a shaped tool. These machines were of two basic types, based on the plane of the ring during rolling:

- Horizontal, in which the ring rotates about its vertical axis
- Vertical, in which the ring rotates about its horizontal axis

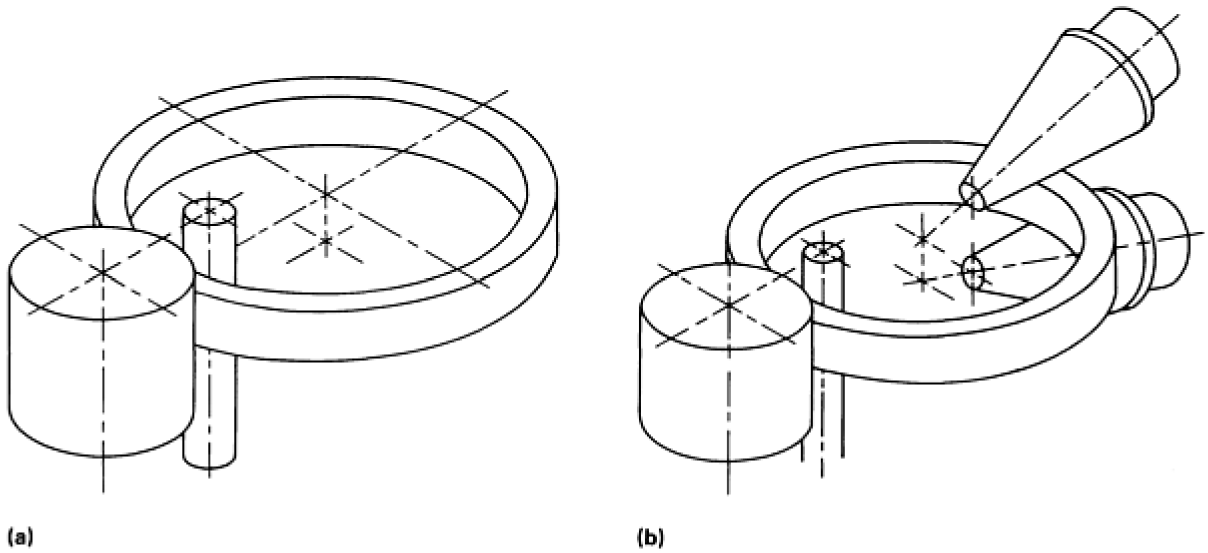

Fig. 4 Schematics showing single-pass (radial) rolling (a) and two-pass (radial-axial) rolling (b)

The vertical machine is limited in its diameter range by practical considerations of floor to working height. The upper diameter limit of the horizontal machine is constrained only by the available floor space. With the horizontal machine some means of supporting the bottom face of the ring must be provided. Either the main roll (older machines) or mandrel of the vertical machine serves as the means of ring support.

As the use of the technique encompassed a greater variety of rings and ring end uses, the fundamental shortcoming of single-pass rolling (end face defects) forced consideration of two-pass rolling (Fig. 4b). By the early 1900s, water-hydraulic horizontal machines with directly operated valves were being constructed with this second pass diametrically opposite the original radial pass for the purpose of (limited) axial height reduction. These machines were termed radial-axial mills. The first oil-hydraulic servo-valve-controlled radial-axial mills appeared in the early 1960s.

From 1930 to 1980, rapidly increasing use of antifriction bearings gave rise to a demand for a particular type of seamless rolled ring. Inner and outer bearing races are manufactured in a wide variety of sizes, those using rolled rings predominantly ranging from 75 to 1000 mm (3 to 40 in.) in outside diameter, 40 to 250 mm (1.6 to 10 in.) in height, and up to 140 kg (310 lb) in weight. High-output multiple-mandrel table mills were specifically designed to meet the lighter end of this need.

Variations on these four basic mill types continue to emerge, with ever-improving machine designs and control systems. Rapid advances in electronics have enabled the application of microprocessor and computer technology to ring rolling equipment.

A variety of special-purpose machines have also been built at various times in the past 70 years. Both vertical and horizontal railroad wheel rolling mills have existed since the turn of the century, although today they are few in number because the wrought wheel has largely given way to the pressure cast wheel.

Of particular note is the recently available closed-die axial rolling (rotary or orbital forging) machine. In this machine, a punched blank or prerolled ring produced on conventional ring rolling equipment is worked between inclining-rotating dies. Annular forgings of very accurate dimensions, and in a range of complex cross sections, can be produced, using only a fraction of the force required by competing forging processes.

Past attempts to employ the principle of rotary (orbital) forging have met with some success. Modern machine design and construction methods have made it possible to build more durable machines. More information on these machines and the rotary forging process is available in the section "Closed-Die Axial Rolling" in this article and in the article "Rotary Forging" in this Volume.

Vertical rolling machines (Fig. 5) offer more rolling force and drive power for a given capital outlay than their horizontal single-pass or two-pass counterparts. This is due to the simplicity of their rugged construction and the minimal requirements in terms of machine-accommodating foundations. Vertical rolling mills have for years been particularly favored by U.S. West Coast producers of jet-engine rings--so much so that they are often termed California mills.

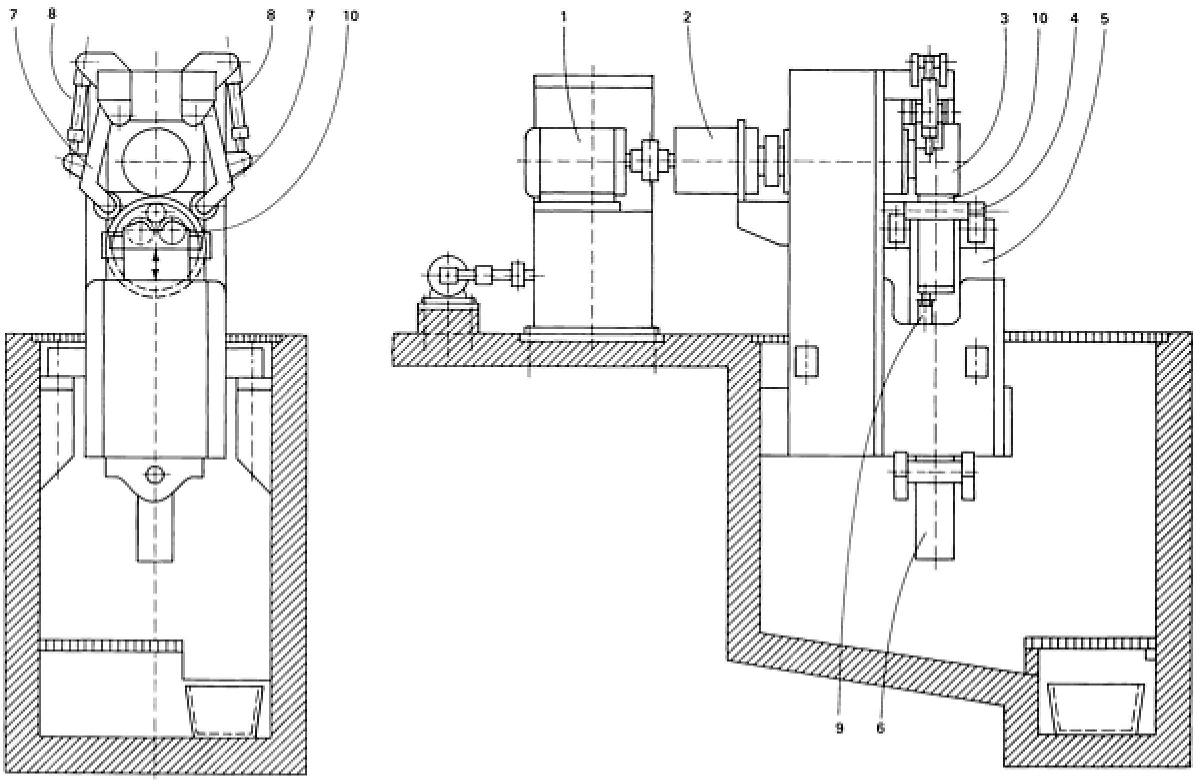

Fig. 5 Schematic of a vertical ring rolling mill. 1, motor; 2, transmission gear; 3, main roll; 4, mandrel; 5, mandrel carriage; 6, hydraulic cylinder to raise and lower mandrel carriage; 7, centering rollers; 8, hydraulic cylinder to control centering rollers; 9, tracer roll; 10, ring

Conventional hammer and press shops find such mills a logical and complementary extension of their facilities. These mills can reduce ring production time to one-tenth that required in hammer forging, can produce smooth concentric diameters, and can leave less allowance for machining.

Blanks are preformed on hammers and presses, and this same equipment is used to flatten the workpiece between operations when open-pass rolling produces the characteristic fish tail defects in ring end faces. Profiled (contoured) main rolls and mandrels can be used to produce correspondingly contoured cross sections. Table 1 lists the capacities of three vertical ring rolling machines.

Table 1 Capacities of three vertical ring rolling machines

Model No.	Maximum rolling force		Approximate rolling speed		Size range of finished rings			
					Outside diameter		Axial height	
	kN	**tonf**	**m/s**	**ft/s**	**mm**	**in.**	**mm**	in.
125	1250	140	1	3.3	250-1000	10-40	35-350	**1.4-14**
160	1600	180	1	3.3	275-1500	11-60	50-425	**2-17**
200	**2000**	**225**	**1**	**3.3**	**300-2000**	**12-80**	**50-500**	**2-20**

Radial-Axial Horizontal Rolling Machines. Although many single-pass horizontal machines are currently in use, very few have been installed in recent years. The predominant modern machine is the two-pass radial-axial machine.

Figure 6 shows a schematic of the operating principles of a radial-axial ring rolling mill. The ring blank is placed over an undriven mandrel (which can be retractable for ease of loading and unloading) and rests on table plates that form part of the radial carriage. A separate roller support carriage is used for larger rings. A backing arm with a mandrel upper bearing is lowered to support the mandrel. This backing arm is connected to the radial carriage so that they move as a unit, hydraulically activated, toward the fixed-axis main roll.

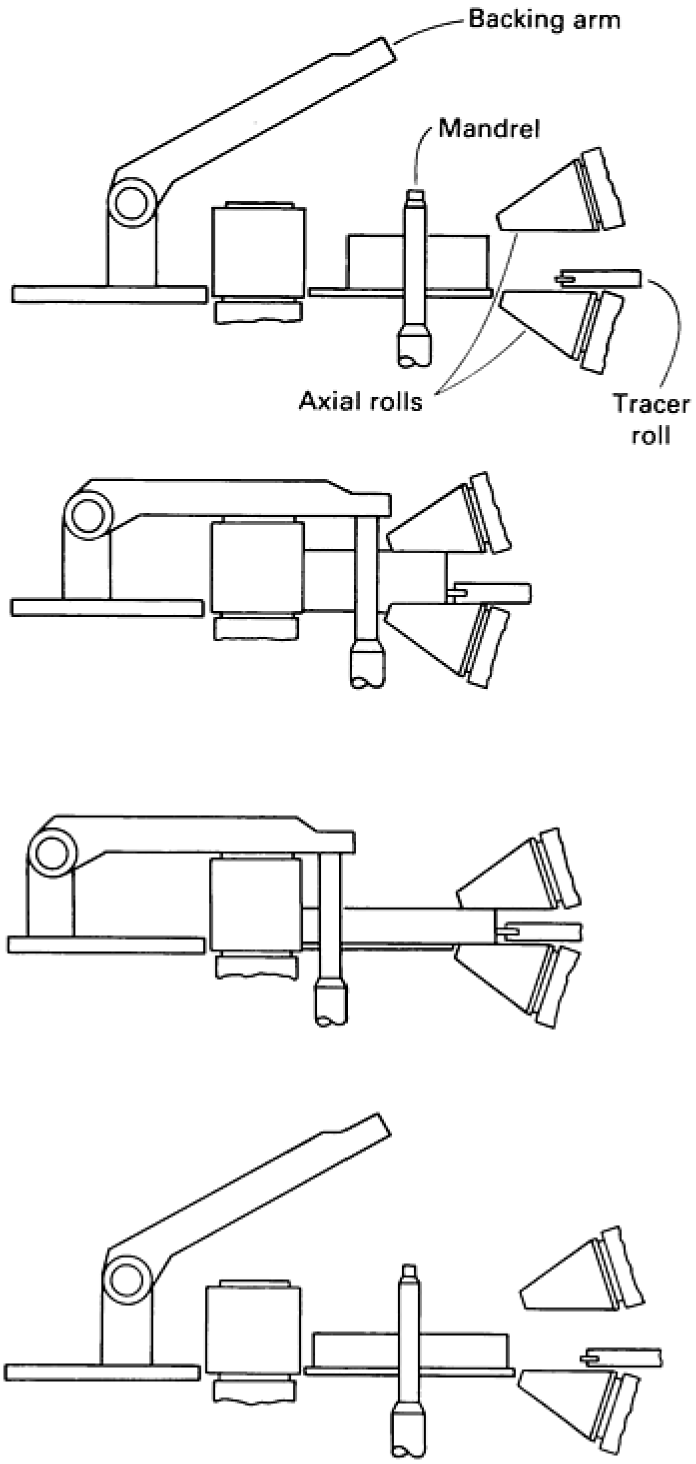

Fig. 6 Schematic showing operation of a radial-axial ring rolling mill.

The main roll rotates at a constant, preselected speed. The ring begins to rotate as the mandrel squeezes the ring wall. This in turn causes the mandrel to rotate.

A separate housing, which holds a pair of conical (axial) rolls, advances until these rolls cover the end faces of the ring blank. The lower conical roll is held in a fixed position such that the roll upper (horizontal) surface is typically 3 to 5 mm (0.12 to 0.2 in.) above the level of the table plates. Both conical rolls are driven, and the upper roll is moved hydraulically. The upper roll slides toward the lower roll to cause axial height reduction of the ring. The axial rolls withdraw as the ring diameter increases, maintaining minimum slip rolling conditions between the conical rolls and the ring end faces.

A tracer wheel mounted on slides between the axial rolls contacts the ring outer diameter. The ring diameter is monitored through measurement of the relative displacement of the tracer wheel and the axial roll carriage.

A pair of hydraulic centering arms (Fig. 7), connected through gear segments, contact the ring outside diameter and ensure that the ring stays round and in the correct position in relation to the longitudinal axis of the mill. Load cells in these centering arms detect differences in force against each centering roll. Through the mill control system, the load cells cause rapid, fine adjustment of axial roll speed to remove any force imbalance and therefore to maintain the correct positioning of the ring during rolling. Either manually (through a potentiometer) or automatically, the centering force is reduced as rolling progresses and the stiffness of the ring decreases.

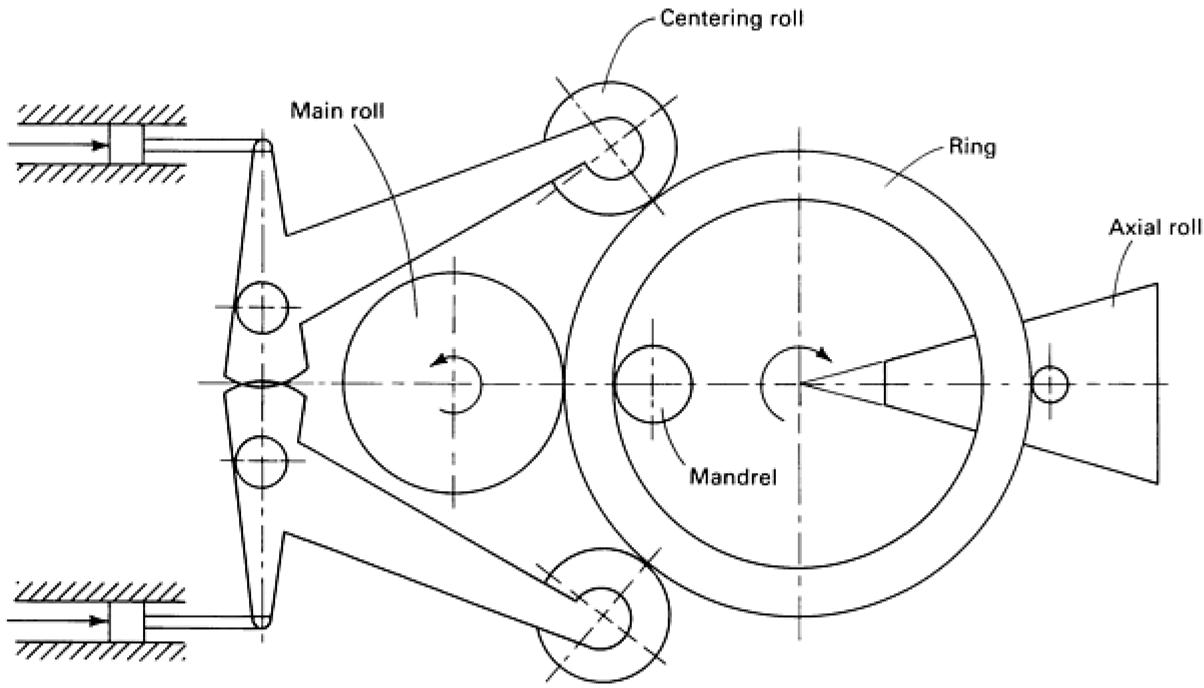

Fig. 7 Schematic of radial-axial mill showing centering rolls. Mounted in hydraulically controlled arms, the centering rolls ensure that the ring does not grow out of round and remains in the correct position relative to the longitudinal axis of the mill.

The relationship between radial (wall thickness) and axial (height) reduction is preselected to ensure the absence of ring surface defects, and it is maintained by computer control. Similarly, the pattern of diameter growth is predetermined and computer controlled. The mill operator need only set blank and finished ring dimensions at the control desk and initiate the rolling cycle. Rolling is automatically stopped when finished outside diameter, inside diameter, or mean diameter (chosen by the operator) is reached.

The reason for the predominance of these radial-axial mills is the wide range of capabilities provided by an individual mill. A typical midrange machine, with 980 kN (110 tonf) horizontal and 780 kN (88 tonf) vertical force capability and total motor power of 500 kW, can roll rings weighing less than 45 kg (100 lb) to more than 2000 kg (4400 lb), ranging in size from 300 mm (12 in.) inside diameter to 3000 mm (10 ft) outside diameter, and from 50 to 500 mm (2 to 20 in.) in height.

The extraordinary demands made on equipment when rolling superalloys, which have considerably higher resistance to deformation than carbon and alloy steels, have forced developments and improvements in radial-axial mill design and construction. These improvements have been beneficial when selectively applied to mills aimed at the less demanding materials.

High forces are required throughout the rolling of superalloys with little opportunity for final sizing (calibration) of the ring at reduced forces. Nevertheless, the expensive materials involved place a premium on near-net shape capability.

The guiding systems on such mills must encounter very low friction and must be free from play and wear. Therefore, hydrostatic bearings are used. Machine control systems are designed to compensate automatically for deflection of machine members on the axial frame. These load-bearing members are designed for maximum rigidity and minimum deflection.

Reversing conventional design, the mandrel is mounted in a fixed lower housing, and the main roll is mounted in a moving carriage. The mandrel can therefore be firmly clamped at both ends. This allows the use of smaller-diameter mandrels, which can better penetrate the ring wall. The maximum radial and axial forces on mills installed in the 1980s for rolling aircraft materials are equal and are high in relation to the overall dimensions of the mill and to their ring-size capabilities. For example, a mill for rolling such materials to 1250 mm (49 in.) diam and 200 mm (8 in.) height would have 980 kN (110 tonf) available both radially and axially.

Older mills, and those intended for rolling less demanding materials, have usually had axial force capabilities lower than their maximum radial force. Machines are usually designated according to the radial and axial rolling forces available; for example, 25/20 indicates a radial rolling force of 245 kN (27.5 tonf) and an axial rolling force of 196 kN (22 tonf). Table 2 lists the characteristics of numerous radial-axial ring mills. The trend of these mills has been toward ever-higher axial-force availability, taking advantage of the improved design prompted by development of the aircraft ring rolling "specials." This is particularly important when rolling washer-type rings (those with high wall-thickness-to-height ratios) free from end face defects.

Table 2 Characteristics of radial-axial ring rolling machines

Machine type	**Rolling force**				**Rolling speed**		Size range of finished rings

Multiple-Mandrel Mills. Four-mandrel mechanical table mills have been extensively used in the production of antifriction bearing races. The undriven mandrels are supported only at their lower ends, where they are mounted in a rotating table (Fig. 8). The driven main roll is set inside the annular table, with its center offset from that of the table.

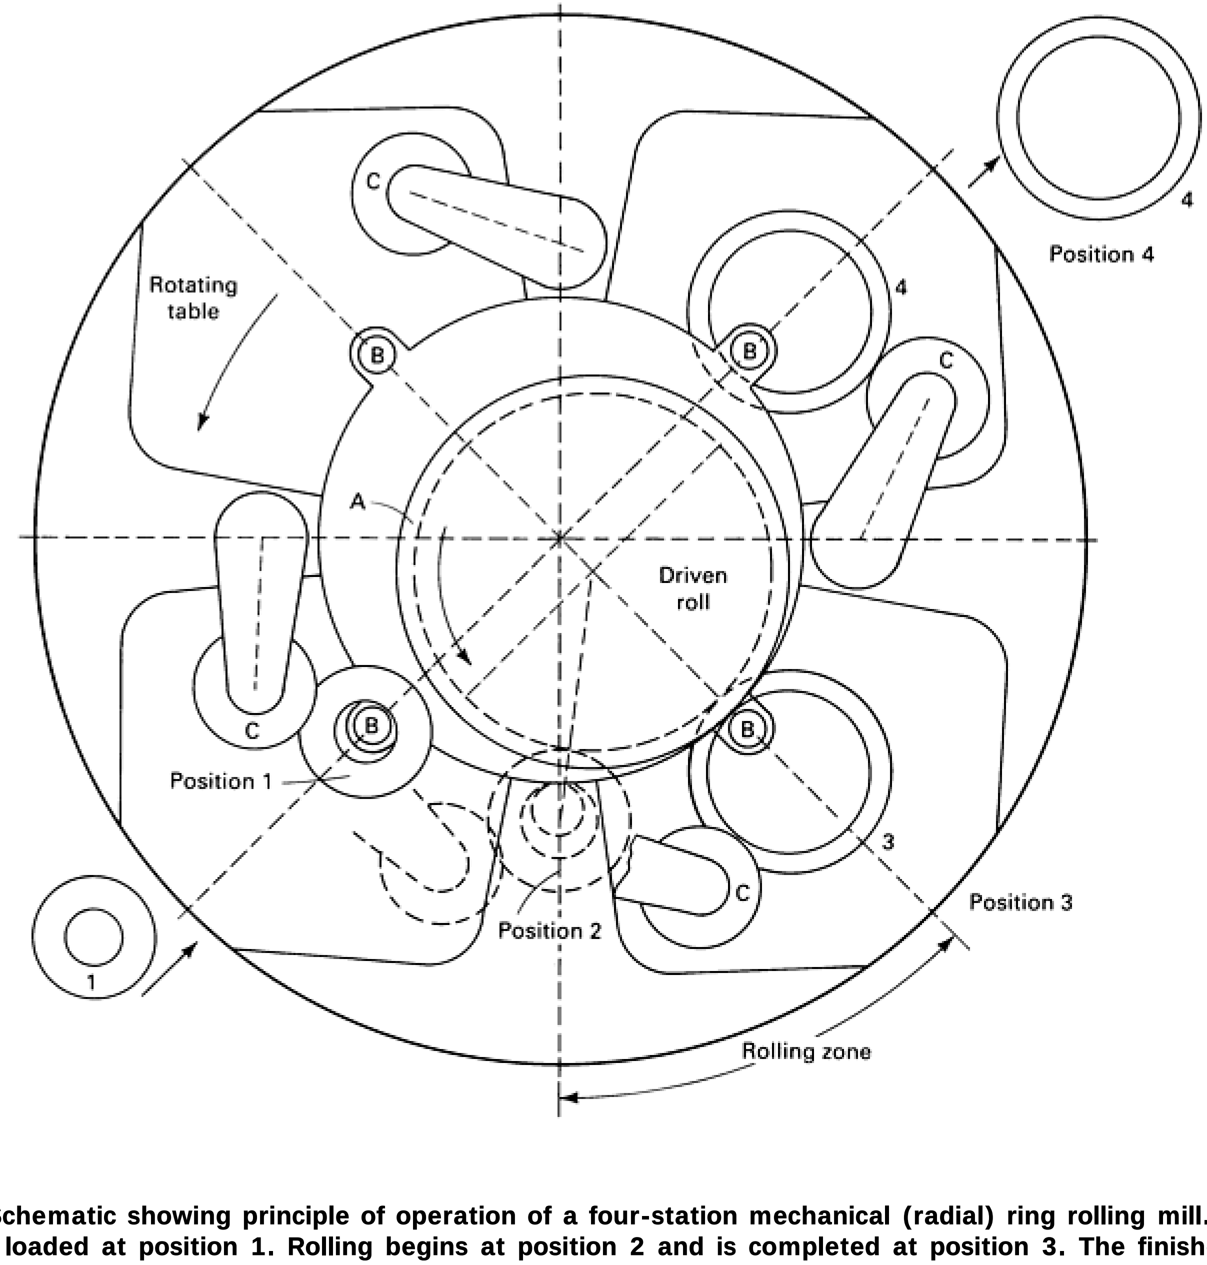

Fig. 8 Schematic showing principle of operation of a four-station mechanical (radial) ring rolling mill. The ring blank is loaded at position 1. Rolling begins at position 2 and is completed at position 3. The finished ring is unloaded at position 4. A, driven roll; B, mandrels; C, guide rolls.

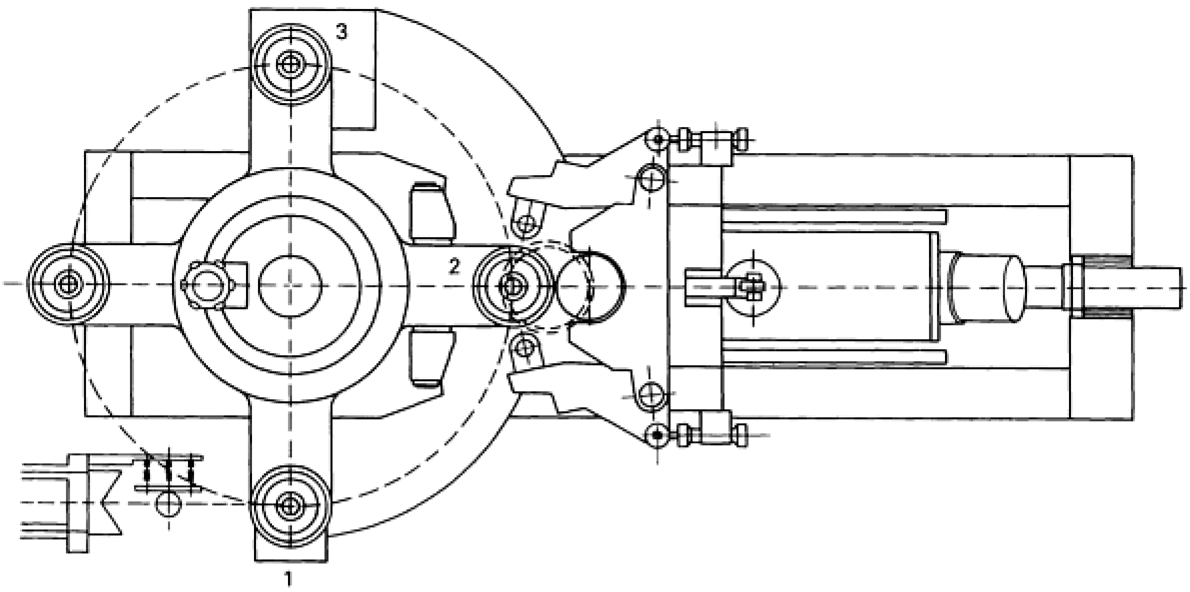
The blank is loaded at position 1, where the eccentricity of the table and main roll centers provides a suitable clearance between the mandrel and the main roll. The table is then rotated by electrical drive, and the gap between the mandrel and the main roll decreases until the ring blank is contacted (position 2). As the table continues to rotate (at much slower angular velocity than the main roll), the gap between the mandrel and the main roll decreases to a minimum (position 3), causing the rapidly rotating ring to be reduced in wall thickness and to increase in diameter. The table rotates to position 4, and the ring is unloaded. The height of the ring is controlled by a closed pass.

Table mills require a pressed blank slightly lower in height than the finished ring. Because the ring dimensions depend entirely on start and finish wall thickness, the weight tolerances on starting material are critical. Although a single cam-operated support roll is used, final ring roundness and diameter variation mean that postrolling sizing presses must be employed.

Extensive tooling is required for such mills, with each ring needing its own special combination. Setup times are long. Although they are very efficient in terms of productivity when in operation, these mills require large production runs in order to be economical. Production rates to 1200 pieces per hour can be achieved with these machines on rings weighing 1.75 to 2.75 kg (3.9 to 6 lb), although outputs of 500 to 800 pieces per hour are more usual.

Automatic Radial-Axial Multiple-Mandrel Ring Mills. The modern computer-controlled, highly flexible, four-mandrel radial-axial ring mill was conceived in Germany in 1976. Again, the principle of using mandrels to transport the ring blank into the rolling position (Fig. 9) and from the rolling position to the unloading position is used in these units. However, the mandrel is housed at its upper end in a quick-change cassette, which is in turn located in a rotating carousel.



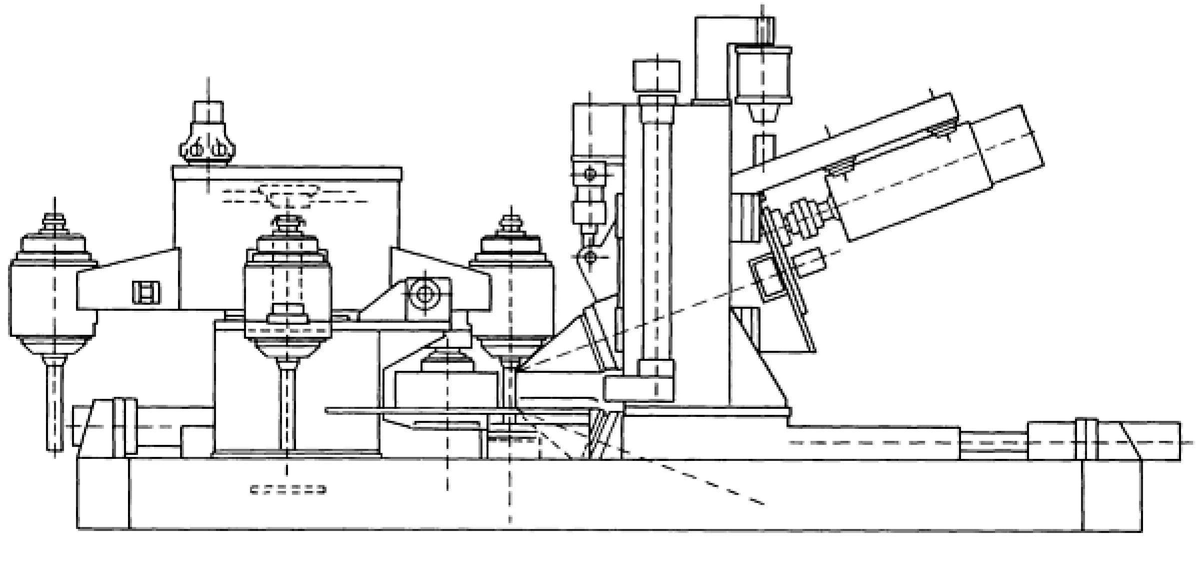


Fig. 9 Schematic of a multiple-mandrel radial-axial ring rolling mill.

A blank is presented at rolling table height to the mandrel at the loading station (position 1, Fig. 9), which then lowers sufficiently to enter the blank, and the carousel rotates, sweeping the blank through 90°, to the rolling position (position 2, Fig. 9). The mandrel is lowered into a bottom bearing housing, and the driven main roll advances hydraulically to provide both the squeezing force and the rotational drive.

Driven conical axial rolls are mounted in a horizontally movable carriage, with the upper roll movable vertically in slides to provide axial rolling force and drive. These rolls advance to cover the blank end faces, and axial rolling begins.

The overall method of operation is as described in the section "Radial-Axial Horizontal Rolling Machines" in this article, with the exception of the moving main roll carriage and centering arms mounted on the axial carriage. This latter feature is dictated by the need for a clear transport path around the main roll.

At the completion of rolling, the mandrel withdraws to clear its bottom bearing housing, the carousel rotates 90°, and the completed ring is swept to the unloading position (position 3, Fig. 9). At this point, the mandrel moves to its uppermost position, allowing the ring to be moved away either on a powered conveyor or by another handling device. Simultaneously, another blank is brought to the rolling position, and the process is repeated.

During rolling, computer controls maintain a preselected relationship between radial and axial cross-sectional reduction. This ensures a defect-free ring and controls the diameter growth rate so that, after a reduced rate of feed (roll gap closure) for the last few ring revolutions, each ring is round and accurately dimensioned.

Tool changing and setup for each ring type usually take 30 min. This assumes that the blanking press is of the preassembled, interchangeable bolster design. Rings that weigh up to 80 kg (175 lb) and are 800 mm (31 in.) in outside diameter are typically rolled on such mills, and production rates of up to 300 pieces per hour are achieved on smaller rings.

Closed-die axial rolling combines the elements of ring rolling with the elements of closed-die forging. Closed-die axial rolling relies on less than full contact area between the tool and the workpiece (Fig. 10) and therefore can produce circular forgings using 90 to 95% less force than would be required in closed-die forging.

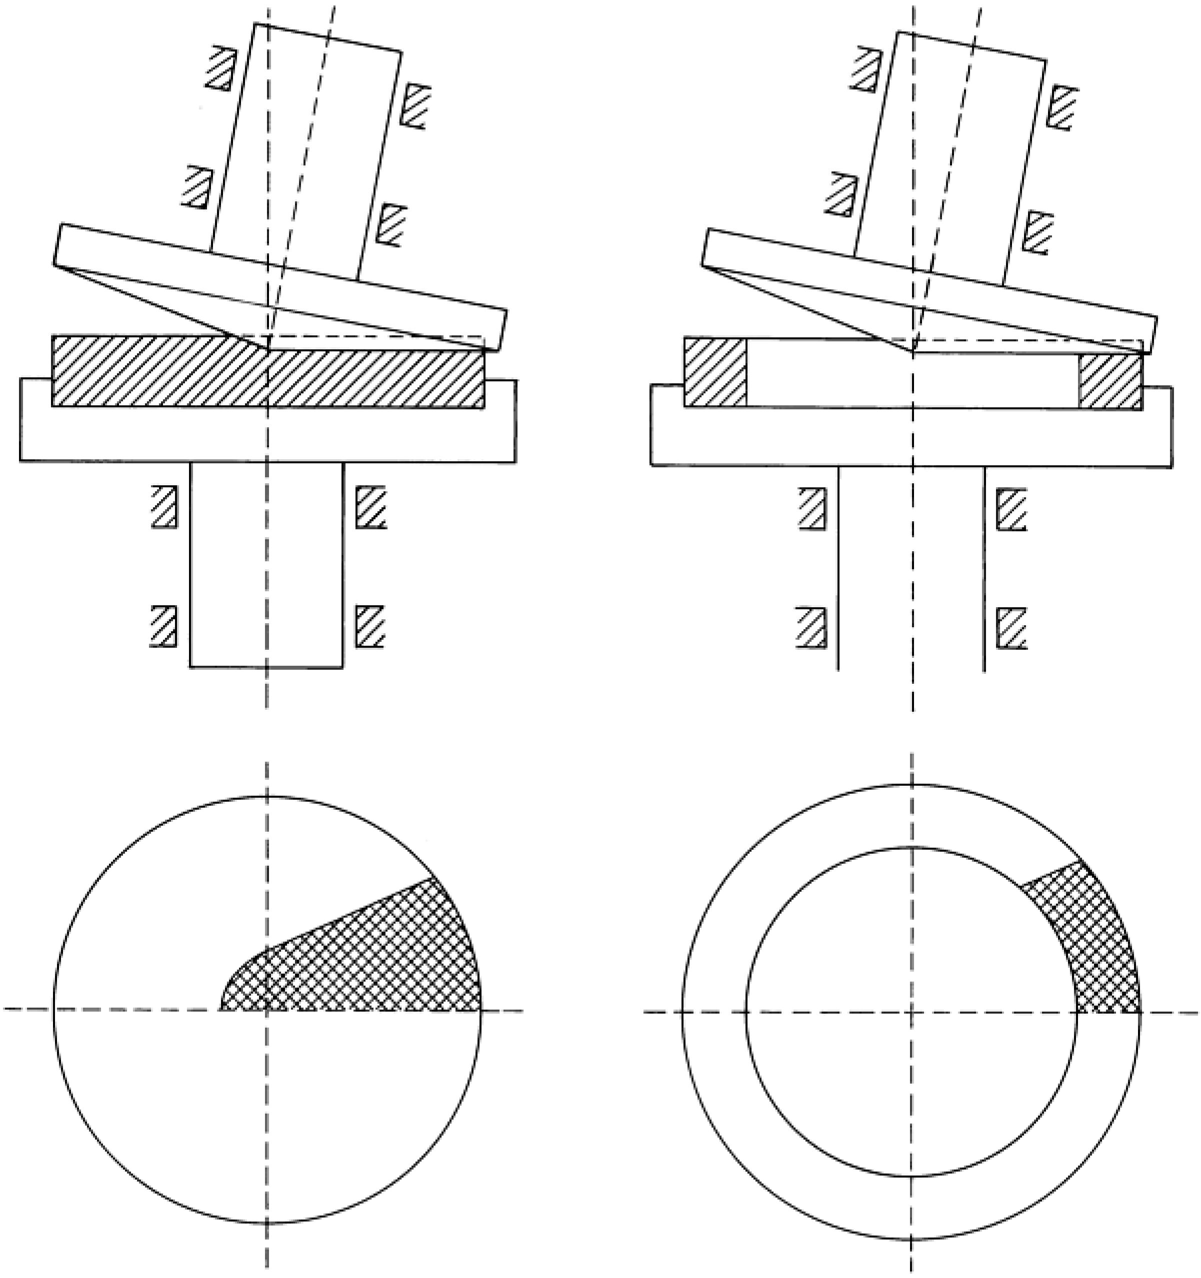

Fig. 10 Operating principle of the axial closed-die rolling process.

In closed-die axial rolling, the lower tool rotates about its vertical axis, typically at 30 to 250 rpm, and contains the workpiece. The upper tool, its axis inclined at some 7° to that of the lower tool, applies the rolling force. Feed rates in the range of 20 to 300 mm/min (0.75 to 12 in./min) are employed. The direction of tool movement is vertically downward. The conical shape of the upper tool, which would generate a parabolic contact area in the absence of tool rotation, is rotated by the bottom tool, through the workpiece. A semiparabolic contact area results.

The starting material may be in the form of a solid block or a prerolled ring. Products can be solid disk-type forgings or annular ring-type components and can be complexly contoured cross sections. Production rates to 120 pieces per hour are possible. More information on this process is available in the article "Rotary Forging" in this Volume.

Ring Rolling

C.R. Keeton, Ajax Rolled Ring Company

Product and Process Technology

To the casual observer, ring rolling is a deceptively simple process. In truth, it is exceedingly complex and as yet not fully understood or fully predictable.

For many years, largely by experience or trial and error, manufacturers of ring rolling equipment and those using the equipment have developed manufacturing techniques that allow production of consistently dimensioned, and often complexly shaped, rings in a wide variety of forgeable materials.

Even today, there are many ring rolling mills in operation that rely heavily on operator skill and dexterity to produce a satisfactory product. However, the ever-increasing understanding of the fundamental behavior of materials during rolling has led to the incorporation of this knowledge as well as the latest prevailing process control technology into successive generations of rolling equipment.

By the early 1980s, the first computer-controlled radial-axial ring rolling machines became operational. These machines were capable of rolling defect-free rings with extremely high height-to-wall ratios at speeds considerably higher than those possible with manual control.

Early investigative work concentrated on the displacement of individual zones of material due to ring rolling (Ref 1). Deformation was found to occur across the entire cross section of the ring if the slip fields (force cones, Fig. 11) overlapped; slip fields are created by the roll indentation of the metal being worked. Considerable displacement of material was found at the inside diameter, with less displacement occurring at the outside diameter, both in the direction of rolling, in relation to the relatively undisturbed material at the ring mean diameter (Fig. 12). The grain flow was confirmed as circumferential (Ref 2).

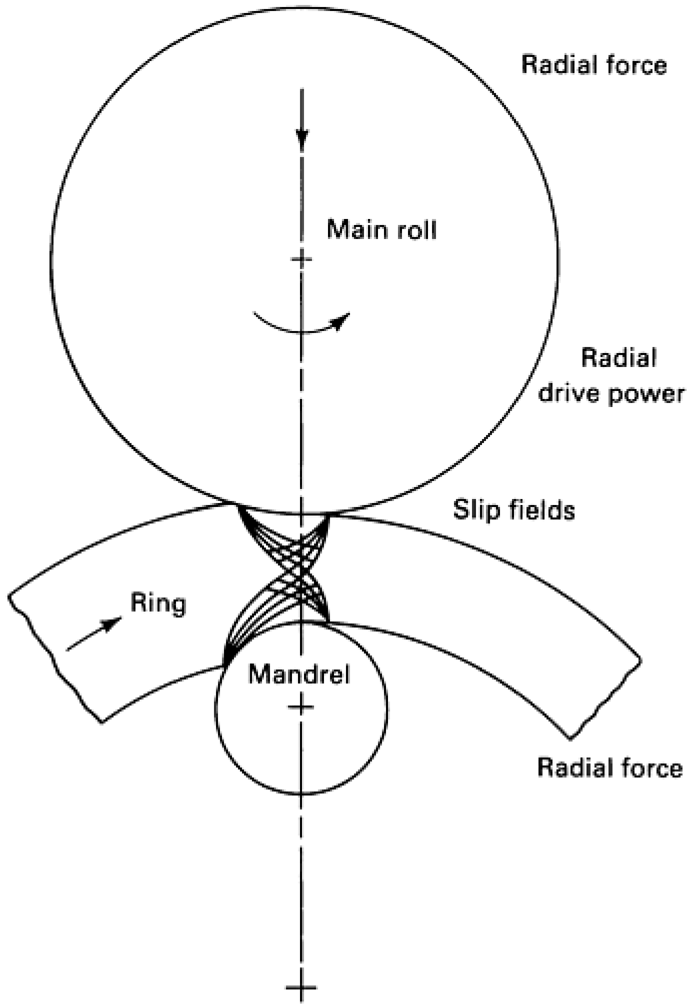

Fig. 11 Slip fields (force cones) generated during ring rolling.

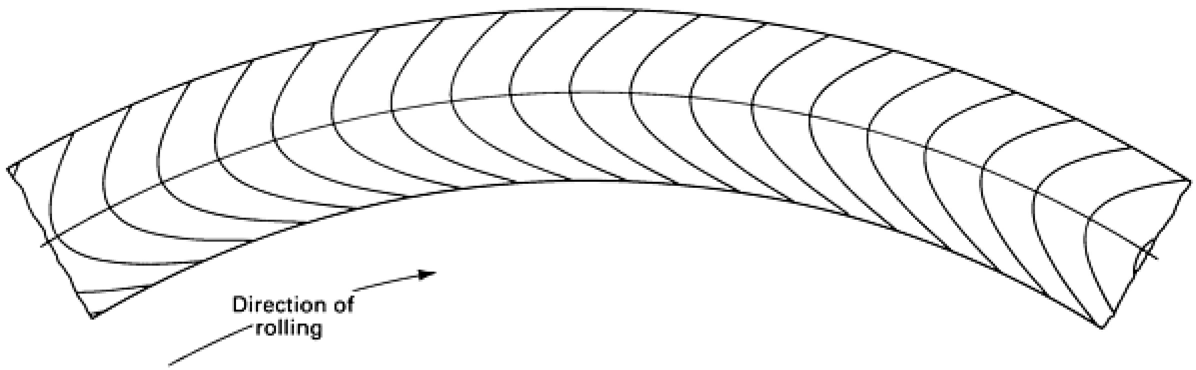

Fig. 12 Relative displacement of material across the ring thickness during rolling. Material near the outer portions of the wall thickness is displaced, while material near the center of the wall is relatively undisturbed.

Basic investigation predicted and confirmed in radial-pass rolling the formation of a plastic hinge (Fig. 13) diametrically opposite the point of roll indentation (Ref 3). This phenomenon was indentified as a possible source of ring roundness control problems at high indentation rates.

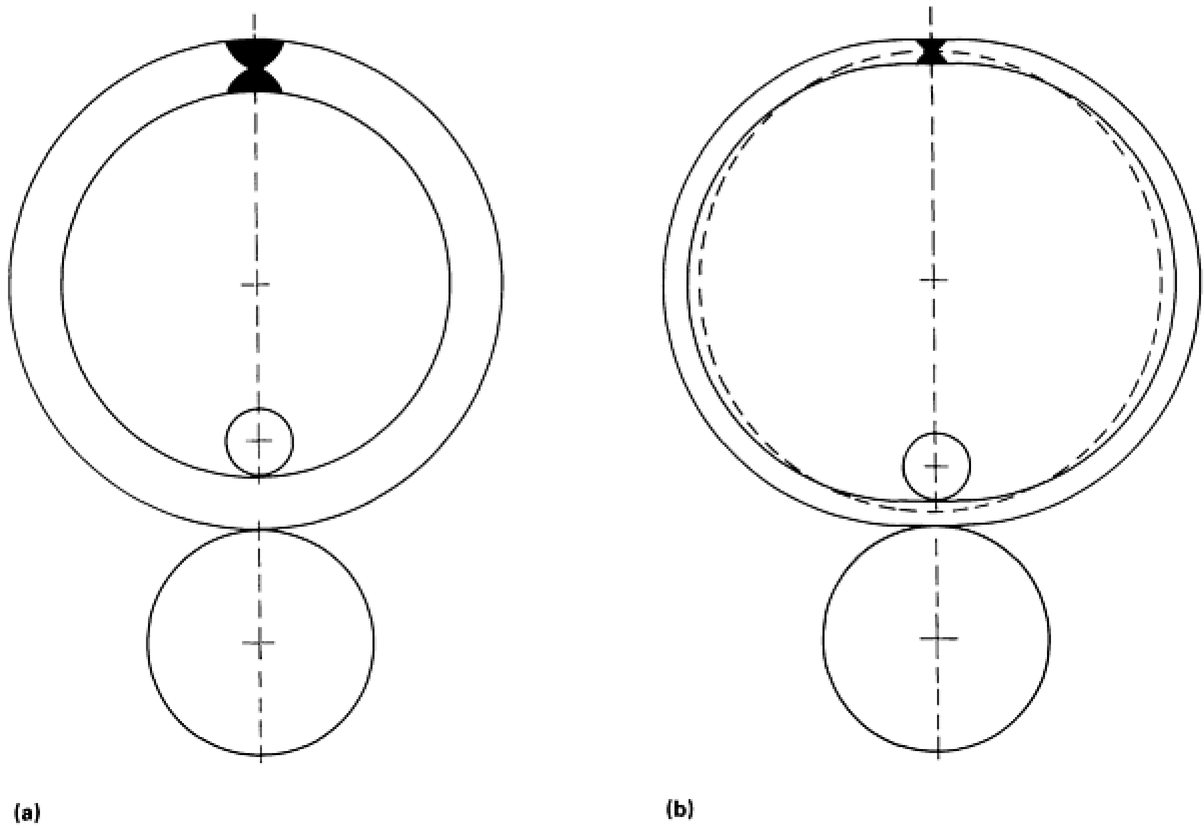

Fig. 13 Formation of a plastic hinge opposite the rolling pass (a) and the resulting ovality (b)

Although this phenomenon is of interest, especially when considering the combined effect of axial rolling and plastic deformation due to the hinge at the same point on a ring, it is of limited practical importance. However, it did represent the first (published) effort to gain a sound theoretical understanding of this complex process. This and further work apparently stimulated experimental and analytical studies into ring rolling at many locations, including Japan, West Germany, Korea, and the United States; this work continues today.

Much of this work is aimed at improving the accuracy of mathematical models of the process so that increasingly realistic computer simulations can be carried out. The ability to roll difficult ring configurations on machines of given characteristics can thus be better predicted, and the direction machine design must take to roll particular ring types and materials can also be determined.

The majority of ring rolling machines installed worldwide since 1960 have originated in West Germany. Not surprisingly, West German companies have been responsible for much of the theoretical and practical development that has occurred in this specialized area of forging. In particular, a researcher at one West German company has developed a combination of theoretical and empirical relationships that has been successfully applied to ring mill design (Ref 4).

A primary objective in two-pass (radial-axial) ring rolling is to achieve diameter growth through cross-sectional reduction (with freedom from surface defects) quickly enough to allow profitable operation. A potential source of end-surface defects and noncircularity arises in the axial roll pass. To avoid slipping and scuffing at the ring end faces, conical roll pairs are necessary for height reduction. In this way, roll and ring surface speeds are matched across the ring faces. To maintain this no-slip condition, the axial roll carriage must withdraw horizontally during rolling at the same speed at which the ring center moves (that is, at one-half the diameter growth rate).

Another benefit of this operational principle is that higher vertical rolling forces can be applied for a given motor power because less power is wasted through slippage. Therefore, flat cross sections with height-to-wall ratios exceeding 1 to 16 can be rolled.

In practice, at the start of rolling, this ideal rolling condition is often not possible, because of mill and blank geometry. The axial roll theoretical centers may be beyond the blank axis to allow the axial rolls to cover the blank end faces completely. In addition, when rolling rings of diameters greater than can be accommodated slip-free by axial rolls of practical dimensions, the axial roll carriage must withdraw as fast as the ring outside diameter grows. This puts the conical roll centers ahead of the ring axis, again preventing an ideal surface speed match between rolls and ring. Because the wall thickness is by this time relatively small in relation to the large diameter of the ring, the speed differential across the ring face is reduced and is usually not a significant disadvantage. With the main roll rotating at a constant preset speed, the rotational speed of the conical axial rolls must decrease as the ring moves onto their progressively larger diameters (Fig. 14).

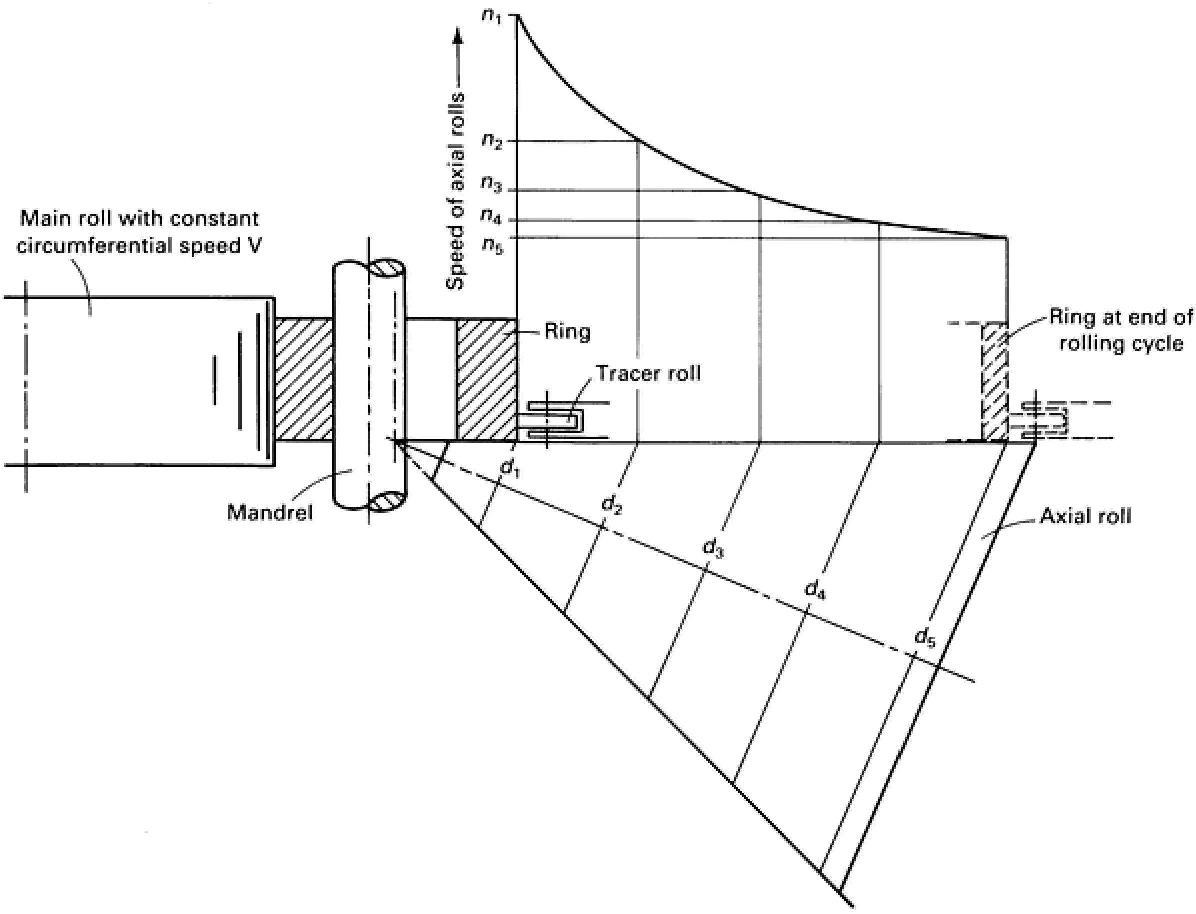

Fig. 14 Control of rpm of axial rolls. The axial rolls must turn more slowly as rolling progresses and the ring moves from d_1 toward d_5 on the axial roll. The rotational speed of the axial roll at a given point is a function of the rpm of the main roll and the diameter of the axial roll.

Depending on the type of hydraulic servovalves used, modern mills may be either force controlled or feed rate controlled. With the latter design, the rate at which the moving rolls are advanced (while not exceeding the capability of the mill) follows a preselected (via computer) pattern. With the former, more common design, horizontal and vertical forces are again applied (via computer) to a predetermined pattern. The objective with both control systems is to:

- Change the cross section of the ring in a specific manner to avoid surface defects
- To control the diameter growth rate in phases to minimize rolling time but to complete rolling with the ring stable and round

With regard to the changes in cross section, the ratio between radial (wall thickness) reduction and axial (ring height) reduction must be constantly maintained according to the following relationship (Ref 4):

$$\frac{\Delta b}{\Delta h} = \frac{h}{b} \quad \textbf{(Eq 1)}$$

where Δb is the wall reduction increment, Δh is the height reduction increment, h is the ring height, and b is the ring wall thickness. Equation 1 is derived from consideration of the spread that occurs when rolling with an open pass (Fig. 15). At the relatively low deformation rates per revolution that occur in ring rolling, plastic deformation takes place in the outer layers of the material, but the center tends to remain rigid/elastic. In the radial pass, this causes beads (Fig. 15) to form because of the lateral spread where the rolls and the ring are in contact. When these beads are rolled by the axial pass, greater circumferential growth takes place at the inner and outer diameters than in the region of the ring mean diameter. The material in this region is stretched, and a further reduction in height results, continuing the formation of hollows in the ring faces. Excess axial rolling removes this defect, but leads to the same type of defect on the inside and outside diameter surfaces of the ring (Fig. 16).

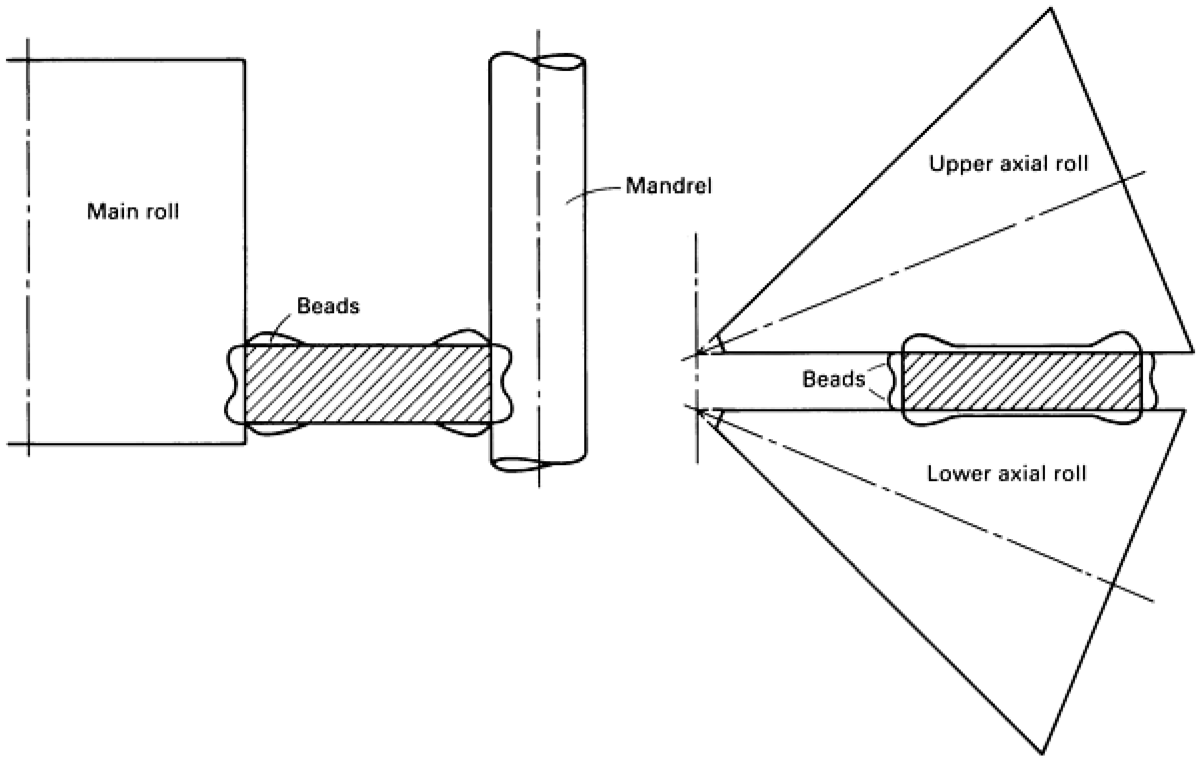

Fig. 15 Formation of beads during radial-axial rolling.

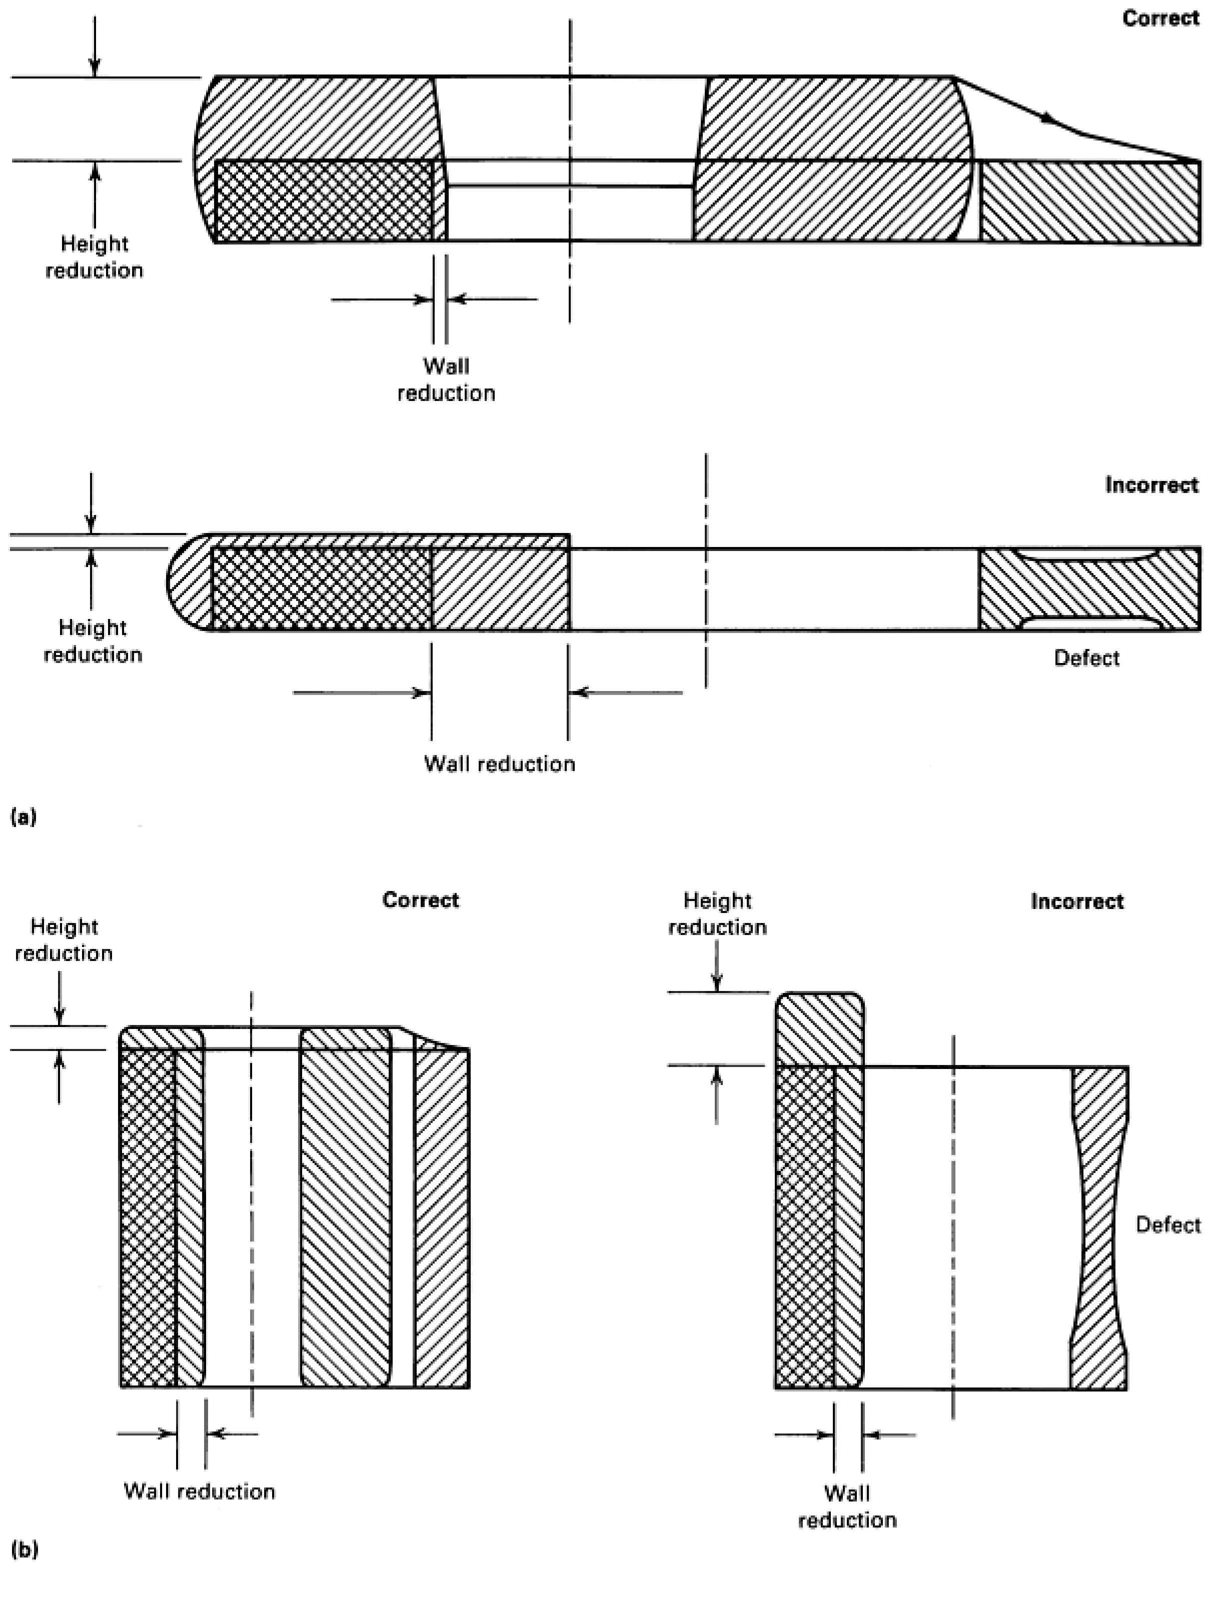

Fig. 16 Effect of blank design and wall-to-height reduction ratios in ring rolling. (a) Rolling of washer-type rings. (b) Rolling of sleeve-type rings

A secondary effect of bead formation caused by excess radial rolling is that ring height on the exit side of the radial pass is significantly greater than that on the ingoing side. Contact between the beaded ring bottom face and the table plate on the exit side of the radial pass causes the ring to lift from the horizontal plane and it attempts to spiral up the radial pass. The ring then either goes out of control and rolling must be halted, or the ring is held down (especially washer-type rings) and the cross section is distorted (takes on a dishlike shape). Maintenance of the Vieregge relationship (Eq 1) between incremental wall-to-height reduction and instantaneous ring-height-to-wall ratio prevents the above defects from forming.

The following relationship results from Eq 1:

$$h^2 - b^2 = \text{constant} \qquad \textbf{(Eq 2)}$$

that is, a hyperbolic relationship exists between wall thickness and ring height. In addition, given a constant volume of material, a hyperbolic relationship must be maintained between instantaneous ring height and diameter (Fig. 17).

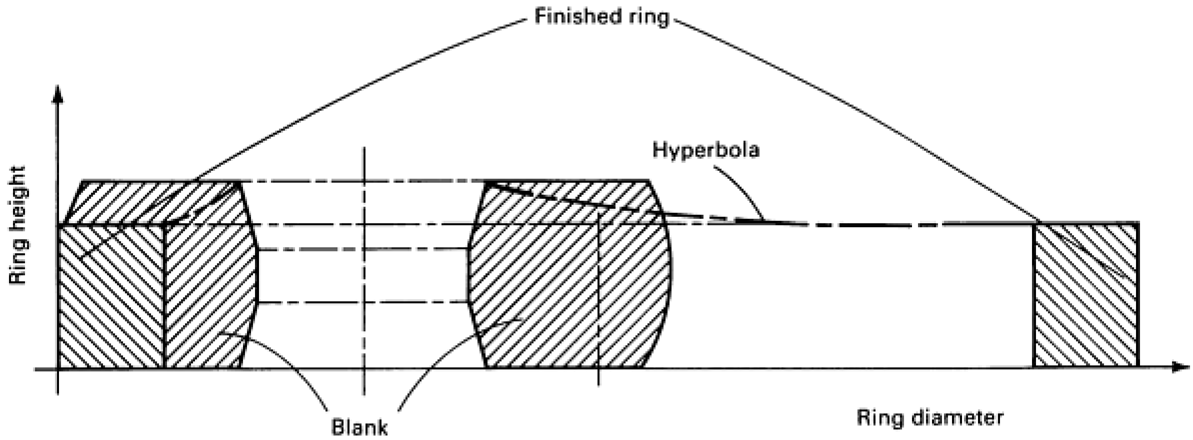

Fig. 17 Hyperbolic relationship between ring height and ring diameter at any instant

Typical cross-sectional rolling curves derived using Eq 1 and 2 are shown in Fig. 18. The critical nature of starting blank design is highlighted by Eq 1 and 2 because there is only one theoretically ideal starting blank cross section for any ring.

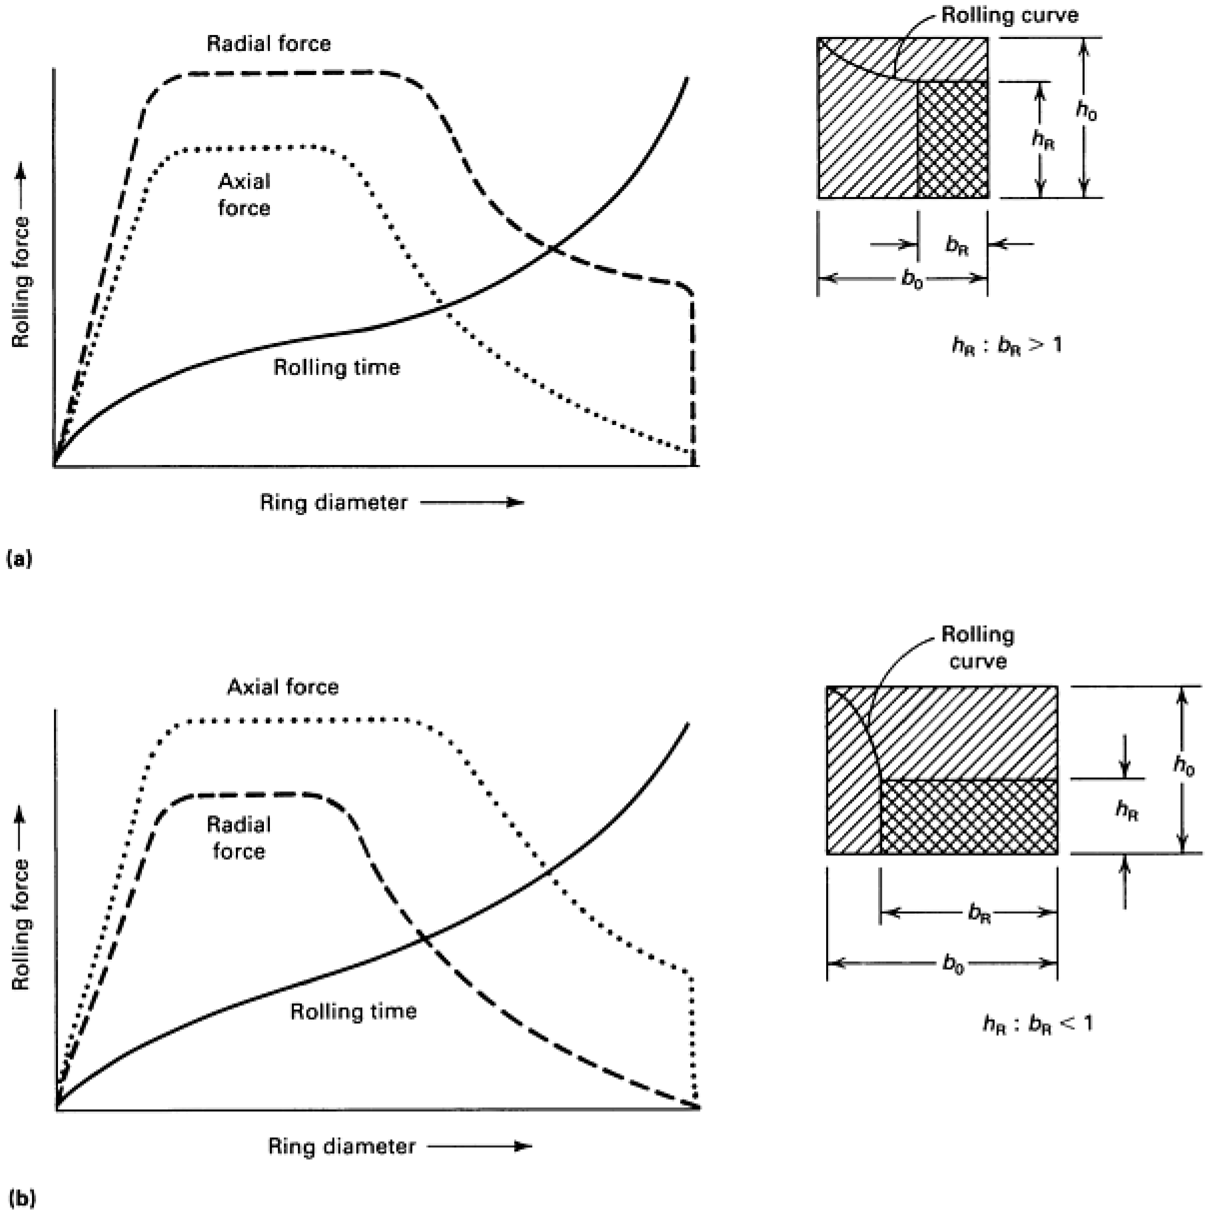

Fig. 18 Rolling strategies for sleeve-type (a) and washer-type (b) rings. b_o, initial wall thickness; h_o, initial height; b_r, final ring wall thickness; h_r, final ring height.

In practice, it has been found that considerable license can be taken with respect to starting blank configuration. This is often necessary because of limitations imposed by the equipment used, both to form blanks and to roll the rings. The most modern rolling mills allow selection of the shape of the height-to-wall reduction curve, enabling the operator to compensate for less-than-ideal blanks and other process variables.

The speed at which the cross section is reduced directly affects diameter growth rate and (depending on ring stiffness) the stability of the ring (roundness) during rolling. Typically, modern mills provide for up to six sequential ring growth control phases, although three are usually adequate (Fig. 19). In the initial phase, the rate of cross-sectional reduction increases from soft contact between rolls and blank to maximum in a few seconds. The second, usually main, phase of rolling involves decreasing cross-sectional reduction rate, resulting in near-constant diameter growth rate. The third phase involves a steadily decreasing diameter growth rate to maintain ring stability with decreasing ring rigidity (cross section versus diameter). The final reduction phase requires very low cross-section reduction rates and therefore low diameter growth rates. Final dimensions are obtained in this phase.

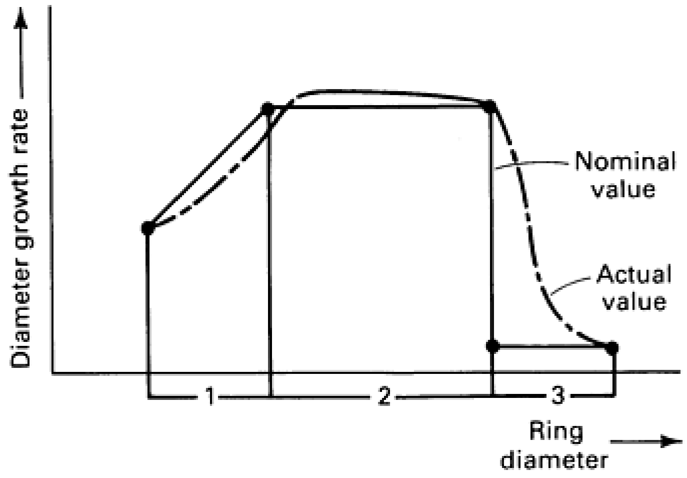

Fig. 19 Schematic of a three-section ring rolling program on a computer numerical controlled ring mill. In section 1, diameter growth rate increases linearly. In section 2, diameter growth rate is constant, compatible with ring stability and machine characteristics. In section 3, diameter growth rate is low as the ring is brought to final dimensions (the diameter is calibrated).

Contour Ring Rolling. With contoured cross sections (Fig. 2), the behavior of the material being worked is even more difficult to predict than with rectangular cross sections. Some experimental and analytical work has been done, mostly at the University of Manchester, England. In addition, a combination of theoretical and empirical relationships has been developed that gives reasonably accurate results when applied to the preforming of blanks and predicting the degree of success in achieving a desired contour from a given blank shape (Ref 4).

The first commercially produced contoured rings were railroad wheels made in the first ring rolling machine, which was built in Manchester, England, in 1852. Then, and in most instances since, blanking design and rolling technique were a matter of trial and error. One of the most important qualities of a successful, modern contour ring rolling company is still the practical experience gained from producing a wide range of shapes in a variety of materials over many years.

Many contours can be rolled from regular rectangular blanks, especially axisymmetric shapes with thinner wall sections at the center (double flanged outside diameter or inside diameter), as shown in Fig. 20. However, once the height of the groove exceeds 50% of the total ring height, the depth of the groove that can be rolled without significant overall shape distortion is progressively reduced. For example, with groove height at 80% of total height, successful groove depth is limited to approximately 20% of final ring wall thickness. This assumes closed-pass rolling and sufficient diameter expansion from blank to ring.

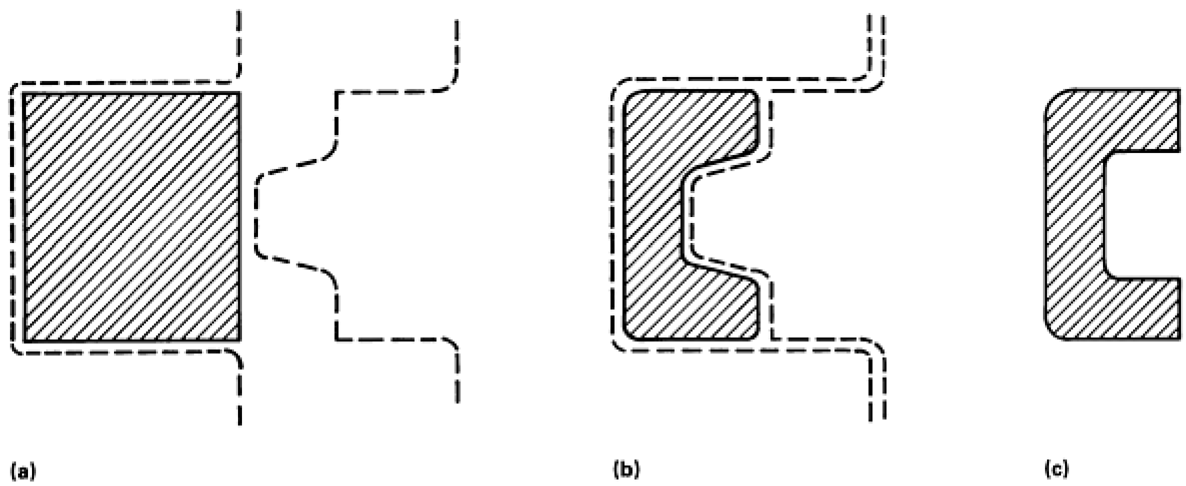

Fig. 20 Stages in the production of a C-profiled ring. (a) Blank. (b) Practical rolled ring. (c) Originally requested

shape. Blank cross-sectional area is approximately twice that of a rolled ring.

When it is found that a rectangular or open-die blank will not yield the desired contour, blank preforming must be used. Typically, the starting point for a new contour shape (from a preformed blank) is the application of a simple volume distribution calculation from ring to blank. The ring is divided into a number of axial slices, or disks, and the volume of each slice is calculated. By knowing the size of the rolling mandrel to be used, and therefore the inside diameter of the blank, a theoretical blank outside diameter can be calculated for each of the corresponding slices (assuming no height change). The theoretical blank outside diameter shape is generated by the aggregate of the individual slice outside diameters.

The resulting blank shape is unlikely to be successful in practice, because it does not take into account the axial flow of the material and because it assumes that each slice is being rolled throughout. For the latter to occur, the shape of the contoured rolls would have to change continually, initially corresponding with blank shape and finishing at ring shape.

In practice, a crude but often effective solution to this requirement consists of two-stage rolling, first using a roll shape intermediate between blank and ring. Some allowance for axial flow of material, when using a radial closed pass, is made by having a blank height lower than the finished ring height.

When using a radial-axial mill, either the blank design must be such that height is reduced to final height before material enters the upper section of the pass or the upper axial roll must operate in reverse of conventional mode and move up during rolling (Fig. 21a).

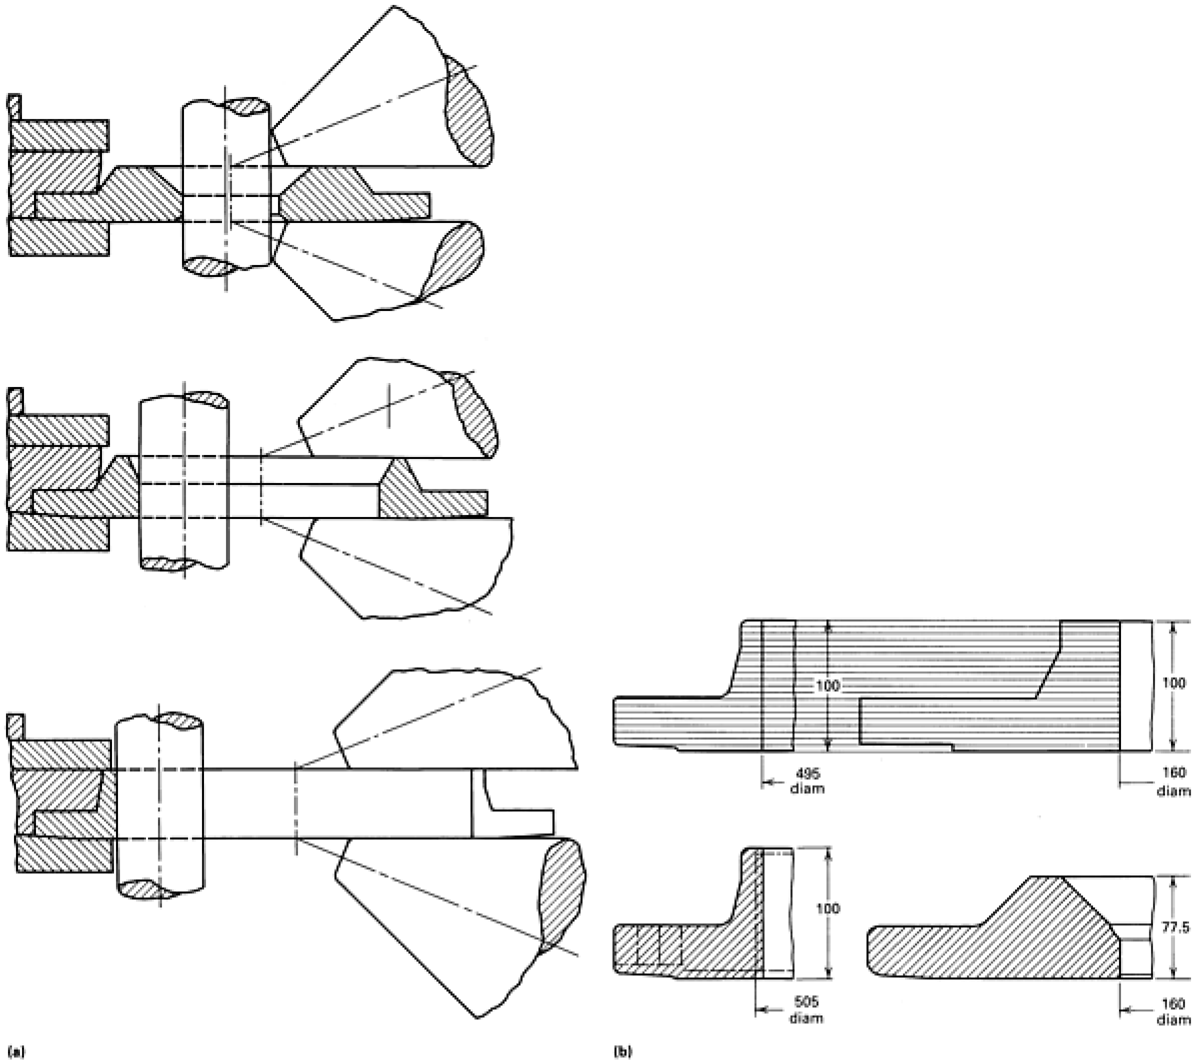

Fig. 21 (a) Rolling of a weld-neck flange in a radial-axial mill with controlled upward movement of the upper

axial roll during rolling. (b) Theoretical (top) and practical (bottom) weld-neck flange preforms (dimensions given in millimeters; 1 in. = 25.4 mm). See text for details.

The practical blank (Fig. 21b, bottom) has a less pronounced flange than that of the simple theoretical blank, but still has the necessary volume of material. A deeper (theoretical) flange (Fig. 21b, top), only partially enclosed by the corresponding groove in the main roll, would result in the folding and lapping of material at the junction of the upper flange face and tapered outside diameter. This is due to localized deformation fields at the junction of the flange and the taper and at the inside diameter, with the core of the ring remaining essentially elastic.

The practical blank is designed to allow for axial flow of material toward the thinner upper section of the ring. Figure 22 illustrates the behavior of simple-theoretical versus practical-successful blank shape.

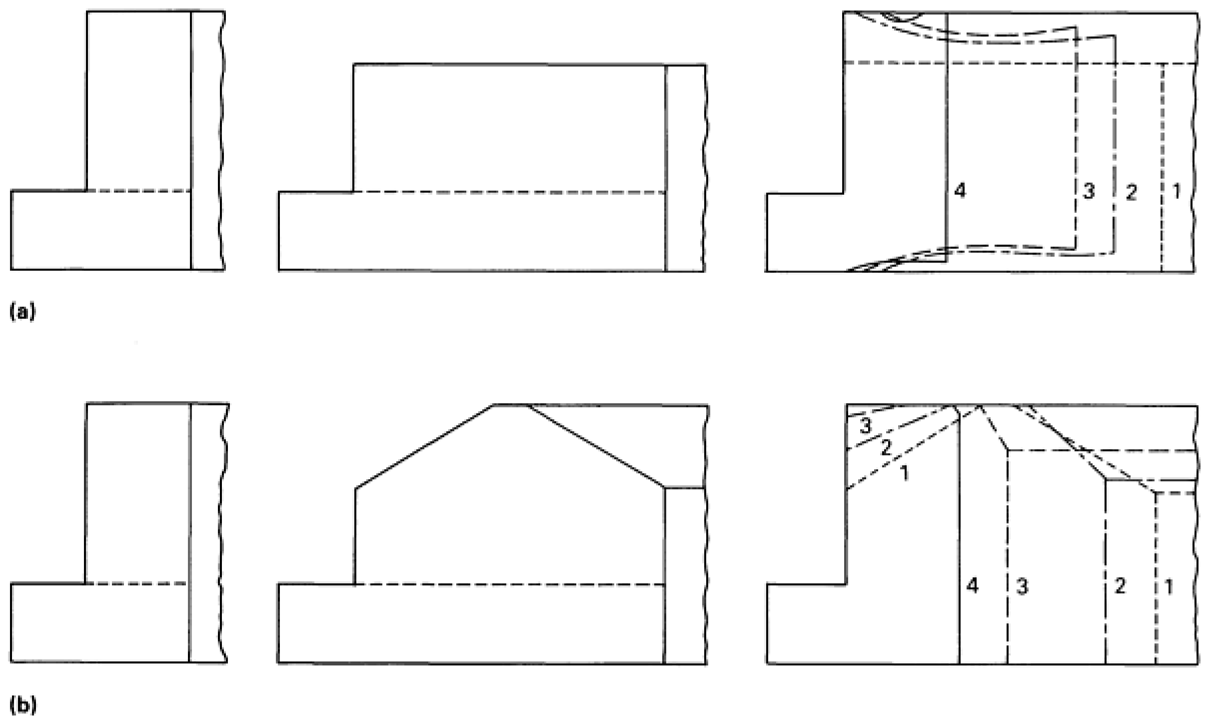

Fig. 22 Development of a finished ring profile from preformed blanks. (a) Theoretical blank shape. (b) Practical blank shape. Shown from left to right are the required profile (which is the same in both cases), the blank shape, and the stages of development during rolling (unsuccessfully in the case of the theoretical blank). Source: Ref 5.

The complete ring cross section must be acquired at the same moment the final diameter is reached for the following reason. Immediately after the pass is filled, the thinner-wall section attempts to grow faster circumferentially than the thicker-wall sections for a given decrease in roll gap. The thicker sections are stretched by the more rapid circumferential growth of the thin sections, and the contour begins to deteriorate in the thicker-wall sections. When preparing to roll an unfamiliar contour shape, blanks are sometimes machined from rough forgings, enabling trial rolling to be carried out without expenditure on possibly inappropriate preforming tools.

Roll diameters are an important consideration in contour forming. The relative curvature between the mandrel and the ring increases throughout rolling, while that between the main roll and the ring decreases. Therefore, as rolling progresses, the penetration of the mandrel into the ring increases, and that of the main roll decreases. Conventional rolling mill design, therefore, lends itself to inside diameter contouring, with mandrel diameters that are small in relation to main rolls.

Special-purpose contouring mills are usually designed to allow use of much smaller diameter main rolls when outside diameter contouring. To a limited extent, the same effect can be achieved by using a large-diameter mandrel sleeve and two-stage rolling on conventional ring mills.

The benefits of contour rolling are reduced material input and reduced machining to finished product. Typically, a weight savings of 15 to 30% can be achieved by using contoured versus rectangular rings.

To determine whether the additional cost of tooling and extended setup time is justified, the break-even point against reduced material and machining cost and minimum order quantity must be determined. Even on lower-cost materials, this quantity may only be 25 to 50 pieces, especially with repeating orders. Where higher-cost materials, such as superalloys, are involved, production of only three or four pieces may justify contouring.

Rolling Forces, Power, and Speeds. Economical production of seamless rings by the radial-axial rolling process requires rings to be rolled as quickly as possible in a manner that is consistent with dimensional accuracy and metallurgical integrity. A primary factor is the resistance of the material to deformation. This is related to the flow stress of the material at a given temperature and to the conditions existing in the rolling pass (roll diameters, frictional resistance, and so on).

With typical ring mill configurations, rolling speeds, and rates of cross-sectional reduction, as well as at temperatures of 1050 to 1100 °C (1920 to 2010 °F), the resistance to deformation of a plain carbon steel is found to be approximately 160 MPa (23 ksi) and that of a bearing steel approximately 196 MPa (28.5 ksi) (Fig. 23). For these materials, a decrease in temperature of 100 °C (212 °F) increases resistance to deformation by approximately 50%. Quite obviously, rolling force requirements can be minimized by operating at the maximum temperature allowable metallurgically. This requires consideration of both the temperature losses due to radiation and conduction as well as the temperature increase caused by plastic deformation.

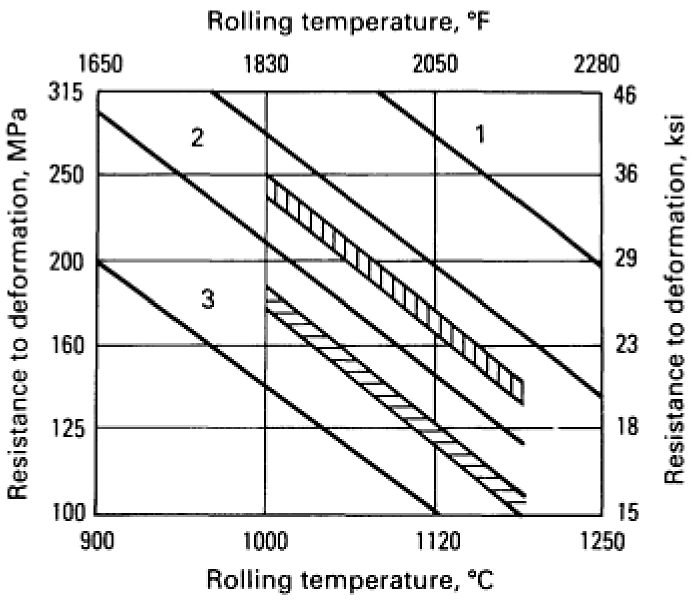

Fig. 23 Resistance to deformation versus rolling temperature for various steels. 1, chromium-nickel steels (>4% alloying elements); 2, bearing steels (chromium-nickel; 1-4% alloying elements); 3, carbon steels.

Rolling forces cannot be dealt with in isolation. The combination of roll force and resistance to deformation determines the extent to which the rolls indent the ring. With increasing indentation, the drive power required increases and, on present-day mills, may reach the mill motor limit well before maximum roll force has been applied. Further, with very heavy indentation, the relatively small diameter, undriven mandrel can exert so much circumferential resistance that the driven main roll is unable to overcome it; the driven roll then slips, and the ring fails to rotate (Fig. 24).

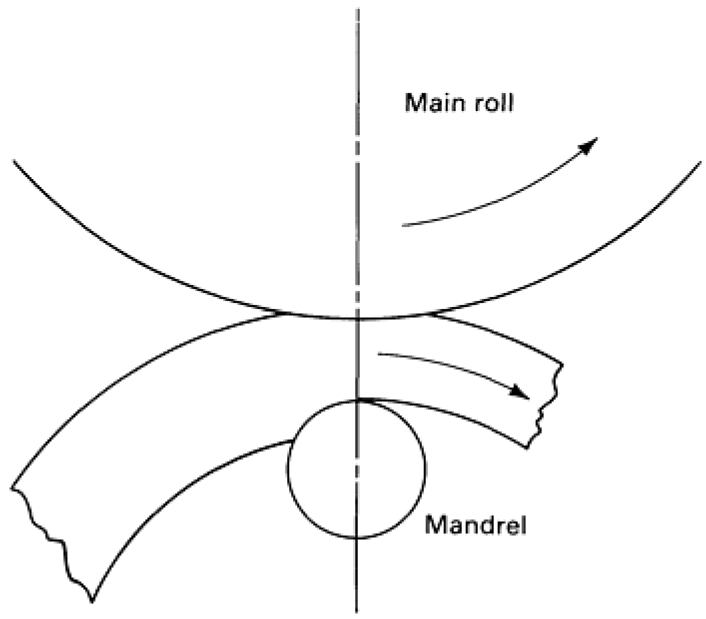

Fig. 24 Excessive indentation by the mandrel, causing the main roll to slip and the ring to stall in the radial pass.

Modern mills apply the principle of adaptive control to avoid such problems. That is, forces and torques are monitored continually by computer, and if they approach the upper limits of the mill and are changing in such a way that these limits are about to be exceeded, then they are automatically reduced in such a way as to maintain predetermined patterns of cross-sectional reduction and diameter growth.

Most theoretical analyses used to date for estimating or simulating the rolling forces and torques required in ring rolling have been derived from the relationships established in the simpler process of the hot rolling of bars. Factors that complicate the situation in ring rolling are:

- Nonsymmetrical rolling due to the differences in roll diameters (radial pass)
- Noncylindrical rolls and changing roll diameters (axial pass)
- One roll only, driven (radial pass)
- Changing ring diameter
- Continuous thickness and height reduction
- Three-dimensional deformation in the direction of roll closure, in the direction of rolling, and lateral spread

It is beyond the scope of this article to present the various complex mathematical relationships involved.

Earlier (three-dimensional) analyses required extensive use of empirically determined factors in order to achieve reasonable agreement between calculated and actual values. By the mid-1980s, extensive experimental work (Ref 6, 7) and considerable theoretical refinement had taken place. The resulting computer-based mathematical models predict material and machine behavior much more realistically. The computer control systems of recent ring mills make direct application of these developments.

A further limiting factor in the speed with which a ring can be rolled is the stability of the ring during rolling. A ring rotating at too high a speed, with excessive speed changes due to extrusion in each rolling pass, may lack the rigidity required to accommodate the various forces and moments acting on it. Gross out of roundness and/or out of flatness can result.

In practice, circumferential speeds to 3.6 m/s (12 ft/s) are used on smaller mills, and 1 to 1.6 m/s (3 to 5 ft/s) on larger mills. Diameter growth rates to 35 mm/s (1.4 in./s) are usually achieved during the main ring expansion phase; growth rates of 1 mm/s (0.4 in./s) are reached during the rounding or calibration phase.

Ring Rolling

C.R. Keeton, Ajax Rolled Ring Company

Blank Preparation

The manufacture of seamless rolled rings consists of two basic processes: the production of a preform or blank, and the expansion of that blank on a ring mill. Blank preparation can be carried out adjacent to the ring mill with no reheating before ring rolling, or--as is often the case in older plants--blank forming can be done separately (even in separate buildings) on several different pieces of equipment. These blanks are then gathered together in logical groups to be reheated prior to rolling.

The separate blanking approach is quite often found where aircraft ring materials are involved. This is because rolling cycle time is usually only a fraction of blank preparation time and because cold inspection and rectification of blank defects may be necessary before rolling.

Because many ring rolling operations are an outgrowth of conventional forge shops, the equipment and methods previously used to produce totally forged rings are often employed in more limited fashion to prepare blanks. Open-die hammers and presses, with highly skilled operators and using a wide variety of loose tooling pieces (for example, punches, saddles, and bars), can often produce practically all required blank sizes and shapes. Hammers are especially versatile and have the advantage of much lower initial cost than the equivalent press. However, environmental noise problems have tended to limit new installations. Hammers and general-purpose presses tend to be labor intensive and have relatively low output rates compared with presses designed specifically for producing blanks.

The trend with most installations in recent years, particularly when the more easily worked materials (for example, carbon, alloy, and some stainless steels) are involved, has been for the blanking press to be integrated with the ring mill into a ring production unit. In these installations, the capabilities of the blanking press are matched to those of the specific ring mill.

Theoretical considerations regarding blank dimensions were explained in the section "Product and Process Technology" in this article, and the importance of starting with the correct blank-height-to-wall thickness relationship was stressed. Beyond this, it is important that the methods used to form the blank do not create quality problems (for example, off-center or ragged punching) at the rolling stage.

Simply put, the first objective of blank making is to put a hole in the workpiece that is of sufficient diameter to allow the blank to fit over the rolling mandrel. The diameter of the mandrel has to be such that sufficient force can be applied to reduce the ring wall section at an acceptable rate. The smaller the hole, the less the material wasted.

Starting material is usually round, although round-cornered-square or octagonal billets can be used. When nonround material is used, initial working is required to convert it to round stock. Otherwise, the first blanking operation upsets the billet to reduce height. The second operation consists of indenting with a punch, leaving a thin web at the bottom of the blank. The third operation punches out this web, creating the doughnut-shaped blank that is ready for rolling. This sequence is shown schematically in Fig. 25. Although a wide variety of rings can be rolled from blanks made by this simple process, alternative methods must be used when large ring-height-to-wall ratios are required and for severely contoured rings with limited rolling reduction (and little diameter growth).

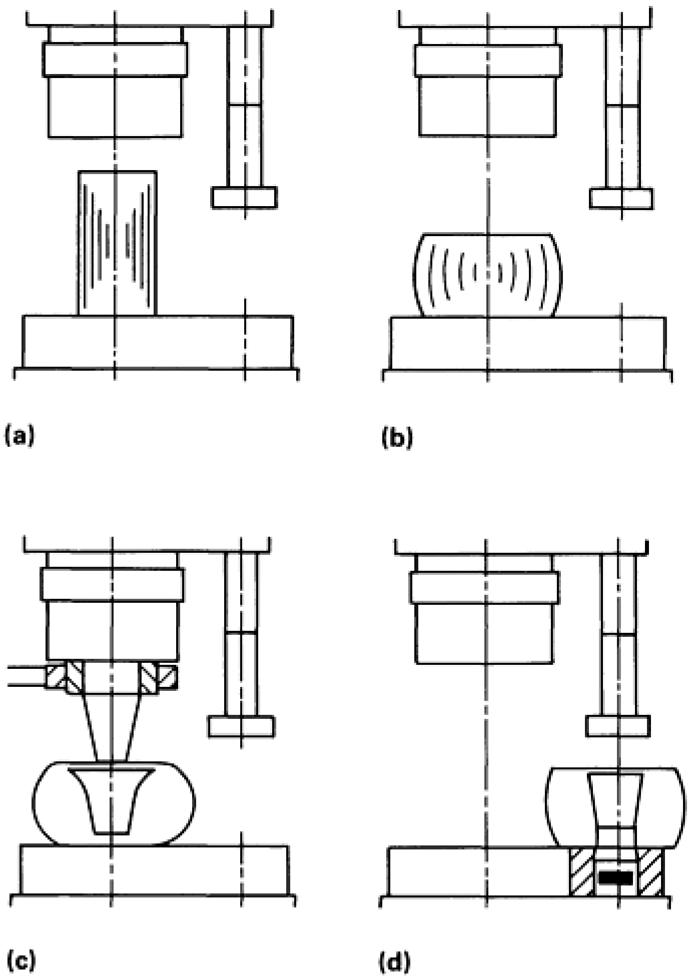

Fig. 25 Schematic showing blank preparation using open dies and a two-station press. (a) Billet centered on press table. (b) Billet upset. (c) Upset blank is indented. (d) Blank is pierced and ready for removal.

With thin-wall sleeves, and even with square cross section rings whose mass is very small in relation to the physical dimensions of the mill, the diameter of the indenting tool may approach that of the upset preform. The indentor then behaves less like a prepiercing tool and more like a flat die. The result is a grossly distorted and unacceptable blank (Fig. 26) with a height less than that of the rolled ring.

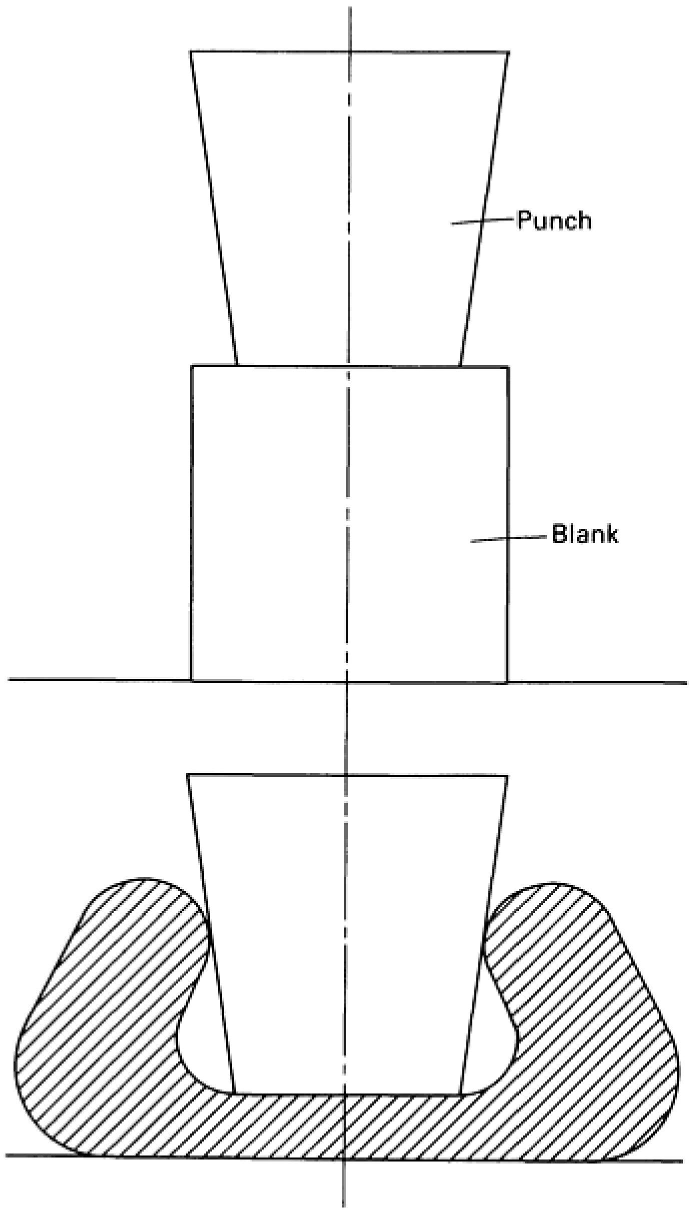

Fig. 26 Blank unacceptably distorted by punch/blank diameter relationship. When the punch diameter is too large in relation to block diameter, it deforms the blank rather than indenting it.

This problem can be overcome either by employing well-tried but slow open-die forging techniques or by indenting the workpiece in a container. The former requires pressing with a loose small-diameter punch. The blank with punch entrapped is then turned onto its outside diameter and forged incrementally so that the inside diameter expands and the height increases.

The use of this method when the press forms part of an integrated line severely curtails output. By using a larger-capacity press and container dies, excellent blanks can be produced at a rate sufficient to maintain full ring mill production. For example, a mill that is rolling rings weighing up to 2000 kg (4400 lb) and using open-die forming blanks from a 15.7 MN (1760 tonf) hydraulic press would require the service of at least a 24.5 MN (2750 tonf) press using container dies to maintain full production on this type of ring.

Figure 27 shows schematically the sequence of operations on a two-station press using a lower container die located in a bolster. A fundamental requirement here is the ease in ejecting the workpiece from the die, using a hydraulic cylinder housed in the lower portion of the press frame. Figure 28 illustrates the use of a two-station press with a shaped upper die to produce blanks for rolling into weld-neck flanges.

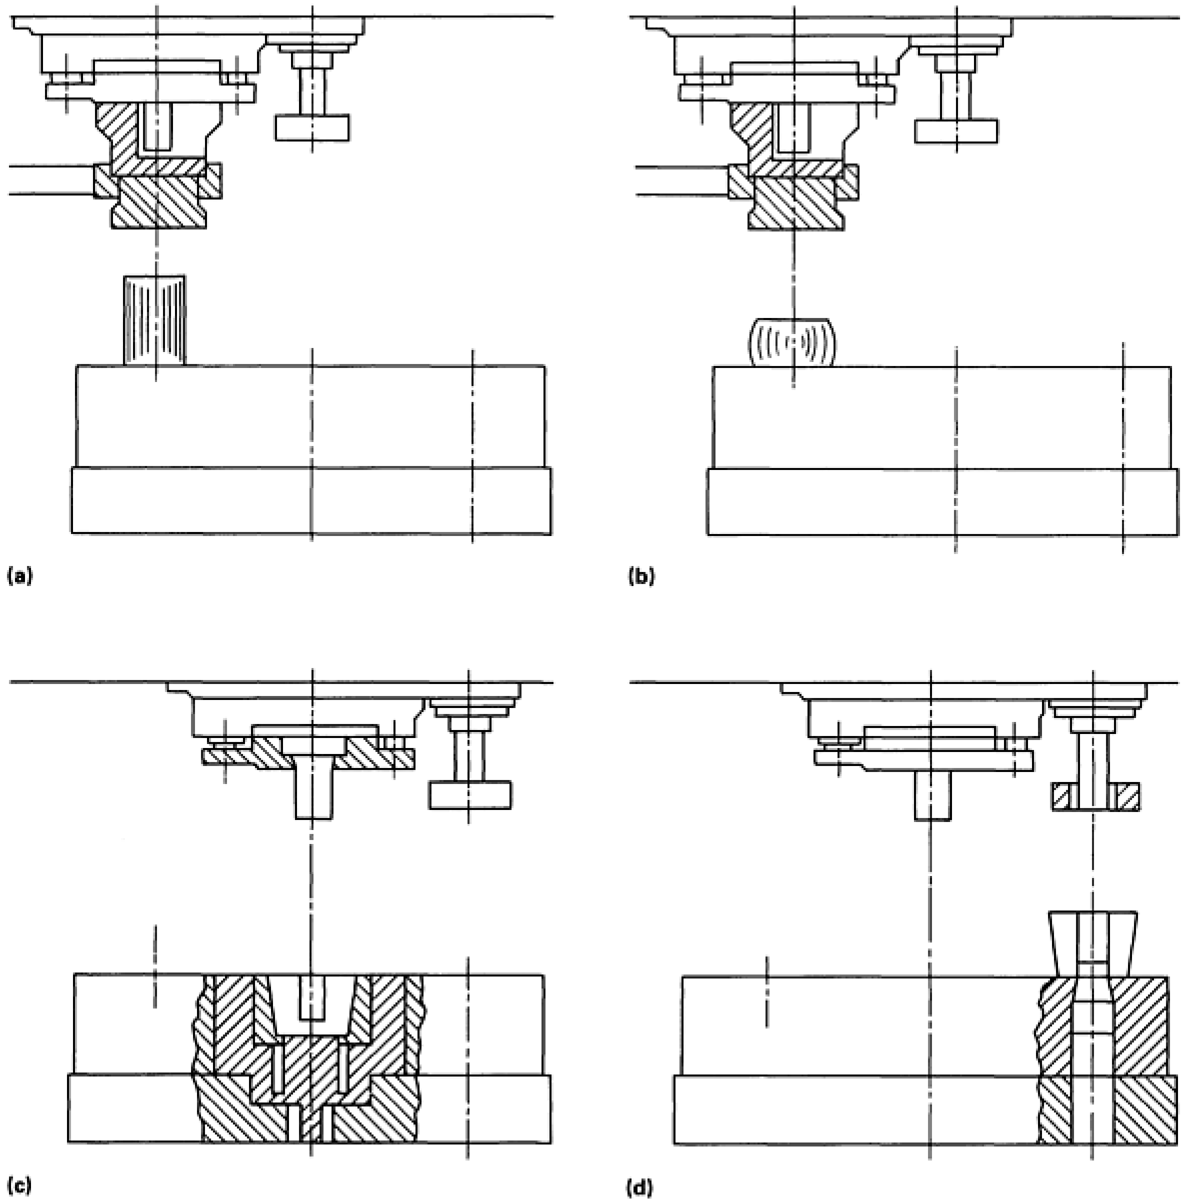

Fig. 27 Manufacture of blanks in a lower container die. (a) Billet centered on press table. (b) Billet is upset. (c) Blank is indented and formed by backward extrusion. (d) Blank is pierced and ready for removal.

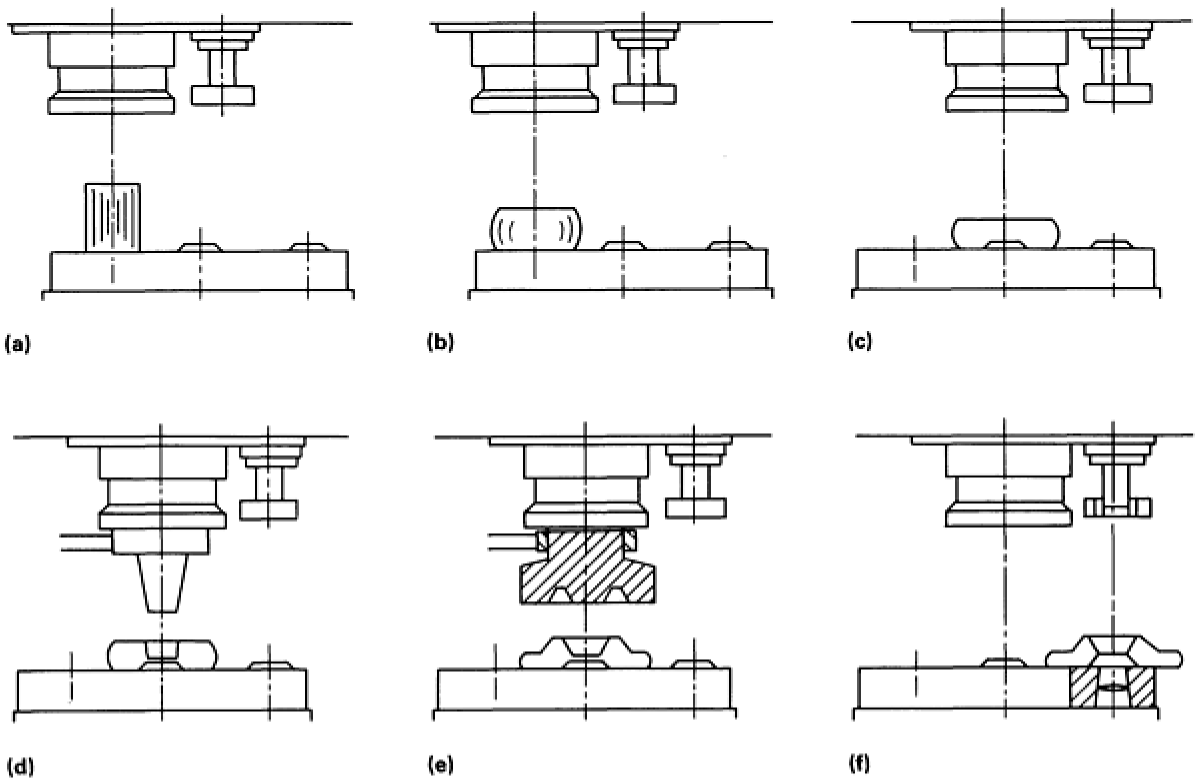

Fig. 28 Manufacture of blanks in a two-station press using profile tools. (a) Billet centered on press table. (b) Billet is pre-upset. (c) Billet is upset. (d), (e), and (f) Blank is indented, formed, and pierced, respectively.

On smaller, high-speed ring mills, a three-station blanking press with an integral workpiece transfer system is required to maintain an adequate supply of blanks. These presses can produce open-die blanks, container-die blanks, and split-die contoured blanks.

Typically, the less demanding operations of initial breakdown and final piercing, which are carried out off-press-center, are done simultaneously on two workpieces. The higher-load main forming operation (indenting, container-die forging, and so on) is done at press center in isolation. Therefore, a block of raw material is loaded on alternate strokes of the press.

A 9.8 MN (400 tonf) press, serving a 390 kN (44 tonf) radial/310 kN (35 tonf) axial mill can produce up to 250 pieces per hour in this manner. On very small rings, all three stations of a three-station press can be used simultaneously, producing one blank per press stroke. This particular press and mill combination can then produce around 300 rings per hour.

Using a modular bottom bolster and top tool holder, tooling can be set up outside the press, and tool sets exchanged in approximately 20 min, thus maximizing the production time available. A wide range of complexly shaped blanks, which may be necessary for rolling rings with complex contours, can be produced using split dies by combining various top and bottom tools at the center station of the press.

Ring Rolling

C.R. Keeton, Ajax Rolled Ring Company

Ancillary Operations

Ring rolling mills must be supported by an array of ancillary equipment. Most important is a means of forming blanks--usually hammers or presses.

Cutting of Billets. Some method of accurately cutting raw material to the required input weight is necessary. Cold and hot shearing are employed; the latter is usually used when an integrated production line is involved. Circular saws, which are sometimes carbide tipped, tend to predominate. Band saws are often used, particularly on stainless steels, and abrasive saws are used on titanium alloys and superalloys. Blocks for railroad wheels are often cut from ingots on multiple-tool special-purpose lathes, flame cut or flame nicked, and then fractured on a large press.

Heating. Reheating of cut blocks is usually done in box or rotary fossil-fuel furnaces. Induction heating is sometimes used for smaller stock and has the advantage of minimal scale formation. Various methods of hot block descaling are employed, both mechanical (for example, flailing cable, chains, or rotating brushes) and high-pressure (14 to 90 MPa, or 2 to 13 ksi) water spray, which is particularly effective.

Other Operations. Some shops employ devices for sizing rings immediately after rolling. These can be straightforward hydraulic presses, in which the ring is forced through a circular sizing die, or complex more expanders, which stretch a ring by applying force to multiple, appropriately shaped segments acting on the inside diameter of a ring.

Appropriate heat treatment facilities are necessary, whether to render the product more easily machinable or to achieve the mechanical properties specified for the end product. Shotblasting is often used to remove scale formed during hot working. The resulting surface is easier to inspect and to machine.

Ring Rolling

Blanking Tools and Work Rolls

Although hot-work tool steels such as H11 and H13 are frequently used for blanking and rolling tools, especially when working heat-resistant alloys, less expensive alloy steels such as AISI 4140 and AISI 4340 find wide application on less demanding work materials. Various types of blanking and rolling tools are shown in Fig. 29.

Fig. 29 Blanking and rolling tools used in ring rolling. (a) Tapered indenting punch. (b) Tapered, swing arm mounted indentor. (c) and (d) Piercing punch and support ring for a blanking press. (e) Typical mandrel for a mid-size mill. (f) Axial roll. (g) Main roll. See text for discussion of tool materials. Dimensions given in millimeters (1 in. = 25.4 mm).

When blanks are open-die forged on hammers or presses, simple tapered indenting punches (Fig. 29a) are driven into the preform. The preform is then turned over, allowing the punch to fall out, and the punch is then used to cut out the slug remaining from indenting, thus forming the doughnut-shaped blank.

A wide range of punch diameters and lengths are typically available to accommodate the many different blank dimensions required. With several punches in each size and each cooled in water immediately after use, AISI 4140 or AISI 4340 are quite adequate in terms of life and cost. If special-purpose ring blank presses are used, tool duplication is usually not feasible, and short periods of cooling between each blanking operation may not be sufficient to allow the use of the regular alloy steels above.

Figure 29(b) shows a 3° tapered, swing arm mounted indentor typically used in blanking presses. A low-alloy steel such as ASM 6F2 (see the article "Dies and Die Materials for Hot Forging" in this Volume) at 38 to 43 HRC (350 to 400 HB) may be necessary to withstand the higher tool working temperature.

Figures 29(c) and (d) show the type of piercing punch and support ring that would be used on a two- or three-station blanking press to shear out the slug created by indenting. Almost invariably, the punch is either solid H13 or has an exchangeable tip in H13 heat treated to about 49 HRC (460 HB). The support ring is also usually made of H13. Typically, the radial clearance between the punch and the support ring is of the order of 2 to 5 mm (0.008 to 0.2 in.) for punches 125 to 220 mm (5 to 8.7 in.) in diameter. On high-speed blanking presses, the indenting punch in the center station is so heavily used that even when it is made of H13, continuous internal water cooling is necessary, along with inter-cycle external water-spray cooling.

Container dies used on a slower-speed, larger press (for example, 24.5 MN, or 2750 tonf, capacity) can often be made from AISI 4140 or 4340 if the duty cycle is long enough and inter-cycle water cooling is adequate. Inserts fabricated from H13 tool steel may be necessary on smaller blanks with shorter cycle times.

On presses where no means are available for stripping blanks off (indenting) punches, these punches typically have a taper of 3° per side. Powdered coal or waterborne graphite lubricants are usually employed to ensure release of the punch from the blank. Where stripping mechanisms (depending on the type) are available to eject the blank, release tapers of about 1° can be employed for both punches and containers.

The consumable tools on radial-axial ring rolling mills are principally the mandrel and, to a lesser extent, the axial (conical) rolls and the main roll. Depending on the mill design and force capability, mandrels may be as small as 30 mm (1.2 in.) in diameter (for a 295 kN, or 33 tonf, mill) and as large as 450 mm (18 in.) in diameter for a mill with a radial capacity of 5 MN (550 tonf).

Figure 29(e) shows a typical 165 mm (65 in.) diam mandrel for a midsize mill with 980 kN (110 tonf) radial capacity. Such mandrels are commonly fabricated from ASM 6F3 at 370 to 410 HB. Again, AISI 4340, at 300 to 350 HB, with adequate water-spray cooling, can be used with good results (that is, producing up to 3000 rings before failing through heat check initiated fatigue). Production of 1500 to 2000 rings can be expected from a 70 mm (2.75 in.) H13 tool steel mandrel used on a high-speed multiple-mandrel mill of 390 kN (44 tonf) radial capacity.

Axial rolls (Fig. 29f) on older machines typically had a 45° included angle, along with relatively short working lengths. This severely limited the ring wall thickness they could cover and led to rapid wear of the conical surfaces. With the resultant need to change axial rolls frequently, two part designs were often employed with the working cone bolted to a semipermanently installed roll shaft.

Modern machines have 30 to 40° included-angle axial cones and longer working lengths. Wear is spread over the greater length, and roll changes are required less frequently (for example, after 600 to more than 1000 h of use).

Axial rolls are usually one-piece designs; AISI 4140, ASM 6F2, and ASM 6F3 are typical materials. These rolls are usually welded and reworked to original dimensions many times before being discarded. Extended service life can be obtained by using a cobalt-base hardfacing alloy, approximately 1.5 mm (0.06 in.) thick, on the working surfaces on these axial cones.

Figure 29(g) shows a typical AISI 4140 main roll for a 980 kN (110 tonf) radial capacity ring mill. Such rolls tend to wear most heavily at the point where the bottom corner of the ring is contacted. To prolong use between roll changes, the roll and shaft assembly are periodically adjusted downward from maximum height setting gradually toward minimum, typically over a full range of 30 mm (1.2 in.).

In addition to ensuring maximum roll life, they are initially made to an acceptably larger-than-nominal diameter and are recut at intervals until the minimum mandrel/main roll gap is unacceptable. At this point, if economical, weld repair and hardfacing can be employed.

Ring Rolling

Combined Ring Rolling and Closed-Die Forging

The combination of ring rolling machines and closed-die hammers or presses in integrated manufacturing cells yields a degree of flexibility and economic benefit not achievable by either process separately. With sufficient ingenuity applied to equipment layout and handling devices, a number of process sequences can be used; the final component forming occurs either on the ring mill or the closed-die unit, depending on the particular component shape and size.

Figure 30 compares the equipment required and the economics of producing a starter ring by closed-die forging and ring rolling combined (Fig. 30a) and by closed-die forging only (Fig. 30b). Similarly, Fig. 31 shows the comparison for weld-neck flange forming.

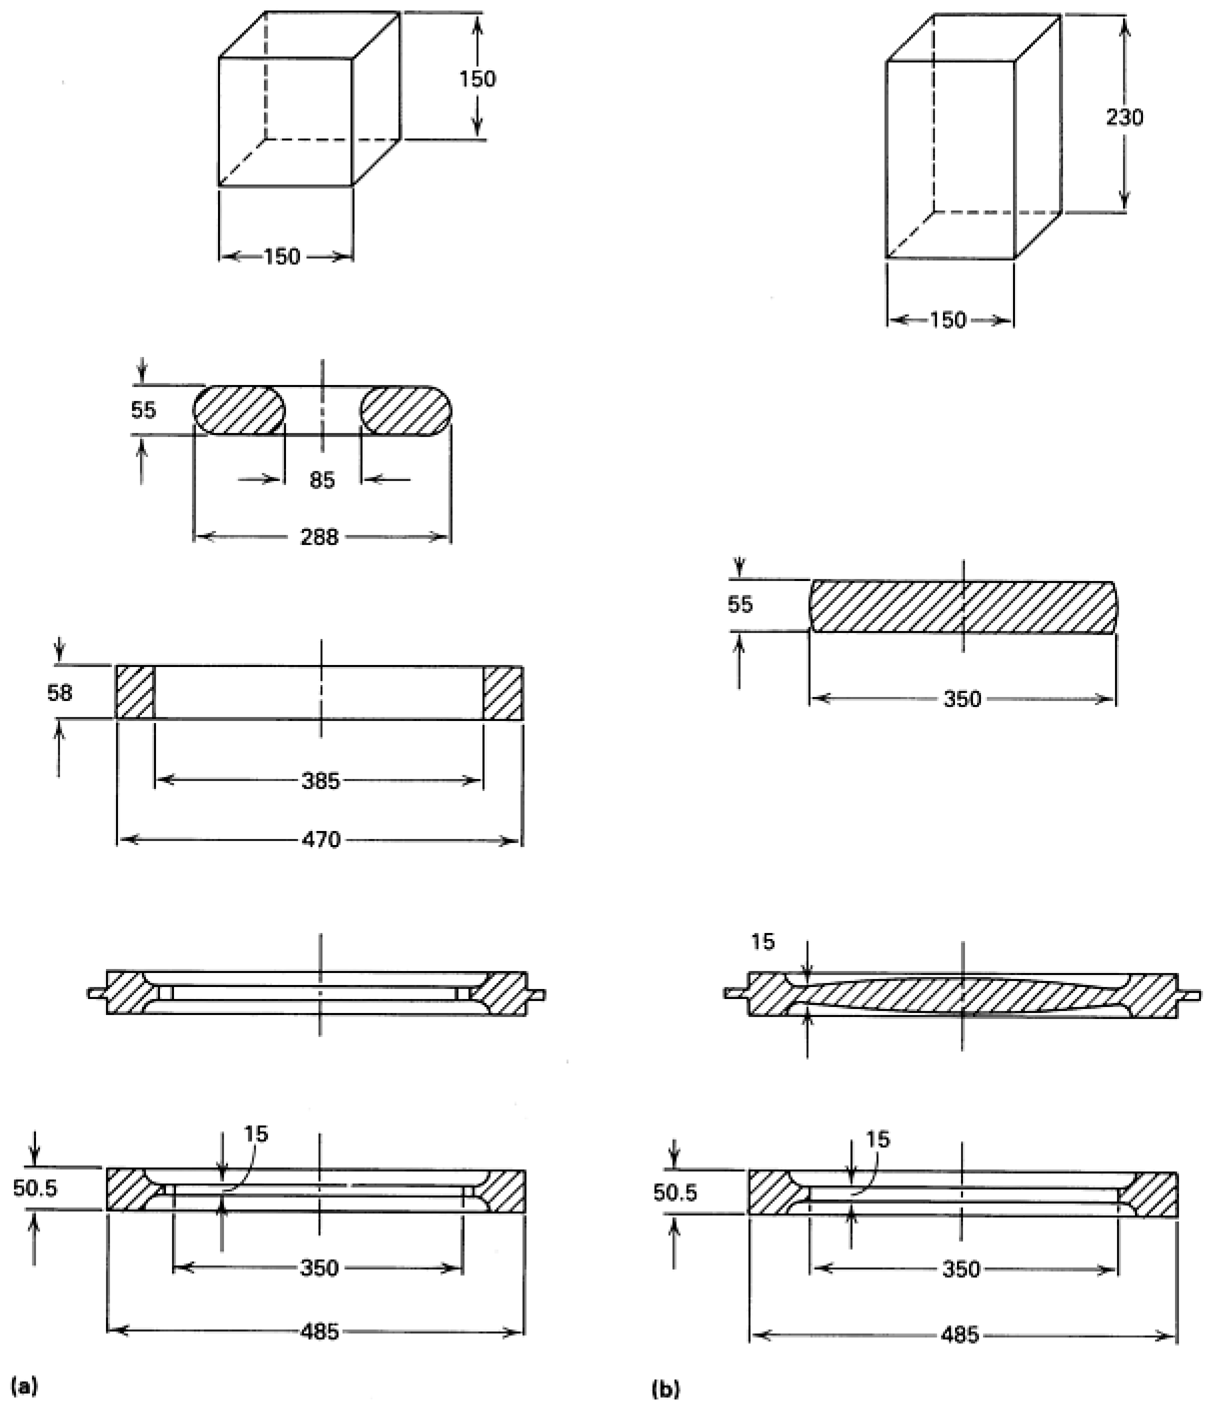

Fig. 30 Comparison of closed-die forging plus ring rolling (a) and closed-die forging only (b) for the production of a starter ring. (a) Top to bottom: billet, pierced blank, rolled ring, die forging, and finished part. (b) Top to bottom: billet, upset disk, die forging, and finished part. Although an additional step is needed when ring rolling is used, the production rate increases from 70 to 110 pieces per hour, and a material saving of 38% per piece is realized. Dimensions given in millimeters (1 in. = 25.4 mm).

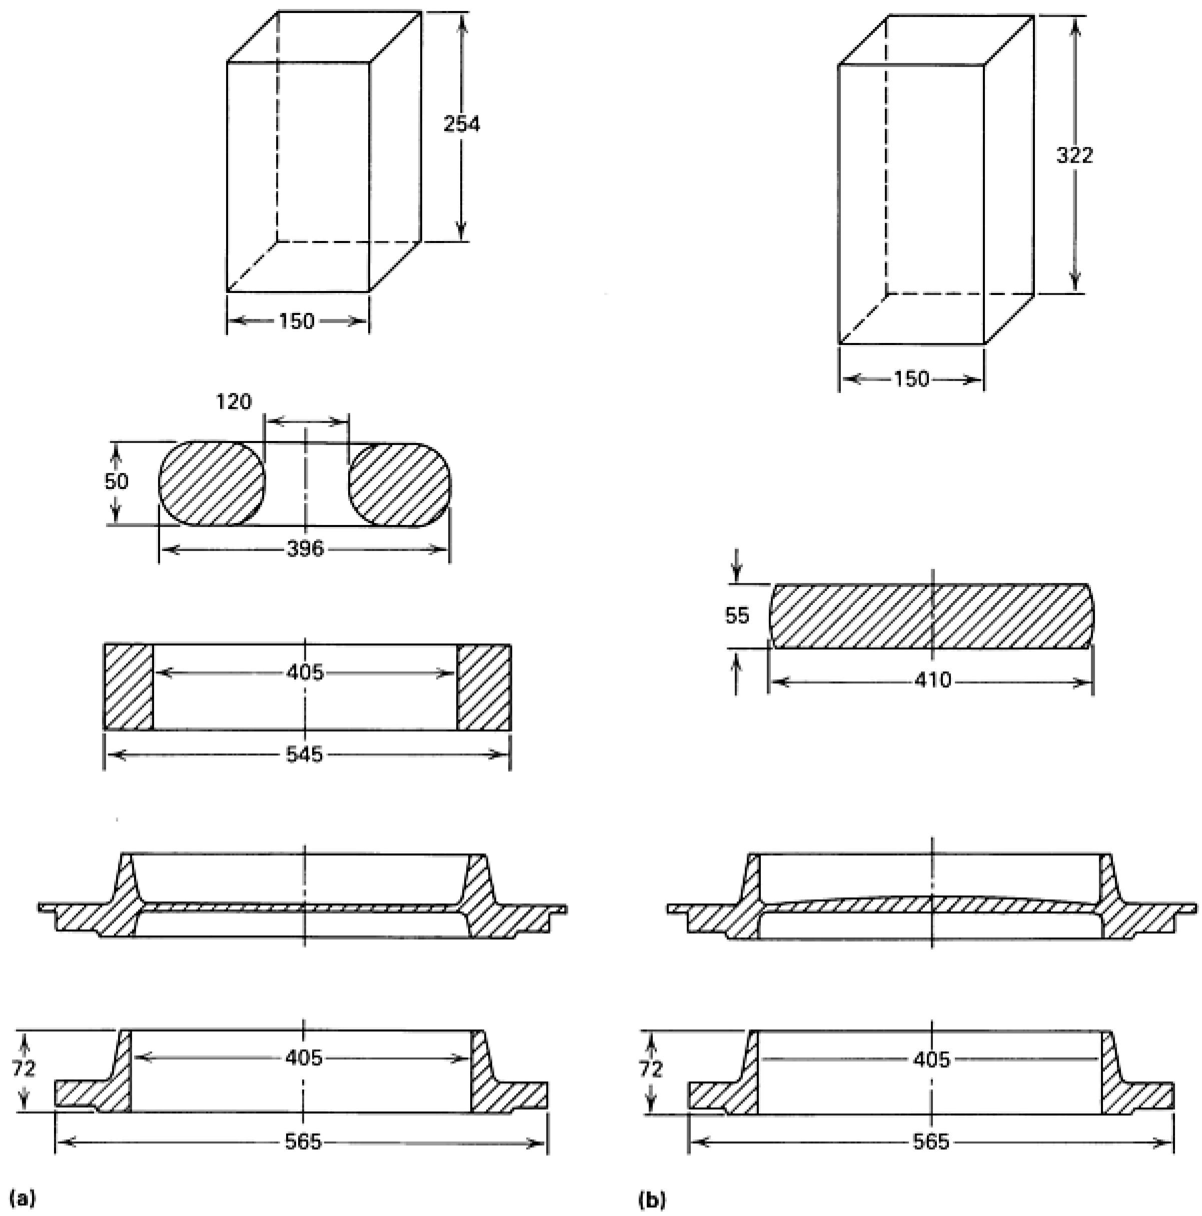

Fig. 31 Comparison of closed-die forging plus ring rolling (a) and closed-die forging only (b) for the production of a weld-neck flange. (a) Top to bottom: billet, pierced blank, prerolled ring, finish-forged part, and trimmed part. (b) Top to bottom: billet, upset disk, finished forging, and trimmed part. Production rate doubled and a material savings of 21% per piece was realized when the ring rolling process was used. Dimensions given in millimeters (1 in. = 25.4 mm).

From these examples, it can be seen that for a given production program new installations can be equipped with appreciably smaller principal forming equipment. Furthermore, despite the additional number of pieces of equipment, the total investment is usually lower than if a 100% closed-die approach were selected. Alternatively, the addition of a ring roller to an existing closed-die plant can extend the production range to substantially larger pieces.

By avoiding large inside flash formation, material input can be reduced by 15 to 35% (Fig. 30 and 31). Production rates 10 to 40% higher than closed-die forging can be achieved through simultaneous operations performed in more, but individually less demanding, steps. The much-reduced inside flash means lower stock-heating costs, and approximately 50% less deformation energy is required at the closed-die stage. The number of operators required usually remains unchanged.

Bevel Gear Manufacture. Figure 32 illustrates five possible methods of manufacturing large bevel gears. Table 3 lists the start/finish material weight relationships for these methods. The capital investment and material yield benefits of ring rolling are obvious from these data. Many bevel gears are therefore manufactured by the preform press plus ring mill approach.

Table 3 Material required for the production of bevel gear blanks by various methods

See Fig. 32 for steps used in each method.

Method	**Required billet weight**		**Weight of unmachined ring**		Weight of scrap	
	kg	**lb**	**kg**	**lb**	**kg**	lb
A (Drop hammer)	44.7	98.5	38.5	84.9	6.2	**13.7**
B (Forging press)	45.9	101.2	38.5	84.9	7.4	**16.3**
C (Drop hammer and ring roll)	42.8	94.4	38.5	84.9	4.3	**9.5**
D (Forging press and ring roll)	43.1	95.0	38.5	84.9	4.6	**10.1**

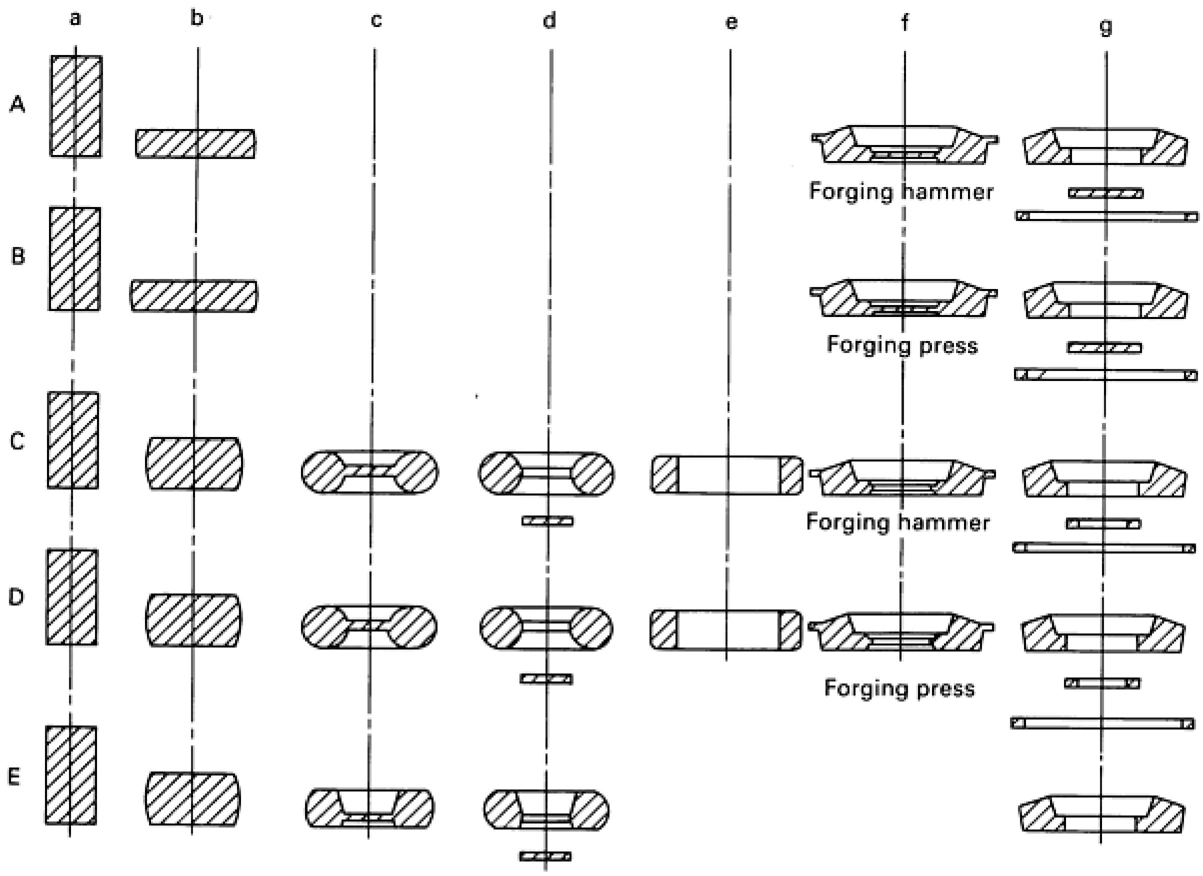

Fig. 32 Five methods of producing bevel gear blanks. A, drop hammer forging; B, press forging; C, ring rolling and hammer forging; D, ring rolling and press forging; E, ring rolling and piercing. Production steps: a, cut billet; b, upset billet; c, ring preform; d, ring blank; e, rolled blank; f, die-forged bevel gear; g, finished,

unmachined bevel gear. See Table 3 for amount of material used in various processes.

However, some bevel gears of complex cross section cannot be easily rolled to near-net shape without the aid of extensive blank preforming on heavier, more expensive presses. Even when appropriate material distribution is achieved in the preform, inside flash diameter may be large so that the resulting hole allows the blank to fit over a deeply contoured rolling mandrel. Material loss can therefore approach that in closed-die forging. The advantage of completing the process on a ring mill is reduced or lost completely.

An alternative method of producing these larger-diameter heavier bevel gears, with the required cross-sectional complexity, is to relegate the ring mill to a preforming role and to finish in closed dies. Equipment size and expenditure are still less than if closed-die forging only were used.

Figure 33 shows schematically a forging line that originally consisted of a 71 MN (8000 tonf) forging press and a 3.5 MN (400 tonf) trimming press. Bevel gears to 440 mm (17.3 in.) in diameter and 50 kg (110 lb) in weight were manufactured. By introducing an 11 MN (1200 tonf) ring blank preforming press and two 390 kN (44 tonf) preforming ring rollers (Fig. 34) plus manipulator, the maximum diameter was extended to 500 mm (20 in.) and maximum weight to 80 kg (175 lb).

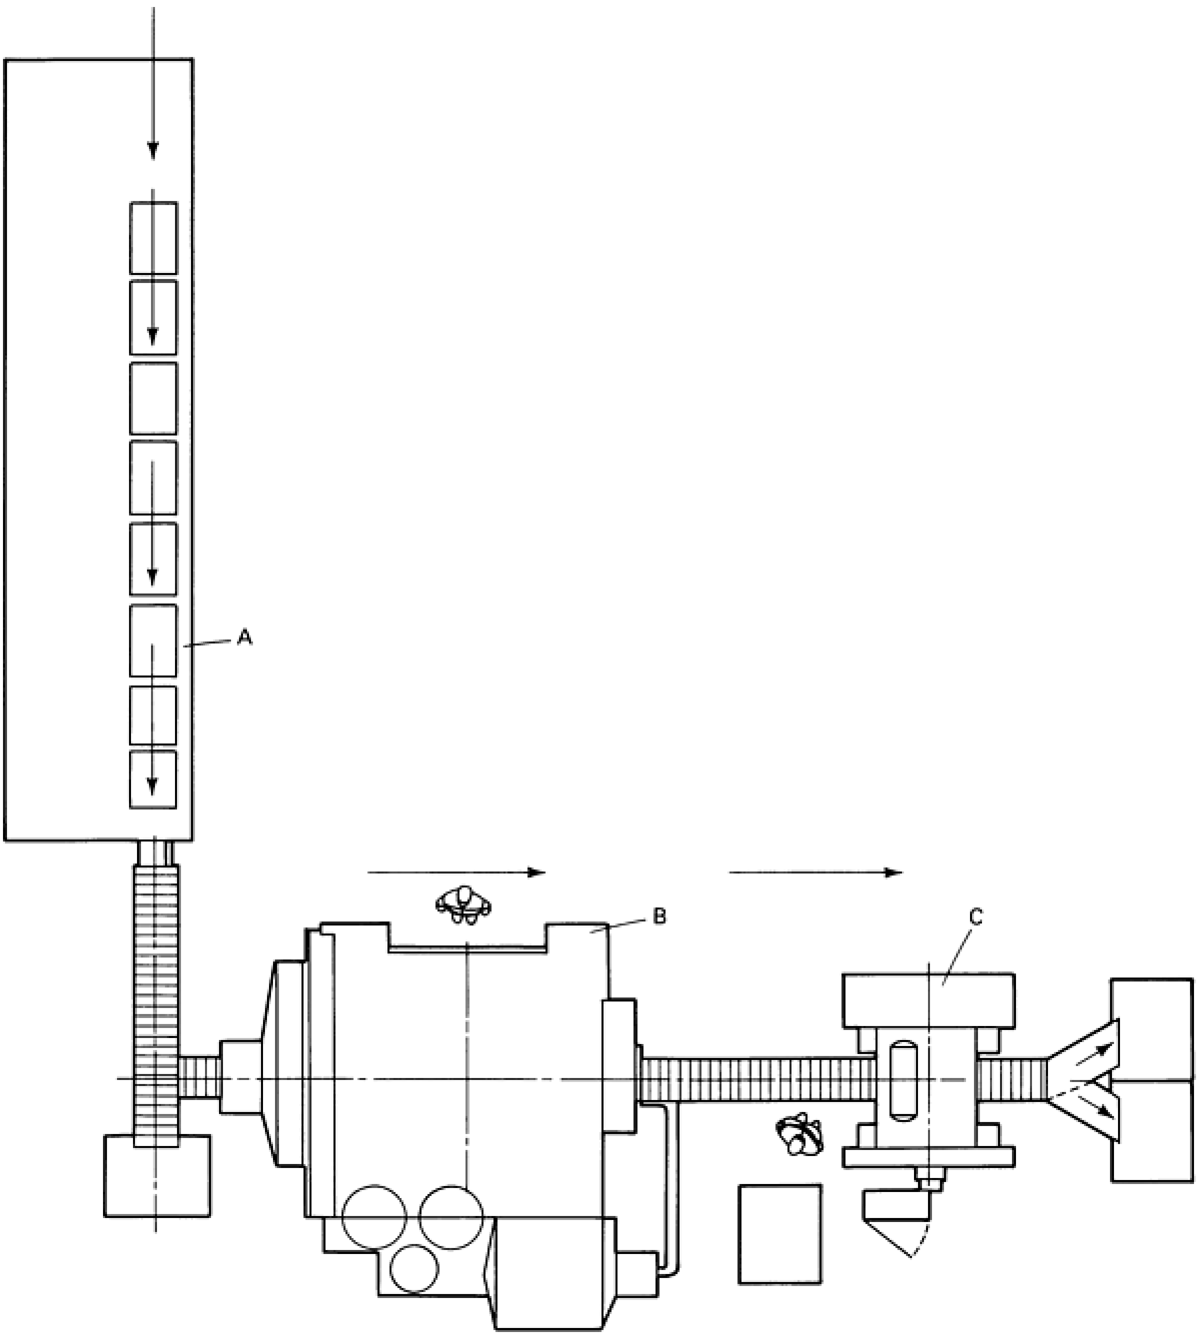

Fig. 33 Schematic of a setup for forging bevel gears. A, induction heater; B, 78 MN (8800 tonf) forging press; C, 3.9 MN (440 tonf) trimming press. See also Fig. 34.

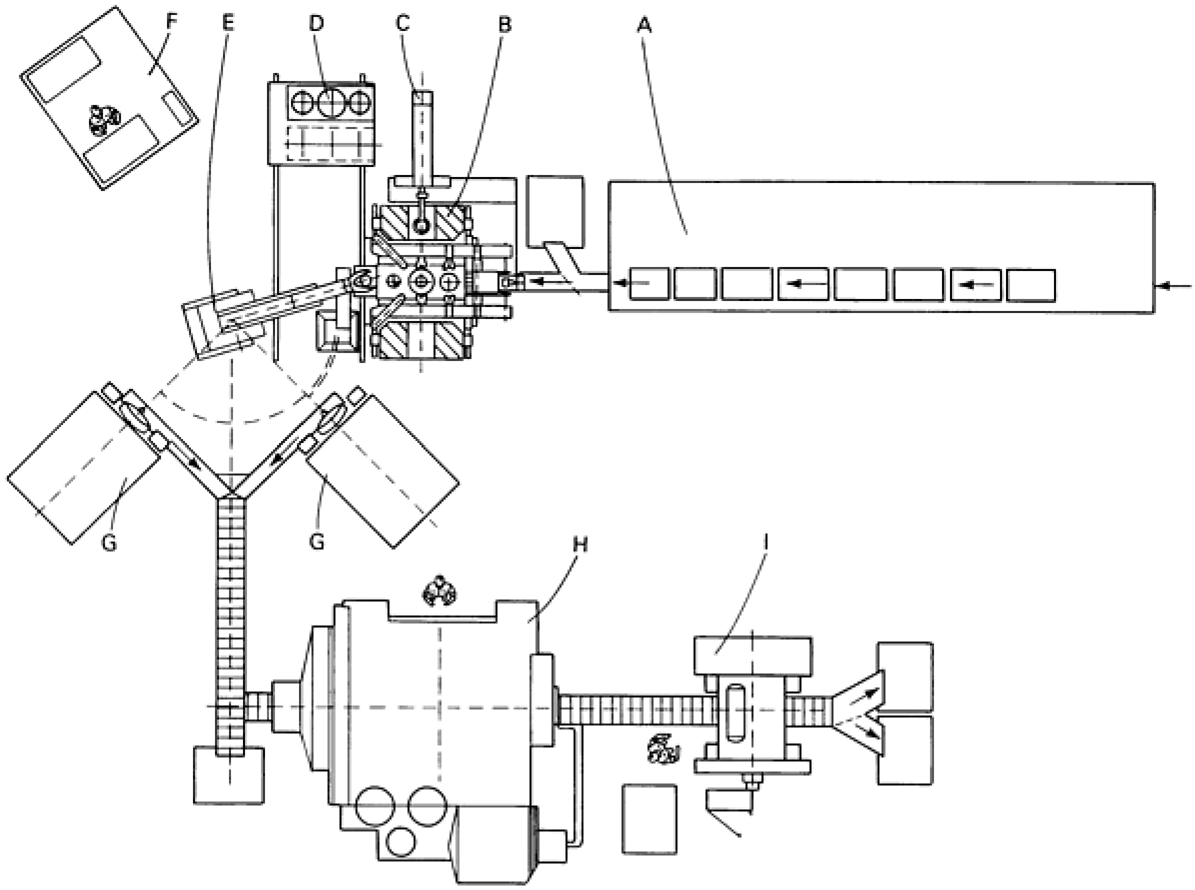

Fig. 34 Extension of die-forging plant for bevel gears shown in Fig. 33 to include a radial ring mill. A, induction heater; B, 12.2 MN (1375 tonf) preforming press; C, die lubrication unit; D, die change carriage; E, manipulator; F, control cabin; G, 390 kN (44 tonf) preforming ring mill; H, 78 MN (8800 tonf) forging press; I, 3.9 MN (440 tonf) trimming press.

Output was increased from 10 to 24 Mg (11 to 26.5 tons) per hour. In addition to the increased material yield on comparable forgings (savings up to 20%), die life was significantly improved because of the reduced material flow needed with a ring rolled preform. In addition, the circumferential grain flow from ring rolling, combined with the radial-axial flow in closed dies, produced a metallurgically improved component.

Ring Rolling

C.R. Keeton, Ajax Rolled Ring Company

Rolled Ring Tolerances and Machining Allowances

There are numerous sources of dimensional variation in the ring rolling process. The volume of material rolled is affected by variation in the cut weight of the billet, scale loss fluctuation due to differing heating conditions, and variation in center-web thickness removed at the blanking stage.

Beyond this, dimensions are affected by rolling temperature. Machine deflection, the accuracy of the measuring instrument, ring circularity, distortion in subsequent heat treatment, surface flaws, and cross-sectional shape inaccuracies also must be taken into account.

The degree of precision attainable using the ring rolling process depends on the design characteristics of particular mill types and varies quite widely throughout the ring rolling industry. With modern computer-controlled ring mills, switch-off accuracies in the range of 0.1 mm (0.004 in.) are achievable; this makes machine controllability a minor consideration and emphasizes the contributions of other factors to dimensional variation. However, because there are many machines that rely on operator skill or solely on weight control (mechanical table mills) for dimensional control, it is quite common for the products of these machines to be sized by pressing them through or over a die or by expanding deliberately undersized rings on a segmental expanding machine.

An increasingly common feature of computer-controlled ring mills is the option to distribute material to best advantage. A decision can be made, even during rolling, to place excess material on the inside or outside diameters or on height. Perhaps the most useful version of this feature is the ability to roll to mean ring diameter, with excess material being equally distributed to the inside and outside diameters regardless of the actual material input volume.

Persistent market pressure for near-net shape rings, wider application of statistical process control techniques, and the use of computer numerical controlled ring rolling machines has generated steadily increasing dimensional precision of rolled rings. Information on allowances and tolerances (Fig. 35 and 36) should therefore be taken only as a generalized starting point, and it should be understood that the ability of individual manufacturers of rolled rings to meet or improve on the tabulated allowances and tolerances varies greatly.

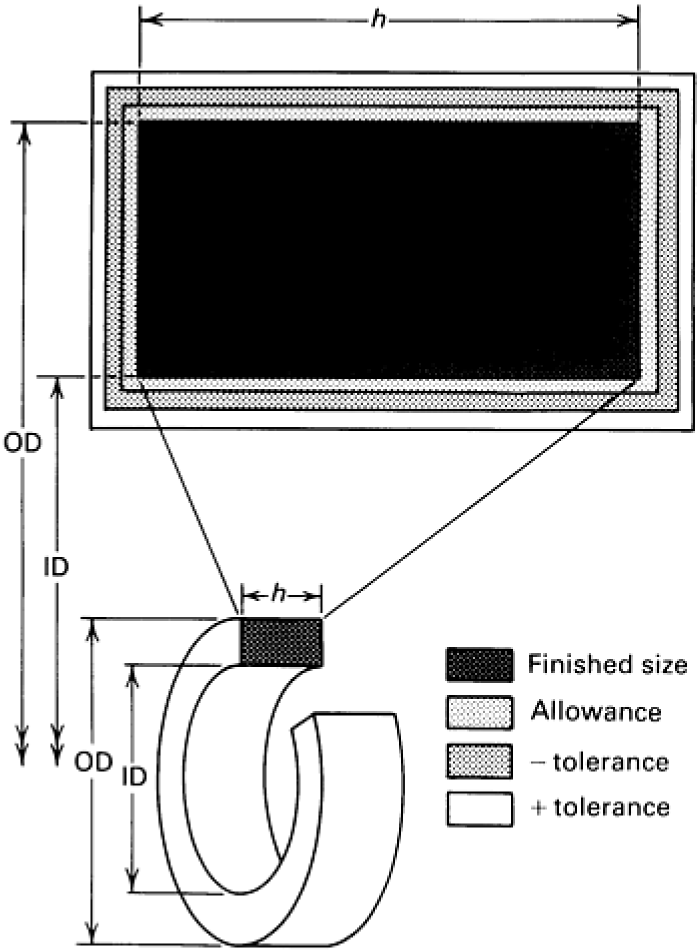

Fig. 35 Allowances and tolerances for seamless rolled rings. Allowance is the amount of stock added to ensure cleanup on any surface that requires subsequent machining. Tolerance is normal dimensional variation limits. See also Fig. 36.

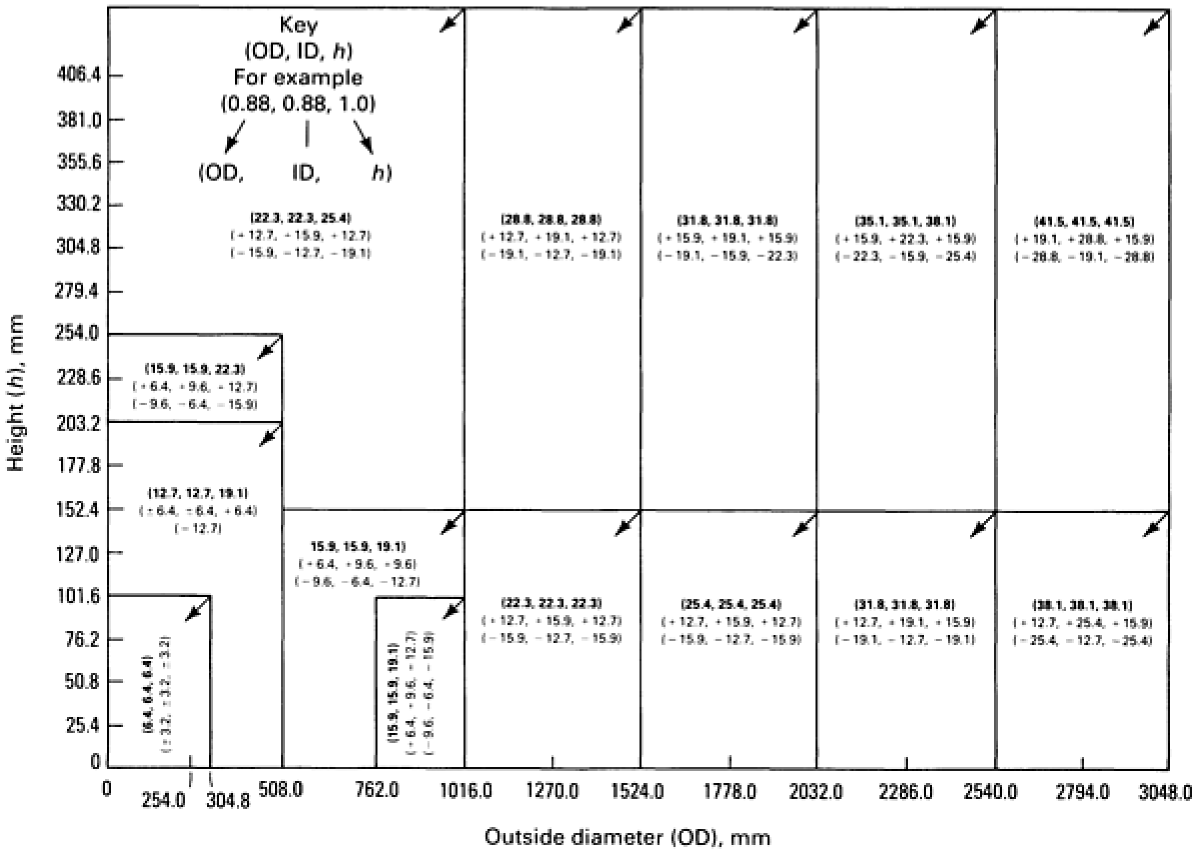
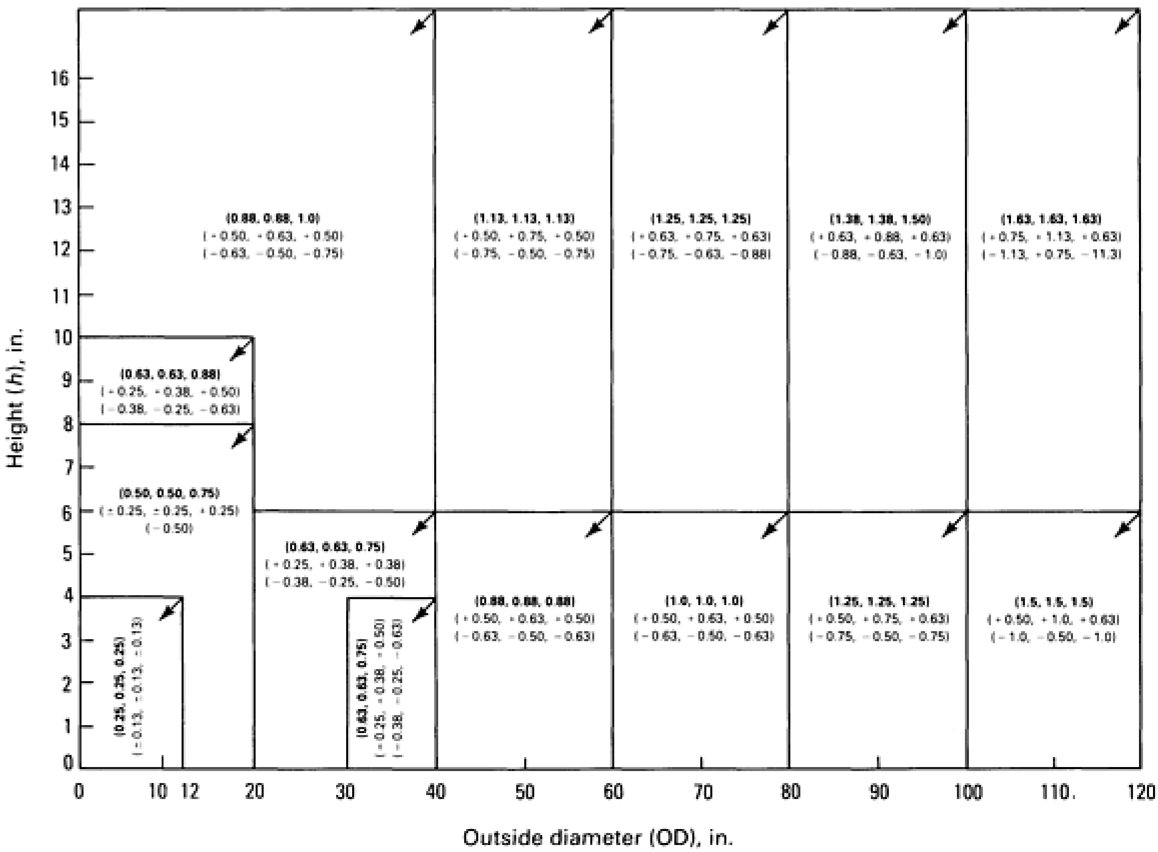


(a)



(b)

Fig. 36 Allowance and tolerance chart for as-rolled carbon, alloy, and stainless steel seamless rings. Allowances

are given in boldface type; tolerances are in regular type. Shaded areas represent allowances and tolerances for sized rings. (a) Chart in millimeters. (b) Chart in inches.

To ensure cleanup of a ring at machining, an envelope is added to the finished (machined) ring dimensions. This envelope, determined by experience, together with a +/- tolerance, is intended to account for the above-mentioned surface condition, cross-sectional inaccuracy, and dimensional variation factors. Figure 35 illustrates the relationship between this machining allowance and dimensional tolerance.

These data (Fig. 35 and 36) are available in Ref 8. Based on historical, averaged industry data, Fig. 36 shows typical machining allowances and as-rolled ring dimensional tolerances for carbon, alloy, and stainless steel rings. Similar data for aluminum, titanium, heat-resistant alloys, brass, and copper are also given in Ref 8.

Ring Rolling

C.R. Keeton, Ajax Rolled Ring Company

Alternative Processes

Relatively small rings can be forged in closed dies. Maximum diameter is limited by the distance between hammer legs, or between press columns, and the available forming energy. Material waste is relatively high, and grain flow is radial unless a preform is ring rolled. Larger rings can be open-die forged using a saddle arrangement (Fig. 37). This method is slow, labor intensive, and tends to produce polygonal rather than smooth-faced rings.

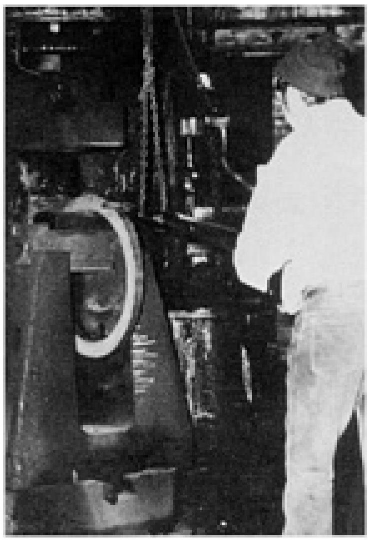

Fig. 37 Open-die forging of a ring using a saddle.

If service conditions are not too demanding, rings of a wide range of dimensions can be gas-cut from plate. Contoured rings are largely impractical to produce by this approach; much material is wasted, and the longitudinal flow from the plate produces variation in mechanical properties around and in the direction of the circumference.

Rings of a wide range of diameters and cross sections can be made by the three-roll forming of bar or plate, followed by welding of the joint. Subsequent cold or warm rolling is sometimes used to form complex thin-wall cross sections. Special-purpose rolling machines have been developed for this purpose.

Small rings up to approximately 330 mm (13 in.) in diameter, especially bearing rings, are sometimes machined from seamless tube. Again, the axial grain flow of the tube may be unacceptable, and maximum wall thickness is quite limited.

Centrifugal casting is sometimes used to produce circular components, and it has its own peculiar advantages and disadvantages. Nonrotating gas-turbine parts are routinely made in heat-resistant materials by this method.

Rotary Swaging of Bars and Tubes

Revised by the ASM Committee on Rotary Swaging*

Introduction

ROTARY SWAGING is a process for reducing the cross-sectional area or otherwise changing the shape of bars, tubes, or wires by repeated radial blows with two or more dies. The work is elongated as the cross-sectional area is reduced. The workpiece (starting blank) is usually round, square, or otherwise symmetrical in cross section, although other forms, such as rectangles, can be swaged.

Most swaged workpieces are round, the simplest being formed by reduction in diameter. However, swaging can also produce straight and compound tapers, can produce contours on the inside diameter of tubing, and can change round to square or other shapes.

Rotary Swaging of Bars and Tubes

Revised by the ASM Committee on Rotary Swaging*

Applicability

Swaging has been used to reduce tubes up to 355 mm (14 in.) in initial diameter and bars up to 100 mm (4 in.) in initial diameter. Hardness, tensile strength, and reduction in area of the work metal have the most significant effect on swageability. Type and homogeneity of microstructure also influence the ease of swaging and the degree to which a metal can be swaged. Maximum reduction in area for various metals is given in Table 1.

Table 1 Maximum reductions in area obtainable by cold swaging for several alloy systems

(a) Low-manganese steels, spheroidize annealed.

(b) Spheroidize annealed.

(c) Annealed

Work Metals. Of the plain carbon steels, those with a carbon content of 0.20% or less are the most swageable. These grades can be reduced up to 70% in cross-sectional area by swaging. As carbon content or alloy content is increased, swageability is decreased. Alloying elements such as manganese, nickel, chromium, and tungsten increase work metal strength and therefore decrease the ability of the metal to flow. Free-machining additives such as sulfur, lead, and phosphorus, cause discontinuities in structure that result in splitting or crumbling of the work metal during swaging.

In the cold swaging of steel (at room temperature), maximum swageability is obtained when the microstructure is in the spheroidized condition. Pearlitic, annealed microstructures are less swageable than spheroidized microstructures, depending on the fineness of the pearlite and on the tensile strength and hardness of the steel. Fine pearlitic microstructures, such as those found in patented music wire and spring wire, can be swaged up to 30 to 40% reduction in area.

Figure 1 shows the relationship between hardness and carbon content for pearlitic and spheroidized microstructures and also shows three zones of swageability, indicating that a maximum hardness of 85 HRB is preferred for carbon steels and that swaging is impractical when hardness exceeds 102 HRB. Figure 2 shows the influence of cold reduction on the tensile and yield strengths of several metals.

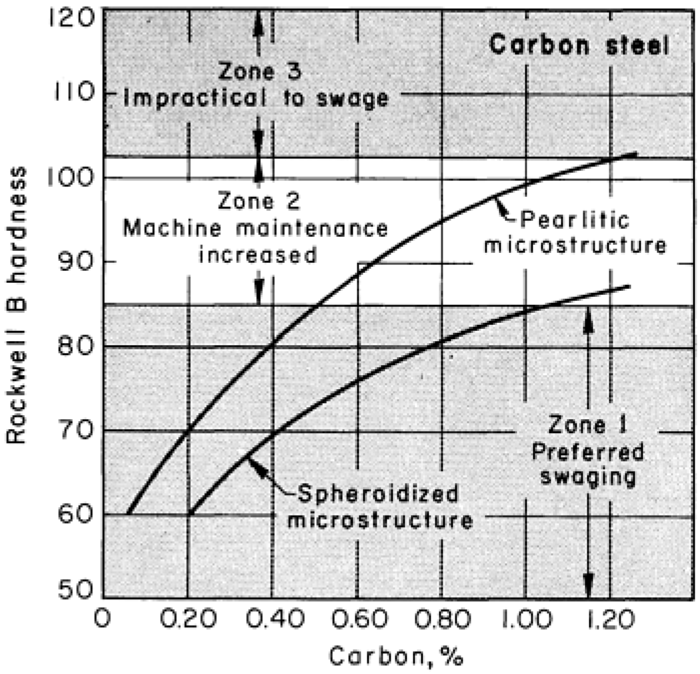

Fig. 1 Swageability of carbon steel as a function of microstructure, hardness, and carbon content.

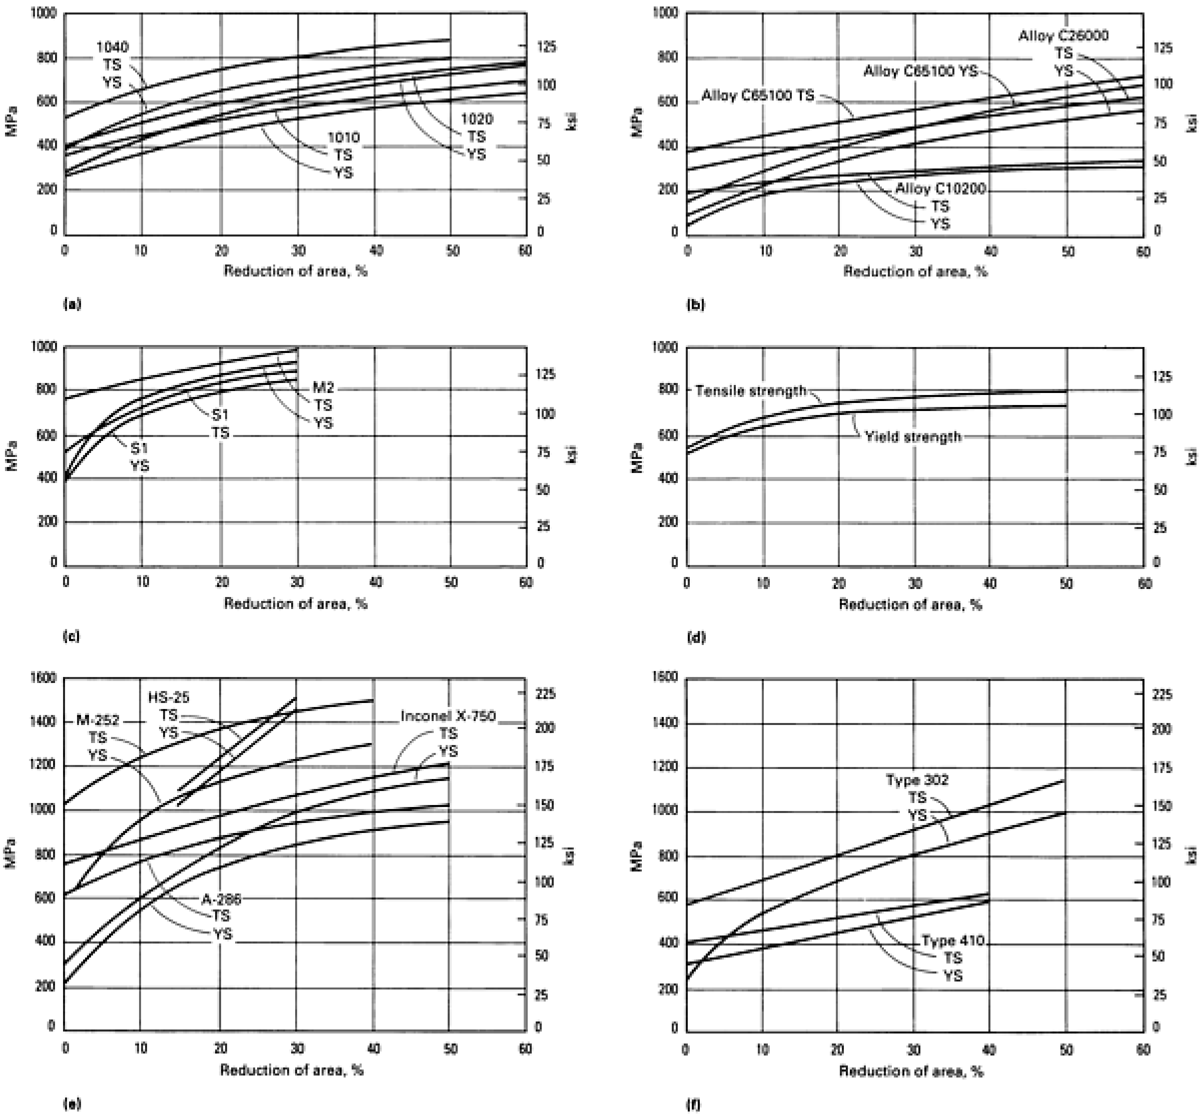

Fig. 2 Influence of cold reduction by swaging on mechanical properties of various alloy systems. (a) Carbon steels. (b) Copper alloys. (c) Tool steels. (d) Commercially pure titanium. (e) Heat-resistant alloys. (f) Stainless steels. TS, tensile strength; YS, yield strength.

Workpieces requiring reductions greater than that which can be accomplished with one swaging pass must be stress relieved or reannealed after the first pass to restore ductility in the metal for further reduction. Stress relieving of steel by heating to 595 to 675 °C (1100 to 1250 °F) often restores ductility, although excessive grain growth may develop when cold working is followed by heating within this temperature range. Stress relieving is of little value under these conditions, and it is necessary to anneal the material fully.

Rotary Swaging of Bars and Tubes

Revised by the ASM Committee on Rotary Swaging*

Metal Flow During Swaging

Metal flow during rotary swaging is not confined to one direction. As shown in Fig. 3, more metal moves out of the taper in a direction opposite to that of the feed than through the straight portion (blade). Some metal flow also occurs in the transverse direction, but it is restricted by the oval or side clearance in the dies (see Fig. 7).

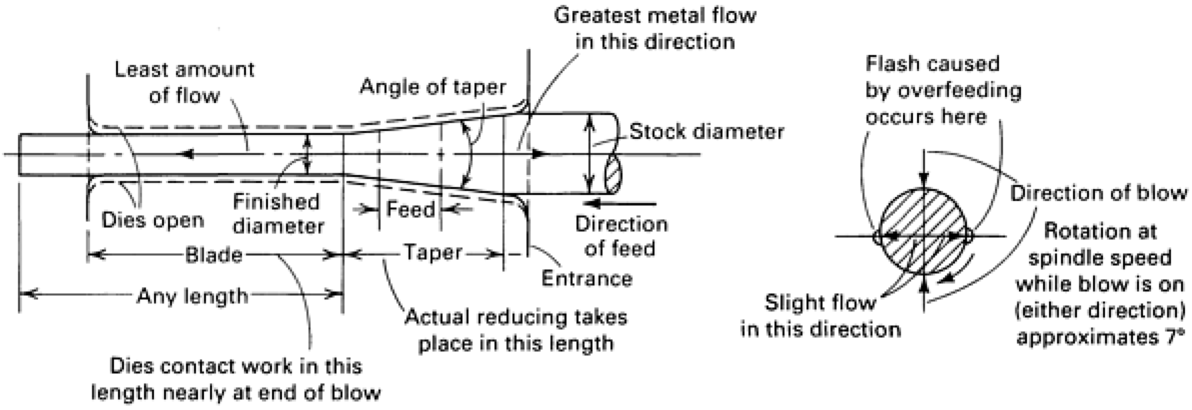

Fig. 3 Metal flow during swaging of a solid bar.

Feedback. The action of the metal moving against the direction of feed is termed feedback, and it results from slippage of the workpiece in the die taper when it is too steep. Feedback manifests itself as a heavy endwise vibration that causes considerable resistance to feeding of the workpiece.

Workpiece Rotation. Unless resisted, rotation is imparted as the dies close on the workpiece, and the speed of rotation is the speed of the roller cage. If rotation is permitted, swaging takes place in only one position on the workpiece, causing ovaling, flash, and sticking of the workpiece in the die. Resistance to rotation is manual when the swager is hand fed; mechanical means are used with automatic feeds.

Rotary Swaging of Bars and Tubes

Revised by the ASM Committee on Rotary Swaging*

Machines

Rotary swaging machines are classified as standard rotary, stationary-spindle, creeping-spindle, alternate-blow, and die-closing types. All these machines are equipped with dies that open and close rapidly to provide the impact action that shapes the workpiece. The five principal machine concepts for swaging are shown in Fig. 4.

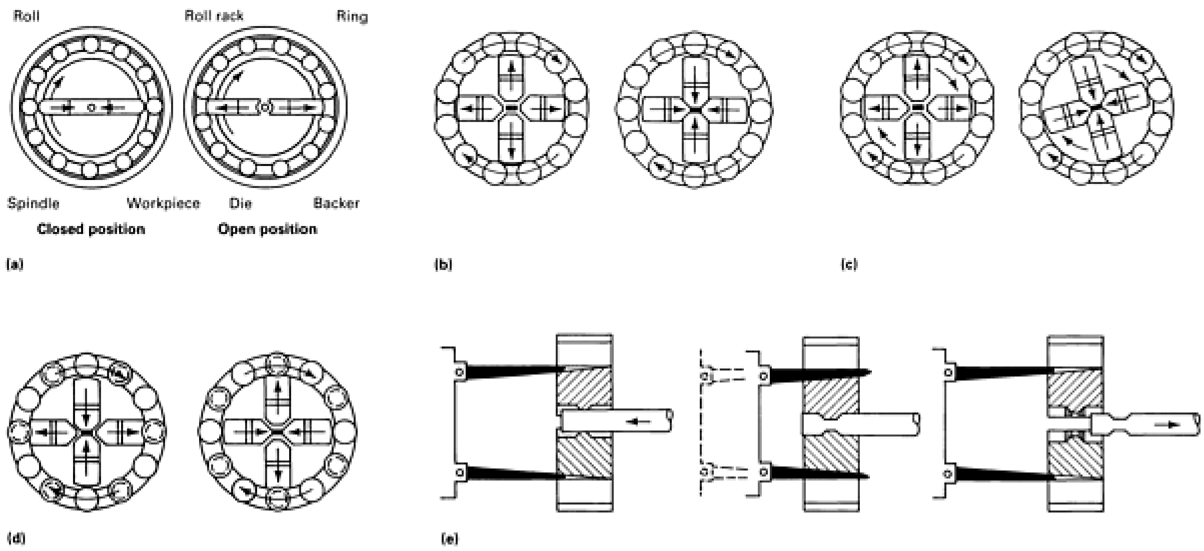

Fig. 4 Principal machine concepts for rotary swaging. (a) Standard rotary swager. (b) Stationary-spindle swager. (c) Creeping-spindle swager. (d) Alternate-blow swager. (e) Die-closing swager.

Swagers allow the work to be fed into the taper entrance of the swaging dies. The amount of diameter reduction per pass is limited by the design of the entrance taper of the dies or the area reduction capability of the machine. The results are expressed in terms of diameter reduction or area reduction.

The two methods of calculating reduction (in percent) are:

$$\text{Diameter reduction} = 100\left[1 - \left(\frac{D_2}{D_1}\right)\right]$$

$$\text{Area reduction} = 100\left[1 - \left(\frac{D_2^2}{D_1^2}\right)\right]$$

A die-closing swager has dies made with side relief that is sufficient to allow the dies to come down directly onto the work. The maximum side relief that can be used limits the reduction in diameter per swaging pass to 25%. The die-closing swager may have a front entrance angle and can be used as a standard rotary swager. When used in this manner, the diameter and area reduction per pass are the same as for a standard rotary swager. However, diameter reduction should not be confused with area reduction.

Standard Rotary Swagers. The basic rotary swager (Fig. 4a) is a mechanical hammer that delivers blows (impact swaging) at high frequency, thus changing the shape of a workpiece by metal flow. This machine is used for straight reducing of stock diameter or for tapering round workpieces.

A standard rotary swager consists of a head that contains the swaging components and a base that supports the head and houses the motor. A hardened and ground steel ring about 0.5 mm (0.020 in.) larger in diameter than the bore of the head is pressed into the head so that the ring is in compression.

The spindle, centrally located within the ring, is slotted to hold the backers and dies and is mounted in a tapered-roller bearing. Flat steel shims are placed between the dies and backers. A roll rack containing a set of rolls is located between the press-fitted ring and the backers. A conventional impact-type backer is shown in Fig. 5. The spindle is rotated by a motor-driven flywheel keyed to the spindle. During rotation of the spindle, the dies move outward by centrifugal force and inward by the action of the backers striking the rolls. The number of blows (impacts) produced by the dies is 1000 to 5000 per minute, depending on the size of the swager. The impact rate is approximately equal to the number of rolls multiplied by the speed (rpm) of the swager spindle multiplied by a correction factor of 0.6, which allows for creep of the roll rack.

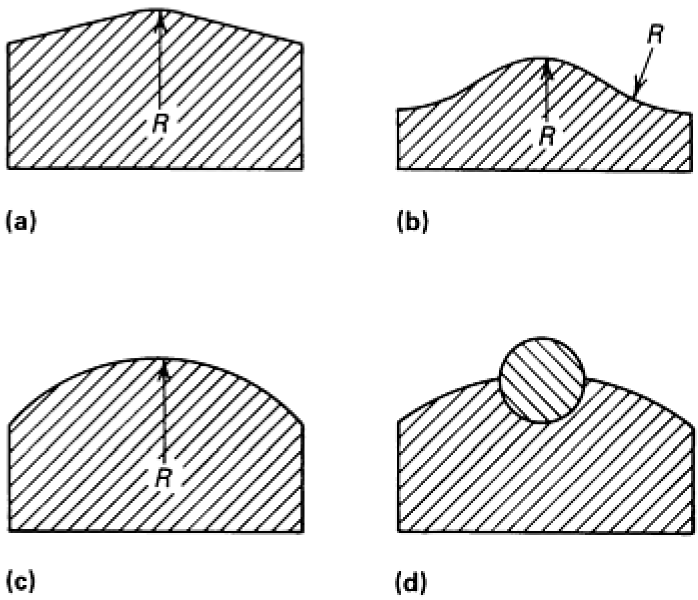

Fig. 5 Designs of four different backer cams used in rotary swaging. (a) Conventional impact-type backer (flat sides). (b) Squeeze-type backer with a sine curve type crown. (c) Squeeze-type backer with large radius on crown. (d) Backer with replaceable insert.

The amount of the die opening when the dies are in the open position--backers positioned between the rolls--can be changed to some extent during operation by a mechanical device that restricts the amount dies and backers can move under centrifugal force. However, the closed position of the dies--backers positioned on the rolls--cannot be changed during operation; the swager must be stopped and shims inserted between the dies and the backers. The severity of the blow can be varied by using shims of different thicknesses. The dies should be shimmed tight enough to obtain a reasonable amount of interference between the backers and the rolls when the dies are in the closed position.

The amount of shimming should be sufficient to bring the die faces together, and generally 0.05 to 0.5 mm (0.002 to 0.020 in.) of preload can be added, according to the size of machine. A swager is shimmed too tightly, or has too great a preload, when it stalls in starting while the swager hammers are off the rolls. The lightest possible shimming should be used; overshimming increases machine maintenance. Additional shimming will not produce a smaller section size, because section size is controlled by the size of the die cavity when the dies are in the closed position. Insufficient shimming, however, will increase the section size and cause variation in results, particularly in dimensions and surface conditions.

Stationary-spindle swagers are sometimes called inverted swagers, because the spindle, dies, and work remain stationary while the head and roll rack rotate. These machines are used for swaging shapes other than round.

The reciprocating action of the dies is the same as in swagers in which the spindle is rotated and the roll rack remains stationary. The principal components of a stationary-spindle machine are shown in Fig. 4(b).

The stationary-spindle swager consists of a base that houses the motor and supports a bearing housing containing two tapered-roller bearings. The head, fastened to a rotating sleeve mounted in the tapered-roller bearings, is motor driven and acts as a flywheel. The spindle is mounted and held stationary by a rear housing that is fastened to a bearing housing.

As the head rotates, the rolls pass over the backers, which in turn cause the dies to strike the workpiece in a pulsating hammer-type action. Die opening can be controlled by the forward feed of the workpiece, although springs are sometimes used to open the dies. The maximum outward travel of the dies in the open position is regulated by a mechanical device in the front of the machine. Shims are used between the dies and the backers, just as they are in swagers with rotating spindles.

Creeping-spindle swaging (Fig. 4c) employs the principles of both standard rotary and stationary-spindle swaging. The spindle and dies are mounted on a shaft that rotates slowly inside the rapidly rotating roller cage, thus permitting more accurately controlled reciprocation of the dies.

Alternate-blow swaging (Fig. 4d) is accomplished by recessing alternate rolls; in this configuration, when two opposing rolls hammer the dies, the rolls 90° away do not. This eliminates fins on the workpiece.

Die-closing swagers (Fig. 4e) are used when the dies must open more than is possible in a standard rotary swager to permit loading. Die-closing swagers are essentially of the same construction as the standard rotary swagers described above. Both have similar components, such as dies, rolls, roll rack, inside ring, spindle, and shims.

The main difference between die-closing and standard rotary swagers is the addition of a reciprocating wedge mechanism that forces closure of the taper-back dies, as shown in Fig. 4(e). The wedge mechanism consists of a wedge for each die that is positioned between the die and the backer. The rotating dies open by centrifugal force and are held open by springs or other mechanical means when the power-actuated wedge mechanism is in the back position. Wedge control of the die opening permits the work to be placed in the machine in a predetermined position when the dies are open. Reduction per pass is limited to 25% of the original diameter of the workpiece, and the wedge angle of the dies should not exceed $7\frac{1}{2}$°.

Swaging by Squeeze Action. The impact action common to standard rotary swagers can be slowed to produce a squeezing action by employing a backer cam. The design of the crown and the width of the backers are such that at least one roll is always in contact with the backer. The shape of the crown can be a single curve or two radii that approximate a sine curve. Both of these backer designs are shown in Fig. 5. Machines that use a sine curve type backer have fewer rolls than a standard swager.

Swaging with squeeze action is used to obtain greater reduction in area than that normally produced by impact action. It is also used to produce intricate profiles on internal surfaces with the aid of a mandrel.

Compared to impact forming with standard swagers, squeeze forming produces less noise and vibration, requires less maintenance of rolls and backers, and can produce greater reduction and closer tolerances. Standard rotary swagers, however, are simpler to operate and lower in cost, require less floor space, and are faster for small reductions.

Rolls and backers used for cold swaging are made from tool steel. The grade of tool steel used varies considerably, although many rolls and backers are made from one of the shock- or wear-resistant grades (depending on application) hardened and tempered to 55 to 58 HRC.

Almost all rolls and backers become work hardened. The degree of work hardening depends on the severity of reduction of the swaged workpiece, the swageability of the work metal, the material used for the rolls and backers, total operating time, and adjustment of the machine. Rolls, backers, and dies used in cold swaging are stress relieved periodically at 175 to 230 °C (350 to 450 °F) for 2 to 3 h in order to reduce the effects of work hardening and to prolong service life. The stress-relieving temperature used must not be higher than the original tempering temperature, or softening will result. The frequency of stress relieving depends on the severity of swaging. Under normal conditions, steel rolls and backers should be stress relieved after every 30 h of operation. Further improvements in tooling life and overall process costs are achieved by using replaceable inserts in the working area of the backers as shown in Fig. 5(d). These inserts can be carbide, and they have contoured forms that improve tool life and precision and reduce noise during swaging.

Stress relieving is usually not required for rolls and backers used for hot swaging, because some stress relief occurs each time heat transfers from the hot workpiece to the rolls and backers. These components are also less susceptible to work hardening than rolls and backers in cold swaging, because less force is required to form the part by hot swaging.

The rolls and roll rack of a four-die machine are subject to about $1\frac{1}{2}$ times as much wear as those in a two-die machine; therefore, they must be replaced more often. Other components, such as the spindle and cap, liner plates, backers, and dies, have about the same rate of wear in both types of machines; however, replacement cost of these components is lower for a two-die machine.

The number of rolls in a four-die machine must be divisible by four, so that they can be placed at 90° spacing. Therefore, a ten-roll machine is limited to using two dies.

Number of Dies. Most swagers have either two or four dies, although three-die machines are available. Most swaging is done in two-die machines, because they are less costly to build and simpler to set up and maintain.

Four-die swaging machines have some advantages. Slightly greater reductions can be made more readily, and cold working of the dies is reduced, because less ovality or side clearance is required than for two dies. Four-die machines are especially useful for swaging workpieces from a round to a square cross section. Four dies are generally not used for workpieces less than 4.8 mm ($\frac{3}{16}$ in.) across (in either round or square section).

A stationary-spindle usually has twelve rolls, and three, four, or six dies can be used. To change the number of dies in a swager, the spindle generally must be changed, because the slots in the spindle accommodate only the number of dies used. Three-die units are typically used to form triangular sections; four-die units, rectangles, squares, and rounds; and six-die units, hexagonal shapes.

Machine Capacity. The rated capacity of a swaging machine is based on the swaging of solid work metal of designated tensile strength and is expressed as the diameter--or the average diameter of a taper--to which the machine can swage a workpiece made from that material. Machine capacity is significantly influenced by the strength of the head. The load on the head is approximately equal to the projected area of the workpiece under compression multiplied by the tensile strength of the work metal.

For example, if the strength of the head limits the safe working load of a two-die machine to 51,000 kg (112 500 lb), the rated capacity (specific diameter) of the machine for a 75 mm (3 in.) long die in swaging solid work metal of 414 MPa (60 ksi) tensile strength can be calculated using:

$$\text{Load} = \text{specific diameter} \cdot \text{die length} \cdot \text{tensile strength}$$

Therefore:

$$\text{Specific diameter} = \frac{\text{Load}}{\text{die length} \cdot \text{tensile strength}}$$

where load is in kilograms (pounds), specific diameter is in millimeters (inches), die length is in millimeters (inches), and tensile strength is in megapascals (pounds per square inch). Therefore, for the process parameters outlined above, and using SI units:

$$\text{Specific diameter} = \frac{51\ 000}{75 \cdot 414} = 16 \text{ mm}$$

Using English units:

$$\text{Specific diameter} = \frac{112\ 500}{3 \cdot 60\ 000} = \tfrac{5}{8} \text{ in.}$$

For work metal of a higher or lower tensile strength, the capacity or specific diameter would be proportionately lower or higher, in accordance with the above formula. For a greater die length, the machine capacity would be lower. To swage parts to a larger final average diameter in this two-die machine, it would be necessary to decrease the working length of the die proportionately and therefore to decrease the area of work metal under compression.

For the swaging of a tube, the capacity of the machine is limited by the cross section of the die, by the compressive strength of the tube, and sometimes by the size of hole through the spindle of the machine. The swaging of tubes with a wall thickness greater than 1 mm (0.040 in.) over a mandrel is considered the same as the swaging of solid bar stock. Tubes with thinner walls require greater force, depending on tube diameter and length of die, because friction traps the metal between the die and mandrel, and there is no bulk metal to move.

Machines with dies that produce a squeezing action are rated according to their radial load capacity. The capacity is usually limited by the stress at the line of contact between the roller and backer. For a reasonable component life, this stress should not exceed about 1170 MPa (170 ksi). Assuming this stress as maximum when rollers and backers are made of steel, the radial load capacity is determined by:

$$L = 0.002\ Nl \left(\frac{D_r D_b}{D_r + D_b} \right)$$

where L is radial load capacity in megagrams, N is the number of backers, l is effective roller length in millimeters, D_r is the diameter of each roller (in millimeters), and D_b is the diameter (in millimeters) of the backer crown contacting the rollers. The coefficient 0.002 converts the Hertz stress formula to megagrams of force based on a value of 1170 MPa for maximum stress. When English units are used, the coefficient is 1.38 based on a maximum stress value of 170 ksi. Radial load capacity would be calculated in tons, and all linear measures would be in inches.

For example, a four-die machine having 100 mm (4 in.) diam rolls with an effective roller length of 250 mm (10 in.) and a 915 mm (36 in.) diam backer crown would have a radial load capacity of 180 Mg (199 tons), determined as follows:

$$L = 0.002 \cdot 4 \cdot 250 \left(\frac{100 \cdot 915}{100 + 915} \right) = 180 \text{ Mg}$$

$$L = 1.38 \cdot 4 \cdot 10 \left(\frac{4 \cdot 36}{4 + 36} \right) = 199 \text{ tons}$$

Rotary Swaging of Bars and Tubes

Revised by the ASM Committee on Rotary Swaging*

Swaging Dies

Resistance to shock and wear are the primary requirements for cold swaging dies. It is sometimes necessary to sacrifice some wear resistance in order to prevent die breakage due to lack of shock resistance. Numerous materials have been used for swaging dies. Typical tool steels for cold swaging include A8, D2, S3, S7, and M2 at hardnesses ranging from 55 to 62 HRC. M2 and H13 are frequently used for hot swaging. Shock-resistant grades of carbide are used for high-production applications. However, the greater density of carbide may lead to increased backer and roll wear.

Types of Dies. Depending on the shape, size, and material of the workpiece, dies range from the simple, single-taper, straight-reduction type to those of special design. Figure 6 illustrates nine typical die shapes. Specific applications for each are outlined below.

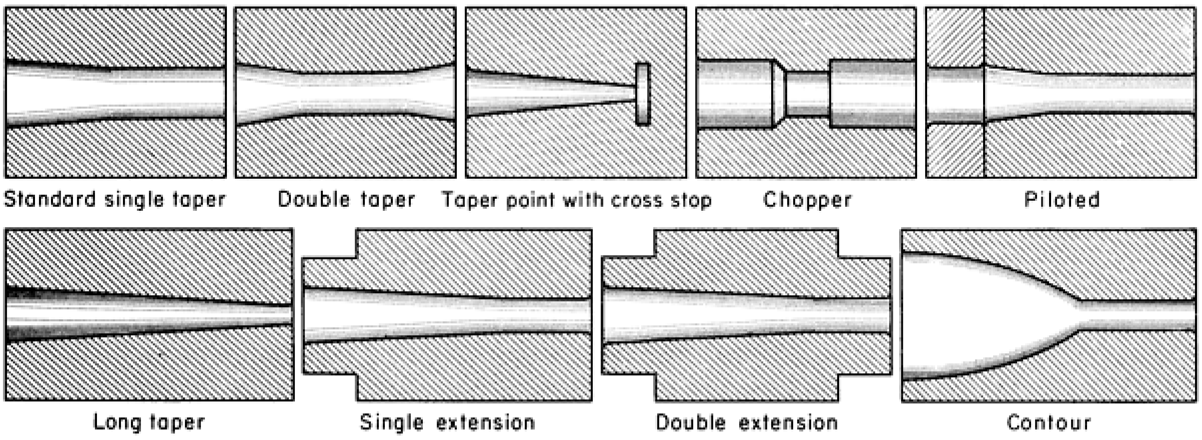

Fig. 6 Typical die shapes used in rotary swaging. See text for discussion.

Standard single-taper dies are the basic swaging dies designed for straight reduction in diameter. One common use is to tag bars for drawbench operations.

Double-taper dies are designed for plain reductions, such as those made in the standard single-taper die described above. A double-taper die can be reversed to obtain twice the life of a single-taper die.

Taper-point dies are used for finish forming a point on the end of the workpiece or for forming a point prior to a drawbench operation. The built-in cross stop ensures equal length of all swaged points.

Chopper dies are fabricated from heat-resistant alloys. These dies are used exclusively for hot swaging.

Piloted dies ensure concentricity between the unswaged section and the reduced section of the workpiece. The front part of the die acts as a guide; reduction occurs only in the taper section.

Long-taper dies are designed with a taper over their entire length. However, the length of the taper produced on the work will be slightly less than that of the die.

Single-extension dies are used for high reduction of solid bars and tubing of low tensile strength. This die produces a longer tapered section than a standard die.

Double-extension dies are extended at both ends to facilitate the swaging of thick-wall tubing and to provide a longer taper section.

Contour dies are used to produce special shapes on tubes and bars.

Die Clearance. Virtually all swaging dies require clearance in the form of relief or ovality in the die cavity. Without clearance, the flow of metal is restricted, and this results in the workpiece sticking to the die.

Ovality in Two-Piece Dies. Dies are oval in both the taper and blade sections. This ovality and side relief provide the necessary clearance for the die to function. Ovality is useful for applications in order to maximize work hardening. The disadvantages of using ovality to obtain clearance are:

- Close tolerances are difficult to maintain
- Dies wear rapidly
- Surface finish on the workpiece is inferior to that produced with dies having side clearance

Ovality in two-piece dies is produced by placing shims between the finished die faces and boring or reaming the assembly to the desired clearance. Smoothly blending the two contours gives an approximately oval shape to the reassembled die. An alternative procedure for producing ovality is to bore the two die blocks oversize and then to grind the die faces until the groove in each half is of the proper depth to produce the desired swaged diameter.

The amount of ovality required varies with the characteristics and size of the work metal to be swaged. Table 2 lists nominal values for determining the amounts of ovality for swaging solid material from 0.8 to 19 mm ($\frac{1}{32}$ to $\frac{3}{4}$ in.) in diameter and tubing covering a range of outside diameters. The following sample calculation shows how Table 2 is used to determine the die ovality required for swaging 12.7 mm (0.5 in.) diam 1020 steel bar to a diameter of 9.5 mm (0.375 in.) using a die with a taper of 8° included angle. From Table 2, the ovality for the die taper for swaging low-carbon steel is 0.025 mm (0.001 in.) per degree of taper plus 0.5% of the maximum diameter of the bar before swaging. Therefore:

$$\begin{aligned} \text{Ovality}_{\text{taper}} &= (0.025 \cdot 8) + (0.005 \cdot 12.7) \\ &= 0.2 + 0.064 \\ &= 0.264 \text{ mm} \end{aligned}$$

Using English units:

$$\begin{aligned} \text{Ovality}_{\text{taper}} &= (0.001 \cdot 8) + (0.005 \cdot 0.5) \\ &= 0.008 + 0.0025 \\ &= 0.0105 \text{ in.} \end{aligned}$$

According to Table 2, ovality of the blade section of the die is 0.075 to 0.1 mm (0.003 to 0.004 in.) less than the ovality of the taper section. Therefore:

$$\text{Ovality}_{\text{blade}} = 0.264 - 0.075 = 0.19 \text{ mm}$$

Using English units:

$$\text{Ovality}_{\text{blade}} = 0.0105 - 0.003 = 0.0075 \text{ in.}$$

Table 2 Nominal values for computing ovality and corner radius on groove of dies for swaging of bars and tubing

Work metal	Percentage of shimming recommended for die diameter of:				
	19-6.4 mm ($\frac{3}{4}$ - $\frac{1}{4}$ in.)	**4.8 mm ($\frac{3}{16}$ in.)**	**3.2 mm ($\frac{1}{8}$ in.)**	**1.6 mm ($\frac{1}{16}$ in.)**	0.8 mm ($\frac{1}{32}$ in.)
Dies for swaging of bars					
Low-carbon steels; hard brass; copper	For die taper: 0.025 mm (0.001 in.) per degree plus 0.5% of max work diameter. For die blade: above value less 0.075-0.1 mm (0.003-0.004 in.)	2[(a)]	3[(a)]	4[(a)]	[(b)]
High-carbon and alloy steels	125% of value for low-carbon steels	2[(a)]	3[(a)]	4[(a)]	[(b)]
Lead	No shimming required	. . .	. . .	. . .	. . .

Dies for swaging of tubing
When OD equals a minimum of 25 times wall thickness, use no shimming.
When OD equals 10 to 24 times wall thickness, use 60% of values for bars (see above).
When OD equals 9 times wall thickness or less, use same values as for bars (see above).
Corner radius on die grooves
For solid work metal, $\frac{1}{16}$ of blade diameter to nearest 0.13 mm (0.005 in.)
For tubing, corner radius should be equal to wall thickness.

(a) Percent of average diameter of work.

(b) Stone edges of die groove

These calculated values determine the thickness of shims that must be used between the die faces during machining of the cavity to produce a die of proper ovality for swaging 1020 steel bars. These values also apply when the alternative method of producing ovality is used.

In addition to ovality, die halves should be provided with corner radius at the exit end of the blade section as well as at the die entrance. Table 2 indicates that the corner radius on the groove should be $\frac{1}{16}$ of the blade diameter to the nearest 0.13 mm (0.005 in.) for swaging solid sections, or equal to wall thickness for the swaging of a tube. Therefore, the die for swaging the 12.7 mm (0.5 in.) diam 1020 steel bar referred to in the sample calculation above would require a corner radius of about 0.64 mm (0.025 in.).

The included angle for the taper section of oval dies should be no more than 30°. An included angle of 8° or less is preferred.

Two-Piece Dies With Side Clearance. Workpieces swaged in 240° contact dies have better surface finish and closer tolerance. The service lives of these dies are longer, and the work metal is cold worked less rapidly than in oval dies. Dies with 240° contact can be used for straight reductions of solid bars or thick-wall tubing.

Figure 7 shows the design of 240° contact dies with die clearance. The dies are first bored or ground without shims to produce the area of work contact. Shims are then inserted to produce side clearance only. Side clearance is then bored or ground until dimension *E* (measured diagonally across the mouth of the die) = $\sqrt{d^2+ds+s^2}$, where *d* is the initial diameter of the taper at the entrance to the die, and *s* is the thickness of the shim stock placed between the die faces. The maximum thickness of the shim should be one-tenth the swaged diameter of the workpiece. This will produce a total contact of 240° along the taper and blade sections. The intersection between the taper and blade must be well blended for best results in feeding and finishing.

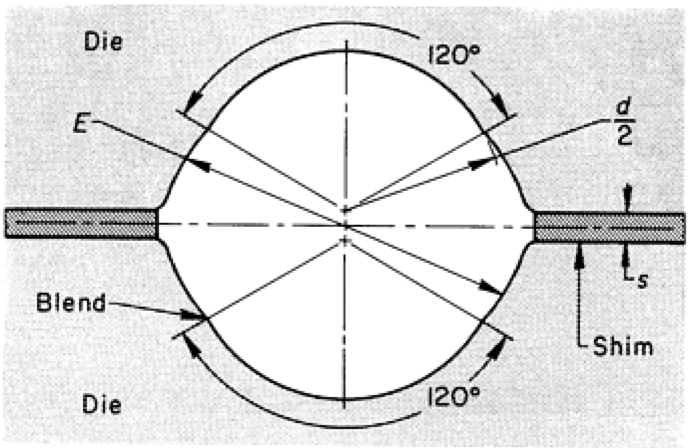

Fig. 7 Design of die with side clearance. See text for discussion.

When swaging tubing, the shim thickness varies with the ratio of outside diameter to wall thickness (D/t ratio) so that the side clearance is nearly zero for thin-wall (D/t = 30 or more) tubing.

The same procedure is followed in determining the side clearance for the blade. The diameter of the swaged workpiece is used instead of the large diameter of the taper. The same shim is used for both taper and blade.

Ovality in Four-Piece Dies. Each piece of a four-piece die makes approximately 90° contact with the surface of the workpiece when the die is not provided with ovality or side clearance. Dies without ovality are used for sizing thin-wall tubes (D/t = 30 or more). For swaging solid sections or thick-wall tubing or for mandrel swaging, oval dies are required; ovality influences circumferential flow of the work metal and reduces the load on the machine.

Oval dies are produced by various methods. A common method involves grinding the dies, which are held by a fixture mounted on the rotating face plate of an internal grinder. The taper is produced by pivoting the grinding wheel slide to the appropriate angle and traversing the surface.

Rotary Swaging of Bars and Tubes

Revised by the ASM Committee on Rotary Swaging*

Auxiliary Tools

Swaging machines may require auxiliary tools for guiding and feeding the workpiece into the die, holding it during swaging, and ejecting it. These tools range from simple hand tools to elaborate power-driven mechanisms. Some of the common types of auxiliary tools are illustrated in Fig. 8, 9, and 10; their uses are described below.

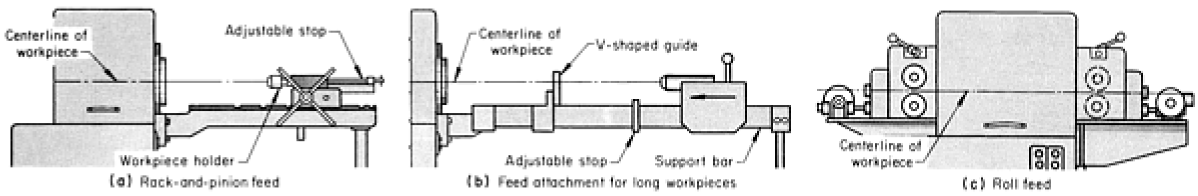

Fig. 8 Three types of mechanisms for feeding the workpiece in rotary swaging. See text for discussion.

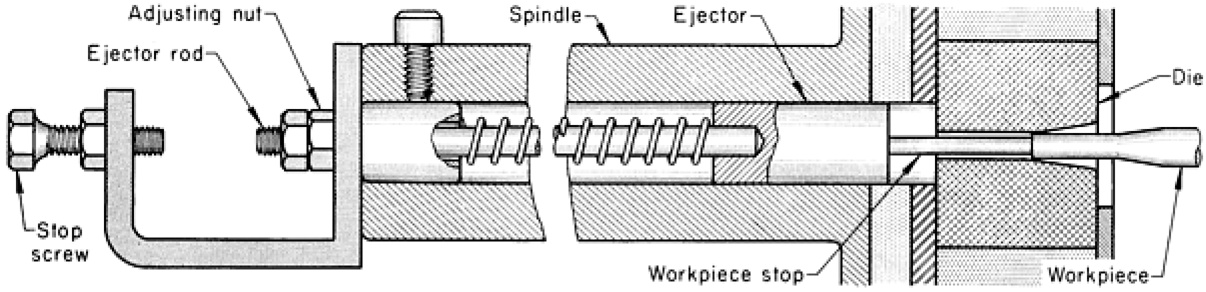

Fig. 9 Principal components of a spring ejector mechanism with an adjustable rear stop.

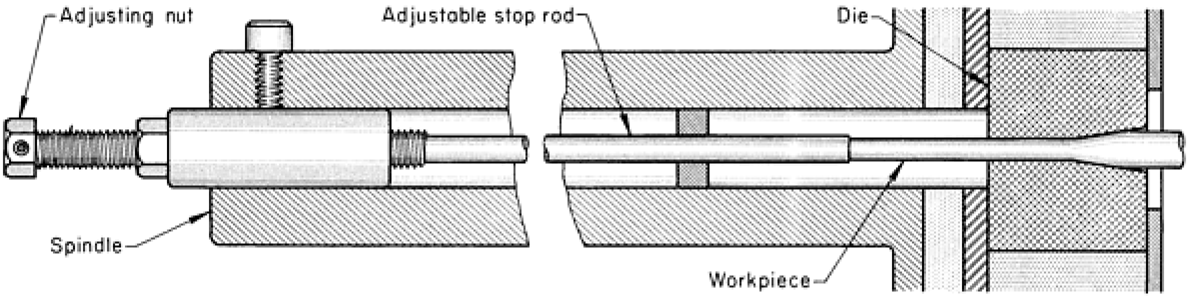

Fig. 10 Principal components of an adjustable stop-rod mechanism.

Rack-and-pinion mechanisms (Fig. 8a) are designed for manual operation and provide more force for feeding the workpiece than can be obtained by hand feeding. Operator fatigue is reduced with these mechanisms, and the workpiece is guided straight along the centerline of the machine.

Feed attachments for long workpieces (Fig. 8b) consist of a carriage with antifriction rollers mounted on a fixed bar that extends from a bracket on the entrance side of the machine for the length of the longest workpiece to be swaged. The outer end of the bar is aligned by leveling screws in the base of a triangular support. The carriage provides a means of attaching plain or antifriction workpiece holders and adapters, as well as a handle for manual feeding toward the swager. An adjustable stop is provided on the support bar to control the length of the swaged section and to reproduce accurate tapers.

Roll-feed mechanisms (Fig. 8c) have rolls at the entrance and at the exit end of the swager. The rolls at the entrance feed the workpiece, and the rolls at the rear pull the workpiece from the machine. Roll-feed mechanisms are used for continuous swaging. Rolls can be made from either metal or a nonmetallic material (such as rubber). Some roll-feed mechanisms have four soft rubber rolls at the entrance to the swager and no rolls at the rear. This arrangement is ideal for swaging small-diameter bars whose surface finish is critical, because it prevents marking of the swaged surfaces when the bars are pulled from the rear of the machine.

V-shape work guides (Fig. 8b) are used to support and center the ends of long tubes or bars as they enter the dies. This type of guide is mounted on the front of the machine and can be adjusted vertically to accommodate a range of workpiece diameters up to the capacity of the machine.

Spring ejectors are required for the removal of short workpieces when size prevents manual withdrawal from the dies or when workpieces are swaged over their entire length and cannot be passed through the spindle to the exit end. Figure 9 shows the principal components of a spring ejector mounted on the rear of a swaging machine spindle. As the workpiece enters the die against the workpiece stop, the ejector rod is forced backward until it contacts the preset stop screw. As soon as the swaging cycle is completed, the spring-loaded ejector forces the workpiece from the front of the machine.

Spring ejectors reduce operator fatigue and shorten the swaging cycle in many applications. A similar mechanism can be used on large machines with power feed. The ejector maintains contact with the workpiece stop on the return stroke, thus supporting the workpiece until it is free from the dies.

Stop rods (Fig. 10) are often used to improve uniformity of swaged pieces in production runs. These rods can be adjusted and locked so that subsequent workpieces will have swaged sections of equal length. The swaged length can be held within 0.025 mm (0.001 in.), depending on the speed and on the feed pressure.

Rotary Swaging of Bars and Tubes

Revised by the ASM Committee on Rotary Swaging*

Automated Swaging Machines

Work-holding fixtures were originally designed for manual operation. These fixtures include a variety of grippers that facilitate workpiece alignment parallel to the feed direction, provide constrained rotation to prevent finning or flashing between the dies, and have capabilities for feed-stroke control. Work holders have been designed for use on a variety of workpiece sizes.

The feed, stop, and ejector mechanisms shown in Fig. 8, 9, and 10, as well as a variety of manual work-holding fixtures, have formed the basis for contemporary automated systems. The range of equipment available includes single-station machines (Fig. 11), which form parts automatically in one or more setups, and multistation transfer machines (Fig. 12) that use different types of swaging heads to perform multiple operations in a single setup.

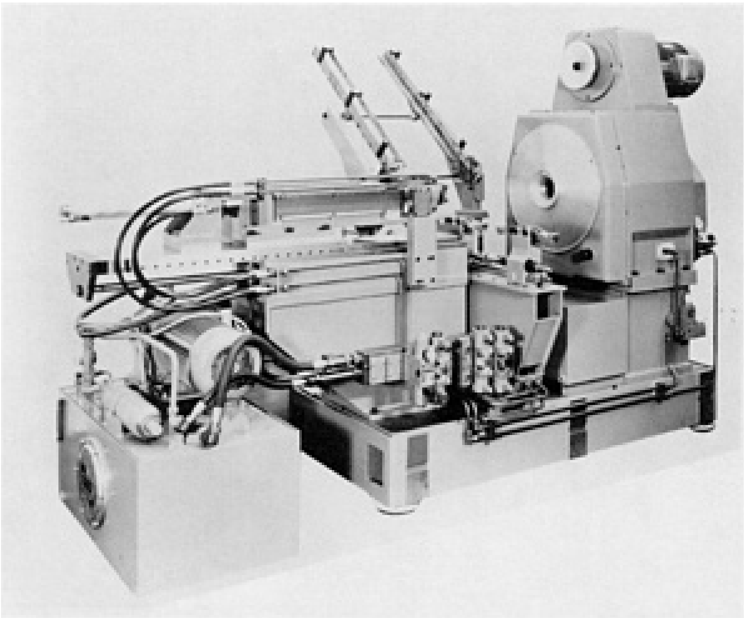

Fig. 11 Automated die-closing swaging machine with a gravity parts feeder, hydraulically operated feeding unit, and part transfer system.

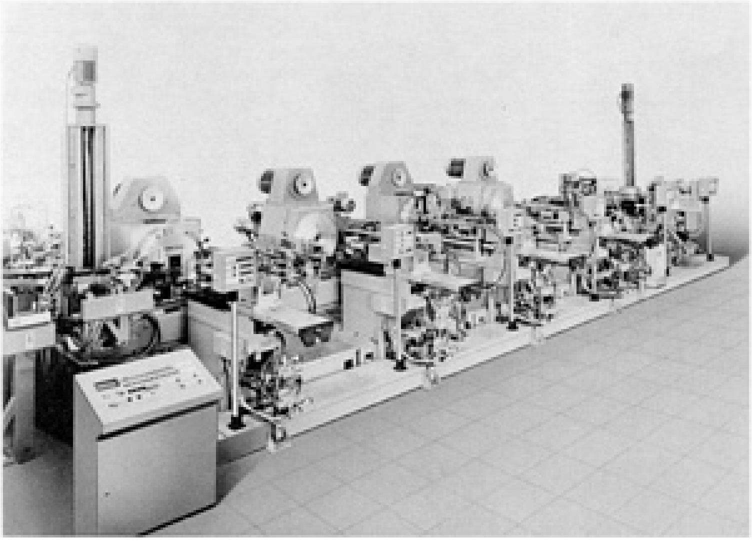

Fig. 12 Multistation automatic swaging transfer machine combining forming and machining operations.

The automatic machines are assembled using a modular concept, and the number of stations can be varied to suit a particular application. Programmable control allows different stations to be actuated, bypassed, or exchanged to process a family of parts on one system.

Secondary operations, such as drilling, turning, reaming, splining, thread rolling, or marking, can also be incorporated into the manufacturing process. Such a sequence of operations is illustrated in Fig. 13 for a torch nozzle.

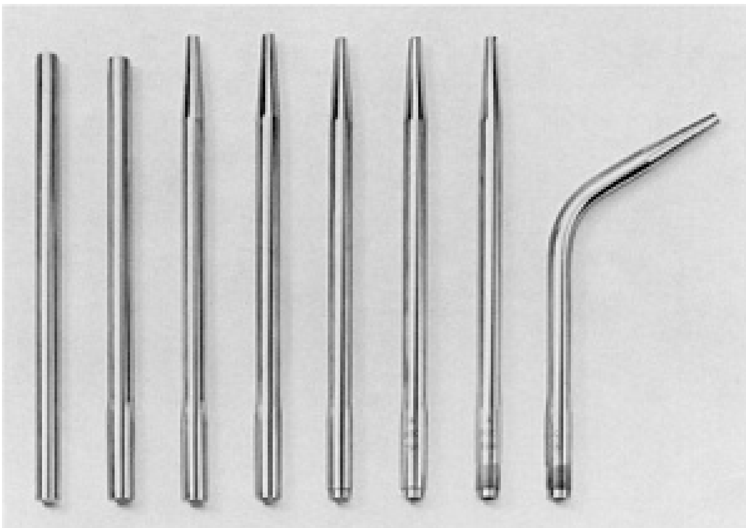

Fig. 13 Torch nozzle produced using a sequence of operations on a multistation transfer machine similar to that shown in Fig. 12.

The material for automatic operation can be supplied either from different types of magazines (such as vibratory feeders, conveyors, and gravity chutes) or directly from coiled stock. This allows the machines to operate unattended for long periods of time, resulting in machine efficiencies of 90% or more. The stroke and speed of each feeding unit can be set according to tolerance and surface finish requirements.

This closely controlled process of automatic swaging provides highly repeatable results and consistent part quality. Automatic operation allows one operator to operate several machines.

Tube Swaging Without a Mandrel

Tubes are usually swaged without a mandrel to attain one or more of the following:

- A reduction in inside and outside diameters or an increase in wall thickness
- The production of a taper
- The conditioning of weld beads for subsequent tube drawing
- Increased strength
- Close tolerances
- A laminated tube produced from two or more tubes

The usual limit on the diameter of tubes that can be swaged without a mandrel is 30 times the wall thickness. Tubes with an outside diameter as large as 70 times their wall thickness can be swaged, but under these conditions, the included angle of reduction must be less than 6°, and the feed rate must be less than 380 mm/min (15 in./min). Under any conditions, the tube must have sufficient column strength to permit feeding. Squareness of the cut ends, roundness, and freedom from surface defects also become more critical as the ratio of outside diameter to wall thickness increases.

Types of Tubes for Swaging. Seamless and welded tubing can be swaged without a mandrel. Seamless tubing is available in greater wall thicknesses in proportion to diameter than welded tubing. However, seamless tubing is the more expensive and may have an irregular and eccentric inside diameter, which will result in excessive variation in wall thickness of the swaged product. When purchasing seamless tubing, it is possible to specify two of the three dimensions: outside diameter, inside diameter, and wall thickness. Therefore, the disadvantage of varying dimensions can be partly overcome by specifying the two dimensions that must be controlled for an acceptable product.

Welded tubing usually has a more uniform wall thickness than seamless tubing and therefore has an inside diameter that is more nearly concentric with the outside diameter. The swaging of certain types of welded tubing (for example, as-welded and flash rolled) can result in bending, because the metal in the weld area flows less readily than the remainder of the tube material. If the weld is defective or if the metal in the weld area is harder than the remainder of the tube, splitting will occur during swaging. Welded tubing must be held in the centerline of the feed direction during swaging to produce a straight product.

Die Taper Angle. In best practice when swaging low-carbon steel, the included angle of die taper should not exceed 8° when using manual feed. For thin-wall tubing of low-carbon steel or for more ductile tubing, such as annealed copper, the included angle may be as great as 15°, provided both pressure and feed are decreased proportionately. When the angle of taper exceeds 15°, mechanical or hydraulic feed should be used.

Reduction per Pass. Multiple passes are necessary to swage tubing in dies with a taper exceeding 30°. Steep taper angles generate excessive heat and feedback and radial pressures. This condition may result in metal pickup by the dies and is more pronounced when swaging aluminum tubing.

Effect of Reduction on Tube Length. In swaging tubes without a mandrel, wall thickening is usually more significant than increase of length. Lengthening of about 5 to 15% can be expected for typical swaging operations on low-carbon steel, copper, aluminum, or other readily swageable metal tubes with outside diameters of 15 to 25 times wall thickness. Lengthening increases as the amount of reduction per pass increases. Because of the uncertainty about the relative amounts of radial and axial movement of metal, percentage reduction is frequently designated in terms of diameter reduction, rather than area reduction. When the tube is reduced to the extent that it approaches a solid, the endwise flow of metal increases. When total reduction in area is greater than 65 to 75% (depending on the ratio of outside diameter to wall thickness), the tube should be considered a solid, and swaging dies should be designed accordingly.

Effect of Reduction on Wall Thickness. Swaging of tubing without a mandrel results in an increase in wall thickness. The increase in wall thickness is greater for larger reductions in outside diameter. Increased ductility of the tube material promotes wall thickening.

The wall thickness that will be produced by swaging a tube without using a mandrel can be calculated to about ±10% from the empirical relation:

$$t_2 = \frac{D_1 t_1}{D_2}$$

where D_1 is outside diameter before swaging, D_2 is outside diameter after swaging, t_1 is wall thickness before swaging, and t_2 is wall thickness after swaging.

Swaging of Long Tapers. The method used for swaging long tapers depends on work metal hardness, outside diameter, wall thickness, and overall length, because these variables determine required machine size, die design, and type of feed mechanism.

Welded tubing sometimes causes difficulty in swaging long tapers because of variations in hardness between the welded seam and the remainder of the tube. Postweld heat treatment is recommended when swaging long tapers from welded tubing.

Almost any reasonable length of taper can be swaged on any length of tube that has a diameter within the capacity of the machine. Long tapers usually require multiple operations.

Table 3 compares the lengths of taper that can be formed in a single operation and in multiple operations on tubes with an outside diameter of 57 mm ($2\frac{1}{4}$ in.) or less, using standard-length and extended-length dies. Standard-length dies refer to manufacturers' catalog sizes; extended lengths are greater than those shown as standard. The longest taper formed in a single operation is fairly close to the length of the die. However, when dies of the same length are used in multiple operations, a smaller portion of the usable length is used for forming the taper, because of the allowance required for blending subsequent passes.

Table 3 Tapers swageable on 57 mm ($2\frac{1}{4}$ in.) maximum OD tubes in single and multiple operations

Die length, mm (in.)	Length of taper swaged, mm (in.)				
	Single operation	Multiple operations			
		First operation	**Intermediate operations**	Final operation
114 ($4\frac{1}{2}$)	105 ($4\frac{1}{8}$)	79 ($3\frac{1}{8}$)	63.5 ($2\frac{1}{2}$)	**89 ($3\frac{1}{2}$)**
162 ($6\frac{3}{8}$)	152 (6)	127 (5)	111 ($4\frac{3}{8}$)	**136.5 ($5\frac{3}{8}$)**
213 ($8\frac{3}{8}$)	203 (8)	178 (7)	162 ($6\frac{3}{8}$)	**187 ($7\frac{3}{8}$)**
380 (15)	375 ($14\frac{3}{4}$)	. . .	. . .	**. . .**

455 (18)	451 (17 $\frac{3}{4}$)	. . .	. . .	. . .
610 (24)	584 (23)	. . .	. . .	. . .
Extended die lengths (standard plus 38 mm, or 1 $\frac{1}{2}$ in.)				
152 (6)	143 (5 $\frac{5}{8}$)	117 (4 $\frac{5}{8}$)	102 (4)	**127 (5)**
200 (7 $\frac{7}{8}$)	190 (7 $\frac{1}{2}$)	165 (6 $\frac{1}{2}$)	149 (5 $\frac{7}{8}$)	**175 (6 $\frac{7}{8}$)**
250 (9 $\frac{7}{8}$)	**241 (9 $\frac{1}{2}$)**	**216 (8 $\frac{1}{2}$)**	**200 (7 $\frac{7}{8}$)**	**225 (8 $\frac{7}{8}$)**

The number of operations needed to produce a specified taper, in addition to the length of taper and length of dies used, is influenced by the following:

- Minimum length of die entrance is 9.5 mm ($\frac{3}{8}$ in.)
- Each succeeding taper must overlap the preceding taper by 25 mm (1 in.) to permit blending
- All operations except the last must allow a straight section (blade), with a minimum length of 25 mm (1 in.) on the tube in addition to the taper being swaged

Example 1: Forming a 760-mm (30-in.) long Taper in Four Operations.

Figure 14 shows the sequence of operations for swaging a 32 mm (1 $\frac{1}{4}$ in.) OD low-carbon steel tube to 12.7 mm ($\frac{1}{2}$ in.) in diameter over a taper length of 760 mm (30 in.). Extended dies 250 mm (9 $\frac{7}{8}$ in.) long were used for the first three operations, and a standard die 210 mm (8 $\frac{3}{8}$ in.) long was used for the final operation. An allowance of 9.5 mm ($\frac{3}{8}$ in.) was made for die entrance, a 25 mm (1 in.) overlap was used for each succeeding taper, and each operation except the last allowed a blade section to remain. The same machine was used for all four operations.

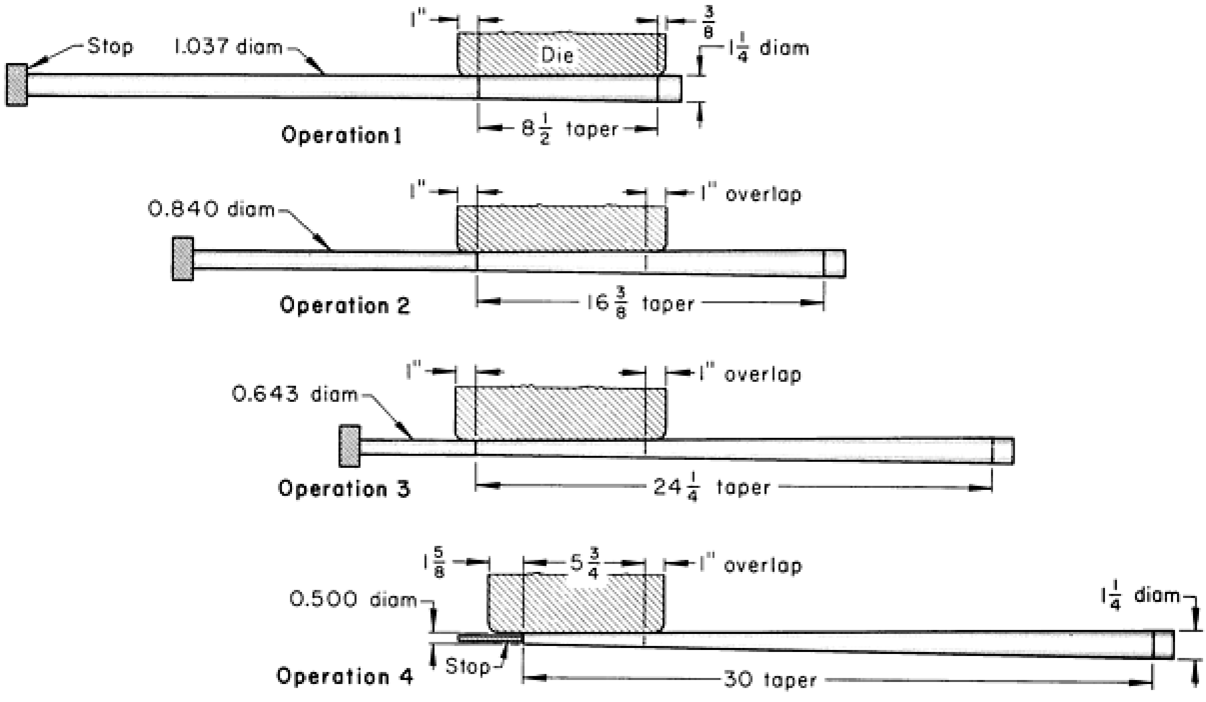

Fig. 14 Sequence of operations for swaging a taper on a long tube. Extended dies are used in the first three operations; the final operation uses standard-length dies. Dimensions given in inches.

In each operation, the tube was fed through the die to a stop, reducing the tube in each operation to the diameters shown in Fig. 14. Each feed length was controlled by a stop so that the newly formed taper blended with the preceding one.

Figure 15 shows how a taper 760 mm (30 in.) long can be formed in two operations by dies 455 mm (18 in.) long. The rate of feed for swaging long tapers is usually 25 mm/s (1 in./s), withdrawal time is 100 mm/s (4 in./s), and handling time requires about 4 s per operation.

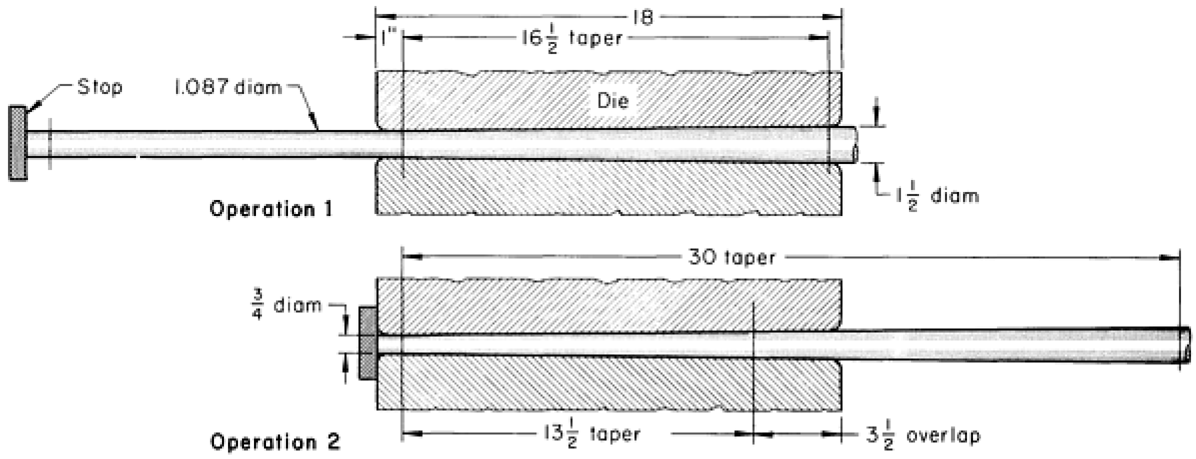

Fig. 15 Swaging a 760 mm (30 in.) long taper in two operations using dies 455 mm (18 in.) long. Dimensions given in inches.

An accurate feeding attachment is necessary to swage long tapers. The attachment must feed the tube to the proper length for each operation to produce a uniform taper. This is accomplished by registering the infeed position of the tube from the butt end by means of stops on the attachment (Fig. 14).

Manually operated feed attachments are generally used for producing tapers longer than 405 mm (16 in.). Either hydraulic or air-actuated feed attachments are more convenient for tapers up to 405 mm (16 in.) in length.

Cost is the deciding factor between using standard or extended dies for swaging a given taper. Cost also usually determines the number of operations to be used. However, when tapers exceed 510 mm (20 in.) in length, there is no alternative but to use multiple operations, because few swaging machines can hold dies longer than 405 mm (20 in.).

Any swaging machine can handle extended dies that are longer than standard for the machine size (see Example 1). A given machine can also accommodate shorter dies when die box fillers are used. Therefore, each machine has considerable flexibility in terms of the length of dies it can handle.

Extended dies cost more than standard dies (usually about one-third more). Therefore, it must be decided if it would be more economical to pay the higher cost for extended dies and use fewer operations, thus increasing productivity, or to use less expensive dies and accept lower productivity. Similar consideration must be given to the use of a larger machine that will accommodate a longer standard die.

Rotary Swaging of Bars and Tubes

Revised by the ASM Committee on Rotary Swaging*

Tube Swaging With a Mandrel

For some applications, it is necessary to reduce the wall thickness of tubing by swaging over a mandrel. A mandrel is used to maintain the inside diameter of a tube during the swaging of its outside diameter, to support thin-wall tubes during reduction in diameter, and to form internal shapes. When extended through the front of the dies, a mandrel can also serve as a pilot to support one of the tubes that are to be joined by swaging.

Mandrels are made from shock-resistant tool steel and high-speed steels. They are hardened, ground and polished, and sometimes plated with about 5 μm (0.2 mils) of chromium to improve wear resistance and surface finish on the inside diameter of the tube. A combination of hardness and toughness is needed for the larger mandrels. Tungsten carbide mandrels are used for superior wear resistance when production volume justifies their increased cost. Mandrels are commonly produced from S group tool steels hardened to 59 to 61 HRC or from A2 or W1 tool steel hardened to 60 to 62 HRC and ground to a finish of 0.06 to 0.075 μm (2.5 to 3 μin.).

Types of Mandrels. The types of mandrels most often used are illustrated in Fig. 16 and are described in the following sections.

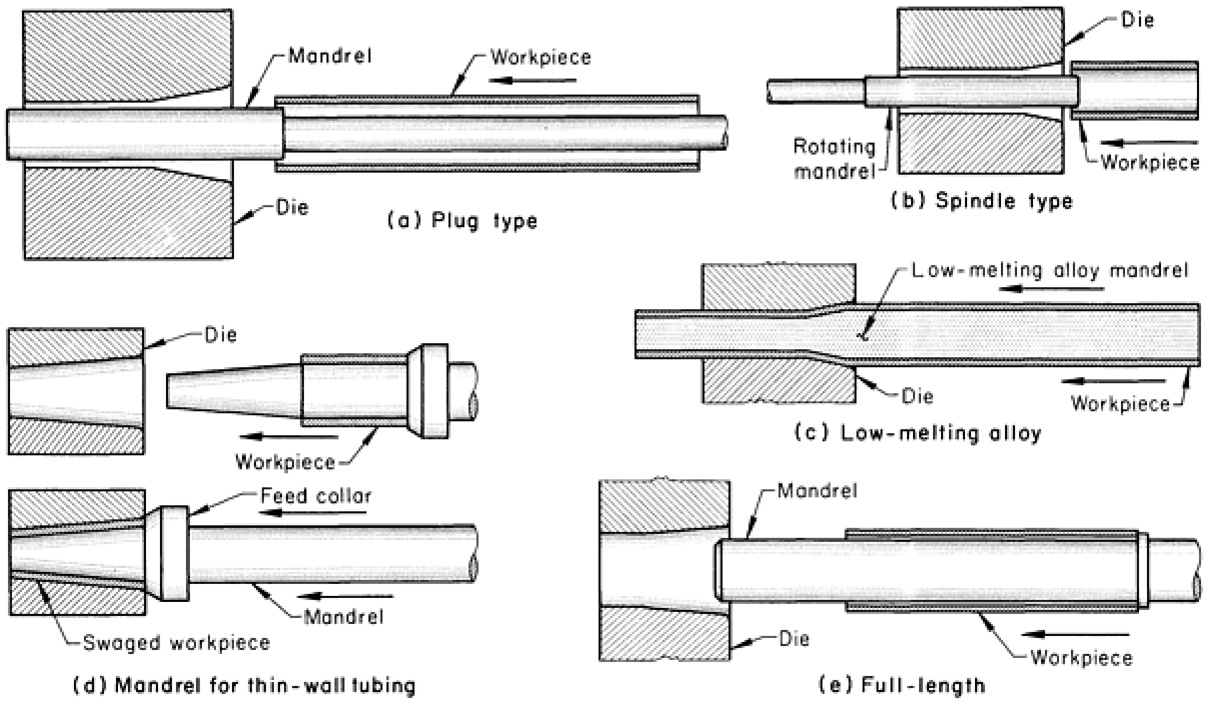

Fig. 16 Five types of mandrels most often used in the rotary swaging of tubes.

Plug-type mandrels (Fig. 16a) are fastened to a mandrel rod that is substantially smaller in diameter than the inside diameter of the tube to be swaged. The mandrel is usually about the same length as the swaging die. The mandrel is placed in the die in a fixed position, and the tube is fed over the mandrel into the swager. The mandrel and mandrel rod are removable to permit loading of the tube.

Spindle-type mandrels (Fig. 16b) are mounted on a rotating mandrel holder that permits the workpiece and mandrel to rotate independently of the machine spindle. The tube is fed into the die while the mandrel is fixed.

Low-melting alloys (Fig. 16c) are sometimes used to support thin-wall tubing during swaging. After swaging, the supporting metal is melted out.

Mandrels for thin-wall tubing (Fig. 16d) are mounted in fixed holders in front of the dies. The mandrel slides back to permit loading of the tube onto the mandrel, after which it slides forward into the die. The feed collar on the mandrel then feeds the tube into the die. Sufficient clearance between the die and mandrel is maintained to permit feeding of the workpiece into the die.

Full-length mandrels (Fig. 16e) are hardened and ground steel bars made slightly longer than the finished length of the swaged tube. The mandrel is inserted into the tube, and both are passed through the machine.

Machine Capacity. Mandrels alter the machine capacity requirement for swaging. When a mandrel is used, the workpiece must be considered a solid bar, and the selection of swaging machine should be based on its capacity to reduce solid work metal. For example, a machine with a capacity sufficient for swaging a 16 mm ($\frac{5}{8}$ in.) diam solid bar is satisfactory for swaging a 25 mm (1 in.) diam tube with a 6.4 mm ($\frac{1}{4}$ in.) wall thickness without a mandrel. However, when a mandrel must be used in the 25 mm (1 in.) tube, a machine capable of swaging a solid bar of the same diameter must be used.

Dies for mandrel swaging must have more ovality than those used for swaging tubing without a mandrel or for swaging a solid bar. Dies that have a nearly round cavity will swage a tube on a mandrel so closely that removing the mandrel is difficult. Ovality overcomes this problem. The amount of die ovality required is proportional to tube wall thickness and diameter.

Internal shapes can be produced in tubular stock by swaging it over shaped mandrels. Workpieces are generally classified as (1) those with uniform cross section along the longitudinal axis and (2) those with axial variations (such as internal tapers or steps.

Workpieces in the first category can be made from long tubular stock swaged over a plug-type mandrel. After swaging, the tube is cut into two or more pieces of the desired length. When swaging shapes with spiral angles, such as rifled tubes, the angles should not exceed 30° as measured from the longitudinal axis, although angles up to 45° have been used for some internal shapes.

Sectional views illustrating the typical internal shapes of workpieces with uniform cross section along the longitudinal axis are shown in Fig. 17. These shapes are made from tubular blanks with the inside diameter 0.5 mm (0.020 in.) larger than the largest diameter of the mandrel. In addition, the difference between the largest and smallest internal diameters of the swaged workpiece is added to the outside diameter of the swaged piece to obtain the correct blank diameter.

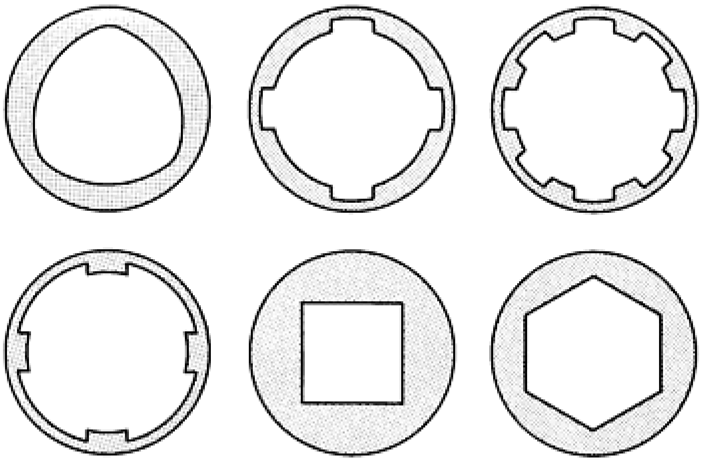

Fig. 17 Typical internal shapes produced in tubular stock by swaging over shaped plug-type mandrels.

For example, an internal 19 mm ($\frac{3}{4}$ in.) square is to be swaged into a 38 mm ($1\frac{1}{2}$ in.) OD tube. The diagonal of a 19 mm ($\frac{3}{4}$ in.) square is 27 mm (1.06 in.). Therefore, the inside diameter of the tubular blank should be 0.5 mm (0.020 in.) larger, or a total of 27.5 mm (1.08 in.). The difference between the maximum and the minimum internal diameters of the swaged piece is 27 - 19 mm (1.06 - 0.75 in.), or 8 mm (0.31 in.). Therefore, the outside diameter of the tubular blank stock should be 38 + 8 mm (1.50 + 0.31 in.), or 46 mm (1.81 in.).

To prevent breakage of the mandrel and to obtain the best tangential flow of metal, a swaging machine equipped with a four-piece die is preferred for producing internal splines in workpieces with the same cross section at any point along the axis. The dimensional accuracy of workpieces with internal splines is improved when they are swaged in a four-die setup rather than a two-die setup, because less work metal is forced into the clearances of four-piece dies. Internal squares or hexagons are less sensitive to the differences between two-piece and four-piece dies.

Figure 18 illustrates several typical work-pieces in which the internal shapes require axial variations of the cross section. Internal shapes that contain stepped contours may require preshaped blanks when the differences between the steps are large. For some shapes that terminate as blind holes, axial back pressure is required to influence metal flow during swaging.

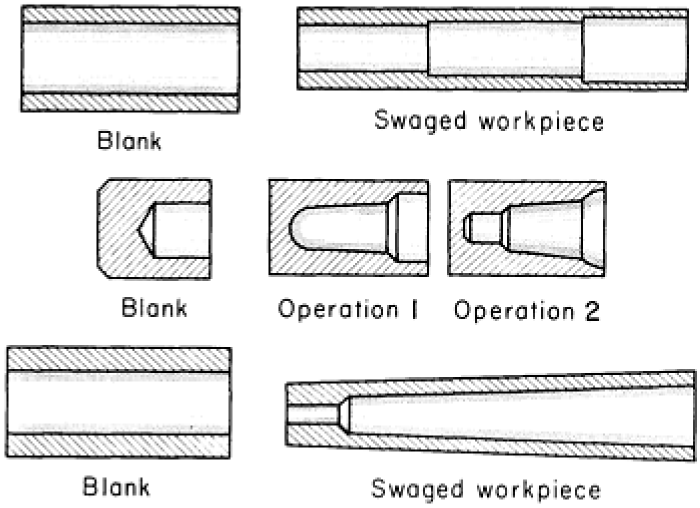

Fig. 18 Internal shapes of nonuniform axial cross section produced by swaging over a mandrel.

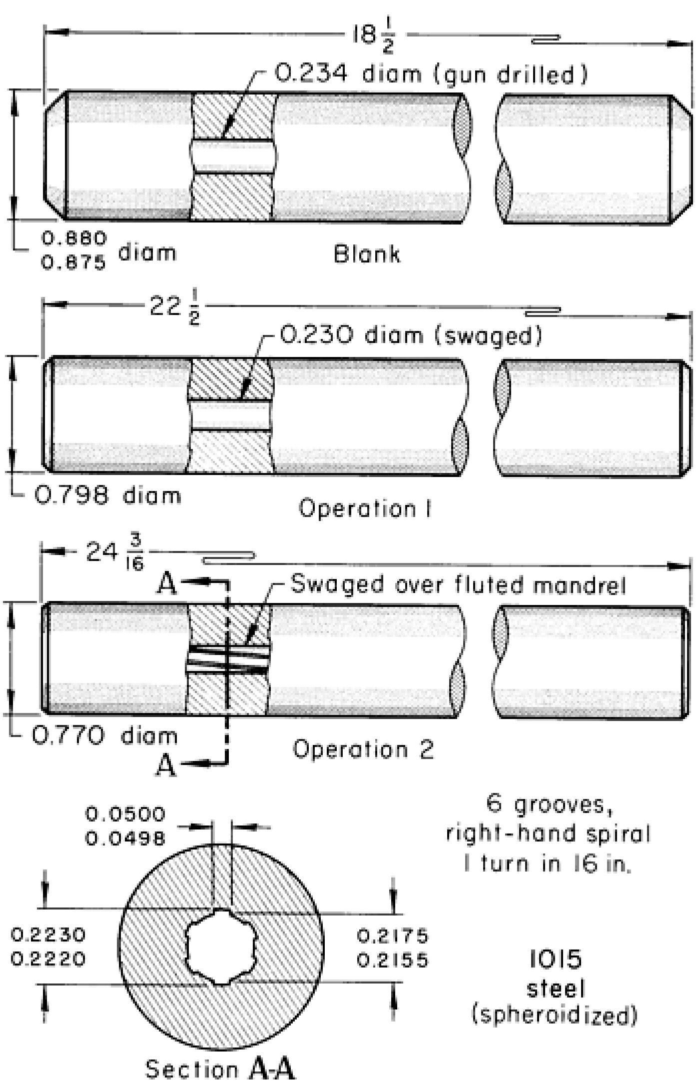
Gun barrels are frequently rifled by broaching. They can also be rifled by swaging with a fluted mandrel, as in the next example.

Example 2: Use of a Fluted Mandrel to Rifle the Bore of a Gun Barrel.

Gun barrels were originally produced by gun drilling 5.6 mm (0.222 in.) diam holes in 19 mm ($\frac{3}{4}$ in.) OD bar sections and then rifling the bore by broaching. After broaching, the gun barrels were turned to a 16 mm ($\frac{5}{8}$ in.) outside diameter.

By the improved method, 470 mm ($18\frac{1}{2}$ in.) long blanks (Fig. 19) were gun drilled so that their inside diameter was 5.9 mm (0.234 in.). They were then turned on centers to obtain precise concentricity between inside and outside diameters. In the first swaging operation, the workpieces were reduced in outside diameter to 20.3 mm (0.798 in.) and in inside diameter to 5.8 mm (0.230 in.), while length was increased to 570 mm ($22\frac{1}{2}$ in.) (operation 1, Fig. 19). In operation 2 (Fig. 19), a fluted mandrel was inserted to form the rifling because swaging further reduced the outside and inside diameters of the workpieces and increased the length to 615 mm ($24\frac{3}{16}$ in.).



Operating condition	**Gun drilling**	Turning
Speed, rpm	1750	**500**

Production rate	**80 pieces per hour**
Surface finish	**Burnished**

Fig. 19 Progression of a gun-drilled and turned blank through two-operation swaging, including rifling with a fluted mandrel, to produce a gun barrel. Dimensions given in inches.

The workpieces were swaged in a $7\frac{1}{2}$ hp two-die machine capable of delivering 1800 blows per minute. Entrance taper of the die was 6° included angle, and the overall length of the die was 75 mm (3 in.). A semiautomatic hydraulic feed mechanism was used; barrels were manually placed into a spring-loaded chuck. The feed was started by the operator, and the mandrel was positioned and held in place by an air cylinder. The workpiece was hydraulically fed over the mandrel and disposed of at the rear of the machine, after which the mandrel returned ready for reloading.

The work metal for the part shown in Fig. 19 was 1015 steel, although other steels ranging from lower-carbon steels (such as 1008) to medium-carbon alloy steel have been used for gun barrels. Gun barrels are swaged from heat-treated blanks to hardnesses as high as 38 HRC.

Tool life is often the limiting factor in producing internal shapes. As the amount of reduction increases and tools (mandrels, specifically) become more delicate, swaging sometimes becomes economically impractical because of short tool life.

Lubrication between the mandrel and the workpiece is essential for most mandrel-swaging operations. Only a thin film, such as that applied with a wiping cloth, is used on the mandrel. The tube and dies are generally wiped clean before the operation begins (see the section "Lubrication" in this article).

Effect of Reduction

Reductions by swaging are limited by machine size; available feed force; die angle and feed rate, which affect the feed force; and the material and its metallurgical condition. Spheroidize-annealed plain carbon steels and other ductile alloys can be swaged to over 40% reduction in area. For larger reductions, however, stress-relief annealing between reductions may be necessary to achieve a crack-free product.

Internal and external surface finishes generally improve with increasing reduction. Figure 20 illustrates the improvement in inside diameter surface finish achieved on tubes by swaging at 20 and 40% reductions in area.

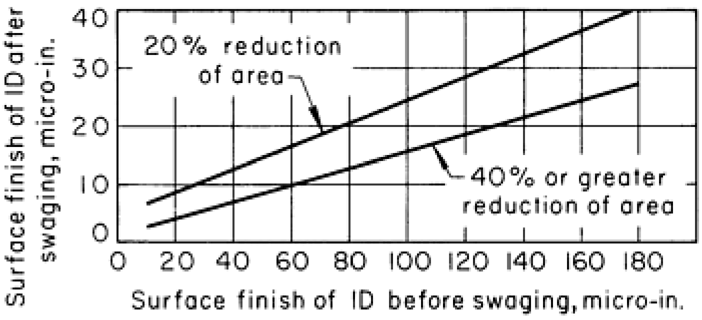

Fig. 20 Correlation between original and swaged surface finishes on the inside diameters of tubes for two different reductions.

Effect of Feed Rate

The feed rate used for rotary swaging may range from 250 to 5000 mm/min (10 to 200 in./min). A common feed rate is approximately 1520 mm/min (60 in./min). The extremely low rate of 250 mm/min (10 in./min) has been used when swaging internal configurations from tubing or for tubing having a diameter to wall thickness ratio of 35 or more. Swaging of simple tapers on an easily swageable material can be performed at feed rates as high as 5000 mm/min (200 in./min).

In general, high feed rates have an adverse effect on dimensional accuracy and surface finish. A spiral pattern on the workpiece surface suggests excessive feed rates.

Effect of Die Taper Angle

In rotary swaging, the angle of the taper at the die entrance influences the method used to feed the workpiece into the die. When the included angle is less than 12°, manual feeding is practical for cold swaging. When the included angle of the die entrance taper is 12° or more, power feeding is required.

Steep die surface angles produce inferior surface finishes and require greater feed force. Steep tapers, therefore, may increase cycle time. Consequently, it may be more cost effective to perform the desired reduction in two passes, first with a shallow taper and then with a steeper taper die or a die-closing swage, rather than in one pass with a steep taper.

Rotary Swaging of Bars and Tubes

Revised by the ASM Committee on Rotary Swaging[*]

Effect of Surface Contaminants

Residues from drawing lubricants, oxides, scales, paint, and other surface contaminants should be removed before swaging. Such contaminants retard feeding of the workpieces into the swager and load the dies and other moving components of the swager.

Abrasive cutoff wheels should not be used in the preparation of tubular products, because abrasive dust from the wheels is detrimental to the swaging dies and to the machine. Although the abrasive dust can be removed from the outside surface of the tube if enough clean wiping cloths are used, it may be difficult to remove the dust from the inside surface and cut edge of the tube.

The workpiece must be cleaned before swaging. Standard cleaning procedures can be used.

Rotary Swaging of Bars and Tubes

Revised by the ASM Committee on Rotary Swaging[*]

Lubrication

The adverse effect of lubrication on feeding conditions eliminates the use of lubricants in many swaging operations (except between mandrels and workpieces). The main disadvantage in using lubricants is that excessive feedback can occur, especially when dies have a steep entrance angle (generally, more than 6°. Feedback cannot be tolerated in manual feeding. An automatic feed must be sufficiently rigid and powerful to overcome this reaction.

A lubricant can usually be employed when the included entrance angle of the dies does not exceed 6°. If a lubricant can be used, a better surface finish and longer tool life generally result.

Lubricants include oils specifically formulated for swaging operations, phosphate conversion coatings, molybdenum disulfide, and Stoddard solvent. Stoddard solvent is a colorless refined petroleum product that is especially useful for swaging aluminum.

Mandrel lubricants must be used during mandrel swaging to prevent seizure between the work and the mandrel. It is important to select a mandrel lubricant that will adhere to the mandrel and to use the correct amount so that it does not drip into the dies during the swaging operation. Most mandrel lubricants have this adherent quality. The lubricant selected must not contaminate the blade and entrance section of the die by forming gummy residues, because the dies must be kept clean. Resistance to heat is also desirable for mandrel lubricants.

When a mechanical feed and ample power are used, lubricants on the work can enhance surface finish and die life, regardless of the entrance angle of the dies. With manual feeding, lubricants on the outside of the work present a hazardous feeding condition.

Rotary Swaging of Bars and Tubes

Revised by the ASM Committee on Rotary Swaging*

Dimensional Accuracy

Dimensions that can be maintained in the normal swaging of steel products in a wide range of sizes are listed in Table 4. These dimensional tolerances apply to solid bars and to tubes swaged over a mandrel. The tolerances listed in Table 4 apply only to the main sections of swaged workpieces. Dimensions at the ends of swaged sections will vary because metal flow is greater, causing the ends to be slightly bell-mouthed. When uniform dimensions are necessary throughout the entire length of the workpiece, suitable allowances must be made for cutting off the ends of the swaged workpiece. For swaging to close tolerances, the workpiece must be within the capacity of the machine, and the work metal must be as ductile as possible to prevent springback to a larger diameter than required.

Table 4 Tolerances on diameter for swaging solid bar stock or for swaging tubing over a hardened mandrel

Nominal outside diameter		Tolerance	
mm	in.	mm	in.
1.6	$\frac{1}{16}$	±0.025	±0.001
3.2	$\frac{1}{8}$	0.05	0.002
6.4	$\frac{1}{4}$	0.075	0.003
12.7-25.4	$\frac{1}{2}$-1	0.13	0.005
51-76	2-3	0.18	0.007
76-114	3-4$\frac{1}{2}$	0.25	0.01
114	4$\frac{1}{2}$	0.38	0.015

Note: Data were compiled using low-carbon steel samples, but are generally applicable to other swageable metals. Tolerances apply only to main sections of workpieces and are based on a feed rate of 1520 mm/min (60 in./min). Tolerances given here can be reduced by about 50% by reducing feed rate to 760 to 1015 mm/min (30 to 40 in./min).

Tolerance for cold-swaged tubular products can be held to closer limits than the tolerances applicable to the outside diameter of standard tubing. The inside diameter, however, cannot be held as close, because of variations in the original wall thickness and because the wall thickens during swaging. When a tube is swaged without a mandrel or without prior reaming, the tolerance for the inside diameter should be twice that for the outside diameter. An exception is welded tubing made from flat stock held to close tolerances on thickness and width. The dimensional accuracy of the inside diameter can be greatly improved by using a mandrel.

Surface Finish

In general, rotary swaging improves the surface finish of the workpiece. The finishes produced are comparable to those obtained in cold-drawing operations.

Swaging in a squeeze-type machine usually causes a distinct spiral pattern on the outside surface of the workpiece. The pitch of the spiral increases as the rate of axial feed increases and as the relative rotation between the die and workpiece decreases. The intensity of the pattern on the inside surface depends on wall thickness. As the wall thickness increases, the spiral pattern gradually fades out. The surface finish of the inside diameter is related to the surface finish before swaging, the surface finish of the swaging mandrel, the amount of reduction, feed rate, rotational control of the tube during swaging, the lubricant employed, and the mechanical characteristics of the work metal.

Figure 20 correlates the surface finish on the inside diameter of tubes before and after swaging to reductions of 20 and 40%. The values shown are based on tooling that was axially polished to a finish of 0.05 to 0.1 μm (2 to 4 μin.) and on the use of a lubricant that was capable of preventing metal pickup. The higher reduction resulted in a finer surface finish on the inside diameter.

These data were obtained from several different tube materials. Starting material was as-received--sometimes seamless tubing that was pickled and sometimes as-welded tubing. This accounts for the range of finish on the inside diameter before swaging.

Rotary Swaging of Bars and Tubes

Revised by the ASM Committee on Rotary Swaging*

Swaging Versus Alternative Processes

There are numerous applications for which swaging is the best method of producing a given shape and is therefore selected regardless of the quantity to be produced. Conversely, there are many workpiece shapes that can be successfully produced by swaging, but can be produced equally well by other processes, such as press forming, spinning, and machining. Applications comparing swaging with alternative processes are described in the following examples.

Example 3: Swaging Versus Press Forming.

The ferrule illustrated in Fig. 21 was originally produced in a press by drawing disks into cups, redrawing to form the taper, and trimming the ends. With this procedure, 500 ferrules per hour were produced.

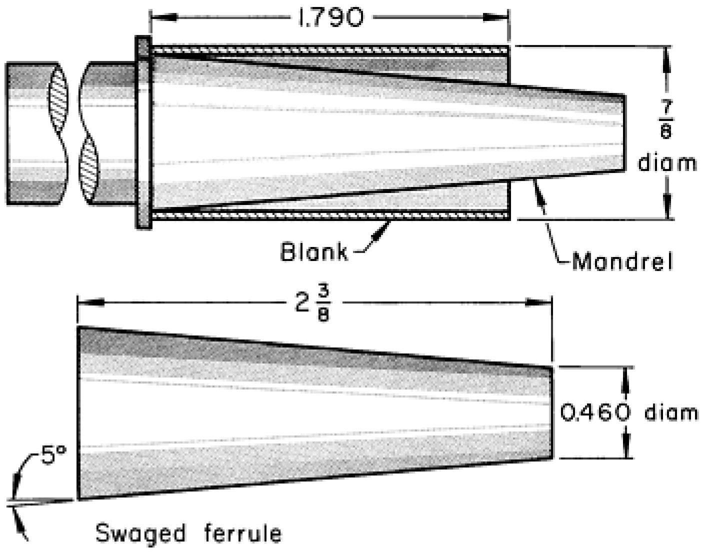

Fig. 21 Swaging a ferrule from tube stock (alloy C26000, cartridge brass, quarter hard, 0.032 in.) in preference to press forming. The change from press forming to swaging lowered tooling costs and resulted in a 50% increase in production. Dimensions given in inches.

The improved method consisted of cutting the blanks from tubing, then swaging them in a 5 hp two-die rotary machine. Dies with an included taper angle of 9° 56' and 0.13 mm (0.005 in.) ovality were used. The production rate was increased to 750 pieces per hour.

Example 4: Swaging Versus Spinning.

Blades for high-voltage switches were swaged from annealed copper tubes (Fig. 22) in three operations using a two-die rotary machine. Each die was 197 mm ($7\frac{3}{4}$ in.) long, 180 mm ($7\frac{1}{8}$ in.) wide, and 127 mm (5 in.) high. The tapered section in each die had a 15° included angle, and side clearance was used instead of ovality. Tubes were fed into the swager by a hydraulically actuated carriage on a long track. An intermediate steady rest moved along the track to help maintain tube alignment.

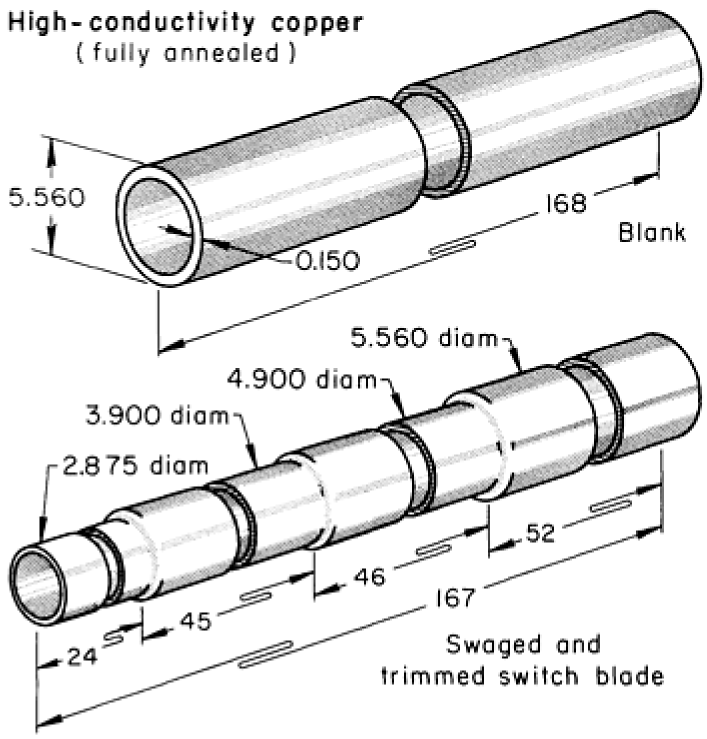

Fig. 22 High-voltage switch blade (bottom) that was swaged from tube stock (top) in three operations. Previously, the part was produced by spinning. Dimensions given in inches.

In the first operation, the tube was swaged through a 124.5 mm (4.900 in.) die up to the first step. In the second operation, a tube length of 1140 mm (45 in.) was swaged to a 99 mm (3.900 in.) outside diameter, and in the third operation, the end portion was swaged to a 73 mm (2.875 in.) outside diameter. In a final operation, the large end was trimmed to obtain an overall workpiece length of 4.2 m (167 in.).

Formerly, these blades had been produced by spinning 4.23 m (168 in.) lengths of annealed copper tubing 73.025 mm (2.875 in.) in outside diameter by 63.5 mm (2.5 in.) in inside diameter. By changing to swaging, production cost was reduced 10%. Swaging provided two additional benefits. First, the center of rotation was shifted toward the large diameter of the workpiece, thus reducing the number of counterweights required to balance the switch blade when in operation, and second, the small end received the most cold work, thus strengthening this portion to the desired condition.

Example 5: Swaging Versus Turning.

The tapered workpiece illustrated in Fig. 23 was originally produced by lathe turning, at the production rate of only 200 pieces per hour. A substantial loss of work metal as chips made this method impractical.

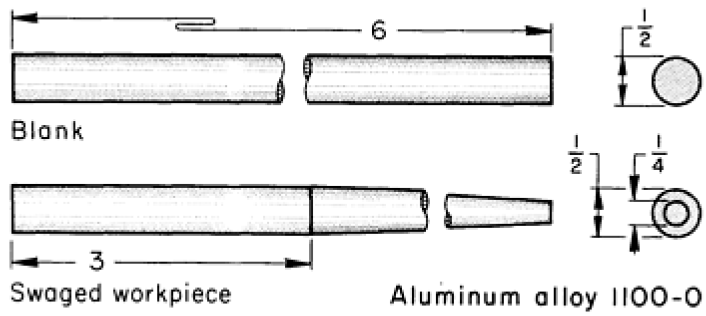

Fig. 23 Tapered aluminum workpiece that was produced by swaging without metal loss. Production increased from 200 to 1200 pieces per hour when the part was fabricated by swaging rather than lathe turning.

Dimensions given in inches.

By changing to swaging, it was possible to produce 1200 pieces per hour with no loss of metal. The operation was performed in a $7\frac{1}{2}$ hp rotary swager using dies with an overall length of 162 mm ($6\frac{3}{8}$ in.), 1° taper, and side clearance (no ovality). An inside spindle stop fastened to a straight rod mounted in and rotated with the spindle allowed adjustment by means of a screw at the rear of the spindle. The work blanks were hand fed, and no special holder or feeding mechanism was used. Additional operating details are listed with Fig. 23.

Swaging Combined With Other Processes

In some applications, the most practical method of producing a given workpiece is to combine two or more processes. Combined processes are used to increase the rate of production, to avoid otherwise costly tooling, to decrease or eliminate the loss of work metal, to provide closer dimensional tolerances, or to provide improved surface finish. The following examples describe applications in which the above advantages influenced the decision to combine machining operations with swaging operations.

Example 6: Combination Turning and Swaging for Increased Production.

The firing pin shown in Fig. 24 (lower view) was originally produced by turning in an automatic lathe at a rate of 60 pieces per hour. Not only was the rate of production unacceptably low, but the required tolerance of ±0.05 mm (±0.002 in.) could not be met consistently. In addition, the finish-turned workpieces showed tool marks.

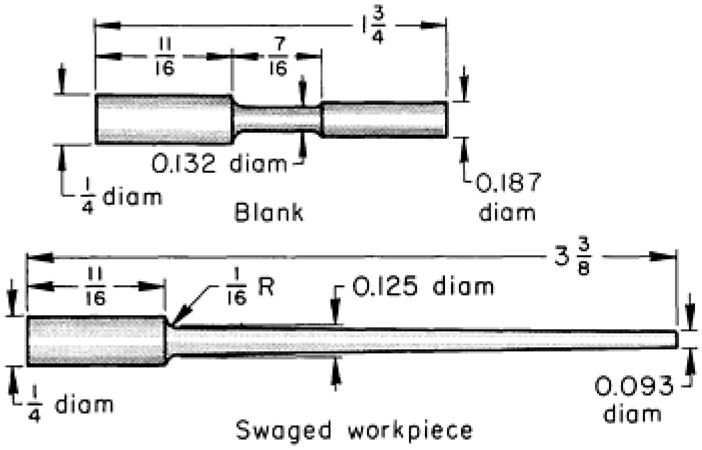

Fig. 24 Rough-turned blank for a firing pin (top) and pin that was produced from the blank by swaging (bottom). Production rate increased more than 200% when the pin was produced by turning and swaging rather than by turning alone. 3140 steel, 85 to 90 HRB. Dimensions given in inches.

The above conditions were improved by rough turning the 3140 steel blank (upper view, Fig. 24) in an automatic lathe and then swaging the blank to the firing pin shape. With this procedure, 180 pieces per hour were produced on the automatic lathe and 300 pieces per hour on the swager (two passes per piece). Other improvements that resulted from the change in method were closer tolerance (±0.025 mm, or 0.001 in.), a burnished finish, and a metal saving of 22%.

The blanks were swaged in a 5-hp rotary swager using dies designed with 30° side clearance and no ovality. The first die had a blade length of 30 mm ($1\frac{5}{16}$ in.); the second a 50 mm (2 in.) blade length.

Example 7: Combining Drilling and Mandrel Swaging to Produce 0.9 mm (0.036 in.) diam Holes.

The copper blank shown in Fig. 25 was produced by drilling six 3.2 mm (0. 125 in.) diam holes in bar sections 17.5 mm ($\frac{11}{16}$ in.) in outside diameter by 89 mm ($3\frac{1}{2}$ in.) long. After drilling, six 0.9 mm (0.036 in.) diam mandrels were inserted into the holes, and the blank was swaged to increase its length to 102 mm (4 in.) to reduce its outside diameter to 15.8 mm ($\frac{5}{8}$ in.) and to reduce the holes to 0.09 mm (0.036 in.) in diameter. The mandrels were withdrawn after swaging.

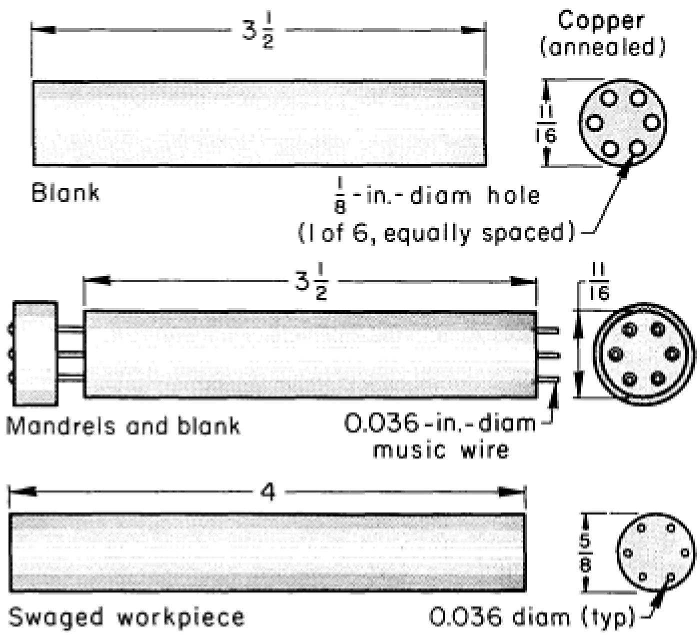

Fig. 25 Blank with drilled holes (top) that was swaged over music wire mandrels (center) to increase length and to reduce outside diameter and hole diameter (bottom). Dimensions given in inches.

The blank was drilled in a specially built horizontal machine and was swaged in a rotary swager using manual feed. The dies had 0.25 mm (0.010 in.) ovality and an included entrance angle of 8°. Overall length of the die was 75 mm (3 in.); blade length was 32 mm ($1\frac{1}{4}$ in.).

Rotary Swaging of Bars and Tubes

Revised by the ASM Committee on Rotary Swaging*

Special Applications

The difficulties of attaching terminals and fittings to cables by welding or soldering are often overcome by the use of swaging. Four types of swaged attachments are illustrated in Fig. 26. The plain ball swaged in position (Fig. 26a) will resist movement from a force equal to 80% of the rated breaking strength of the cable. The ball with single shank (Fig. 26b) is used when the load stress is applied in one direction only. The ball with double shank (Fig. 26c) is used when load stress is applied in opposite directions. In Fig. 26(d) and 26(e), the plain shank terminal is assembled on the cable and staked in position before swaging.

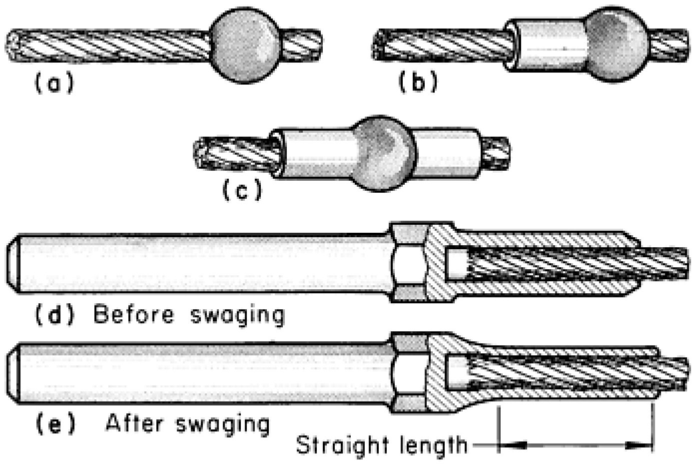

Fig. 26 Four types of terminals that can be attached to cables by rotary swaging. (a) Ball swaged in position. (b) Ball with single shank. (c) Ball with double shank. (d) Shank terminal before swaging. (e) Shank terminal after swaging.

Swaging can also be used to form wire or tubing from metals that are not strong enough to be formed completely by wire drawing or tube drawing. Solder, for example, can be reduced only about 10% in cross-sectional area by wire drawing, but a reduction of up to 60% can be obtained by swaging.

Swaging is applicable to the forming of small-diameter thin-wall shells that are difficult to make by drawing in presses. Shells can be drawn in presses provided the drawing force does not exceed the tensile strength of the material. If the tensile strength is exceeded, the bottom of the shell will be pushed out. This factor limits the length and wall thickness to which small-diameter shells can be formed by drawing. In swaging, the length of shell that can be produced is limited only by the ability of the wall to withstand thinning.

Rotary Swaging of Bars and Tubes

Revised by the ASM Committee on Rotary Swaging*

Hot Swaging

Hot swaging is used for metals that are not ductile enough to be swaged at room temperature or for greater reduction per pass than is possible by cold swaging. The tensile strength of most metals decreases with increasing temperature; the amount of decrease varies widely with-different metals and alloys. The tensile strength of carbon steels at 540 °C (1000 °F) is approximately one-half the room-temperature tensile strength; at 760 °C (1400 °F), about one-fourth the room-temperature strength; and at 980 °C (1800 °F), about one-tenth the room-temperature strength. In practice, reductions greater than those indicated in Table 1 are sometimes possible by cold swaging without intentionally heating the work metal, because sufficient heat is generated during swaging to cause a substantial decrease in strength and increase in the ductility of the work metal.

The decrease in strength at elevated temperature does not make possible unlimited reductions at high temperatures. Because of the design and capabilities of swaging machines, the work metal must be strong enough to permit feeding of the workpiece into the machine. When the work metal has lost so much of its strength that it bends rather than feeds in a straight line, chopper dies must be used (Fig. 6). This type of die limits the reduction in area to 25% regardless of work metal ductility. The temperature to which a work metal is heated for swaging depends on the material being swaged and on the desired reduction per pass.

Alloy steels harder than 90 HRB are difficult to cold swage and can cause premature failure of the dies and machine components. Hot swaging should be considered for these steels. For metals that work harden rapidly and require intermediate annealing during cold swaging, hot swaging is often more economical.

Tungsten and molybdenum must be worked at elevated temperature (900 to 1605 °C, or 1650 to 2925 °F, for tungsten; 605 to 1425 °C, or 1125 to 2600 °F, for molybdenum) because of their low ductility at room temperature. A tungsten ingot is usually swaged to about 3.2 mm ($\frac{1}{8}$ in.) in diameter, although it can be swaged to a diameter of 1 mm (0.040 in.). After this, the ingot is ductile enough to be hot drawn. The procedure for swaging molybdenum is essentially the same as for tungsten.

Equipment for Hot Swaging. All machines employed for cold swaging can be used for hot swaging by incorporating either a water jacket or a flushing system. A water jacket is simply a groove in the bore of the swager head in the area of the inside ring. The groove is connected to a continuous water supply to dissipate heat.

A flushing system introduces a cooling compound at the upper rear of the head. The compound is pumped through the machine and exits at the lower front, from which it flows by gravity through a water cooler before entering the supply tank. This tank is equipped with a filter through which the cooling medium passes before re-entering the machine.

In addition to cooling, the flushing system removes accumulated foreign matter and lubricates the working parts of the swager. Although flushing removes foreign substances such as scale and sludge, the method used for heating the workpiece should produce the least possible oxidation.

Dies for hot swaging must be made of material that will resist softening at elevated temperature. High-speed steels and cemented carbides are satisfactory materials for hot swaging dies.

A common production procedure for hot swaging is the tandem arrangement of several swagers, each of which is equipped with a heating furnace in front of the machine and close to the dies. The furnaces are mounted so that they can be pushed aside for quick changing of the dies. Drag rolls are mounted at the rear of each swager to pull the workpiece through the furnace and the machine. Each drag roll mechanism is equipped with a variable-speed drive to regulate the rate of feed into the swaging machine. Feed for this type of operation ranges from 1520 to 6000 mm/min (5 to 20 ft/min).

Lubrication. In addition to preventing seizure between the dies and the workpiece, lubricants minimize wear of the backers, shims, dies, spindle side plates, back plates, rolls, and swager gate. However, the flow of the lubricant must be controlled to prevent excessive cooling of the workpiece. Lubricants used for hot swaging should be free from chlorine and sulfur.

Material Response

In addition to the effect of inclusions and high initial hardness on promoting fracture during swaging, the cold-swaged products may exhibit unanticipated mechanical properties--for example, reduced hardness, reduced yield stress, and either growth or constriction of the tube inside diameter after machining of the outside diameter. These unanticipated properties have been attributed to the Bauschinger Effect (that is, a reduction of the yield stress following a stress reversal) and to residual stress.

Decreasing yield stress with continued reduction, to a minimum at 20 to 30% area reduction, has been observed during the swaging of rifle barrels. At higher reductions, the yield stress continued to increase.

Radial hardness variations have been observed after tube swaging over a mandrel. The difference between the highest and lowest readings was 8 Rockwell C points, and the readings were typically equal to or less than the original blank hardness. After a low-temperature stress-relief treatment (10 °C, or 50 °F, below the tempering temperature of the steel blank), the swaged tubes had hardnesses greater than the original heat-treated blank by up to 3 Rockwell C points, which would be expected for a 20% area reduction.

Residual stress after cold tube swaging can be controlled by tool design. For example, the same product could be produced with either compressive or tensile residual stresses at the inside diameter or negligible residual stress throughout the product. The significant tool design parameters affecting residual stress are ovality, die angle, blade length, reduction in area, and secondary reductions (small, usually less than 0.05% area reductions near the start of the die exit relief), usually on the die. Ovality (expressed as percent overgrind of the final product diameter relative to the ground die inside diameter) in four-die tube swaging is the most significant parameter affecting residual stress, as shown in Fig. 27. The data in Fig. 27 show the dependence of the outside diameter (diametral expansion) on percent overgrind for 7.9 mm (0.31 in.) ID tubes produced by swaging 33 mm (1.300 in.) OD tubular blanks. The OD expansion was measured after electrochemically machining the 7.9 mm (0.31 in.) inside diameter to 14.2 mm (0.560 in.) and was accompanied by axial expansion. The data for diametral expansion are indicative of the magnitude of residual stress existing in the swaged tubes and were subsequently related to changes in the inside diameter upon machining of the outside diameter.

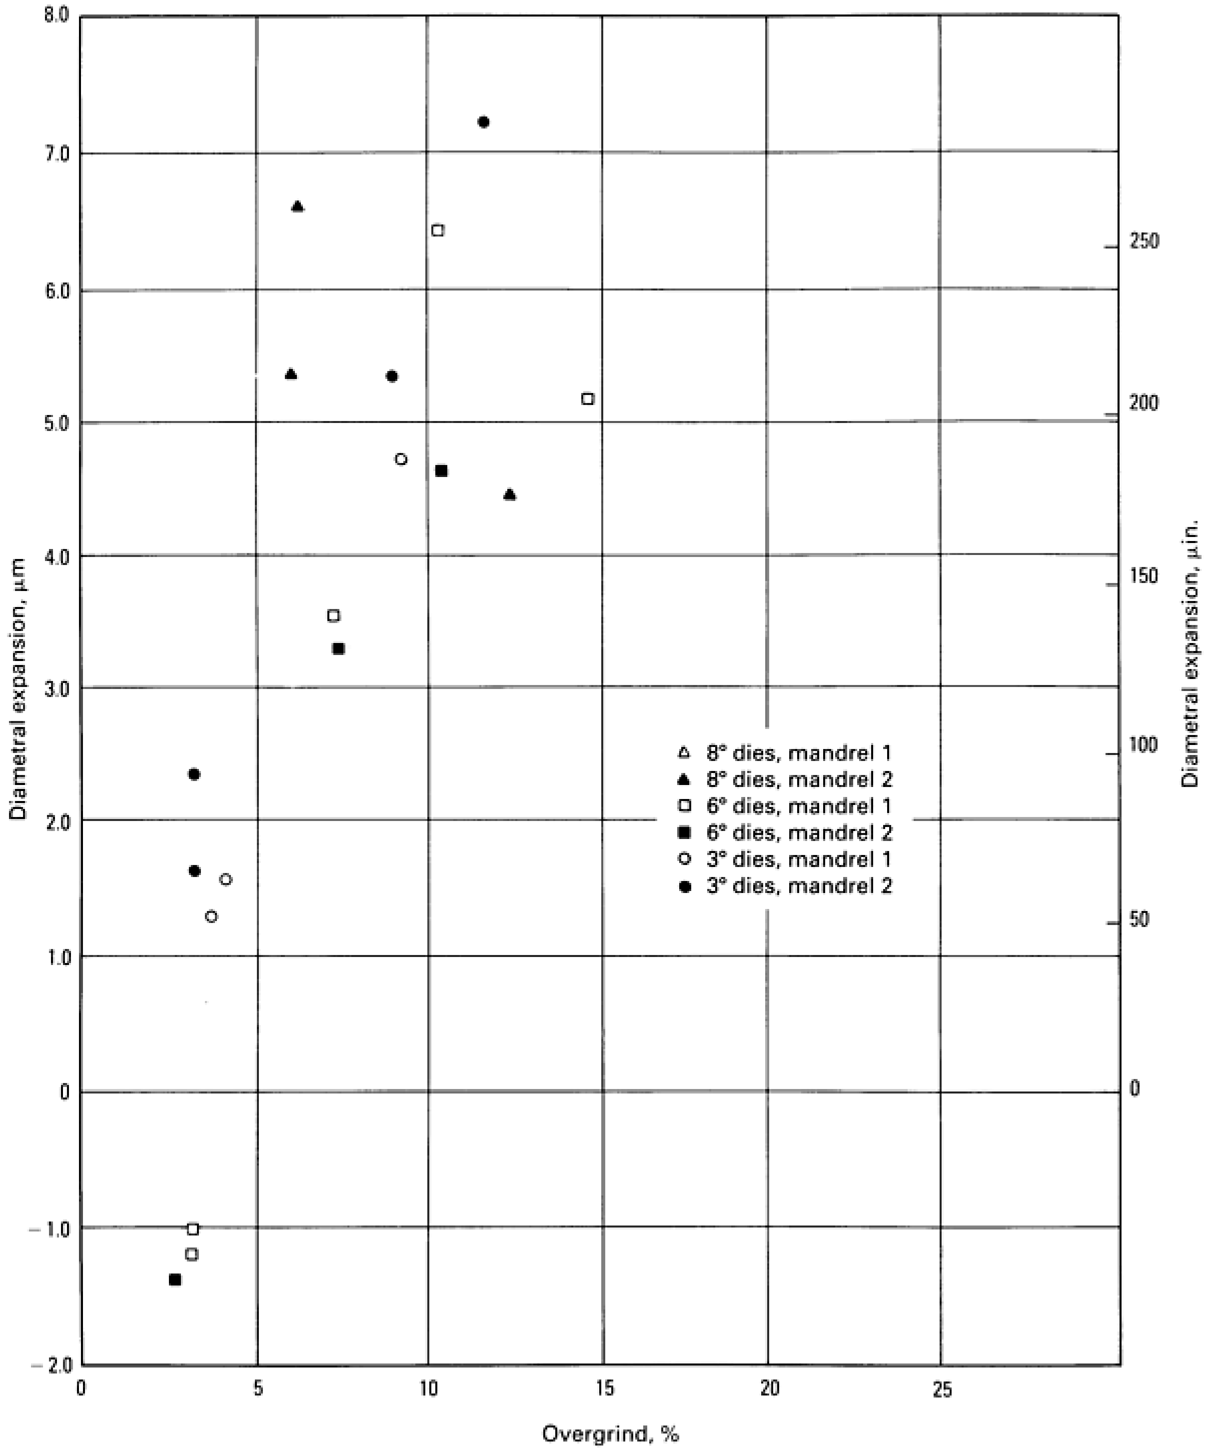

Fig. 27 Dependence of diametral expansion on overgrind.

The data in Fig. 27 were obtained from tubes swaged with 3, 6, and 8° (one-half the included angle) dies and two mandrel designs. Mandrel 1 was a conventional straight mandrel, and mandrel 2 was a tapered mandrel that expanded to 0.025 mm (0.001 in.) outside the die exit relief. The maximum residual stresses were in the range of ±550 MPa (80 ksi), or ±60% of the yield stress of the blank.

Noise Suppression

The noise from rotary swaging operations is so great that special protection of the operator is required. Noise intensity of the average swager in a range of up to 20 hp is about 93 to 95 dB at frequencies of 1000 to 3000 Hz. For most factory conditions, a level no higher than 85 dB should be permitted.

Methods of protecting personnel from excessive noise include the following:

- Earmuffs are effective, but are uncomfortable to wear for long periods
- Earplugs are fairly effective, but can cause ear infections
- Machines can be insulated during manufacture. The use of such insulation can decrease noise to an acceptable level
- Housing the machine is the most effective method of controlling noise. The housing can consist of a wooden frame covered inside and out with 12.7 mm ($\frac{1}{2}$ in.) thick fiberboard insulation

Machines placed on floors above the other work areas should have vibration dampers under the base. Vibration dampers for machines mounted on ground-level floors have no effect on noise levels in the surrounding area if the floors are soundly built.

Rotary Swaging of Bars and Tubes

Revised by the ASM Committee on Rotary Swaging*

Swaging Problems and Solutions

Some of the problems that are commonly encountered in swaging operations include difficult feeding; workpieces with roughened surfaces after swaging; peeling, cracking, and wrinkling of workpieces; sticking in dies and on mandrels; and breaking mandrels. The causes of these problems and suggested solutions are presented in Table 5.

Table 5 Some swaging problems, potential causes, and possible solutions

Problem	**Potential causes**	Solutions
Difficult feeding	Work material too hard	**Anneal or stress relieve to remove effects of cold working.**
	Work material too oily or greasy	**Thoroughly clean workpiece and die grooves.**
	Backer bolt setting improper	**Reset backer bolts so that dies will open one or two thousandths of an inch for each degree of included angle of the die entrance taper.**

	Die entrance too small	**Enlarge die entrance.**
	Steps worn in die taper	**Replace or remachine dies.**
	Inadequate side clearance	**Increase side clearance.**
Work has rough surface	Inadequate side clearance	**Increase side clearance.**
	Work sticks to die entrance taper	**Wipe every fourth or fifth workpiece with graphite or molybdenum disulfide powder.**
	Too much die opening	**Reset machine with proper shims.**
	Dirt and scale in die	**Clean dies and remove loose scale and other contaminants from workpiece.**
Peeling	Die groove too long	**Shorten die groove.**
	Excessive pressure within die groove	**Decrease length of work in the dies with respect to diameter (swaging length should not exceed 10 times the workpiece diameter).**
Cracking of tubing	Material too hard	**Stress relieve or anneal before swaging.**
	Inside surface may have lines or scratches that become cracks as tubing is swaged.	**Improve ID surface finish.**
	Excessive ovality	**Rework dies to remove all ovality; use side clearance only.**
Cracking of bar stock	Seams or pipes in work metal	**Upgrade work metal quality.**
	Material too hard	**Anneal or stress relieve.**
	Excessive reduction per pass	**Reduce amount of reduction; stress relieve between passes.**
Wrinkling or corrugating of tubing	Tube OD more than 30 times wall thickness	**Use a mandrel that is within the solid material capacity of the machine.**
	Feed too fast	**Decrease feed rate.**
	Excessive ovality	**Use round die groove.**

	Material too hard	**Stress relieve or anneal.**
Work sticks in dies and rotates with swager spindle	Side clearance of both taper and blade of die inadequate	**Increase side clearance.**
	Workpiece is crooked.	**Straighten workpiece.**
Workpiece sticks to mandrel	Inadequate ovality	**Increase ovality.**
	Inadequate lubrication	**Use proper lubricant.**
	Mandrel improperly hardened, causing flat spots or sinks	**Be sure mandrel is in correct metallurgical condition.**
Mandrel breaks	**Mandrel material not suited to high shock**	**Use proper mandrel material.**

Radial Forging

Hans Hojas, Gesellschaft für Fertigungstechnik und Maschinenbau mbH

Introduction

RADIAL FORGING was first conceived in Austria in 1946. The first four-hammer machine was built in Austria in the early 1960s. Since then, machine capacities and the number of applications for radial forging have continued to increase. More than 400 radial forging machines have been installed around the world, with maximum forging forces per die of up to 30 MN (3400 tonf) (Table 1).

Table 1 Sizes and capacities of four-hammer radial forging machines

Proprietary designation	Largest possible starting size for steel work metal				Smallest size forgeable for bar materials				Maximum length of finished workpiece		Maximum forging force per die		Number of blows per minute
	Round (diameter)		Square		Round (diameter)		Square						
	mm	in.	mm	in.	mm	in.	mm	in.	m	ft	MN	tonf	
SX-10	100	4	90	3.5	30	1.2	35	1.4	5	16.5	1.25	140	900

Radial forging is sometimes confused in the literature with rotary (orbital) forging. In the rotary forging process, the axis of the upper die is tilted at a slight angle with respect to the axis of the lower die, and one or both dies rotate. Additional information is available in the article "Rotary Forging" in this Volume.

Radial forging was initially used for the hot forging of small parts and for the cold forging of tubes over mandrels. Current applications include:

- Bars with round, square, or rectangular cross section starting from ingots or blooms
- Stepped solid shafts and axles for locomotives, railroad cars, and trucks
- Stepped hollow shafts for components in the automotive and aircraft industries
- Preforms for turbine shafts or for subsequent closed-die forging
- Thick-wall tubes forged over a water-cooled mandrel
- Necks and bottoms of steel bottles
- Couplings and tool joints

Figure 1 illustrates typical parts formed by radial forging.

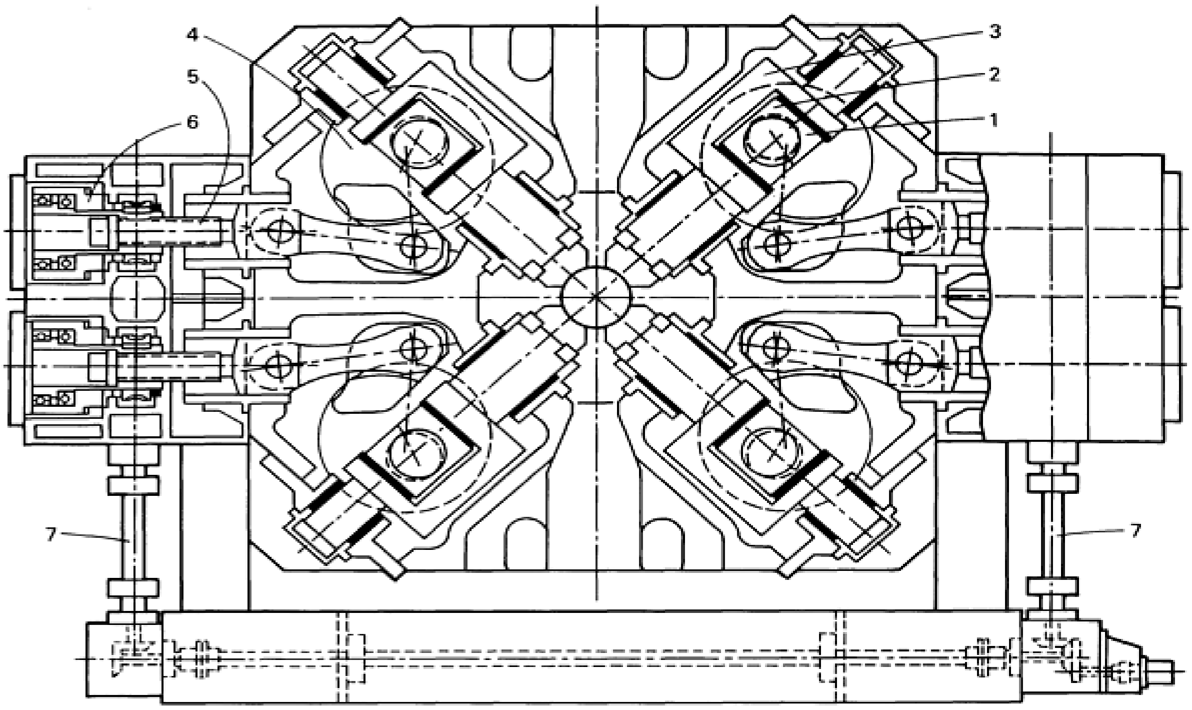
Fig. 1 Typical parts formed by radial forging.

Radial Forging

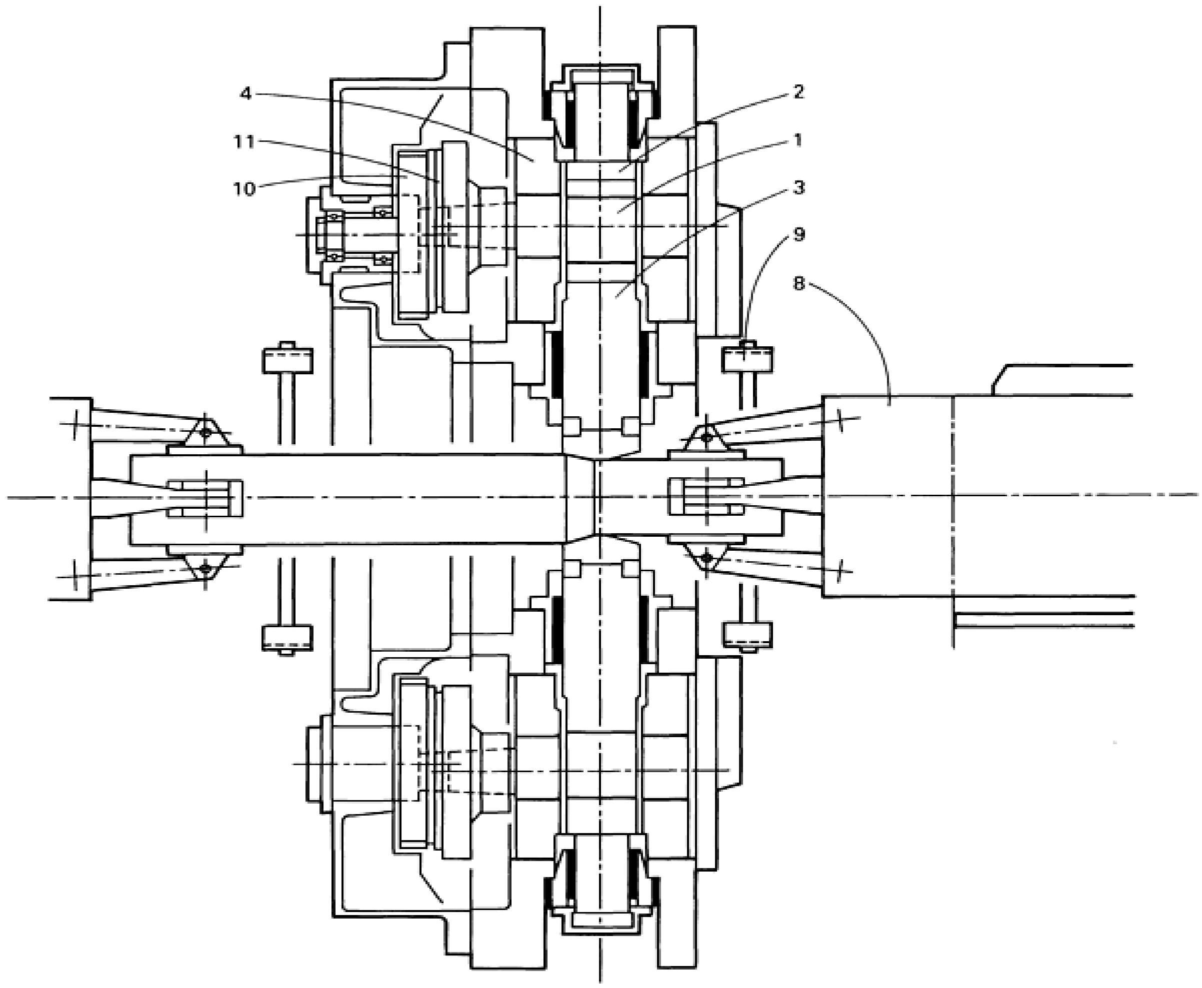
Hans Hojas, Gesellschaft für Fertigungstechnik und Maschinenbau mbH

Equipment and Process

The four-hammer radial forging machine (Fig. 2) is basically a short-stroke mechanical press. The stroke of the forging connecting rods is initiated through eccentric shafts. The eccentric shafts are supported in housings that allow adjustment of the stroke position of the four forging connecting rods. One or two electric motors drive the eccentric shafts through a drive gear, which simultaneously controls the synchronization of the four eccentric shafts. The forging connecting rods can be changed in their stroke position either in unison or in pairs so that round, square, or rectangular cross sections can be forged.



(a)



(b)

Fig. 2 Schematic of four-hammer radial forging machine with mechanical drive. (a) Cross section through

forging box. (b) Longitudinal section through forging box. 1, eccentric shaft; 2, sliding block; 3, connecting rod; 4, adjustment housing; 5, adjusting screw; 6, hydraulic overload protection; 7, hammer adjustment drive shafts; 8, chuckhead; 9, centering arms; 10, clutch; 11, clutch disk.

Depending on its application, the part-handling system of the machine can be equipped with either one or two workpiece manipulators, which differ widely from conventional forging manipulators. In contrast to press or hammer forging, the workpiece axis in radial forging is always maintained on the forging machine centerline, regardless of the diameter. The manipulator moves only in the longitudinal direction. In order to achieve exact guidance, the chuckhead slides on a machine bed. During the forging of round cross sections, the chuckhead rotates the workpiece in cycle with the forging hammers; that is, the rotary movement will be stopped during the time the hammers are in contact with the workpiece. The rotary movement of the chuckhead spindle is synchronized with the hammer blows; therefore, twisting of the workpiece is eliminated. The indexing positions of the chuckhead spindle required for forging squares, rectangles, or hexagons can be set automatically.

In radial forging, the entire forging process, including loading and unloading, can be performed automatically by computer numerical control (CNC). The forging process is no longer dependent on the discretion of the operator, and an optimal forging program is maintained in an unchanged manner. This guarantees the manufacture of uniform forged pieces, which are trimmed to optimal machining allowances. These workpieces are well suited to subsequent machining on CNC lathes because of their consistent dimensional accuracy.

The technology of the four-hammer forging machine differs from that of all other hot-forming methods. Conventional presses and hammers, or even rolling mills, use only two tools per forming operation. In the radial forging machine, however, a workpiece is formed at the same time by four hammers arranged in one plane (Fig. 3). The free spreading that occurs between the two contacting tools in all conventional forging methods is eliminated. A radial press contacts the circumference of the workpiece equally and puts the entire surface of the workpiece under compressive stresses. These compressive stresses prevent the formation of surface cracks during the forging process and improve existing defects.

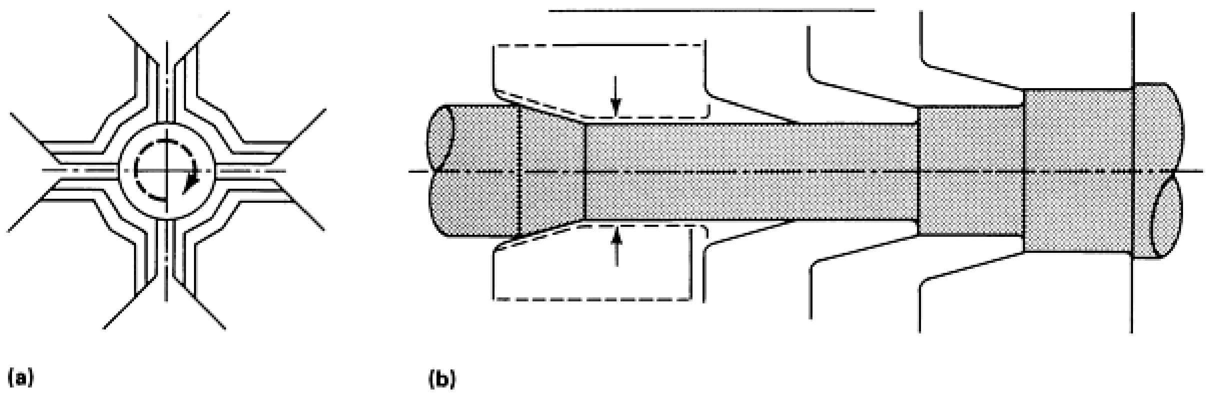


Fig. 3 Arrangement of hammers in a four-hammer radial forging machine. The workpiece rotates intermittently, and the diameter of the forged part is determined by the stroke position of the tools. (a) Front (end) view. (b) Side view

In forging between four hammers, temperature increases will occur in the work material that depend on the deformation rate and the forming resistance of the material. The higher the forming resistance, the higher the temperature increase at each pass. Therefore, the temperature loss of the workpiece (because of heat radiation) can be compensated for by preselecting the correct deformation rate, and forming of the workpiece can take place in temperature ranges with the highest material ductility. In practical terms, this means that all forming can be done in one heat from the ingot to finished bar steel, regardless of the alloy. Chamber furnaces, pit furnaces, and hearth-type furnaces can therefore be replaced by continuously operating furnaces. Material can be transported to and from the machine on roller conveyors, and the entire manufacturing process--heating the ingot, radial forging, dividing and cutting the ends of formed parts, and cooling or annealing--can be done continuously and automatically.

Forging Over a Mandrel. Equipment for mandrel forging (Fig. 4) is available in different designs for the hot and cold forging of tubular workpieces. Figure 4 illustrates the forging of tubular parts over short and long mandrels.

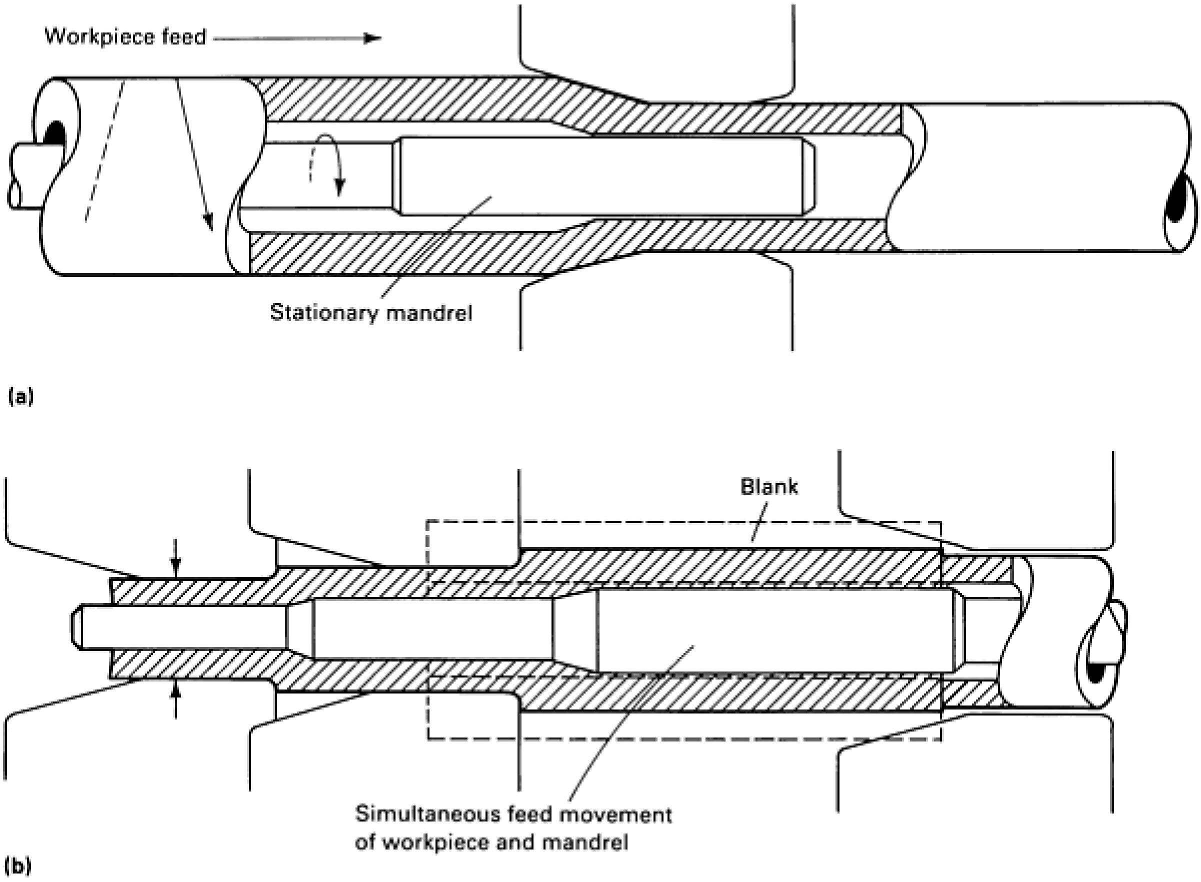

Fig. 4 Forging of tubular parts over a short mandrel (a) and a long mandrel (b)

Long tubes with cylindrical bores are forged over a short mandrel. The short mandrel is held in position between the forging tools with a mandrel rod while the chuckhead moves the workpiece through the forging plane. The mandrel is slightly tapered, and this makes it possible to perform corrections on inside diameter dimensions by changing the position of the mandrel between the hammers. During loading and unloading of the workpiece, the mandrel is automatically retracted into the hollow spindle of the chuckhead.

Forging over a long mandrel is used for relatively short tubes with stepped bores and stepped, cylindrical, or conical contours. The long mandrel is clamped by the chuckhead and moves together with the workpiece feed. After forging, the mandrel is pulled out of the workpiece and retracted into the hollow spindle of the chuckhead.

During hot forging, the mandrel is water cooled while in contact with the workpiece. Tungsten carbide mandrels are often used in cold forging for improved mandrel life.

Radial Forging

Hans Hojas, Gesellschaft für Fertigungstechnik und Maschinenbau mbH

Advantages of Radial Forging

Some of the most important advantages of radial forging are:

- High production. Production of low-alloy steel products using radial forging is approximately four times greater than that of hammer or press forging; high-alloy steel production is six times higher (Fig. 5)
- Low energy consumption as a result of a single ingot heating and continuously operating furnaces
- Close tolerances, which result in less wasted material in subsequent operations. Required machining allowances are approximately 33% of the usual allowances on conventional forged products (Fig. 6)

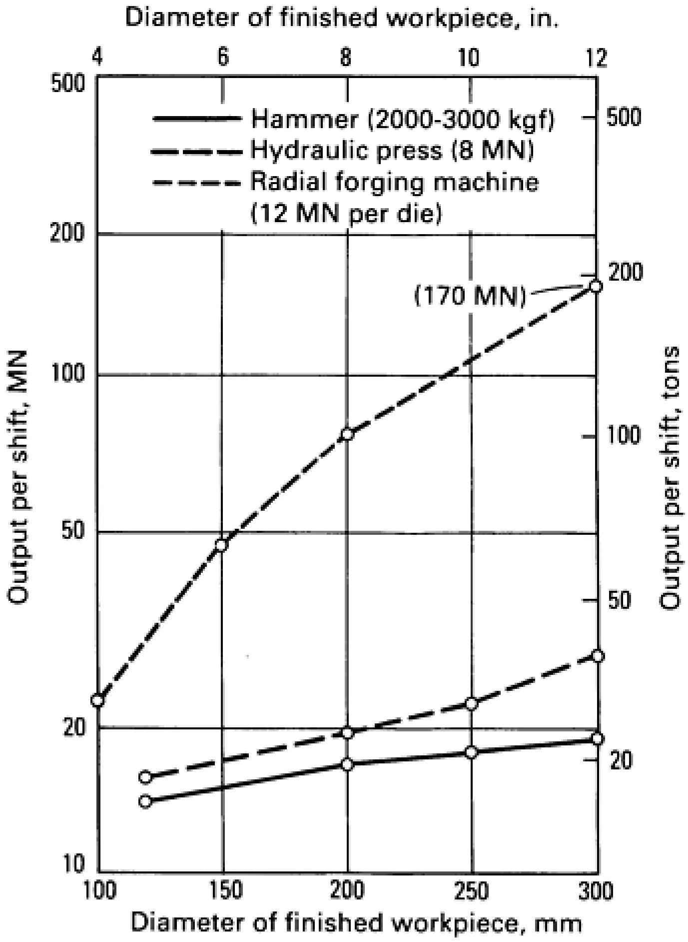

Fig. 5 Comparison of production rates of radial forging and hammer and press forging in the production of alloy steel bars. Starting diameter of the steel was 550 mm (22 in.).

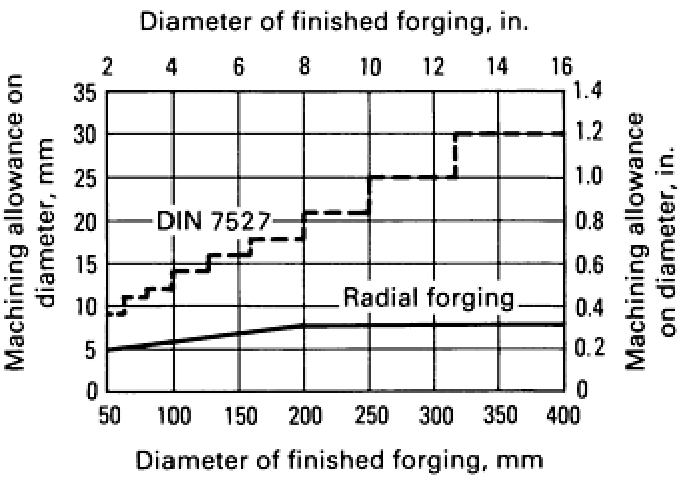

Fig. 6 Typical machining allowance versus diameter for radial forging. Machining allowances are about 33% of

those allowed in a German standard (DIN 7527).

Radial Precision Forging. Full CNC radial precision forging machines are available for hot or cold forging and are built in different capacities with appropriate special equipment as required. Radial precision forging offers the following advantages:

- Forging to net or near-net shape
- Precise, repeatable forging operations
- Low tooling costs
- High flexibility
- Fully automatic operation
- Excellent workpiece surface finish, especially on tube inside diameters
- Forging of internally profiled components to finished inside dimensions

---

Radial Forging

Hans Hojas, Gesellschaft für Fertigungstechnik und Maschinenbau mbH

Examples of Applications

Example 1: Automotive Transmission Shaft.

Figure 7 shows a typical transmission shaft used in an automobile automatic transmission. With conventional manufacturing, it is difficult to machine a stepped bore with a surface roughness in the range of 0.4 μm (16 μin.), which is necessary on some areas of the inside diameter. An additional requirement is a maximum run-out of 0.05 mm (0.002 in.) on the inside diameters.

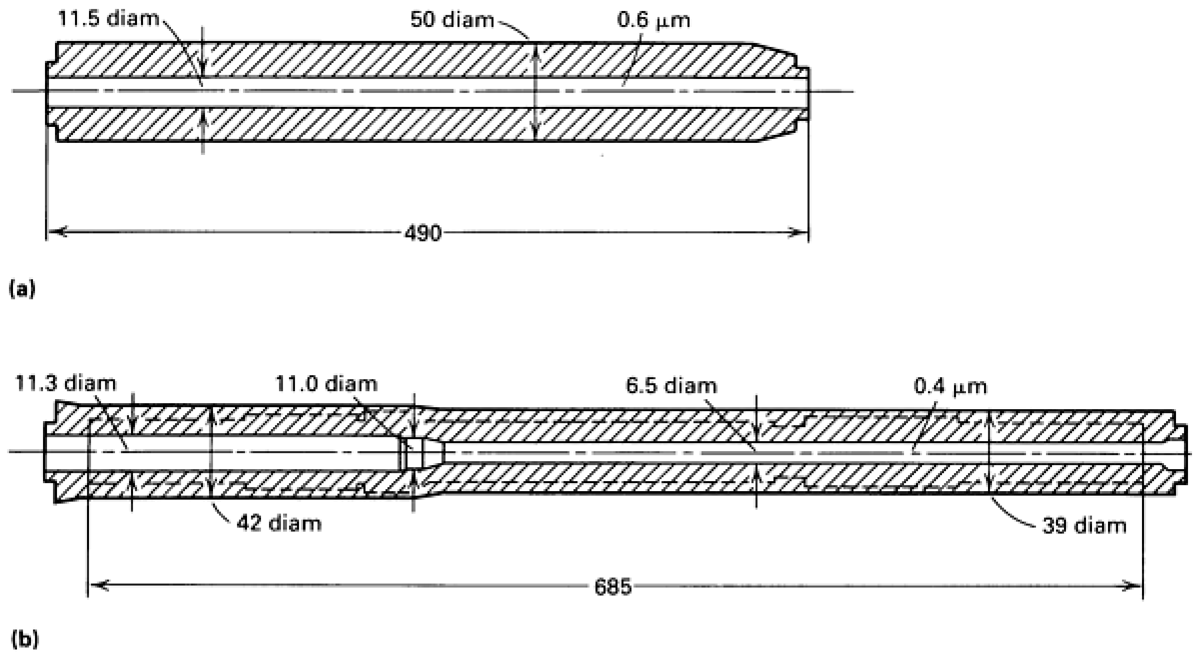

Fig. 7 5120 steel shaft for automobile automatic transmission produced by cold radial forging. The shaft inside diameter is formed to net shape. Dimensions given in millimeters (1 in. = 25.4 mm). (a) Blank. (b) Forged

shaft.

These requirements can be met if the shaft is radial forged over a short tungsten carbide mandrel. Inside diameter surface quality is improved, and the blank can be kept shorter because the reduction in cross-sectional area creates an elongation of the shaft. The proper reduction in area is between 28 and 40%.

The tolerance for the bores of this 5120 steel shaft is ±0.02 mm (±0.0008 in.). The cycle time of the shaft is approximately 2.3 min. Typical cycle times depend on part length.

Example 2: Turbine Shaft Preform.

Figure 8 shows a radial forged turbine shaft preform with the proper volume distribution. The subsequent closed-die forging operation results in an almost flashless workpiece. The material is either a titanium or a nickel-base alloy, both of which have a narrow temperature range for forging. The correct forging temperature range is maintained by varying feed rates (and therefore deformation rates) during the forging process. A higher feed rate creates more deformation per unit time, which results in higher temperatures in the workpiece. Tolerances on the outside diameter are approximately 1% of the diameter.

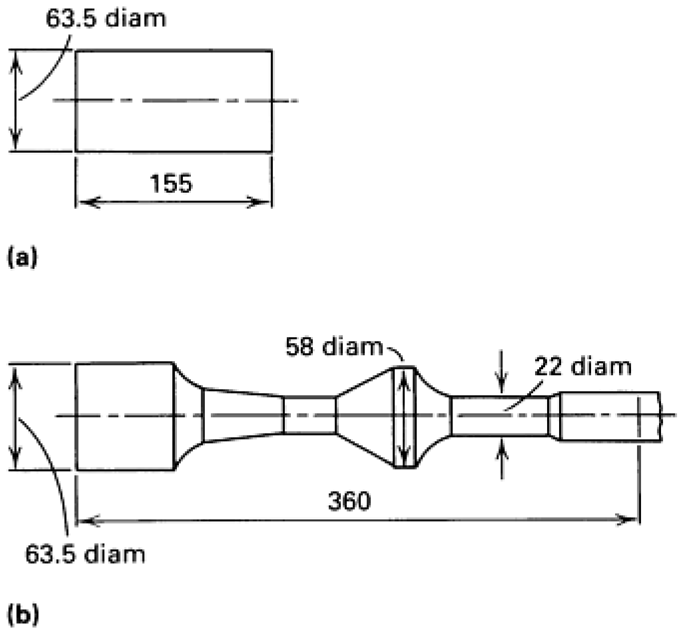

Fig. 8 Blank (a) and turbine shaft preform (b) produced by hot radial forging from titanium or nickel-base alloys. Dimensions given in millimeters (1 in. = 25.4 mm)

Example 3: Hollow Axle With Center Upset.

Figure 9 shows the production sequence for the radial forging of a hollow axle. The upset portion near the center of this part is heated to a higher temperature than the other sections. During upsetting, the forging hammers are closed on the outside diameter of the intermittently rotating workpiece. An axial force applied along with the radial forging force ensures that the work material flows toward the center of the axle.

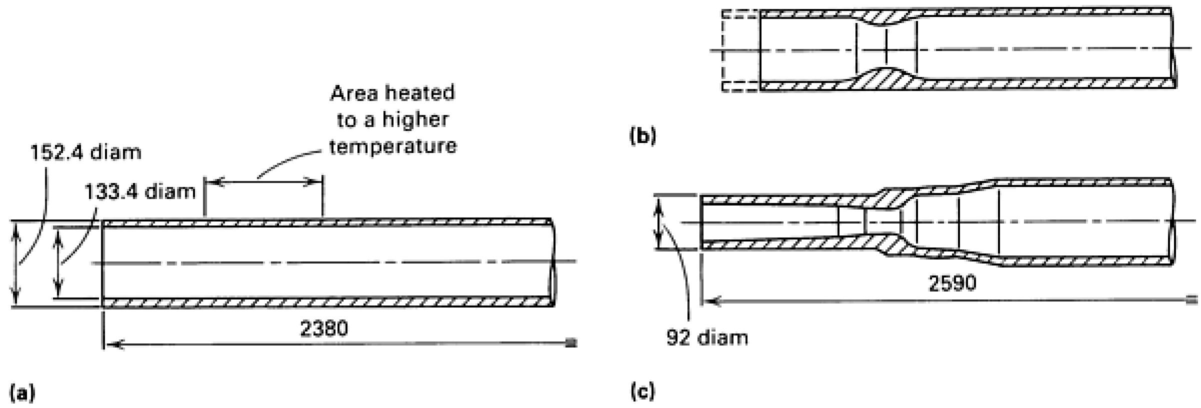

Fig. 9 Steps in the production of a hollow axle with a center upset by radial forging. (a) Tube blank before forging. (b) After center upsetting. (c) Stepped inside diameter contour formed over a water-cooled mandrel. Dimensions given in millimeters (1 in. = 25.4 mm)

After upsetting of the center portion, the stepped contour of the axle end is formed over a water-cooled mandrel. The inside diameter is controlled by the mandrel; normal tolerances on both inside and outside diameter are 1% of the diameter. Total cycle time for one end is approximately 40 s.

Radial Forging

Hans Hojas, Gesellschaft für Fertigungstechnik und Maschinenbau mbH

Two-Hammer Radial Forging Machines

The two-hammer radial forging machine was developed for the forging of unalloyed or low-alloy structural steels. The primary design feature of this machine is the two horizontally arranged, mechanically driven, high stroke rate press rams (Fig. 10) that radially forge the workpiece while it is guided by two forging manipulators. During forging, the workpiece rotates between the two forging tools, as in the four-hammer radial forging machine. The tool layout on the two-hammer radial forging machine is such that the working surfaces of the forging tools are at an obtuse angle to each other; thus, four forming surfaces contact the workpiece with each stroke. Control is numerical, as in the four-hammer precision forging machine. Semiautomatic control is usually used for the forging of bars. Stepped shafts are forged automatically.

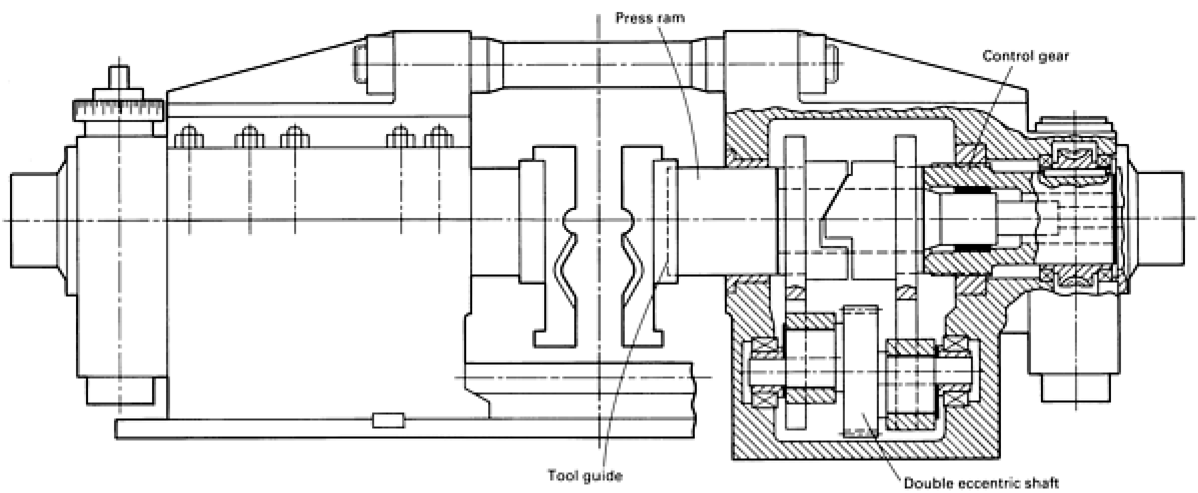

Fig. 10 Schematic showing the mechanical drive of a two-hammer radial forging machine

The stroke motion of the press rams in two-hammer machines is initiated by the rotation of a double eccentric shaft (Fig. 10). The stroke position of the press rams can be changed by means of control gears, making it possible to determine the reduction per pass and therefore the final dimensions of the forged workpieces. The height of the forging tools can be adjusted in a tool guide. It is possible, therefore, to accommodate two different tool impressions in one forging tool. The hammer position can be changed automatically within a few seconds during the process.

Isothermal and Hot-Die Forging

Sanjay Shah, Wyman-Gordon Company

Introduction

HOT-DIE AND ISOTHERMAL FORGING are special categories of forging processes in which the die temperatures are significantly higher than those used in conventional hot-forging processes. This has the advantage of reducing die chill and results in a process capable of producing near-net and/or net shape parts. Therefore, these processes are also referred to as near-net shape forging processes. These processing techniques are primarily used for manufacturing airframe structures and jet-engine components made of titanium and nickel-base alloys, but they have also been used in steel transmission gears and other components.

Isothermal and Hot-Die Forging

Sanjay Shah, Wyman-Gordon Company

Isothermal Forging

In the isothermal forging process, the dies are maintained at the same temperature as the forging stock. This eliminates the die chill completely and maintains the stock at a constant temperature throughout the forging cycle. The process permits the use of extremely slow strain rates, thus taking advantage of the strain rate sensitivity of flow stress for certain alloys. The process is capable of producing net shape forgings that are ready to use without machining or near-net shape forgings that require minimal secondary machining.

Hot-Die Forging

The hot-die forging process is characterized by die temperatures higher than those in conventional forging, but lower than those in isothermal forging. Typical die temperatures in hot-die forging are 110 to 225 °C (200 to 400 °F) lower than the temperature of the stock. When compared with isothermal forging, the lowering of die temperature allows wider selection of die materials, but the ability to produce very thin and complex geometries is compromised.

Advantages

The principal criterion for selecting these processes in production is the economic advantage offered because of reduced input material and/or reduced machining. Therefore, they are primarily used for expensive and difficult-to-machine alloys such as titanium and nickel-base alloys. The main advantages of isothermal and hot-die forging are discussed below.

Reduced Material Costs. These near-net shape processes allow the forging to be designed with smaller corner and fillet radii, a smaller draft angle, and a smaller forging envelope. These design features reduce the additional material incorporated to protect the finished part geometry and therefore reduce the weight of the forging considerably. An example of this weight reduction for the isothermal forging of a nickel-base alloy disk is shown in Fig. 1. A similar comparison for the hot-die forging of a Ti-6Al-4V structural forging is shown in Fig. 2, in which a typical cross section is shown for comparison between conventional and hot-die designs. At current material prices, the reduction in input weight amounts to a significant cost savings.

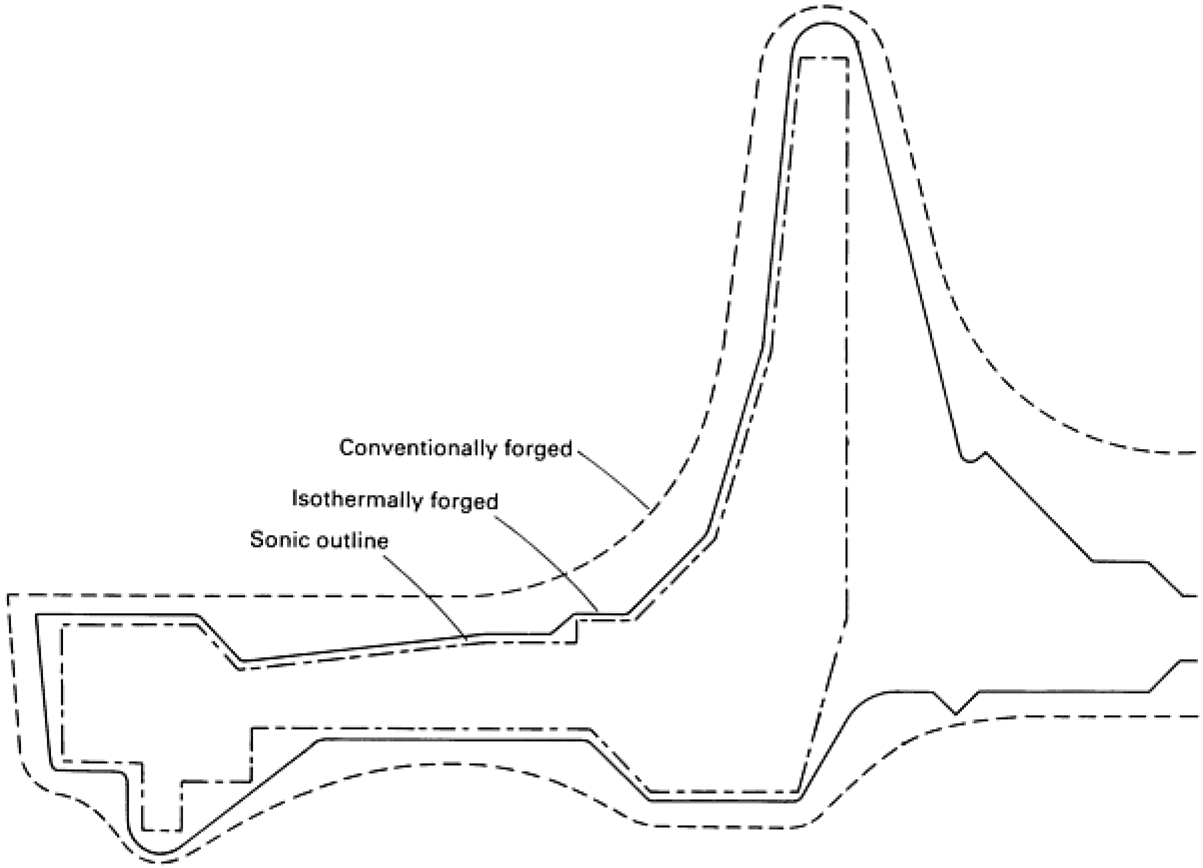

Fig. 1 Weight reduction obtained by the isothermal forging of a disk instead of conventional forging methods. A 27 kg (60 lb) weight reduction was obtained in the production of the nickel-base disk by isothermal forging.

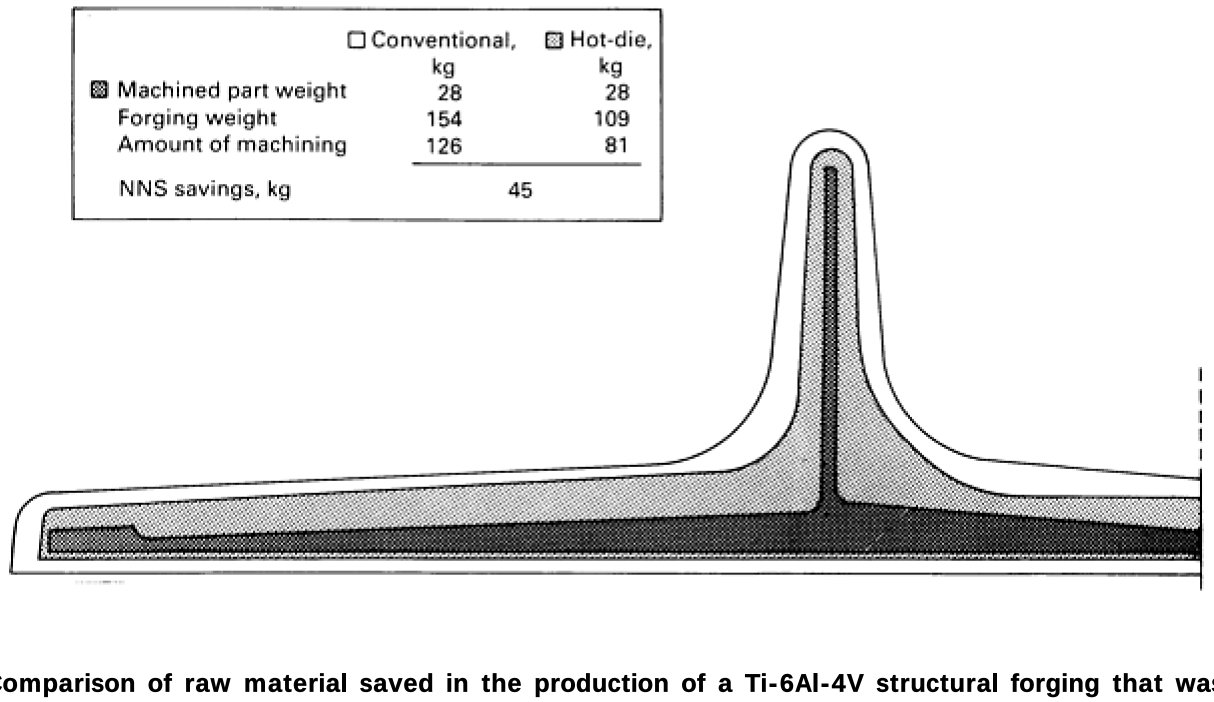

Fig. 2 Comparison of raw material saved in the production of a Ti-6Al-4V structural forging that was hot-die forged versus a conventionally forged part (see cross-sectional areas and legend)

Reduced Machining. Because near-net shape forgings are produced close to end use weight and configuration, less material removal is required during machining when compared with conventional forgings, as shown in Fig. 1 and 2. In most cases, no machining is required, or only finish machining cuts are required to produce the final part. The elimination of complex machining can sometimes justify the use of these processes even for less expensive alloys, as in the case of steel gears forged with net tooth geometry.

Uniformity of Product. The final product produced by isothermal and hot-die forging exhibits more uniform properties because of lower or nonexistent thermal gradients within the forging.

Forgeability. For alloys such as Alloy 100 (Ni-15.0Co-10.0Cr-5.5Al-4.7Ti-3.0Mo-0.6Fe-0.15C-1.0V-0.06Zr-0.015B) that have a narrow range of working temperatures, a conventional forging process will result in severe forge cracking and cannot be used to produce the parts. In these cases, isothermal forging improves the forgeability and makes it possible to forge the alloy.

Isothermal and Hot-Die Forging

Sanjay Shah, Wyman-Gordon Company

Process Description

In conventional forging operations, the dies are heated to 95 to 205 °C (200 to 400 °F) for hammer operations and to 95 to 425 °C (200 to 800 °F) for press operations. These temperatures are significantly lower than the 760 to 980 °C (1400 to 1800 °F) stock temperature for titanium and the 980 to 1205 °C (1800 to 2200 °F) stock temperature for nickel-base alloys and steels. In addition, these operations are performed at relatively high speeds, resulting in high strain rates. Typical strain rates range to 50 mm/mm/min (50 in./in./min) for hydraulic presses, to 700 mm/mm/min (700 in./in./ min) for screw presses, and exceed 12,000 mm/mm/min (12,000 in./in./min) for hammers.

For titanium and nickel-base alloys, the flow stress in general has a high sensitivity to both temperature and strain rate. This effect is illustrated for Ti-6Al-4V in Fig. 3 and for Alloy 95 (Ni-14.0Cr-8.0Co-3.5Mo-3.5W- 3.5Nb - 3.5Al - 2.5Ti - 0.3Fe - 0.16C-0.05Zr-0.01B) in Fig. 4. As shown, a decrease of 110 °C (200 °F) due to die chill can more than double the flow stress. An order of magnitude increase in strain rate has a similar effect. In addition, the workability range for some of these alloys is limited to a narrow temperature range. Therefore, conventional forging for these alloys is characterized by high resistance to deformation, high forging loads, multiple forging operations, and sometimes cracking.

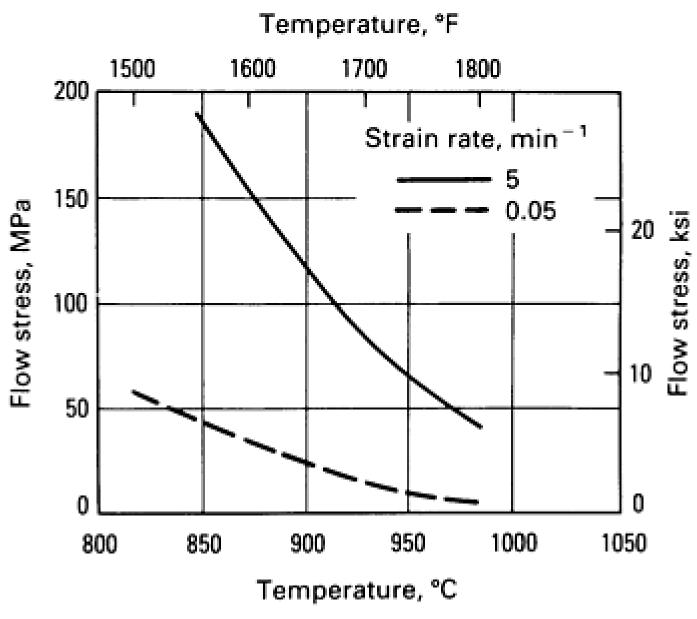

Fig. 3 Effect of temperature and strain rate on flow stress for Ti-6Al-4V

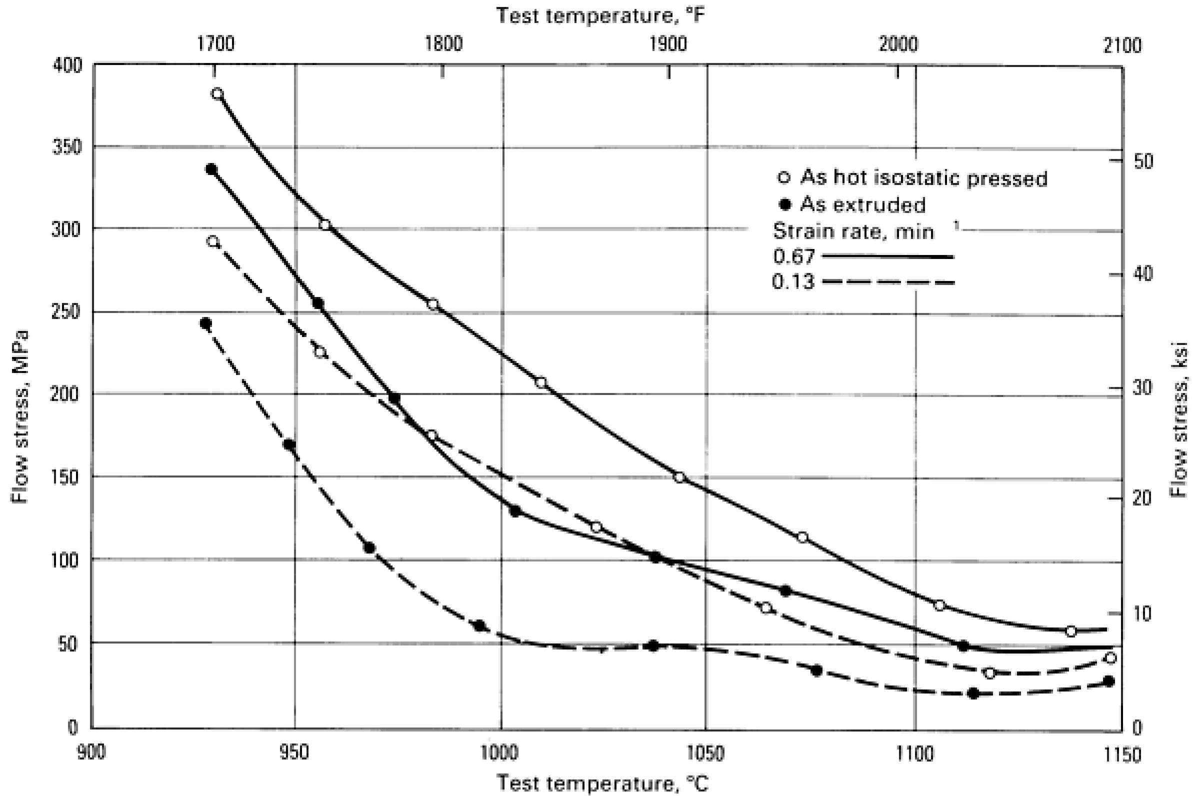

Fig. 4 Effect of temperature and strain rate on flow stress for Alloy 95

The isothermal forging and hot-die forging processes overcome some of these limitations by increasing the die temperature so that it is close to the temperature of the forging stock. The die temperatures are maintained at these high levels through continuous heating of the dies during the forge operation using induction heating, gas-fired infrared heating, resistance heating, and so on. The heating arrangement is combined with the press so that heat can be provided to the dies during the forging operation.

Figure 5 shows a typical arrangement for induction heating. In this setup, a set of induction coils is placed around the dies (Alloy 100, Fig. 5). The electrical power input to the induction coils is controlled by thermocouples buried in the dies, and it maintains the dies at a specified temperature. The arrangement also incorporates a die stack consisting of several plates, some of them made from superalloys, to be placed between the dies and press platen. The die stack protects the press platen from the heat of the dies and maintains the platen below a specified temperature. This arrangement prevents excessive temperature at the press platen, which could severely affect the functioning of the press hydraulics and/or the dimensional stability of the platen.

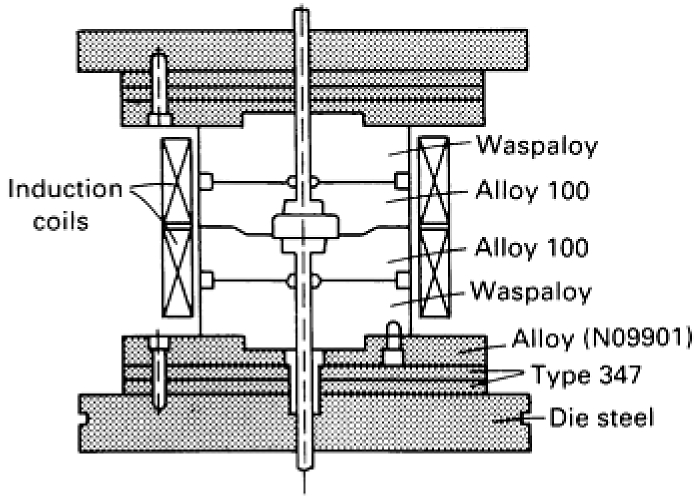

Fig. 5 Schematic of induction heating system for hot-die or isothermal forging

Another heating arrangement, using gas-fired infrared heaters, is shown in Fig. 6. This illustration also shows a resistance heated heater plate situated under the dies.

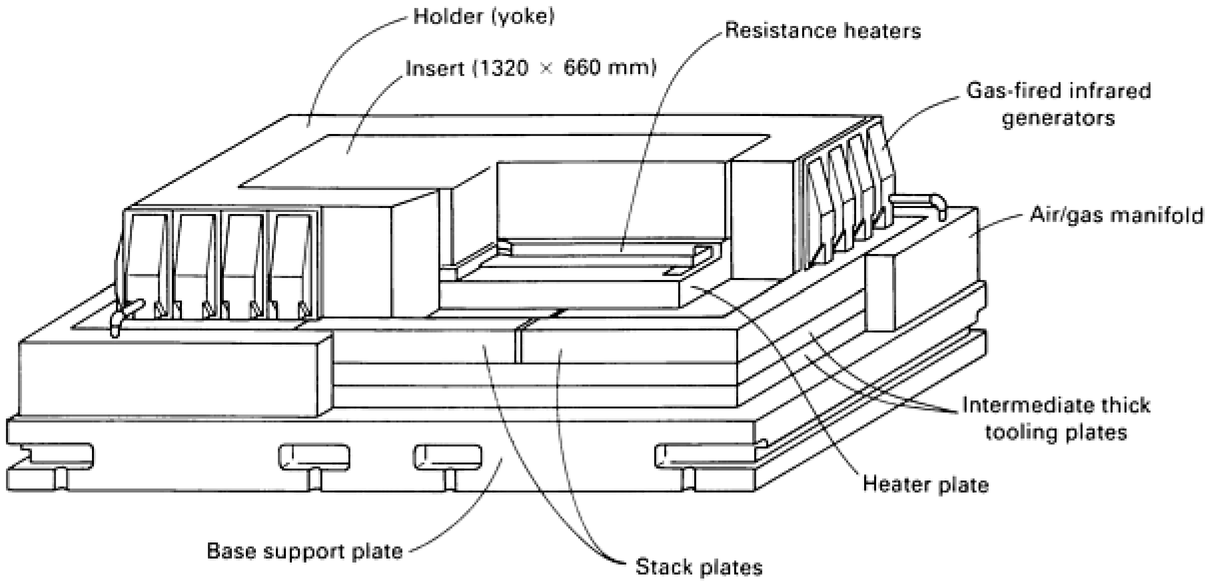

Fig. 6 Gas-fired infrared heating setup for hot-die forging

The higher die temperatures for these processes allow for forging stock to remain at a higher temperature for a longer time during die contact. This has the added advantage of reducing the forging speed, thus lessening the strain rate. The beneficial impact of reduced strain rate on flow stress is shown in Fig. 3 for Ti-6Al-4V and in Fig. 4 for Alloy 95. Typical strain rates used for isothermal forgings are 0.5 mm/mm/min (0.5 in./in./min) or lower, while hot dies use strain rates in the range of 3 to 10 mm/mm/min (3 to 10 in./in./min).

Forging Alloys

The hot-die and isothermal forging processes typically result in higher tooling costs due to higher die temperatures, as well as higher costs for forging operation due to slower strain rate, when compared to conventional forging. However, their ability to forge to a near-net shape results in lower material costs. Therefore, they are typically used for expensive alloys where material content represents a large portion of the total cost of forging.

Alloys forged using these processes include titanium alloys, such as Ti-6Al-4V, Ti-6Al-2Sn-4Zr-2Mo, and Ti-10V-2Fe-3Al and superalloys, such as Alloy 100, Alloy 95, Alloy 718 (UNS07718), and Waspaloy. In the case of β-titanium alloys such as Ti-10V-2Fe-3Al, the typical forging temperatures range from 760 to 815 °C (1400 to 1500 °F), and the near-net shape processes are especially attractive because of the availability of relatively inexpensive alloys for die materials. In the case of superalloys such as Alloy 100, the working temperature range is so small that the isothermal and hot-die methods are the only feasible forging processes currently available. In addition, at specific temperatures and strain rates, Alloy 100 exhibits superplasticity, as shown in Fig. 7. When forged within this temperature range and strain rate range, the alloy can be deformed to large strains at low loads and to fairly complex geometries.

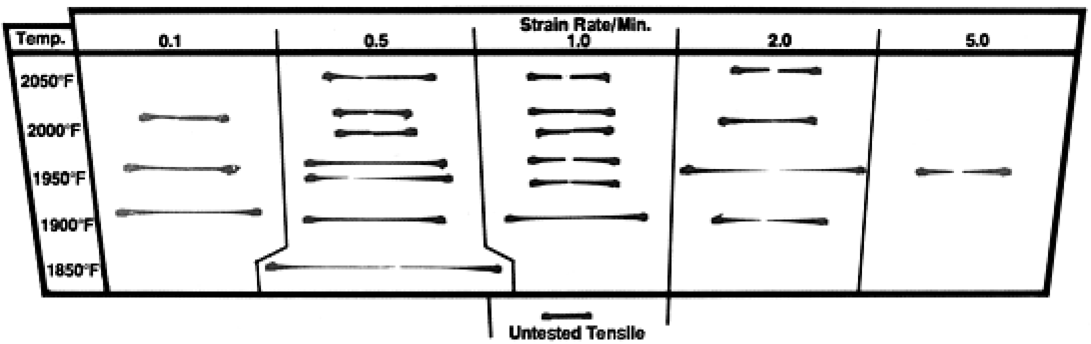

Fig. 7 Superplastic behavior of extruded Alloy 100 at various temperatures and strain rates

Typical parts forged in the above alloys include structural components for air-frames; jet-engine disks, shafts, and seals; and other aerospace components. The processes have also been used for some steel alloys to make complex geometries, such as gears, in order to produce net surfaces and to eliminate expensive machining.

Process Selection

Lower overall cost is one of the major reasons for selecting hot-die or isothermal forging over a conventional forging process. Several factors influence this overall cost, and a complete value analysis is necessary for each part or part family to determine its potential as a candidate for hot-die or isothermal forging. These factors are described in the section "Cost" in this article.

Another criterion for selecting these processes is the need for uniformity and product consistency. In conventional forging processes, there is a temperature gradient from the surface to the center of the forging because of die chill. This gradient results in different areas of the part being forged at different temperatures and could cause a variation in microstructure from the center to the surface of the forging. When this structural variation is not acceptable, the higher die temperature process offers the advantage of a more uniform temperature during deformation and therefore less variation in microstructure. In addition, because the die temperature and strain rate are controlled within a narrow range, there is improved consistency from part to part.

The process selection for some alloys, such as Alloy 95 and Alloy 100, is based on their inherent tendency to develop forge cracking under conventional forging conditions. Hot-die forging and isothermal forging represent the only suitable forging processes available for these alloys.

Isothermal and Hot-Die Forging

Sanjay Shah, Wyman-Gordon Company

Process Design

The same factors that affect conventional forging processes also affect near-net shape processes. However, because of tighter forging designs and the requirements for strict uniformity and consistency, stringent controls on the following process parameters are necessary.

Forging parameters such as forge temperature, strain rate, preform microstructure, forging pressure, and dwell time are all important factors in deciding the degree of dimensional sophistication and the resultant microstructure of the finished part.

In general, lower strain rates and increased dwell time increase the potential degree of shape complexity and shape sophistication of the forging, but could influence microstructure due to exposure to high temperatures for long periods of time during and after deformation. In addition, very low strain rates cannot be used in hot-die forging, because of the potential decrease in the stock temperature. Preform microstructure has a direct influence on the flow stress and superplasticity of the material, sometimes requiring extruded billet with fine-grain structure as the starting material. Some of the alloys that are forged achieve their final mechanical properties by thermomechanical processing; in this case, the selection of the forge temperature and the amount of deformation are controlled by property requirements.

Close control of the above parameters and the entire deformation process is necessary to achieve proper results. New analytical tools, such as deformation mapping and computer simulation of the deformation process, are very useful for optimization of the processes.

Die Temperature. Proper selection of die temperature is one of the critical factors in process design for hot-die and isothermal forging. The effect of die temperature on forging pressure is illustrated in Fig. 8 for Ti-6Al-4V. As shown in Fig. 8, a decrease in die temperature from 955 to 730 °C (1750 to 1350 °F) may result in doubling the forging pressure and may affect the shape capability available. It will also have an impact on the selection of die materials and economics. In addition, for some alloys, the surface microstructure is affected by die temperature.

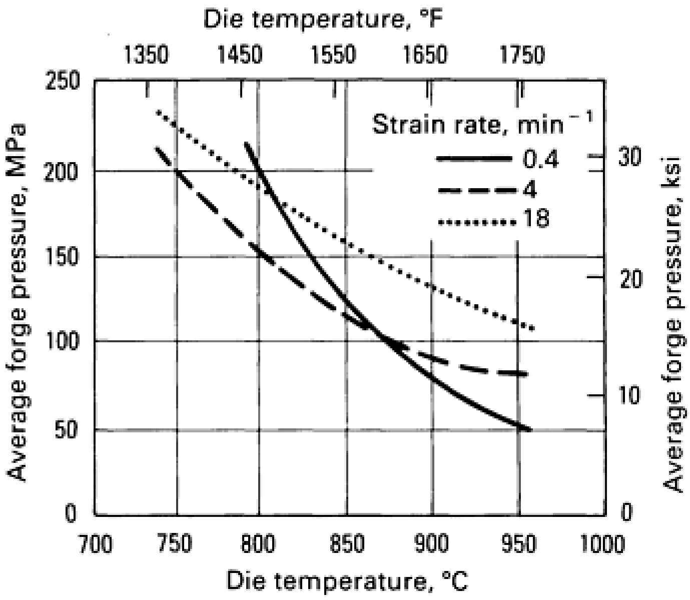

Fig. 8 Effect of die temperature on forging pressure at various strain rates for Ti-6Al-4V

Lubrication. In these near-net shape processes, lubrication plays an important role because of the precision of the forgings, the existence of net surfaces, and the high interface temperatures. Standard practice is to apply coatings to the billet or the preform prior to forge heating. They are sometimes supplemented by die lubrication during the forging operation. The lubrication/coating systems must provide proper lubrication and must act as a good parting agent for the easy removal of the forging from the dies. They also have to protect the forging surface in order to maintain acceptable surface finish for the forgings and must not build up in the dies. For die temperatures to 650 °C (1200 °F), graphite lubricants are acceptable, but for higher die temperatures, glass frits with proper additives or boron-nitride coatings find wider use.

Preform Design. Another significant factor in process design is the design of the preform. One approach is to design a fairly complex preform that is produced by a conventional forging process. The near-net shape process is then used to size the part to tight geometries and tolerances. This approach was prevalent during the early development of hot-die technology. A recent trend is to start with a conventionally forged blocker geometry and to finish forge using a hot-die or isothermal process. In some cases, such as the isothermal forging of superplastic alloys, it is possible to start directly with a billet geometry and produce the finish geometry with a single near-net shape forging operation. Preform design must also take into consideration the amount of deformation needed during the finish forge operation to obtain the desired mechanical properties.

Post-Forge Operations. After the parts are forged using the hot-die or isothermal forging methods, they are subjected to the same clean-up, heat treatment, machining, and nondestructive evaluations as the conventional forgings. These processes are described in detail in the articles "Forging of Nickel-Base Alloys" and "Forging of Titanium Alloys" in this Volume.

Sanjay Shah, Wyman-Gordon Company

Die Systems

The principal difference between conventional forging and hot-die/isothermal forging is the die temperature. Therefore, the die systems affect the successful implementation of these processes.

Die Materials. Conventional die steels do not have adequate strength or resistance to creep and oxidation at near-net shape temperatures. Hot-die/isothermal forging dies must maintain precision while resisting the excessive high-temperature-induced stresses that are caused by tight, complex geometries. Therefore, expensive nickel-base alloys such as Alloy 100, B-1900, MAR-M-247, Astroloy, Alloy 718, and NX-188, as well as molybdenum alloys such as titanium zirconium-modified molybdenum or TZM must be used for these applications. The yield strength and 100-h stress rupture strength of some of these alloys are shown in Fig. 9 and 10 at typical near-net shape temperatures. Table 1 gives the compositions of die materials for isothermal and hot-die forging.

Table 1 Compositions of die materials for isothermal and hot-die forging

(a) Nominal unless otherwise indicated

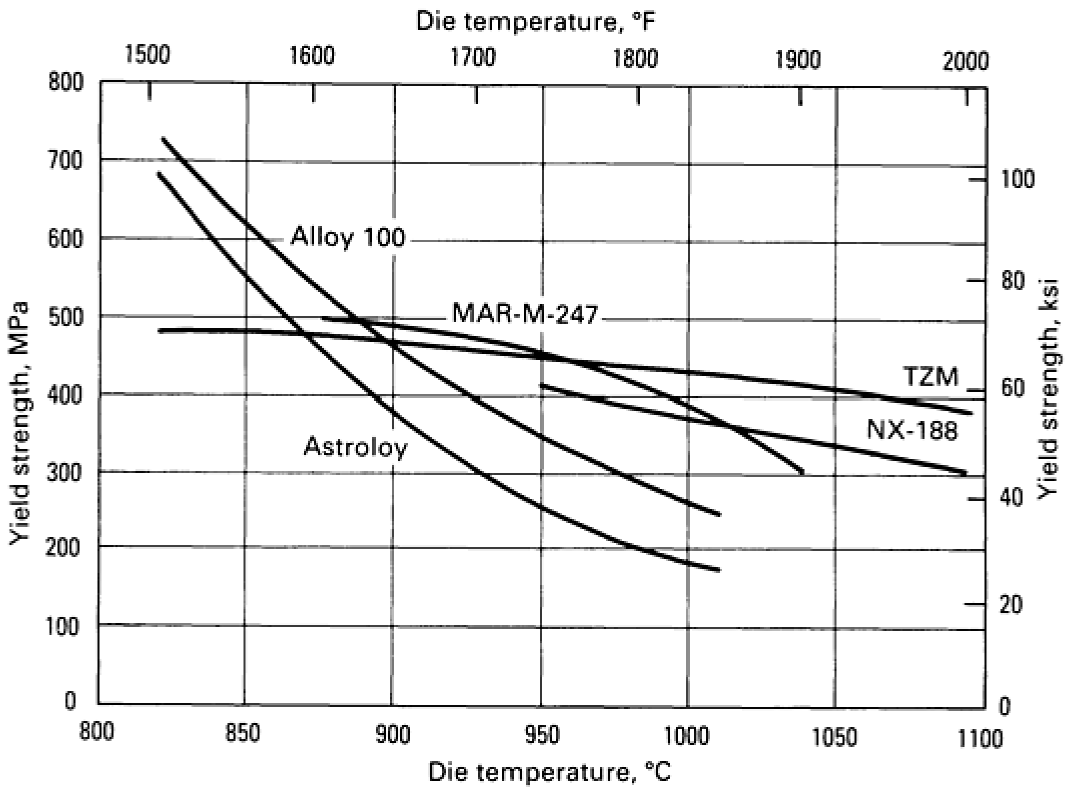

Fig. 9 Yield strength as a function of near-net shape die temperature for numerous nickel-base alloys and a molybdenum alloy (TZM)

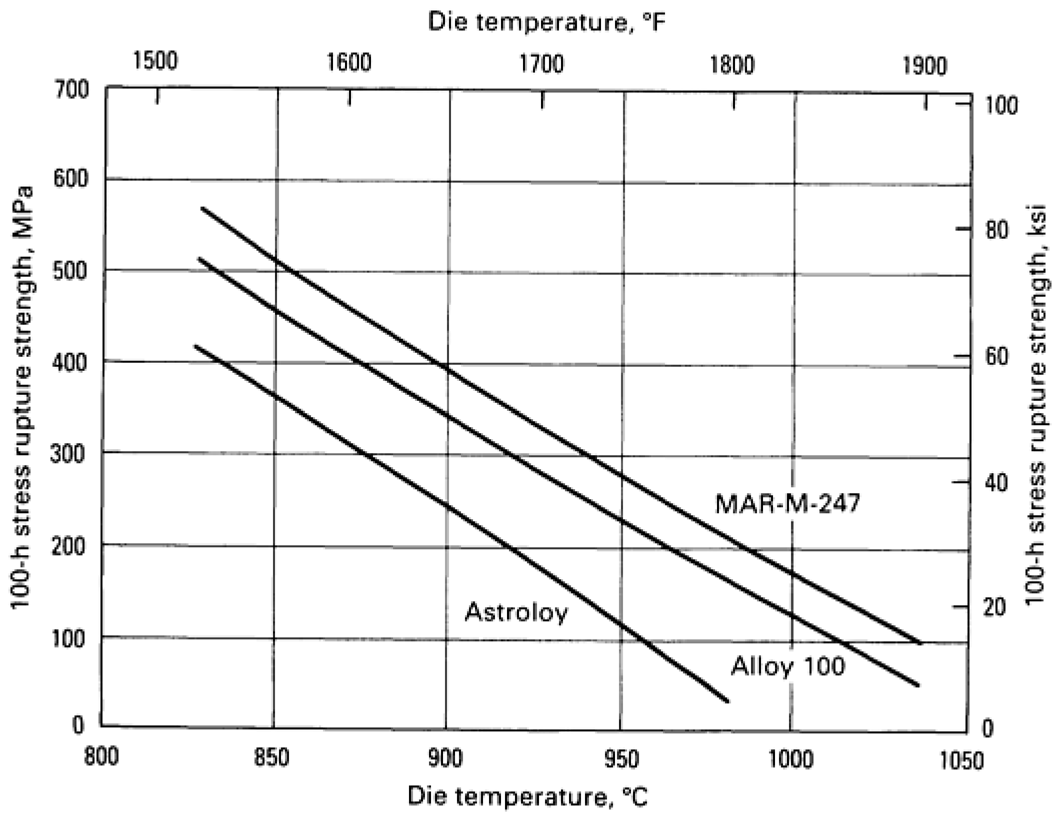

Fig. 10 100-h stress rupture strength as a function of near-net shape die temperature for selected nickel-base alloys

Proper selection of die material for a given application depends on the operating temperature, forging pressure requirements, and anticipated die life. As shown in Fig. 9, TZM is the most practical die material for the isothermal forging of nickel-base alloys (which are forged at 1040 °C, or 1900 °F, or higher), while Alloy 100 and Astroloy are better suited to the hot-die and isothermal forging of α-β titanium alloys, such as Ti-6Al-4V, forged at 925 to 980 °C (1700 to 1800 °F). For β-forged titanium alloys such as Ti-10V-2Fe-3Al, which can be forged at 815 °C (1500 °F) or lower, Alloy 718 or Alloy 713LC dies at 650 to 705 °C (1200 to 1300 °F) may provide a satisfactory cost-effective alternative. Astroloy or Alloy 718 dies have also been successfully used for forging of superalloys such as Alloy 718 at 650 to 760 °C (1200 to 1400 °F). When large quantities of parts are to be produced, die life becomes an important consideration, and the cost of die material becomes a secondary issue.

Die Manufacturing. The die materials used for hot-die and isothermal forging are more difficult to machine than conventional die steels. Most dies manufactured for axisymmetric forgings are turned on a lathe, but dies for asymmetric parts may have to be milled, which can be very expensive. Two approaches have been used in these cases to reduce the cost of die manufacturing. Several early attempts with smaller die sizes and simple geometries used precision cast dies. The more widely used technique is to produce these dies for structural shapes by electrical discharge machining using a precision-machined graphite electrode. The tolerances on die sinking are held to better than ±0.1 mm (±0.005 in.). Because most of the die materials are not weld repairable, accuracy is critical in the machining of the dies.

Atmospheric Control. When TZM is used as a die material, a special atmospheric control with either vacuum or inert gases is necessary because of the tendency of molybdenum alloys to oxidize severely at temperatures greater than 425 °C (800 °F). This necessitates the introduction of a special enclosure in the press around the die system and associated enclosures for heating of multiples and material handling. Therefore, processes using TZM dies (mostly isothermal forgings) have dedicated equipment. On the other hand, most nickel-base alloys can be heated in a normal atmosphere; therefore, most hot-die forging operations that use these die materials are performed in conventional presses, with the only additional requirement being the introduction of the die stack and/or the die heating system described earlier. These presses do not have to be dedicated, and they can be used interchangeably for conventional forging as well as hot-die forging.

Isothermal and Hot-Die Forging

Sanjay Shah, Wyman-Gordon Company

Forging Design Guidelines

The principal criterion in designing hot-die and isothermal forgings is to design the forging as close as possible to the machined part with a potential of using as-forged surfaces if feasible. Beyond this, it is difficult to establish one set of guidelines for a variety of parts that may be considered for near-net shape applications. Each part family must be considered individually in order to ensure the optimal, most cost-effective design. There are, however, some general guidelines that can be used in designing these parts.

Guidelines for forging design parameters, such as minimum web and rib thicknesses, corner and fillet radii, draft angle, and design cover, are presented in Table 2 for various alloys and geometries. These values indicate the current industry capabilities, and a significant amount of research and development effort is being applied to improve them, including an increased size capability, geometries that are closer to the finished part, and the ability to provide negative draft and contour capabilities through the use of split dies.

Table 2 Typical near-net shape forging design parameter

Material	Parameters						
	Miximum plan view area	**Forging envelope**	**Draft angle, degrees**	**Minimum corner radius**	**Minimum fillet radius**	**Minimum web thickness**	Minimum rib width

	m^2	$in.^2$	mm	in.		mm	in.	mm	in.	mm	in.	mm	in.
Near-net axisymmetric Alloy 718	0.645	1000	1.5	0.06	3	6.4	0.25	19	0.75	15	0.60	. . .	**. . .**
Near-net axisymmetric titanium	0.645	1000	1.5	0.06	3	3.3	0.13	6.4	0.25	13	0.50	. . .	**. . .**
Near-net structural titanium (Ref 3)	0.387	600	1.5-2.3	0.06-0.09	3	3.8	0.15	6.4	0.25	10	0.40	6.4	**0.25**
Net structural $\alpha + \beta$ titanium (Ref 3)	0.194	300	0.0	0.0	1-3	1.5	0.06	3.3	0.13	4.8	0.19	4.8	**0.19**
Net structural β titanium (Ref 1)	**0.081**	**125**	**0.0**	**0.0**	**0-1° 30'**	**1.5**	**0.06**	**3.3**	**0.13**	**2.3**	**0.09**	**2.3**	**0.09**

Generally, the tolerances considered for conventional forgings, such as those for length and width, die closure, straightness, contour, radii, and draft angle, must also be considered for near-net shape forgings. For the near-net shape parts, the tolerances are dictated by the process and part size. Tolerances to ±1.5 mm (±0.06 in.) and greater have been acceptable for near-net forgings, while tolerances of ±0.5 mm (±0.02 in.) and tighter have been achieved for small net surface titanium structural parts. In general, they are determined on an individual part basis and are negotiated between the forging vendor and the customer.

In designing the dies for these forgings, accurate calculation of the die shrinkage allowance is important because of the tight tolerances associated with these parts. Typically, the die geometries are machined using less than 20% of the tolerance spread allowed for the forgings. When fairly tight draft wall and/or complex contours are features of the forge design, segmented dies with a holder system (described in the article "Forging of Aluminum Alloys" in this Volume) are used to achieve accuracy while maintaining the ease of removing the forging from the dies. Most hot-die and isothermal forging processes also use a knock-out system for removing forgings from the dies.

Isothermal and Hot-Die Forging

Sanjay Shah, Wyman-Gordon Company

Cost

The total cost basis of producing a part has a major impact on the selection of the hot-die or the isothermal forging process for a given part. This total cost includes not only the cost of the forging material and the forging conversion but also the cost of machining this forging to the final shape, the cost of tooling, and the cost of maintaining the tooling.

The initial cost of these processes is high because of the expensive die materials, such as TZM and Alloy 100, which can sometimes cost in excess of ten times the conventional die materials, and because of the high cost of machining the dies. The setup cost during forging for these processes may also be higher than that for conventional forging because of the need for die stack and die heating and, in case of isothermal forging, the need for an enclosed atmospheric chamber. On a per-part basis, the conversion cost may be higher than that for conventional forging in some cases, but lower in other cases, depending on geometry and the potential for using smaller equipment to make the same part. For these processes to be economically feasible, there must be a significant savings in material costs and machining costs to offset the higher costs of tooling and setup.

To determine whether to use hot-die/isothermal forging or conventional forging and whether to use near-net geometry or net geometry, the following factors should be considered:

- Total part quantity
- Part geometry and complexity
- Forging temperature and die temperature
- Savings in material and machining
- Die sizes and expected die life
- Cost of maintaining tooling to produce desired tolerances

The design and the process are selected by considering the above factors and their influence on the cost of tooling and the cost of individual parts. A break-even analysis is then performed to determine the quantity at which the competing processes break even, and based on the total quantity required for the part, the most economical process is selected.

Example 1: Comparative Costs of Conventional Forging Versus Hot-Die Forging in the Manufacture of a Connecting Link.

Figure 11 shows relative comparison of costs for a conventional forging versus a hot-die forging for a connecting link (Ref 2). This part, 0.048 m^2 (75 $in.^2$) in plan view area (PVA), was made of Ti-6Al-4V. The forging for this part using conventional design weighed 17.4 kg (38.3 lb), while a hot-die forging weighed 13 kg (29 lb). The hot-die design was based on the use of Astroloy dies at approximately 925 °C (1700 °F) with some net surfaces. The die system for this part required a die stack. Figure 11 shows that there was a significant difference in initial tooling costs and that it took over 500 forgings for the savings in material and machining to pay for the difference in the cost of hot-die tooling versus conventional tooling. Hot-die near-net forging was not cost effective for this part at quantities under 500.

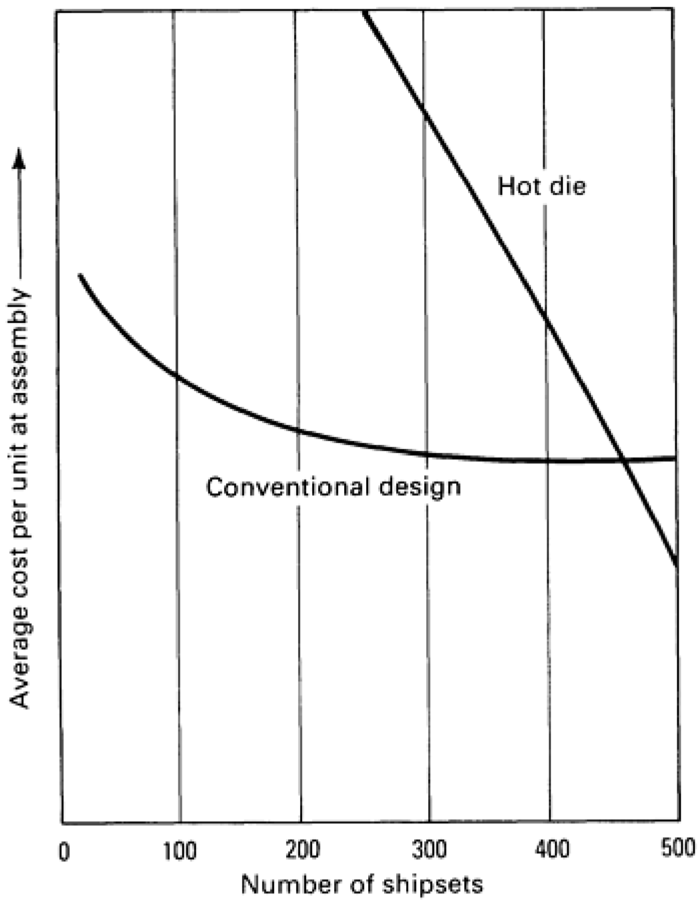

Fig. 11 Cost comparison between conventional design versus hot-die design for the manufacture of a connecting link forging made of Ti-6Al-4V

Example 2: Comparative Costs of Conventional Forging Versus Hot-Die Forging in the Manufacture of a Bearing Support.

Figure 12 shows a comparison similar to that in Fig. 11 but for a different part--a bearing support (Ref 2). This part was also made of Ti-6Al-4V and was 0.178 m^2 (275 $in.^2$) in plan view area. Conventional forging for this part weighed 55.3 kg (122 lb), while hot-die near-net forging using Astroloy dies at 925 °C (1700 °F) weighed 21.1 kg (46.5 lb). Because of the larger size of this part compared to the forging in Example 1, the difference in die costs between conventional forging and hot-die forging was greater for this part. However, because of a significant reduction in material costs and machining costs, the break-even point for the part was at a quantity of less than 200.

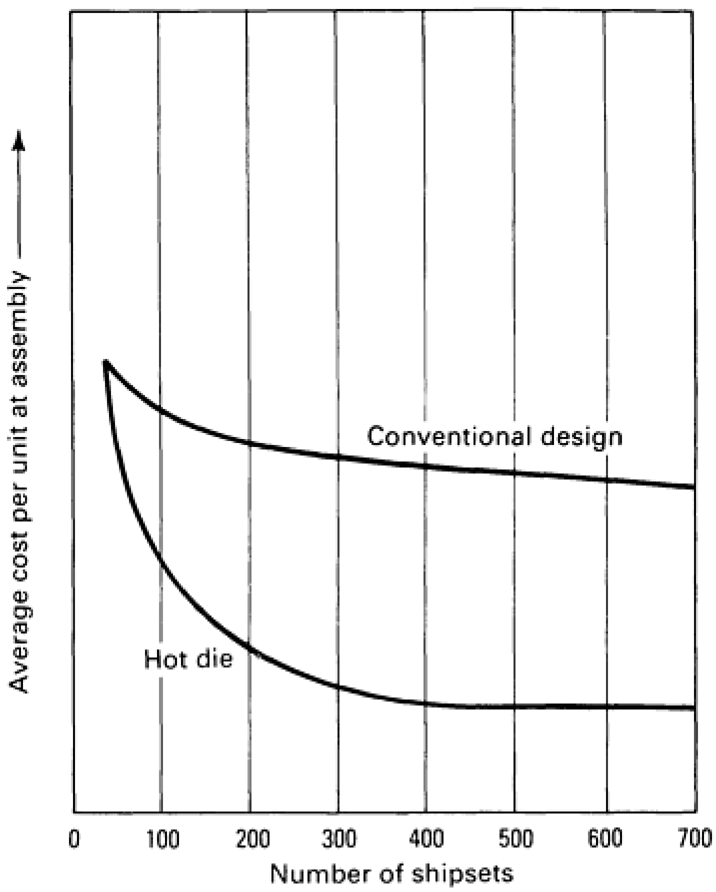

Fig. 12 Cost comparison between conventional design method versus hot-die design for the manufacture of an F-15 bearing support made of Ti-6Al-4V

Production Forgings

The hot-die and isothermal forging technologies emerged as development efforts in the early 1970s and have become production realities since the late 1970s. Some examples of production forgings are given in this section.

Figure 13 shows a Ti-6Al-4V hot-die forging for the F-15 bearing support referred to in Example 2. The part required three closed-die operations to produce. The first two operations--preblock and block--were performed with conventional forging processes, and the parts were then finish forged as doubles (0.355 m^2, or 550 $in.^2$, PVA) in Astroloy hot dies. A cost comparison of this part for conventional forgings versus hot-die forging is shown in Fig. 12.

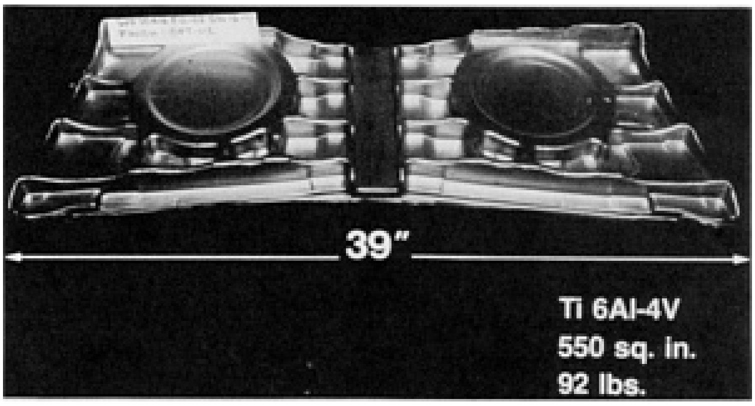

Fig. 13 F-15 bearing supports weighing 21.1 kg (46.5 lb) individually, made of Ti-6Al-4V that was finish forged with a hot-die near-net forging process in Astroloy dies at 925 °C (1700 °F). Bearing supports were finish forged as doubles.

Other examples of these technologies in production mode are presented in Fig. 14, 15, 16, and 17. Figure 14 shows a Ti-6Al-4V engine mount that was hot-die forged with most surfaces being net on the side shown. The back side, which is flat, was machined during final machining operations. Figure 15 shows a Ti-10V-2Fe-3Al engine-mount forging that was hot-die forged with net surfaces. An isothermally forged Alloy 100 disk is shown in Fig. 16. This part was forged in a single forging operation from billet using TZM dies. The forging had no net surfaces and was machined all over to yield the sonic shape. The main criteria for selecting the isothermal forging operation in this case are forgeability and savings in material cost. A hot-die forged Alloy 718 disk is shown in Fig. 17. This forging was machined all over to yield the sonic shape. For this part, the hot-die forging operation reduced the weight by 9 kg (20 lb) as compared to conventional forging.

Precision Forging

R.J. Shipley, Textron Inc.

Introduction

THE TERM PRECISION FORGING does not specify a distinct forging process but rather describes a philosophical approach to forging. The goal of this approach is to produce a net shape, or at least a near-net shape, in the as-forged condition.

The term net indicates that no subsequent machining or finishing of a forged surface is required. Thus, a net shape forging requires no further work on any of the forged surfaces, although secondary operations may be required to produce minor holes, threads, and other such details. A near-net shape forging can be either one in which some but not all of the surfaces are net or one in which the surfaces require only minimal machining or finishing. Precision forging is sometimes described as close-tolerance forging to emphasize the goal of achieving, solely through the forging operation, the dimensional and surface finish tolerances required in the finished part.

Cold-forging processes are traditionally precision processes. These are discussed in the Section "Cold Heading and Cold Extrusion" in this Volume and therefore will not be considered further in this article. Similarly, powder forging processes would also be classified as precision forging under the above definition (see the article "Powder Forging" in this Volume). It should be noted at this point, however, that a powder forging approach is often adopted only when it is not economical to precision forge a component from a wrought preform.

In most contexts, including this article, precision forging indicates a hot or warm closed-die forging process that has been upgraded to achieve greater process control. Traditionally, hot forging has not been regarded as a precision process. The term precision warm forging can be regarded as somewhat redundant because one of the motivations for selecting a forging temperature below the hot range is to achieve the advantages in precision associated with lower temperatures.

The examples in this article focus on the precision forging of steel. Detailed information on the precision forging of both aluminum and titanium alloys is available in the articles "Forging of Aluminum Alloys" and "Forging of Titanium Alloys" in this Volume.

Precision Forging

R.J. Shipley, Textron Inc.

Advantages of Precision Forging

Due to difficulties in achieving close tolerance and acceptable surface finish, hot forgings have traditionally been designed with a generous machining allowance, sometimes 3 mm (⅛ in.) or more. The motivation for precision forging is the elimination, or at least the reduction, of the costs associated with this machining allowance. These costs include not only the labor and indirect costs of the machining and finishing operations but also the cost of the excess raw material that is lost during machining.

The savings achieved through material conservation may not be as obvious as the savings obtained by eliminating production machining operations, but it can be quite substantial. Material costs are a significant fraction (often more than half) of the total cost of a forging. The cost of excess material includes not only the purchase price of that material but also the cost associated with handling it in the plant and the energy cost associated with heating it to the forging temperature.

The weight of a traditional forging is often more than twice the weight of the finished part after machining. The machining allowance is responsible for some of this excess material. Significant amounts are also associated with the forging flash. Generous allowances are made in traditional forging for excess material to escape from the die cavity as flash. A study performed by the Forging Industry Association estimated that 20 to 40% of the weight of conventional closed-die forgings is expended as flash. Although flash is sometimes considered necessary for trapping the metal in the die and for ensuring that tight corners or other details are filled, the design of a precision forging usually minimizes and sometimes completely eliminates the flash (see Example 1 in this article).

Another motivation for precision forging is that the mechanical properties of a precision forging are often superior to those of a forging that has undergone extensive machining. This occurs because the forged microstructure is preserved intact in the precision forging. Precision forging may also be attractive to a forge shop because the precision forging represents a higher-value product than a conventional forging; that is, the forge shop achieves a higher "value-added."

Precision Forging

R.J. Shipley, Textron Inc.

Applications of Precision Forging

After it has been decided that a given part will be manufactured by forging, either a traditional or a precision forging process must be selected. Not all part designs are candidates for precision forging.

As presented above, the precision of a forging is defined in terms of its conformity to finished-part requirements concerning overall geometry, dimensional tolerance, and surface finish. These requirements should be derived from the performance of the part that is desired in service. The impact of the requirements on manufacturing options should also be included in the design analysis. Specifically, the application of precision forging can be enhanced by considering the capabilities of the technology during the design process.

Given the nature of forging technology and the wide range of geometries that are forged, the determination of appropriate applications for precision forging processes is best begun through a process of elimination, that is, through consideration of those characteristics that tend not to favor precision forging.

Physical Considerations. A primary consideration is that the forging must be able to be removed from the tooling after the forging process is completed. Thus, geometries that would interlock with the forging dies cannot be forged net. Furthermore, surfaces parallel to the forging axis will often generate high frictional forces with the tooling during ejection of the part. Therefore, forgings are often designed with a slight draft added to such surfaces to facilitate ejection. Although forgings with no draft have been demonstrated, elimination of draft is limited by:

- The capacity of the ejection mechanism of the forging equipment to provide the increased load that will be required
- The strength of the workpiece material at the ejection temperature; the workpiece must also accommodate the increased ejection loads
- Wear of the tooling and/or damage to the surface of the workpiece that might occur because of friction

The physics of the metal flow during the forging process also limit the application of precision forging concepts. For example, it may not be possible for the metal to flow to fill sharp corners or thin sections. Excessively high tooling loads or rupture of the workpiece material may result from problems in metal flow.

Chilling of the workpiece material by the relatively cooler tooling restricts the metal flow. One of the motivations for the development of isothermal and hot-die forging processes (see the article "Isothermal and Hot-Die Forging" in this Volume) is to improve precision.

Alternatively, metal flow issues in precision forging can be addressed by including additional preform steps in the forging process. However, this may not be a practical option in all cases.

Economic considerations also affect the application of precision forging. If only the costs of the forging process itself are considered, precision forging will generally be more costly than traditional forging. This is due to the large number of factors that must be considered in a precision forging process, as discussed in the following sections in this article. Many of these factors are ignored in traditional forging.

The increased cost associated with precision forging will be offset by savings in subsequent manufacturing steps, as discussed above. However, if the number of parts required is relatively small, the savings in material, machining, and so on, may not be sufficient to offset the increased costs of precision forging. This may occur because a significant portion of the cost differential associated with precision forging is a fixed cost, that is, independent of the actual number of pieces forged.

Precision forging is especially attractive in the case of parts with complex surfaces that are difficult or costly to machine. Turning is a relatively inexpensive operation in comparison with milling, grinding, or gear cutting. Not surprisingly, many precision forging applications involve gears and similar types of parts (see Example 2).

Given a geometry that is amenable to precision forging, tolerances of ±0.25 mm (±0.010 in.) can generally be achieved. In many cases, significantly better tolerances have been demonstrated. Comparison of the forging tolerances and surface finish with the part requirements determines whether any machining will be required. Again, economic analysis is critical in determining the benefits of a net shape forging versus a conventional forging or a near-net shape forging versus a conventional forging.

R.J. Shipley, Textron Inc.

Tooling Design Considerations

The design of the forging tools must include analysis of all effects that could impact on the precision of the process. Allowance should be made for the thermal expansion of the tooling because it is generally at some elevated temperature during the forging process. Similar allowance should be made for contraction of the workpiece as it cools after forging. Thermal contraction is estimated from the workpiece temperature at die closure (see Eq 1). These allowances are typically of the order of hundredths of a millimeter (thousandths of an inch)--comparable to the tolerances desired in the precision forging process.

Elastic deflection of the tooling and the forging equipment can also occur during the forging process and can affect the tolerance achieved. In many cases, the elastic deflections are small and may be safely neglected. However, this is not always the case, as demonstrated in Example 1. Elastic expansion of the workpiece as the forging load is released is usually not significant and can be neglected, because the flow stress is low at elevated forging temperatures.

The dimensions of the forged part will be decreased relative to the dimensions of the die cavity by the thickness of the forging lubricant at die closure. The thickness at die closure will generally be less than the thickness applied to the dies and/or forging preform. In many cases, the lubricant layer is very thin and can be neglected. In other cases, it may be significant. Thicker coatings are sometimes applied to billets prior to forging as protection against oxidation during subsequent heating. Buildup of the lubricant in the tooling can also be a problem in some cases.

As discussed above, metal flow patterns are an important consideration in precision forging. The design of the tooling must ensure an appropriate preforming sequence to control the metal flow in order to fill the die contours and to achieve an acceptable surface finish. The magnitude of chilling must also be evaluated because the flow stress of the metal is a function of temperature.

To assess the feasibility of a precision forging design, both the forging load and the workability of the workpiece material must be considered. As mentioned above, an estimate of the forging load is necessary for calculating elastic deflections in the tooling and fixturing. Excessively high loads cause premature failure of the tooling, either through increased friction and wear or gross overload.

The workability of the workpiece material is a quantitative measure of how much deformation can be accommodated without cracking or other forms of failure. Workability is more critical in precision forging than in conventional forging because higher deformation levels may be required to achieve the tolerances required in precision forging. Deformation levels can be especially high in localized areas. Furthermore, the workability index of the material can be decreased in a precision forging process if the forging temperature is decreased in an effort to improve precision. (There would be exceptions in the case of materials whose workability actually improves with decreased temperature.) Workability tests and theory are discussed in the Section "Evaluation of Workability" in this Volume.

In practice, consideration of the above-mentioned factors is extremely difficult for all but the simplest forging geometries. Accurate calculation of the temperature gradients in the workpiece and tooling requires a heat transfer analysis. Calculation of elastic deflections requires knowledge of the forging loads and a stress analysis of the tooling and associated fixturing. Calculation of metal flow for preform design is even more complex.

Mathematical models of the forging process based on the finite-element method have been developed to aid the forging design engineer in the required analyses. These models have been implemented through computer programs that provide the required temperature and stress profiles and allow the designer to simulate the metal flow that occurs during forging. Process modeling and simulation are discussed in detail in the article "Modeling Techniques Used in Forging Process Design" in this Volume.

Analysis of a precision forging process through computer-based models is most readily accomplished if the forging tooling is initially designed on a computer-aided design and manufacturing system. Even if computer models are not employed, computer-aided design and manufacturing will still be valuable in the design of precision forging tooling. The goal of net shape, or at least near-net shape, dictates that precision forging tooling will be more detailed and complex in comparison with conventional tooling. Furthermore, the accurate calculation of volumes and surface areas, which is done automatically with computer-aided design and manufacturing, is more critical in precision forging than in conventional forging. Applications for computer-aided design and manufacturing in forging are discussed in the article "Forging Process Design" in this Volume.

Physical modeling is an alternative to mathematical simulation of the forging process on a computer. Physical modeling involves construction of an analog model of the tooling and workpiece material. For example, observation of the flow of Plasticine (a modeling clay) at room temperature has been found to be helpful in understanding metal flow during forging. The tooling in a physical model is typically fabricated of Plexiglas to enable continuous observation during deformation. Metal flow patterns may be highlighted by constructing the preform from different colors of clay. Physical modeling is discussed in the article "Modeling Techniques Used in Forging Process Design" in this Volume.

Even with the most sophisticated analytical techniques, some further development of the precision forge tooling may be necessary on the shop floor. In some cases, forging parameters and/or the dimensions of the die cavity may have to be adjusted to achieve the required tolerances. In other cases, a preforming sequence may have to be redesigned. The amount of development would generally be decreased with a greater amount of analytical work. The optimal approach to implementing a precision forging process will be determined by an economic balance of the costs of analysis versus the costs of some trial and error on the shop floor. This balance will generally be different for every shop.

The analytical approach to design is most appropriate if one has little or no experience in precision forging the type of geometry being considered. The difficulties of implementing the process for a given part are clearly lessened if a forge shop has experience with other parts of similar geometries. In this case, the required analysis and trial and error on the shop floor will both be minimized. The precision forging tooling will be designed based on heuristics, that is, empirical correlations or rules of thumb that have been established through experience. Computer programs known as expert systems represent an attempt to capture and promulgate this type of practical knowledge. Ideally, the empirical and analytical approaches can be combined so that new applications of precision forging technology can be developed by building on the experience base already in place.

Precision Forging

R.J. Shipley, Textron Inc.

Process Control Considerations

After a candidate part for precision forging is identified and the tooling is designed, implementation requires increased attention to detail and process control at every step of the manufacturing process. At a minimum, all of the factors discussed below usually must be considered. The significance of a given factor depends on the geometry and tolerance requirements of a given forging. In addition, there may be other factors not listed here that are unique to a particular application.

Precision of the Tooling. A precision forging requires precision tooling. The tolerance achieved in the forging will clearly be no better than the tolerance of the tooling. Because many factors influence the forging tolerance, it will typically be significantly worse than the tooling tolerance. Therefore, the tolerance bands for precision forge tooling must be set at a small fraction (for example, $\frac{1}{10}$ to $\frac{1}{3}$) of the desired forging tolerances. This is similar to the rule of statistical process control that the capability (variation) of a gage must be an order of magnitude better than the allowable variation of the machine or workpiece being measured.

After the precision forge tooling is built, it should be inspected to ensure that it meets the design requirements. This inspection may be difficult if the tooling has contoured surfaces. Nevertheless, if the tooling is not inspected, it will be that much more difficult to determine the causes of any out-of-tolerance condition in the forgings.

Gaging developed for inspection of the forged part generally cannot be used for inspection of the tooling, even if a cast impression of the die cavity is obtained. Due to the various allowances included in the tooling design, the dimensions of the die cavity will be distinct from those of the forging. Coordinate-measuring machines are often used to inspect precision forge tooling. The inspection data can be kept on file and referenced later to determine the extent of wear after the tooling has been in service.

Concern regarding the tolerance of the forging tools may require the forge engineer to consider the capabilities of the machining processes employed to build the tools. In particular, if the die cavities are produced by electrical discharge machining (EDM), the tolerance of the tools will depend on both the tolerance of the electrode and the tolerance achieved in the EDM process itself. In machining the electrode, allowance may have to be made for the spark gap in the EDM process.

After the tooling is placed in service, its precision will deteriorate because of wear. Die wear is an important factor in determining die life in precision forging. Even a small amount of wear can result in an unacceptable loss of precision. The cost of reworking or replacing worn tools must be included in the analysis of the economics of precision forging.

Precision of the Setup. Control of the alignment and setup of the tooling in the forging press is just as important as the tolerance of the tooling itself. The fixtures used to hold the die blocks for precision forging in presses are frequently designed with posts or similar devices for maintaining alignment.

The setup of the tooling affects the thickness of the forged part. Thickness may be important in its own right, if there is a close tolerance on any of the thickness dimensions of the part. However, thickness is also important because the overall volume of the forged part is dependent on thickness. Because precision forgings are usually designed with little or no flash, the volume of the finish forging in relation to the volume of the preform is critical. If the tooling is set up so that the volume of the finish forging would be too great, a lack of fill in the corners would generally result. If the setup is such that the volume of the finish forging cannot accommodate the entire preform, the tooling or the forging equipment could be damaged.

Precision of the Preform. In a one-hit precision forging process, the preform is simply the slug of raw material sheared or cut from bar or coil stock. In a progressive forging operation, the preform is the product of a series of intermediate forging operations. In both cases, the quality of the preform is of concern because it limits the precision of the finished forging.

As discussed above in connection with the setup of the tooling, the relationship between the volume of the preform and the volume of the finish forging is critical. If the geometry of the preform is complex, the distribution of volume in the preform may also be important to ensure the proper metal flow in the finish forging. Thus, precision forging requires a precision preform. In progressive forging, each forging step must be considered to be a precision operation.

With respect to the raw material, the volume of the slug or starting billet is the product of its cross-sectional area and length. Tolerance on the area is controlled by the capability of the mill. Tolerance on length is determined by the capability of the shear or other billet separation equipment employed by the forge shop. In some cases, existing tolerance capabilities may not be adequate for the requirements of precision forging. Machining of the raw material (turning in the case of round stock) and/or saw cutting would be options in this situation, but would generally add significantly to manufacturing cost. Purchasing cold-drawn stock or cold drawing immediately prior to shearing is another way to achieve a precise cross-sectional area, again at some cost penalty.

Volume can also be controlled by weighing the slugs prior to forging and rejecting those outside specified limits. This would be economical only if the rejection rate were not too high. Another approach to controlling volume would be to introduce a simple upset of a few percent as the first forging step. In this approach, the blank could be slightly oversize, and the upset tooling would allow for flash. After removal of any flash, a precision slug would remain, its volume being determined solely by the upset tooling.

The surface condition of the preform is also important because it can affect the surface quality of the finish forging in regions where it is desired to minimize or eliminate machining. Prevention of oxidation (scale) is one concern and is discussed in more detail in the section "Selection of Process Temperature" in this article. The quality of the sheared or cut surfaces on the starting billet is also of special concern. The precision forging may sometimes be designed so that those surfaces will correspond to noncritical areas.

Control of the chemical composition and metallurgical microstructure of the raw material may also be important in some applications of precision forging. For example, in the precision forging of steel, there may be requirements that net surfaces cannot be decarburized. In addition, for certain alloys, variations in microstructure and/or composition may affect the metal flow during forging.

Control of Lubrication. Of all forging variables, the performance of the lubricant may be the most difficult to quantify. However, lubrication is also recognized as one of the factors that is most critical to the success of any forging process, precision or otherwise. Lubrication influences the total forging load, the degree to which the metal will fill the cavities of the dies, the uniformity of the resultant metallurgical microstructure, and the surface quality of the forged product.

Control of lubrication in precision forging can be approached indirectly by stressing consistency in the lubricant composition and application. Samples of the lubricant should be taken upon delivery from the supplier and after any dilution. Samples should also be taken to ensure consistency during production.

Application of the lubricant is also critical. If the lubricant is sprayed manually, variations in the precision of the forging can often be correlated with the different techniques employed by various operators. Automatic lubrication equipment is frequently used to achieve greater consistency. Even in this case, though, attention still must be given to lubrication to ensure that the equipment is functioning properly, that all nozzles are clear, and so on. If a coating is applied to the billet or preform prior to forging for lubrication or other purposes, the same care must be exercised to achieve consistency.

Control of Workpiece Temperature. The temperature of the workpiece is a critical variable in precision forging. This section discusses the control of temperature within the context of total control of the forging process. This assumes that the forging temperature has already been specified. A subsequent section in this article will discuss the selection of an appropriate process temperature.

Strictly speaking, it is not correct to refer to the temperature of the workpiece. With the exception of isothermal forging, there will actually be a temperature gradient in the workpiece that will be continuously changing during the forging process. In most cases, forging temperature refers to the temperature of the workpiece at a point of measurement (for example, in the furnace, as it exits an induction coil, before it is placed in the die, and so on). For a precision process, this temperature must generally be controlled to within ±10 to ±20 °C (±20 to ±35 °F). This tolerance may be tighter in some critical applications, and a slightly less stringent tolerance may be allowed in others.

It is generally not practical or necessary to measure the temperature gradient directly. However, control of the gradient can still be achieved by control of the nominal workpiece temperature before forging and by consistency in all other aspects of the process that could affect the heat transfer from the workpiece.

The workpiece begins to lose heat as soon as it is removed from the furnace or other heating equipment. Variation in the timing of the transfer or variation in the ambient conditions in the forge shop can affect the temperature of the workpiece as it is forged. Automated handling equipment can be employed to achieve greater consistency in transfer of the workpiece into the forging dies.

The workpiece is chilled further when it comes into contact with the tooling. Heat transfer to the tooling is a function of the tooling temperature and the heat transfer coefficient established across the lubricant interface. Heat transfer is increased by the close contact that occurs under forging pressures. Therefore, die contact time under load also affects the extent of chilling that will occur. For a given forging geometry, die contact time should be constant because it is determined by the operating characteristics of the forging equipment. Contact time is an important parameter, however, in comparing different types of forging equipment.

In some analyses of forging temperature, it may also be necessary to account for the heat of deformation. A high percentage (usually over 90%) of the mechanical energy of the forging process is converted into heat within the workpiece. The temperature of the workpiece would tend to increase as a result. Therefore, the temperature of the workpiece during forging is determined by an energy balance involving the heat lost to the environment and the heat generated by deformation.

The workpiece temperature affects the precision of the forging through:

- The effect of thermal contraction
- The effect of temperature on material flow stress and elastic compliance of the tooling and forging equipment
- The effect of temperature on lubricant performance

As discussed above with respect to tooling design, the dimensions of the forged part are directly related to the anticipated forging temperature because of the thermal contraction that occurs as the forging cools. The calculation of the thermal contraction allowance assumes that the workpiece conforms perfectly to the die cavity when the dies are fully closed. An average workpiece temperature must be estimated, taking into account the extent to which the workpiece has cooled up to this point. Analyses of heat transfer in forging have been developed for this purpose. Equation 1 can be used to estimate the allowance for thermal expansion:

$$D_F \cdot [1 + \alpha_F \cdot (T_F - T_o)] = D_D \cdot [1 + \alpha_D \cdot (T_D - T_o)] \quad \textbf{(Eq 1)}$$

where D refers to a linear dimension, T is temperature, and α is the thermal expansion coefficient. The subscripts F and D refer to the forging and the die, respectively. The subscript o refers to ambient temperature. As indicated above, the workpiece temperature will be an average value. The die temperature will also generally be an average value. If thermal expansion is not linear over temperature for the die or workpiece material, an average value should also be used here.

In addition to thermal contraction, temperature affects the precision of the forging process through the variation in the flow stress of the workpiece material that occurs with changes in temperature. As discussed in the section "Selection of Process Temperature" in this article, material flow stress and workability are important considerations in the selection of a forging temperature.

As discussed in the section "Tooling Design Considerations" earlier in this article, once the forging temperature has been selected, flow stress can be estimated and the magnitude of the forging load can be calculated. The elastic deflection of the tooling, fixturing, and in some cases the forging equipment itself can then be estimated, and the appropriate allowance can be made in the tooling design. If elastic deflections are significant and a change in workpiece temperature occurs that significantly alters the flow stress, then the elastic response would also be affected with a resultant change in the as-forged dimensions.

Concern regarding changes in material flow stress with temperature is most likely in the case of precision warm forging (see the section "Selection of Process Temperature" in this article) because the flow stress is most sensitive to changes in temperature in the warm range. In addition, the flow stresses are higher in the warm range, so elastic effects will be more significant.

The temperature of the workpiece can influence the behavior of the forging lubricant. The importance of consistent lubricant performance in achieving a precision process has already been noted above. Workpiece temperature will have an especially important effect on the process lubrication if a lubricant coating is applied directly to the preform in addition to (or instead of) the lubrication of the tooling.

If scaling (oxidation) of the workpiece is of concern, it should be noted that this too will be a function of temperature, as shown in the section "Selection of Process Temperature" in this article. Generally, oxidation must be avoided in precision forging.

Control of forging temperature may also be mandated to control the metallurgical response of the workpiece material. The extent of the work hardening and recrystallization that occurs will depend on forging temperature. Metallurgical transformations may also occur during forging, depending on the process temperature. Consideration of the metallurgical behavior is particularly important if it is desired to minimize or eliminate heat treatment after forging. Metallurgical transformations can also influence the dimensions of the as-forged part if they result in a change in volume. Metallurgical considerations are particularly important in the case of warm forging of steel, in which the warm temperature range is defined as approximately 540 to 815 °C (1000 to 1500 °F).

Steel undergoes a metallurgical phase transformation at temperatures within or slightly above the warm-forging range. This transformation is associated with a change in volume distinct from that which is due to purely thermal effects. It occurs over a range of temperature that is dependent on alloy content. Depending on the requirements of a particular application, the warm-forging temperature may be below, within, or above the transformation temperature range. The relationship of the forging temperature to the transformation temperature determines the metallurgical microstructure that will be developed in the forging upon cooling.

Therefore, variation of process temperature can lead to inconsistent metallurgical response in ferrous warm forging through the influence of temperature on work hardening, recrystallization, and phase transformation processes. This would be an especially significant issue if it were desired to avoid heat treatment after forging. Variation in forging temperature could also lead to lack of control in workpiece volume due to phase transformation, in addition to purely thermal effects.

Finally, concern regarding the workpiece temperature does not end after the precision forging process is completed. Controlled cooling of the workpiece may be necessary after forging to avoid distortion and to control the metallurgical microstructure.

Control of Tooling Temperature. Tooling temperature is important in precision forging for many of the same reasons as workpiece temperature is important. The temperature of the tooling directly affects the workpiece temperature through the heat transfer, which is dependent on the temperature differential between the workpiece and the tooling. The chilling of the workpiece by the tooling is especially significant if thin sections are being forged. Flash, if present, is one example of this effect. The flow stress within the flash is typically much higher than that in the die cavity because of chilling. If the tooling temperature is greater than ambient, the thermal expansion of the tooling will affect the final dimensions of the forged part, as indicated by Eq 1.

The temperature of the tooling also affects the behavior of the forging lubricant. Specifically, the die lubricant is carefully formulated to be applied to tooling at a temperature within a narrow range. A temperature that is too high or too low will affect the quality of the lubricant coating and the performance during the subsequent forging operation.

It was noted above that the workpiece cannot be characterized in terms of a single temperature, because a thermal gradient occurs as heat is lost from the surface. The same type of situation occurs in the tooling, but temperature decreases with distance from the surface because heat is introduced there by contact with the hotter workpiece. When the workpiece and tooling are in contact during forging, the gradient can be imagined to be continuous across the interface.

Dies are usually preheated prior to forging so that the tooling temperature during a production run will be relatively constant. One reason for this is because the toughness of many tool materials is very low at ambient temperatures. With these materials, if the tooling were not preheated, it might crack as the initial pieces were forged.

A second benefit of preheating, important in precision forging, is that variations in tooling temperature do not affect the precision of the process over the course of the production run.

Knowledge of the thermal gradient in the tooling is important because the different effects of temperature discussed above actually depend on the magnitude of the temperature in specific locations. The performance of the lubricant depends on the temperature of the surface to which it is applied. The overall thermal expansion of the tooling will be a function of a volume average temperature. Distortion and thermal stresses may occur if the gradient is too severe.

Toughness is a material property that will vary with the temperature at each location. If toughness is a concern, it is important that the entire die be above a minimum temperature.

The potential for thermal fatigue (heat checking) of the tooling can also be related to the thermal gradient. Stresses can be generated at the surface of the tooling as it is alternately exposed to the workpiece at high temperature and then to the cooling effect of the die lubricant. Thermal fatigue is controlled by selection and heat treatment of the die material so that it is appropriate for the workpiece temperature and lubricant employed.

Control of thermal fatigue is demonstrated in such applications as some of the automated formers to be discussed in the section "Equipment Considerations" in this article as well as the flashless forging in Example 1. The tooling is maintained at essentially ambient temperature by a flood of coolant that also functions as a die lubricant. In the case of the formers, a relatively short contact time also helps to prevent thermal fatigue.

As a first step in obtaining data on tooling temperature, the surface temperature of the dies can be measured with a contact pyrometer as the forging is removed. Temperatures in the interior can be monitored through thermocouples inserted into the tooling or the associated fixtures.

Equipment Considerations

The importance of process control in precision forging was discussed in the preceding sections in this article. An initial step in achieving the required level of control is a careful evaluation of the capability of all equipment to be employed in the precision forging manufacturing process. Requirements for lubrication equipment were summarized previously. This section will discuss equipment for billet separation and heating, as well as the actual forging operation itself. Further details on the various types of forging equipment mentioned can be found in the appropriate Sections in this Volume. The treatment here follows a previous assessment by the author of equipment capabilities within the context of precision forging at warm temperatures (Ref 1).

Billet Separation Equipment. To achieve the required dimensional tolerance and surface finish, precision forging requires greater care in billet preparation than does traditional hot forging. Shearing is the most efficient billet separation method because production rates can be high and there is no material loss. Control of billet length at the shear is critical in order to maintain the precise volume control required by precision forging. Control of billet diameter on the raw material is also critical for the same reason. Material is frequently cold drawn to a slight reduction prior to shearing to ensure a precise diameter. Cold drawing has also been said to improve the microstructure to facilitate the shearing process itself.

Tolerance capabilities claimed by builders of shearing equipment are generally found to be adequate for precision forging. However, this must be verified for each application.

The design of the handling system used to feed bar or coil into the shear affects the precision obtained. Rebound of the raw material, if it is stopped prior to shearing, could be a problem. In the case of a coil, binding at any point in the uncoiling or straightening process could potentially affect billet length.

In addition to billet volume, the quality of the sheared end surfaces is another important consideration for precision forging. Because the as-forged component includes little or no machining allowance, surface imperfections generated during shearing may affect the quality of the forging. In general, the sheared surfaces should be smooth and free from hollows, burrs, or any type of crack. They should also be parallel and perpendicular to the axis of the bar. Where quality requirements associated with a specific surface of the precision forging are particularly stringent, it may be possible to design the tooling so that the critical surface corresponds to the circumferential surface of the billet rather than the sheared end.

When precision forging is done in multiple deformation steps, the first step is often a simple upset, either done in the first station of a transfer press or header or in a separate machine set up just for that purpose. Any deviations in billet volume will be revealed at this point, and upsetting ensures square ends to avoid misalignment and nonuniform loading, which could cause breakage of tooling in subsequent operations.

As indicated above, shearing is generally the method of choice for billet separation. In some instances, larger-diameter billets or higher-strength material might not be able to be sheared with the existing equipment in a particular shop. In these cases, preheating the billet before shearing may enhance the capability of the shear. The automatic formers described later in this article often shear billets from a preheated coil in the first station.

Billets can also be prepared by sawing. Sawing is a slower and generally more costly process than shearing, and burrs may be more of a problem; but it may be easier to address concerns regarding volume control and quality of the cut surface. In addition, sawing is more readily adapted to billets of different sizes, so it may be indicated for relatively short production runs involving larger-diameter or higher-strength billets that cannot be sheared on existing equipment.

Heating Equipment. As is the case with the preparation of the forging billet, heating of the billet to the forging temperature also requires greater care than in traditional hot forging if increased precision and improved surface finish are to be realized. Formation of oxide scale is a particular problem in the precision forging of steel. Any tendency to form scale can be minimized by rapid heating. Although the oxidation rate at the lower process temperatures often used for precision forging is significantly less than at traditional hot-forging temperatures for steel (see Fig. 7), which are in excess of 1100 °C (2010 °F), oxide scale could still be a problem if the time at forging temperature is extended unnecessarily. Where rapid heating is not practical or the thickness of the oxide layer is still unacceptable, an oxygen-free atmosphere (for example, nitrogen) can be used to control oxidation.

As discussed previously in this article, accurate control of temperature is critical in precision forging. The temperature distribution within the billet should also be as even as possible to avoid temperature-dependent variation in flow stress or variation in the metallurgical response within the workpiece. Temperature gradients within the workpiece can arise as the billet is being heated, but they are also influenced by handling of the billet after leaving the furnace. Portions of the billet that are in contact with tongs, conveyors, clamps, or other handling equipment will be cooler than portions that do not make contact. Contact with the tooling itself prior to forging also tends to chill those portions of the workpiece involved. Therefore, the design, consistency, and timing of manual operators or automated billet handling equipment can affect the precision forging process.

Tolerances on temperature of ±10 to ±20 °C (±20 to ±35 °F) have been found to be adequate in most precision forging applications. The tolerance required is dependent on the details of the application. Closer temperature control may be required as increased precision is attempted.

Induction heating is often used for precision forging because it reasonably meets the criteria outlined above. However, resistance-heating, gas-fired continuous, and gas-fired batch furnaces are also successfully used. Control of an induction furnace is not always as straightforward as with other heating systems, especially if the same coil is used with billets of different diameters or cross section and/or multiple billets are being heated within the coil at the same time.

Forging Equipment. Many of the same types of forging equipment used for traditional nonprecision forging can also be used for precision forging. However, if the intention is to reduce the forging temperature to achieve greater precision, the flow stress of the material, and therefore the forging load, can be increased and can exceed the capacity of the equipment previously used successfully for nonprecision forging at a higher temperature. Furthermore, before precision forging is attempted, the operating characteristics of the equipment must be examined from a process control perspective.

No one type of forging equipment will necessarily be best for all precision forging applications. Furthermore, there may be many options for a given application, and the decision, to a great extent, can be reduced to what equipment a particular forge shop may have available. Factors that must be considered in evaluating equipment for a particular application include the size and configuration of the part, type of material, production quantity, production rate, raw material requirements, tolerance, and amount and cost of scrap generated. Labor, overhead, and energy are also important factors. A proper balance of these various considerations will ensure that the part is produced at lowest cost.

Hammers could conceivably be used for precision forging. However, achieving the required level of process control would be difficult because hammers are generally not operated as precision forging machines. Fixed stop blocks would be required in the tooling to control the thickness of the forging. Attention would also need to be given to controlling the stroke(s) to be as reproducible as possible. The sensitivity of flow stress to temperature could cause problems, especially if multiple blows were required and if excessive chilling of the workpiece occurred. The lack of knockouts in hammers would make it difficult or impossible to implement flashless forging with little or no draft.

It is conceivable that hydraulic presses could also be used for precision forging. As with hammers, the thickness of the forging could be controlled with stop blocks incorporated into the tooling. However, stop blocks might not be absolutely necessary with a hydraulic press if the ram position could be precisely controlled. If forging temperatures were relatively high, the relatively slow ram velocity and long dwell time of the hydraulic press would be a concern because of the increased potential for chilling of the workpiece and overheating of the tooling.

Screw presses offer much potential for precision forging, especially in cases in which the thickness of the forging is critical. A screw press has some of the characteristics of a hammer in that the stroke is not fixed. However, the stroke of a screw press can be controlled much more precisely. The thickness tolerance for a part forged on a screw press can be closely controlled through stop blocks or kiss plates built into the tooling.

Because a screw press is an energy-controlled machine (that is, the ram is not forced to move through a fixed stroke as is the case for mechanical presses), the energy and/or load that the ram exerts can be limited to that necessary to form the part. There is less concern that an oversize billet will result in damage to the press or tooling. In most cases, however, an oversize billet will result in an excessively thick forging. Therefore, volume control is still critical to the precision of the process, especially when there is a close tolerance on the thickness dimensions.

Some designs of screw presses may not have sufficient energy for workpieces requiring extensive deformation (for example, extrusion operations). However, higher-energy screw press designs have also been developed. In applying a screw press to a high-speed automated operation, there would be concerns regarding its stroking rate. In a transfer forging operation, there would also be concerns regarding its ability to accommodate off center loading with multiple-cavity tooling. Traditionally, mechanical presses are superior to screw presses in these respects, but improvements in screw press design have been demonstrated.

Many precision forging applications have been developed on mechanical crank type presses. In a mechanical press, the stroke is fixed by the characteristics of the drive mechanism. Therefore, mechanical presses differ in a fundamental way from hammers, hydraulic presses, and screw presses, in which the stroke is not fixed. In a mechanical press, the thickness of the forging will be affected by changes in the stroke. For example, if the temperature of the press increases during a production run, the thermal expansion of the press components could affect the thickness tolerance of the forging.

Furthermore, the components may deflect under the forging load, also affecting thickness. Although these changes are small and are normally not even considered in conventional forging, they can be significant in comparison with tolerances of hundredths of a millimeter (thousandths of an inch).

A mechanical press with a tension knuckle joint drive mechanism has been said to offer advantages for precision flashless forging (see Example 1). The tension knuckle drive pulls, rather than pushes, the ram. The toggle or tension link elongates under forging pressure. The elongation of the tension link results in a press that is less stiff than conventional mechanical presses; that is, the tension link stretches to a greater extent under forging load than the frame of a mechanical press does. In precision flashless forging, the tension link can stretch without damage to accommodate variations in the volume of the forging billet, thus protecting the tooling and the press itself from damage.

In comparison with a crank press operating at a comparable stroking rate over a comparable stroke length, the tension knuckle drive will result in a slower ram velocity during the actual forging process. This results in lower impact forces on the tooling upon striking the forging billet and should tend to increase tool life. The tension link itself also tends to act as a shock absorber to alleviate impact loading imposed on the tool. However, the tendency of the slower ram velocity to increase contact time and heat transfer to the tooling (thus decreasing tool life) must also be considered. The lower impact velocity in this type of press does result in a reduced level of forging noise and vibration, which may be important from an environmental perspective.

Horizontal forging machines (also known as formers, upsetters, or headers) have also been developed and employed for many precision forging applications. The capabilities of formers overlap those of presses. Advantages include high production rate, short dwell times, and good die cooling. Generally, they are limited to smaller workpieces and longer production runs than presses. These machines are designed and built to facilitate automated forging with multiple dies arranged horizontally. In many cases, they are automated coldforming machines that have been modified to operate with the workpiece material at elevated temperatures. Typically, raw material in the form of coiled wire is preheated by induction to the forging temperature before it enters the former. However, heating by resistance or with gas-fired furnaces and raw material in the form of bar stock or precut slugs are also not uncommon.

In the case of coils or bar stock, the incoming material is first sheared and then transferred from die to die until the finish-formed part is ejected. Production rates are dependent on part size and are usually of the order of 1000 to 5000 or more pieces per hour. With these high production rates, formers are most applicable to high-volume production requirements. Material handling to and from the former must also be adequate to ensure continuous production.

To offset the cost of tooling and setup times, automatic forming processes generally require production quantities of about 25,000 pieces for relatively large parts; production quantities can range to 100,000 pieces or more for smaller parts. The specific details of each case may shift these breakpoints. For example, the use of quick die change procedures to minimize setup times and group technology programs to take advantage of commonalities among setups for similar parts may allow for shorter production runs.

Control of die and workpiece temperature is critical with all automated forging equipment and especially with formers. If workpiece temperature is too low, excessive machine and tooling loads and/or cracking problems may be encountered. If workpiece temperature is too high, the metallurgical microstructure of the part may be adversely affected, the metal may smear over the cutoff tooling, and/or metal flow patterns may be uncontrolled. Examples of precision forgings produced on formers are shown in Fig. 1(a), 1(b), 1(c), 1(d), and 1(e).

Precision Forging

R.J. Shipley, Textron Inc.

Selection of Process Temperature

As mentioned in the definition of the scope of this article, the greatest precision in forging is almost always achieved in cold forging. Therefore, from the perspective of precision, if it is possible to forge a part cold, that will generally be the method of choice.

Higher forging temperatures are usually employed only if:

- The forging load at ambient temperature would exceed the capacity of existing, economical equipment and/or tools. This could be due to a high flow stress of the workpiece at ambient temperature, the complexity of the metal flow, and/or the overall size of the part
- The material workability at ambient temperature does not allow for the required metal flow
- An excessive number of intermediate anneals would be required to overcome the effects of work hardening

In practice, the above restrictions mean that a wide range of parts and materials must be forged at elevated temperatures. Cold forging cannot even be considered in many cases.

Increasing the workpiece temperature results in decreased flow stress and usually increases workability (ductility). The Section "Evaluation of Workability" in this Volume contains more details regarding workability. Therefore, for a given part configuration, tool stresses will be lower, and the total press load will be reduced. Alternatively, for a given equipment capacity, increased process temperature allows for the production of larger parts.

Some materials that are difficult or impossible to forge cold can be successfully formed at higher temperature, thus expanding the range of materials used in cold forging. Many materials must be annealed prior to cold forging. For example, for medium-carbon to high-carbon steels, a long spheroidize anneal may be necessary. In parts requiring extensive deformation, one or more intermediate anneals may be necessary to counteract the effect of work hardening. Increasing the forging temperature can eliminate the need for these relatively costly and energy-intensive anneals. Within limits determined by the metallurgical response of the workpiece material, the process temperature can be adjusted so that the strength level in the forging is at the desired level. This can help to eliminate the need for heat treatment after forging.

Some geometries that may be difficult to forge cold can be readily accomplished with increased forging temperature. For example, for a given material, thinner flanges and sharper corners and shoulders could usually be produced at increased temperatures. A given material can generally accommodate greater deformation before cracking when forged at higher temperature, and a given geometry can sometimes be forged in fewer stations in comparison with cold forging.

Selection of the process temperature will be based first on the workpiece characteristics to ensure that the metal flow stress is low enough to allow forging on available equipment and that workability is sufficient to allow the required deformation without cracking. Unfortunately, in comparison with what is needed, the literature contains limited data on material flow stress and workability as a function of temperature.

At relatively low temperatures, flow stress is primarily a function of strain. At higher temperatures, strain is less important than strain rate. At intermediate (warm) temperatures, both strain and strain rate may be important. Flow stress data can be presented in either graphical or tabular form. In the case of the latter, values of coefficients for a constitutive equation are tabulated.

Both strain dependent and strain-rate dependent coefficients have been obtained for numerous materials by utilizing the least-mean-square-fit technique to calculate the coefficients from stress-strain curves. An empirical expression for the strain dependency of the flow stress, $\overline{\sigma}$, is:

$$\overline{\sigma} = K(\overline{\epsilon})^n \qquad \textbf{(Eq 2)}$$

where $\overline{\epsilon}$ is the true or logarithmic strain, and K and n are empirical constants. Strain dependent data for carbon steels are shown in Table 1 and data for alloy steels in Table 2.

(a) HR, hot rolled; N, normalized; SA, spheroidize-annealed.

(b) K_f, strength coefficient; TS, tensile strength; YS, yield strength; RA, reduction of area; *n*, strain-hardening exponent

At higher temperatures, above the recrystallization temperature, the flow stress is influenced mainly by the strain rate, and can be approximated as:

$$\overline{\sigma} = C\,(\dot{\overline{\epsilon}})^m \qquad \textbf{(Eq 3)}$$

where $\dot{\overline{\epsilon}}$ is the strain rate, and *C* and *m* are empirical constants. Strain rate dependent data for numerous steels, aluminum alloys, and titanium alloys are shown in Table 3, Table 4, and Table 5, respectively.

Table 3 Summary of *C* (ksi) and *m* values describing the flow stress relation, $\overline{\sigma} = C(\dot{\overline{\epsilon}})^m$, for steels at various temperatures

Material	**Material history**	**Strain rate range, s^{-1}**	**Strain**	***C***	***m***	***C***	***m***	***C***	***m***	***C***	***m***	***C***	*m*

Source: Ref 3

The elevated-temperature flow stress data in Table 3, 4, and 5 primarily cover the traditional hot-forging temperature ranges for the various materials. With respect to ferrous materials, warm forging is becoming more and more common as a means of increasing precision. Tables 1 and 2 cover the warm-forging temperature range for many steels. Trends can be more easily discerned if the data are plotted. Figures 2, 3, 4(a), and 4(b) are typical examples of a graphical presentation.

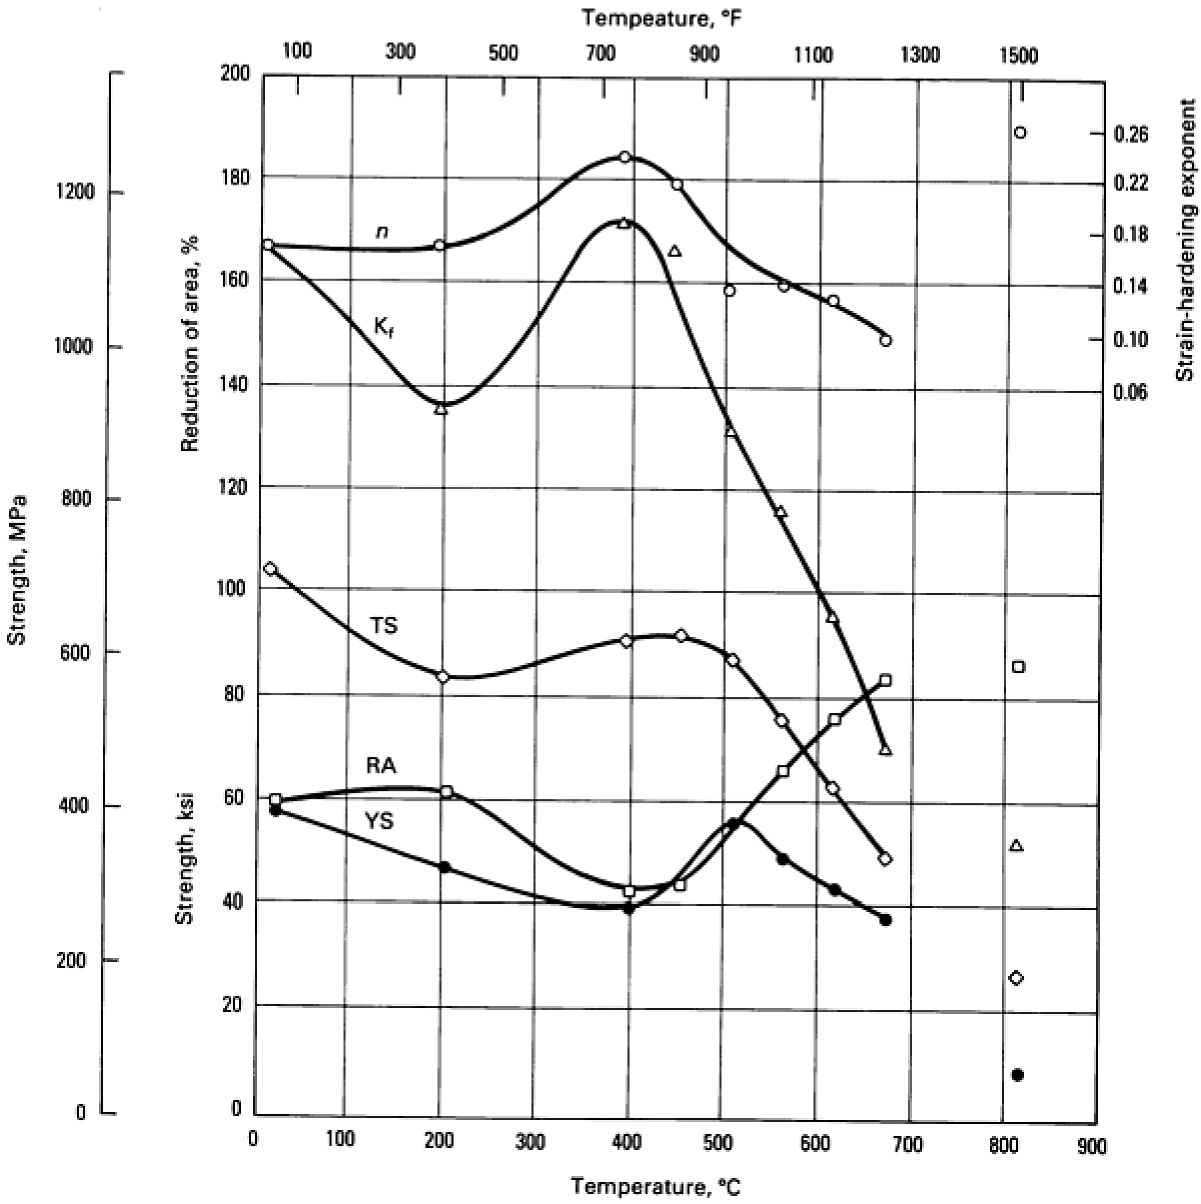

Fig. 4(b) Mechanical properties of 8620 hot-rolled bar from room temperature to 815 °C (1500 °F). Source: Ref 2.

Workability data for common forging alloys are also scarce. Some data for various steel alloys are shown in Fig. 5, which illustrates the effect of working temperature on warm workability, and in Fig. 6, which illustrates the effect of the carbon content of steel on warm workability.

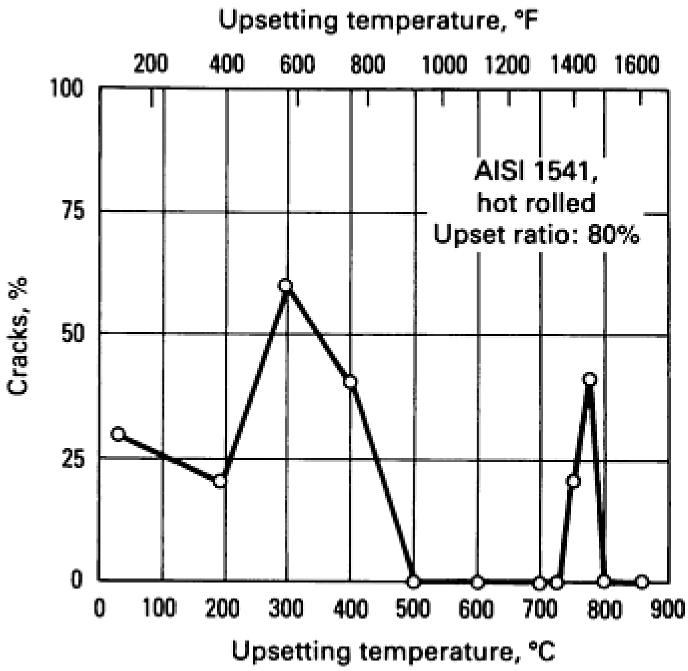

Fig. 5 Effects of working temperature on warm workability. Source: Kobe Steel Ltd.

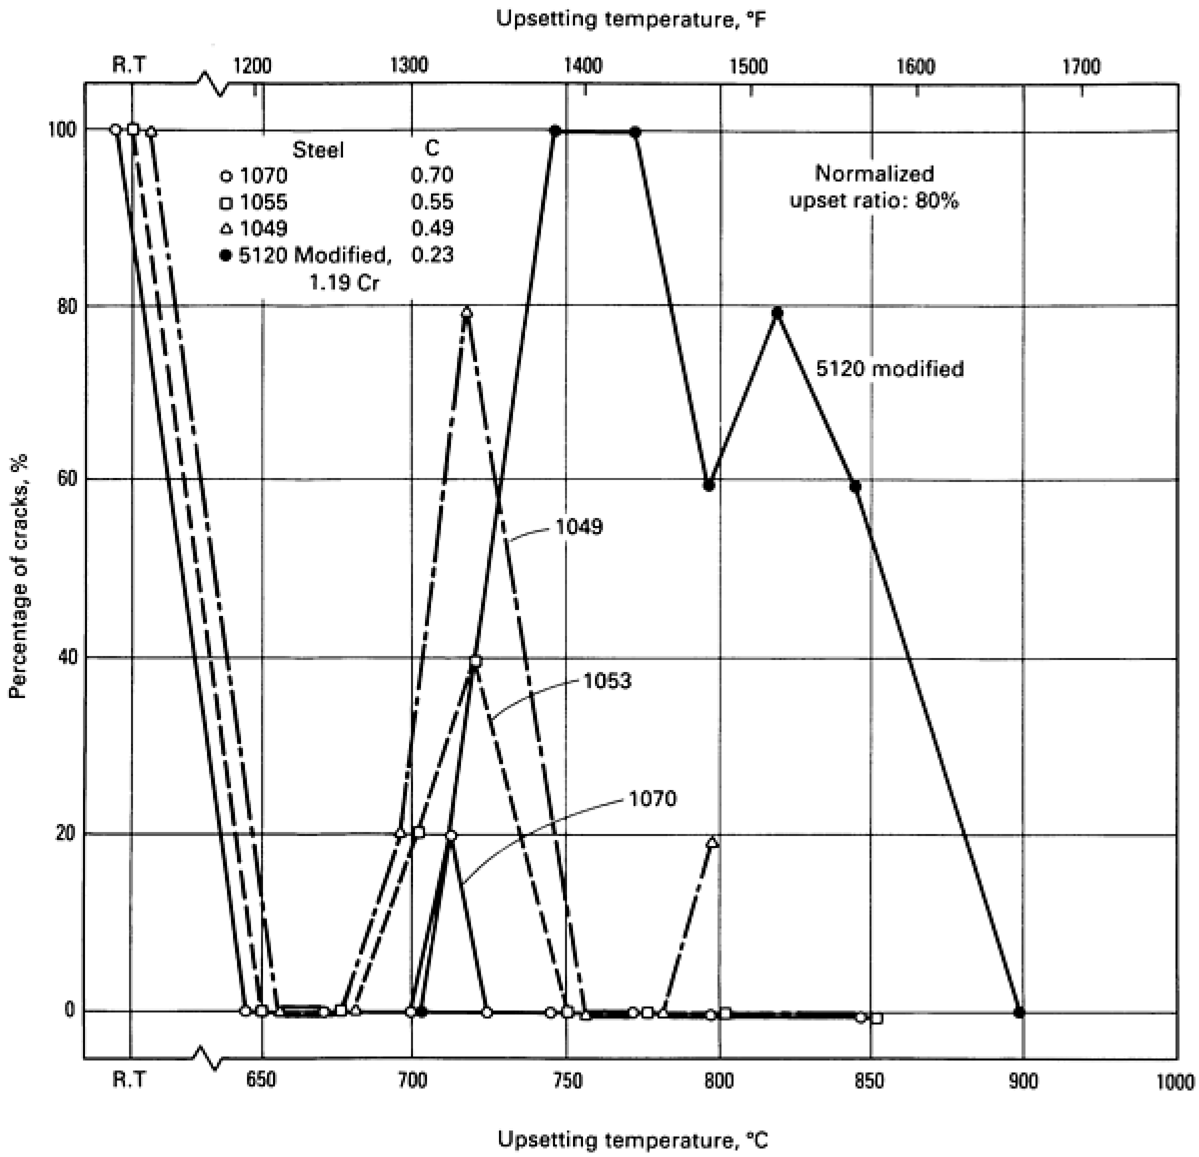

Fig. 6 Effect of carbon content in carbon and alloy steels on warm workability. Source: Kobe Steel Ltd.

Although higher forging temperatures may be desired to decrease flow stress and to improve workability, lower temperatures are favored if oxidation or scaling is a problem. For the forging of steel, the effect of temperature on scale formation is shown in Fig. 7. Scale can also be controlled by heating in an inert atmosphere.

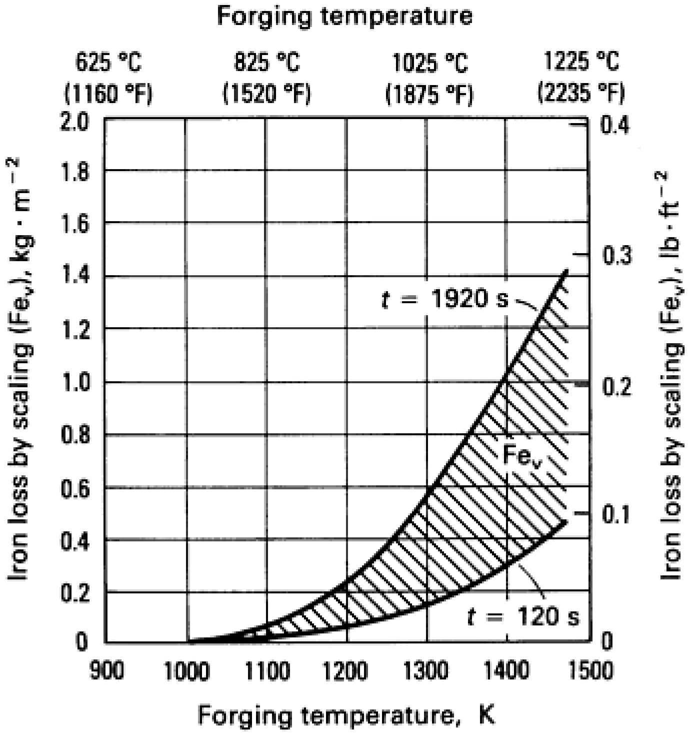

Fig. 7 Effects of temperature on scale formation for the forging of steel. Source: Ref 4.

The effect of workpiece temperature on the tooling is also an important consideration for both selection of the process temperature and specification of the tool materials and heat treatment. Lower temperatures minimize the problems associated with overheating and heat checking (thermal fatigue) of the tooling. The process temperature also affects the performance of the forging lubricant.

Finally, a lower process temperature is desirable from the standpoint of energy conservation. The energy required to heat material to a higher forging temperature is generally much greater than the savings in mechanical energy due to a lower flow stress.

Precision Forging

R.J. Shipley, Textron Inc.

Precision Forming Applications

Example 1: Flashless Forging with a Tension-Knuckle-Drive Mechanical Press.

A closed-die flashless warm-forging process was developed with the capability to generate vertical sides (no draft) and square (filled) corners (Ref 5). In the context of applying this process for ferrous forging, the warm temperature range was considered to extend to approximately 1000 °C (1830 °F). The process is also applicable to the forging of brass, aluminum, copper, and titanium.

Dimensional tolerances of this process are ±0.25 mm (±0.010 in.). All forged surfaces have a finish of 3.20 μm (125 μin.) rms or better.

Because there is no flash to absorb variations in the billet material volume, control of that volume is critical. Any material in excess of the volume of the die cavity must be accommodated by elastic deflection of the tooling and the press. During the development of the flashless process, it was found that a mechanical press with a tension knuckle drive (Fig. 8) system would be an advantage because it would have a higher compliance than other types of mechanical presses. Specifically, it was determined that a 5300 kN (600 tonf) tension knuckle press would stretch 2 mm (0.080 in.) when fully loaded. A comparable top (compression) driven mechanical press would deflect only 0.2 mm (0.008 in.), an order of magnitude less.

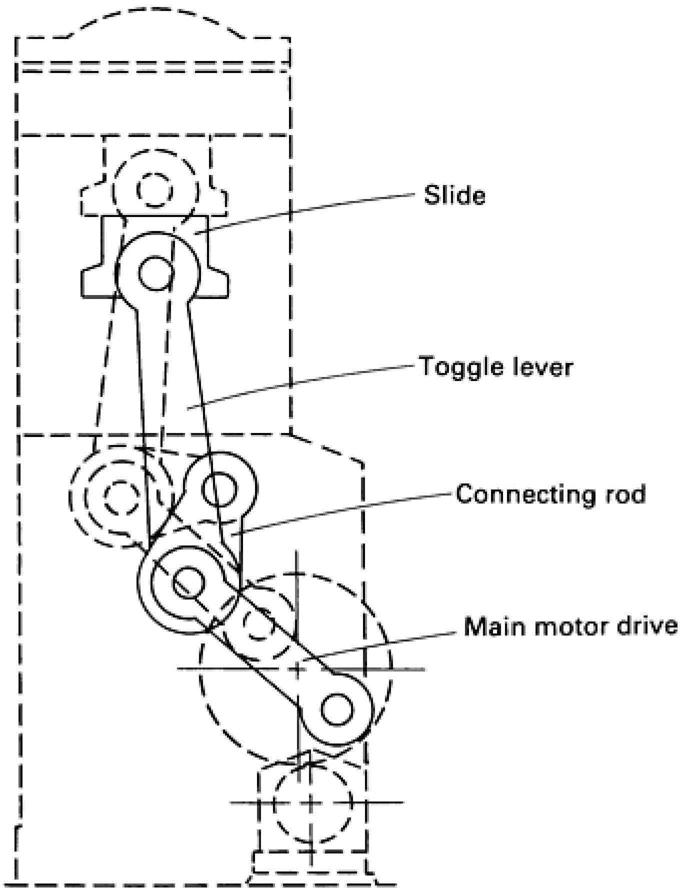

Fig. 8 Schematic of tension knuckle drive forging press. Source: Komatsu, Ltd.

With the tension knuckle drive press, the allowable variation in preform volume is -0.0/+1.4%. Preforms are headed (upset) prior to forging to control weight within this tolerance. Preform volume is also affected by temperature because of the effect of thermal expansion. Temperature control within ±28 °C (±50 °F) was found to be acceptable.

The relationship of the volume of the preform to the volume of the die cavity is also affected by any changes in the tooling itself. Therefore, the tooling temperature is held within 17 °C (30 °F) of ambient by using a flood of coolant. The coolant also contains graphite and therefore functions as a lubricant. Buildup of lubricant within the tooling would effectively decrease the volume of the die, and the lubricant is controlled to prevent this. Tool wear is also closely monitored because this increases the die volume. Such an increase would result in an underfill condition because there is no excess of raw material.

Selection of tool material and heat treatment, which is considered proprietary by the developer, was a critical factor in the success of this flashless forging process. Very high tool loads are encountered, and thermal fatigue is also a problem. With respect to thermal fatigue, in comparison with a stiffer mechanical press of conventional design, the increased deflection of the tension knuckle press will result in longer die contact times during the forging process and therefore increased heat transfer from the workpiece to the tooling.

Flashless forging can be implemented somewhat more easily if region(s) of nonfill (for example, corners) are permitted to allow for some variation in preform volume. The simultaneous achievement of filled corners and zero flash represented the real challenge in the above example.

Example 2: Precision Forging of Spiral Bevel Gear.

A research program was conducted to develop a precision forging process for the manufacture of 250 mm (10 in.) diam spiral bevel gears (Ref 6). The design of the forging dies included correction of the geometry for:

- The elastic deflection of the tooling under mechanical loading
- Bulk contraction due to the shrink fitting of the die assembly
- Thermal contraction of the workpiece from the forging temperature
- Thermal expansion of the tooling under forging conditions

The calculation of the correction for elastic deflection was based on the forging stress distribution and total forging load. These were estimated using both the slab method and the finite-element method of analysis. The average forging pressure at die closure, estimated in terms of the material flow stress at forging temperature, was p = 3.5 = 620.5 MPa (90 ksi). The calculations assumed an average value for the friction coefficient of μ= 0.35. Flow stress of the workpiece material, 8620 steel, at the forging temperature was in turn estimated based on the results of compressive flow stress tests. These results were similar to the results of the tension tests shown in Fig. 4(b).

Using the average forging pressure and the dimensions of the gear, the stresses in the horizontal (x) and vertical (y) directions were estimated. The elastic deflections of the tooling were then expressed as:

$$e_x = \frac{\sigma_x}{E} - \nu \frac{\sigma_y}{E}$$
$$e_y = \frac{\sigma_y}{E} - \nu \frac{\sigma_x}{E} \qquad \textbf{(Eq 4)}$$

where ν is Poisson's ratio and E is the modulus of elasticity.

Estimation of the elastic contraction of the tooling due to shrink fitting was formulated in terms of the classical mechanical engineering analysis of thick circular cylinders under internal pressure.

Calculation of the thermal effects and the estimation of the material flow stress was based on the temperature distributions within the forging and the die. These were estimated through a heat transfer analysis employing the finite-difference method. The thermal profiles after 0.1 s are shown in Fig. 9. To simplify the computations, average temperatures were calculated and used to estimate the thermal corrections and material flow stress. The equations used were based on the same concept as Eq 1.

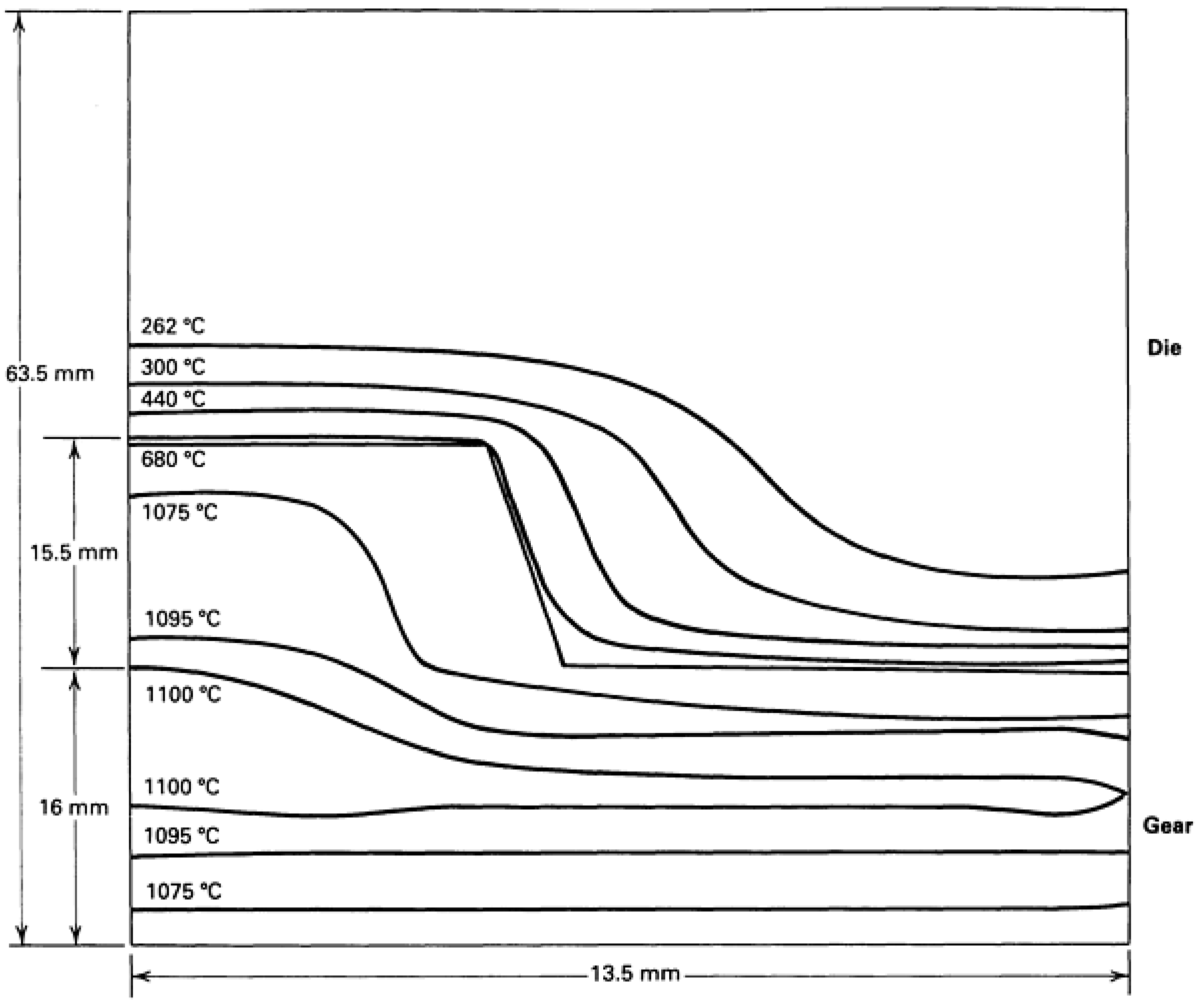

Fig. 9 Example temperature distribution (isotherms) in gear and die after 0.1 s. Initial billet temperature: 1100 °C (2012 °F). Initial die temperature: 260 °C (500 °F)

The results of the analytical work are summarized below. In this case, the thermal effects are the most significant. The elastic deflection in the horizontal direction is compensated by the radial contraction because of shrink fitting of the tooling. It does not always follow, however, that elastic deflections can be neglected. In this example, the most critical dimensions of the tooling were those associated with the gear teeth, the most difficult surfaces to machine. The thickness dimension was not as critical, because allowance was made for machining of the back of the gear after forging:

Effect	Correction mm/mm (in./in.)
Difference between thermal contraction of workpiece and thermal expansion of tooling	**0.02**
Elastic deflection in vertical direction due to forging load	**0.002**
Elastic deflection in horizontal direction due to forging load	**0.001**

Elastic deflection in radial direction due to shrink fitting	**0.001**

An interactive graphics system of computer programs was developed to integrate the geometric representation of the gear and all of the above analyses required for tooling design. The dies were manufactured by the EDM process. It was deemed uneconomical to machine the EDM electrode with numerically controlled machine tools. Instead, the computer system generated parameters for a gear-cutting machine that would result in an electrode incorporating all of the necessary correction factors as described above, as well as allowances for electrode overburn and wear during the EDM process. A total of six EDM electrodes were used in sequence for sinking of the dies.

The precision forging of the spiral bevel gears was done on a 29 MN (3300 tonf) mechanical forging press. Total forging load was estimated at 22 MN (2500 tonf).

The die was vented to allow entrapped gases and lubricant to escape during the forging operation. The preforms were ring shaped, with the outer diameter as close as possible to the outer dimensions of the forged gear. The preforms were heated to 1095 °C (2000 °F) by induction with a nitrogen atmosphere. A schematic of the tooling is shown in Fig. 10. Flash is formed only in the center portion of the forging.

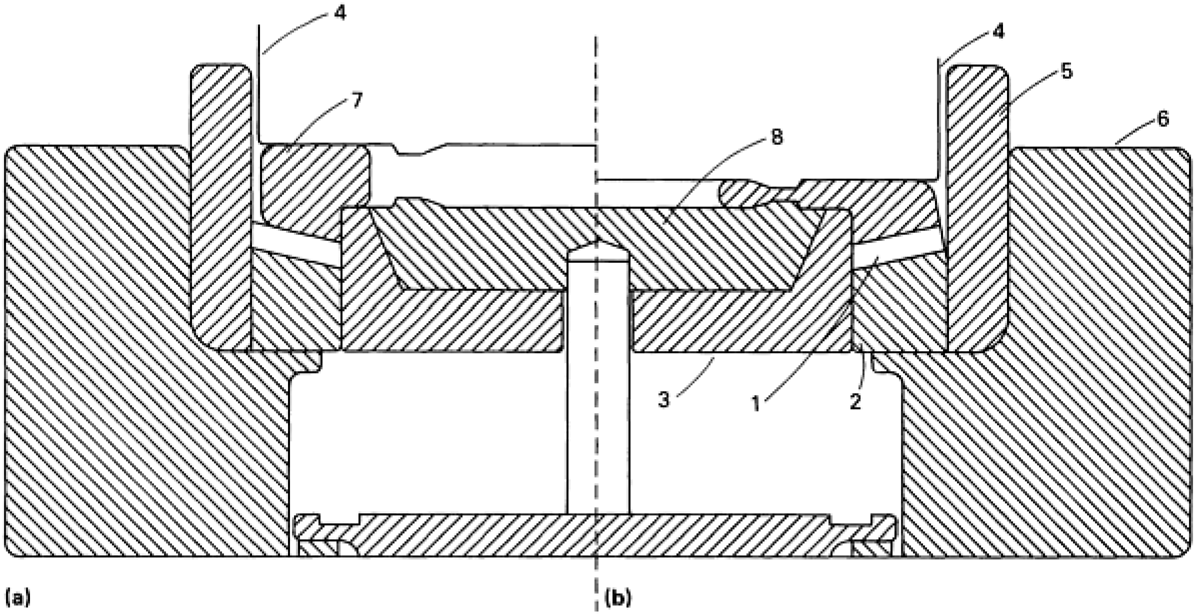

Fig. 10 Schematic of tooling for a preform before (a) and after (b) forging. 1, ring gear; 2, die bottom (with teeth); 3, inner die bottom; 4, punch; 5, die ring; 6, die holder; 7, preform; and 8, kick-out ring

Both H-11 and H-13 die materials were used in this program. The dies were lubricated with a water-base graphite die lubricant sprayed on the die surfaces. In early trials, the billets were precoated with a different water-dispersed graphite lubricant by dipping the billets in a bath containing the lubricant. However, for later trials, it was determined that precoating was not required when the protective atmosphere was used during induction heating. Die temperature was 150 °C (300 °F).

The precision forgings were cooled with the teeth buried in a mixture of sand and graphite. Because the forging lot sizes were small (approximately 20 gears), no data were obtained on die wear under anticipated production conditions.

Two lots of precision forgings were produced in this research program. In the first, the gears were forged with a 0.18 mm (0.007 in.) machining allowance on both sides of the tooth surfaces. In the second lot of forgings, the teeth were forged net. In this case, a maximum variation on the tooth form of 0.08 mm (0.003 in.) was acceptable.

Rotary Forging

Arthur C. P. Chou, Dyna East Corporation; P.C. Chou and H.C. Rogers, Drexel University

Introduction

ROTARY FORGING, or orbital forging, is a two-die forging process that deforms only a small portion of the workpiece at a time in a continuous manner. Unfortunately, the term rotary forging is sometimes used to describe the process that is more commonly referred to as radial forging, causing some confusion in terminology. Radial forging is a hot- or cold-forming process that uses two or more radially moving anvils or dies to produce solid or tubular components with constant or varying cross sections along their lengths. The differences between rotary and radial forging are illustrated in Fig. 1. Radial forging is discussed in detail in the article "Radial Forging" in this Volume.

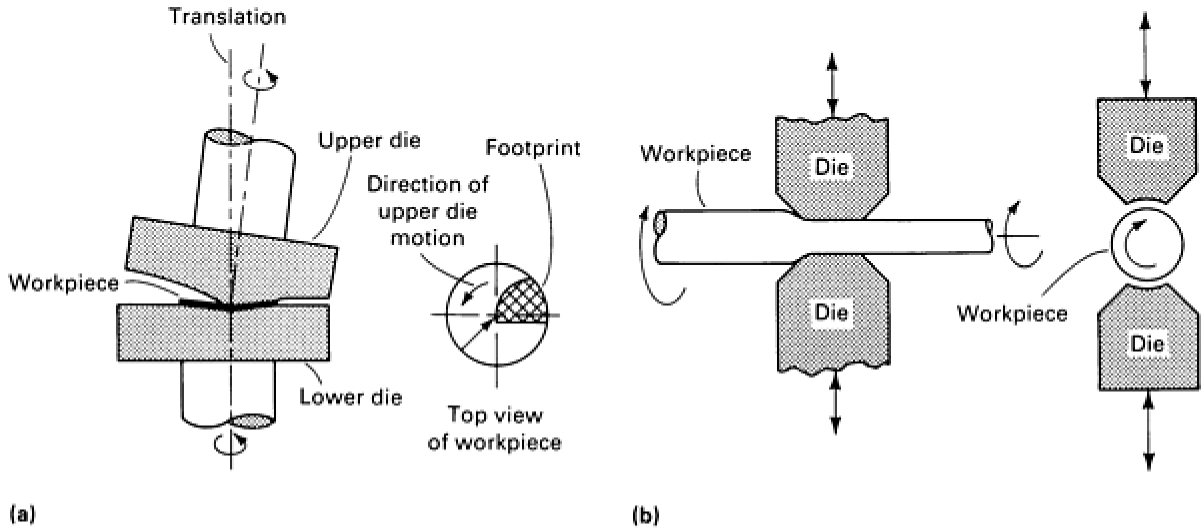

Fig. 1 Differences between rotary and radial forging. (a) In rotary forging, the upper die, tilted with respect to the lower die, rotates around the workpiece. The tilt angle and shape of the upper die result in only a small area of contact (footprint) between the workpiece and the upper die at any given time. Because the footprint is typically only about one-fifth the workpiece surface area, rotary forging requires considerably less force than conventional forging. (b) In radial forging, the workpiece is fed between the dies, which are given a rapid periodic motion as the workpiece rotates. In this manner, the forging force acts on only a small portion of the workpiece at any one time.

In rotary forging (Fig. 1a), the axis of the upper die is tilted at a slight angle with respect to the axis of the lower die, causing the forging force to be applied to only a small area of the workpiece. As one die rotates relative to the other, the contact area between die and workpiece, termed the footprint, continually progresses through the workpiece, gradually deforming it until a final shape is formed. As is evident in Fig. 1(a), the tilt angle between the two dies plays a major role in determining the amount of forging force that is applied to the workpiece. A larger tilt angle results in a smaller footprint; consequently, a smaller amount of force is required to complete the same amount of deformation as compared to a larger contact area. Tilt angles are commonly about 1 to 2°. The larger the tilt angle, however, the more difficult are the machine design and maintenance problems, because the drive and bearing system for the tilted die is subjected to large lateral loads and is more difficult to maintain. In addition, a larger tilt angle causes greater frame deflection within the forge, making it difficult to maintain a consistently high level of precision.

Rotary forges can be broadly classified into two groups, depending on the motion of their dies. In rotating-die forges, both dies rotate about their own axis, but neither die rocks or precesses about the axis of the other die. In rocking-die, or orbital, forges, the upper die rocks across the face of the lower die in a variety of fashions. The most common form is where the upper die orbits in a circular pattern about the axis of the lower die. In this case, the upper die can also either rotate or remain stationary in relation to its own axis. Other examples of rocking-die motion include the rocking of the upper die across the workpiece in a straight, spiral, or planetary pattern (Fig. 2).

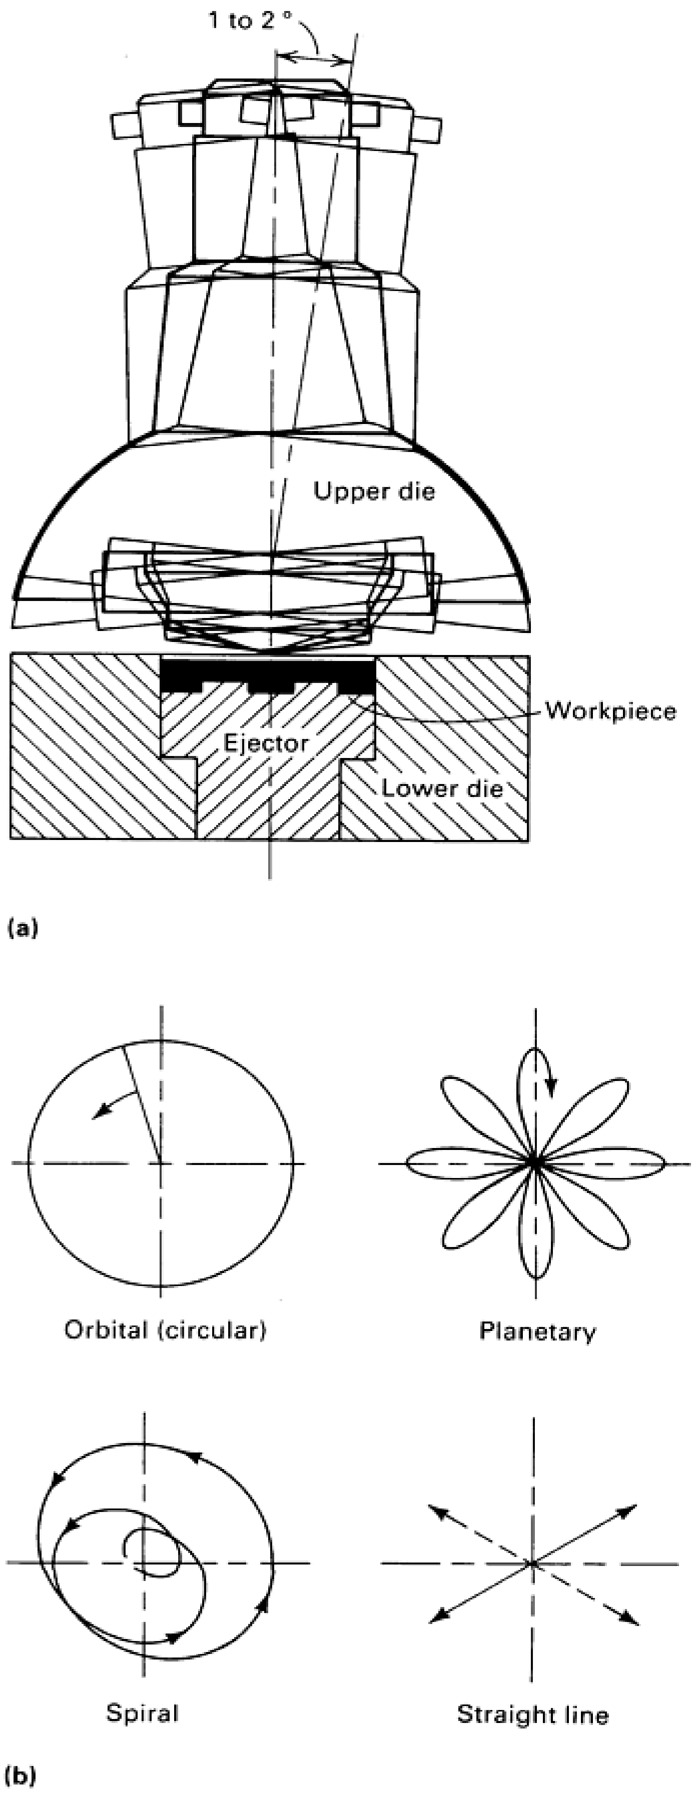

Fig. 2 Schematic of rocking-die forge (a) and sample patterns of upper die motion (b).

Rotary Forging

Applications

Rotary forging is generally considered to be a substitute for conventional drop-hammer or press forging. In addition, rotary forging can be used to produce parts that would otherwise have to be completely machined because of their shape or dimensions. Currently, approximately one-quarter to one-third of all parts that are either hammer or press forged could be formed on a rotary forge. These parts include symmetric and asymmetric shapes. In addition, modern rotary forge machines use dies that are 152 to 305 mm (6 to 12 in.) in diameter, limiting the maximum size of a part. In the current technology, rotating or orbiting die forges are mainly limited to the production of symmetrical parts. Through a more complex die operation, rocking-die forges are able to produce both symmetric and asymmetric pieces.

Workpiece Configuration. Parts that have been found to be applicable to rotary forging include gears, flanges, hubs, cams, rings, and tapered rollers, as well as thin disks and flat shapes. These parts are axially symmetric and are formed by using an orbital die motion. More complex parts can be forged through the use of such rocking-die motions as straight-line, planetary, and spiral. Straight-line die motion is most commonly used to produce asymmetric pieces, such as T-flanges.

Rotary forging is especially effective in forging parts that have high diameter-to-thickness ratios. Thin disks and large flanges are ideally suited to this process because of the ability of rotary forging to produce a higher ratio of lateral deformation per given downward force than conventional forging. There is also very little friction between the dies. Therefore, the lateral movement of workpiece material in rotary forging is as much as 30% more than that in impact forging.

Rotary forging is also used to produce intricate features on workpiece surfaces. Parts such as gears, hubs, and hexagonal shapes have traditionally been difficult to produce by conventional forging because die-workpiece friction made it difficult to fill tight spots properly on the dies.

Workpiece Materials. Any material, ferrous or nonferrous, that has adequate ductility and cold-forming qualities can be rotary forged. These materials include carbon and alloy steels, stainless steels, brass, and aluminum alloys. In the past, cold-forged production parts were primarily steels with a Rockwell C hardness in the mid-30s or lower. Generally, harder materials should be annealed before forging or should be warm forged.

Warm rotary forging is used when the material has a Rockwell C hardness greater than the mid-30s or when an unusually large amount of lateral movement in the workpiece is required. Materials are heated to a point below their recrystallization temperature; for steels, this is generally in the range of 650 to 800 °C (1200 to 1470 °F). Because the working temperature is below the recrystallization temperature, the inherent structure and properties of the metal are preserved.

Warm rotary forging results in an increased forging capability compared to cold rotary forging. However, some disadvantages are inherent in higher temperature forging. The work-hardening effects on the material that are associated with cold working are not as prominent, even though the working temperature is below the recrystallization temperature. In addition, as with any forging process, higher working temperatures result in increased die wear. Dies not only wear at a faster rate but also must be fabricated from more durable, more expensive materials.

Rotary Forging

Advantages and Limitations

Advantages. The primary advantage of rotary forging is in the low axial force required to form a part. Because only a small area of the die is in contact with the workpiece at any given time, rotary forging requires as little as one-tenth the force required by conventional forging techniques.

The smaller forging forces result in lower machine and die deformation and in less die-workpiece friction. This low level of equipment wear makes rotary forging a precision production process that can be used to form intricate parts to a high degree of accuracy.

Rotary forging achieves this high level of accuracy in a single operation. Parts that require subsequent finishing after conventional forging can be rotary forged to net shape in one step. The average cycle time for a moderately complex part is 10 to 15 s, which is a relatively short time of deformation from preform to final part. In addition, it is unnecessary to transfer the workpiece between die stations; this facilitates the operation of an automatic forging line. A cycle time in the range of 10 to 15 s will yield approximately 300 pieces per hour. The resulting piece is also virtually flash free. Therefore, rotary forging results in a much shorter operation from start to finish.

Tooling costs for rotary forging are often lower than those for conventional forging. Because of the lower forging loads, die manufacture is easier, and the required die strength is much lower. Die change and adjustment times are also much lower; dies can be changed in as little as 15 min. These moderate costs make the process economically attractive for either short or long production runs, thus permitting greater flexibility in terms of machine use and batch sizes.

Because impact is not used in rotary forging, there are fewer environmental hazards than in conventional forging techniques. Complications such as noise, vibrations, fumes, and dirt are virtually non-existent.

The smaller forging forces allow many parts to be cold forged that would conventionally require hot forging, resulting in decreased die wear and greater ease in handling parts after forging. This is in addition to the favorable grain structure that results from the cold working of metals.

Disadvantages. The principal disadvantages of rotary forging lie in the relative newness of the current technology. First, there is a need for a convenient method of determining whether or not a piece can be produced by rotary forging. Like other forging processes, the current process is basically one of trial and error. A set of dies must be constructed and tested for each part not previously produced by rotary forging in order to determine whether or not the part is suitable for rotary forging. This need, however, is inherent in any forging operation that uses a specific set of dies for every different part that is produced. This obviously creates a greater initial capital investment than that required in machining, which does not require specific die construction. Depending on the material as well as the specific shape and geometry, parts that are usually machined may not be suitable for rotary forging for a variety of reasons. For example, the material may experience cracking during the forging process; the finished part may undergo elastic spring-back; or there may be areas on the workpiece that do not conform to the die contour, leaving a gap between die and workpiece, such as central thinning.

Second, the rotary forges that are currently in use are adequate for forming the parts that they presently produce, but the accuracy of these parts is not as great as it can be. Further research and additional production experience are necessary before these forges reach their full practical potential.

Finally, a major problem lies in the design of rotary forge machines. The large lateral forces associated with the unique die motion make the overall frame design of the machines more difficult. These large forces must be properly supported by the frame in order for the forge to maintain a consistent level of accuracy. Conventional forges present a less troublesome design problem because they do not experience such a wide range of die motion.

Machines

As previously discussed, rotary forging machines are classified by the motion of their dies. These dies have three potential types of motion: rotational, orbital, and translational. Rotational motion, or spin, is defined as the angular motion of the die about its own axis. Rocking, or orbital, motion is the precession of a die about the axis of the other die without rotation about its own axis. Rocking patterns that are currently in use include orbital (circular), straight-line, spiral, and planetary. Translational motion, or feed, is the motion of a die in a linear direction indenting into the workpiece. Machines with three different combinations of these motions are illustrated in Fig. 3.

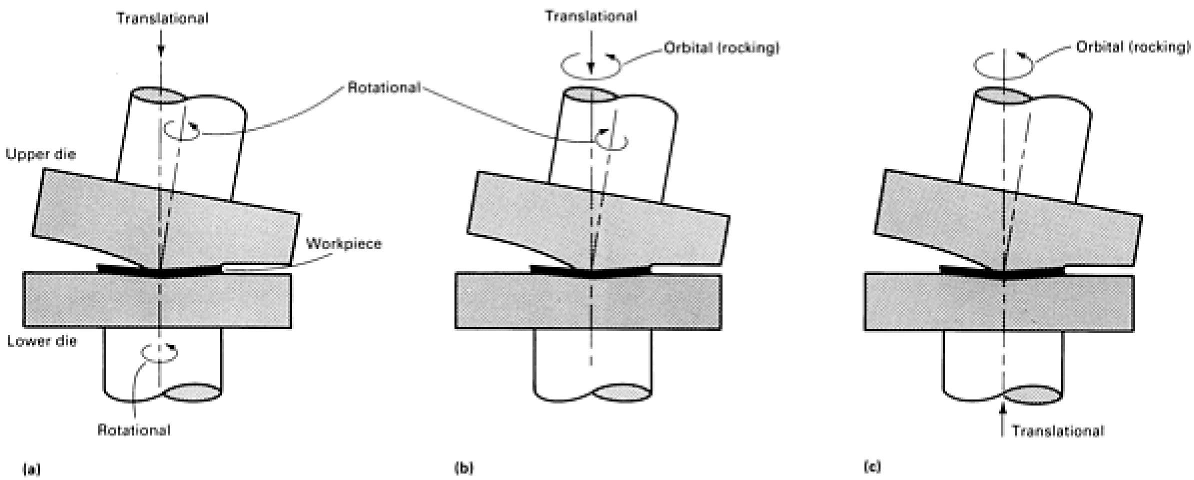

Fig. 3 Examples of die motion in rotary forging. (a) Upper die has both translational and rotational motion, while lower die rotates. (b) Upper die has translational, rotational, and orbital (rocking) motion; lower die is stationary. (c) Upper die has orbital (rocking) motion only; lower die has translational motion.

In modern rotating-die machines, the upper, or tilted, die has rotational and translational motion, while the lower die has only rotational motion (Fig. 3a). Depending on the specific machine, both dies can be independently driven or only the lower die is power driven while the upper die (the follower) responds to the motion of the lower die.

In modern rocking-die forges, the upper die always has rocking motion. In addition, the upper die has both translational and rotational motion (Fig. 3b) or has neither motion (Fig. 3c). In cases in which the upper die does not have translational motion, the lower die has the ability to translate.

The selection of machine type is primarily based on the construction and maintenance of the machine. In general, the machines that use more involved die movement are more difficult to maintain, particularly because of the loss of accuracy due to die and frame deflection.

Rocking-die machines are able to produce parts in a larger variety of shapes and geometries (particularly asymmetric parts). However, because of the large amount of die and frame movement, these parts may not be as precise as those produced with rotating-die machines. In addition, rocking-die machines require more frequent maintenance in order to retain their original level of accuracy.

Rotating-die machines are commonly used to forge symmetric parts. Included among these types of machines is the rotary forge that has the simplest die motion, in which both dies have rotational motion and one also has translational motion. In this case, the forging force always acts in one direction; therefore, the press design is simplified, and the minimal amount of frame deflection results in maximum precision. In addition, any error in the part is uniformly distributed around the circumference of the part, thus facilitating the alteration of die design to compensate for the error.

Rotary Forging

Dies

Rotary forging dies will typically produce 15,000 to 50,000 pieces before they must be refinished. Naturally, die life depends on the material being forged and on the complexity of the piece.

Because rotary forging dies experience a much lower forging force than normal, they are generally small and are usually made of inexpensive materials, typically standard tool steels. Therefore, die cost is lower than in other conventional forging methods. Lubrication of the dies, although not essential, is suggested in order to increase die life.

Both dies can be changed within 15 min. Complete job change and adjustments require approximately 30 min. This makes rotary forging particularly attractive for short production runs.

Examples

Example 1: Rotary Forging of a Bicycle Hub Bearing Retainer.

A rocking-die forge was used to produce the bearing retainer shown in Fig. 4(a). This part is used in bicycle hubs.

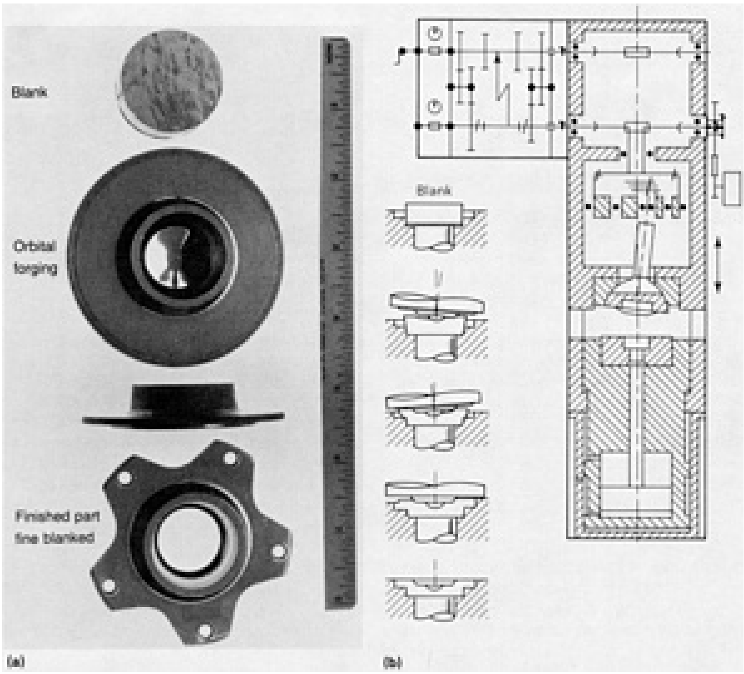

Fig. 4 Rotary-forged aluminum alloy 6061 bearing retainer (a) used in bicycle hubs. (b) Schematics of the rotary forge used to produce the bearing retainer and the workpiece deformation process (left).

The material of construction was aluminum alloy 6061. The aluminum was first saw cut from 33.3 mm ($1\frac{5}{16}$ in.) diam bar stock into 19 mm (0.75 in.) thick pucks. The material was heat treated from an initial hardness of T4 to a hardness of

T6. The puck was then placed on the lower die, and the upper die, using an orbital rocking pattern, deformed the material to fill the lower die mold. A schematic of the forge and the workpiece deformation is shown in Fig. 4(b).

After the deformation was complete, the upper die was raised, and the piece was ejected from the lower die. The resulting part had an outside diameter of 88.9 mm (3.5 in.). The retainer was then fine blanked to the final shape.

The production rate was approximately 6 to 7 parts per minute. This process is noticeably faster and less expensive than the conventional alternative of turning these parts down from 88.9 mm (3.5 in.) diam preforms, which involves a large amount of material waste. In addition, the rotary-forged pieces exhibit a higher density and a more beneficial grain structure as a result of the cold working of the material.

Example 2: Warm Rotary Forging of a Carbon Steel Clutch Hub.

A rocking-die press with a capacity of 2.5 MN (280 tonf) was used to warm forge a clutch hub. The medium-carbon steel (0.5% C) blank was first heated to a temperature of 1000 °C (1830 °F) and then placed on the lower die. Both upper and lower dies were preheated to about 200 °C (390 °F) and maintained in the range of 150 to 250 °C (300 to 480 °F) during forging. The lower die was raised until die-workpiece contact was made, and the upper die was rocked in an orbital pattern. Water-soluble graphite was sprayed onto the dies as a lubricant. The working time for forging was approximately 1.5 s per piece. The working load was about 0.75 MN (84 tonf), or about one-tenth the load required for conventional hot forging.

The quenching, tempering, and finish machining processes associated with conventional hot forging are not required for the rotary-forged part. After forging, the piece is merely cooled and then blanked to final dimensions. The surfaces of the piece have the same smoothness as the two dies. Flange flatness deviation and thickness variation are less than 0.1 mm (0.004 in.). An additional benefit of the lower forging temperature (conventional hot forging of these parts is done at 1250 °C, or 2280 °F) is a reduced grain size, which improves the strength of the part. A comparison between conventionally and rotary warm forged hubs is shown in Fig. 5. The rotary-forged hub requires a smaller billet weight, thus decreasing the amount of material waste. The rotary-forged hub also has closer tolerances than the conventionally forged hub, demonstrating the precision of the rotary process.

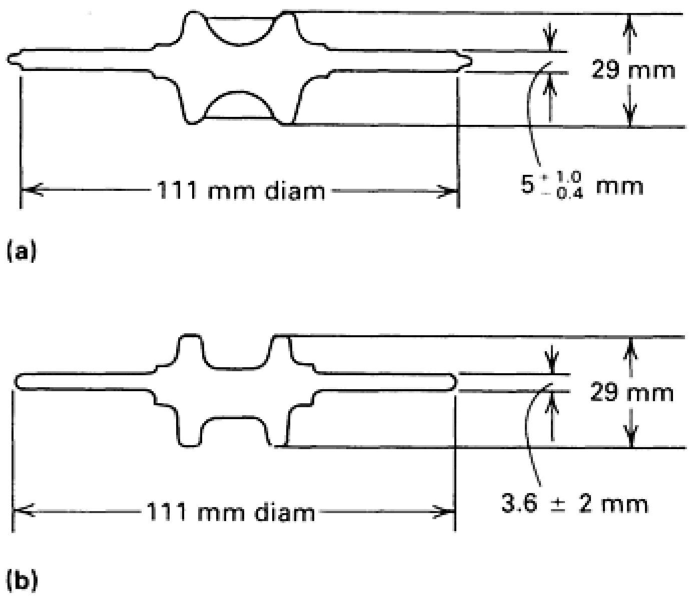

Fig. 5 Comparison of conventionally forged (a) and rotary hot forged (b) carbon steel clutch hubs. Billet weight: 0.63 kg (1.39 lb) for conventional forging, 0.44 kg (0.97 lb) for rotary forging.

The higher temperatures associated with warm rotary forging cause more rapid die-wear than that found in cold rotary forging. In this example, the dies, made of AISI H13 tool steel with a hardness of 50 HRC, exhibited noticeable wear after only 50 pieces had been forged.

Example 3: Rotary Forging of a Copper Alloy Seal Fitting.

A rotating-die machine was used to cold forge a naval brass seal fitting. This fitting is used in high-pressure piping, such as in air conditioners or steam turbines.

The initial preforms were 86.4 mm (3.4 in.) lengths of 44.5 mm (1.75 in.) OD, 24.1 mm (0.95 in.) ID tube stock. As shown in Fig. 6, the tube preform was fitted over a cylindrical insert that protrudes from the lower die. The upper die was lowered until indentation was made. Die rotation then began. The workpiece was deformed to fit the dimensions of the lower die and then ejected. The rotary-forged product was 39.7 MM ($1\frac{9}{16}$ in.) long with a minimum inside diameter of 23.6 mm (0.93 in.) and a maximum outside diameter of 55.6 mm ($2\frac{3}{16}$ in.). Minimal machining was required to bring the part to final dimensions.

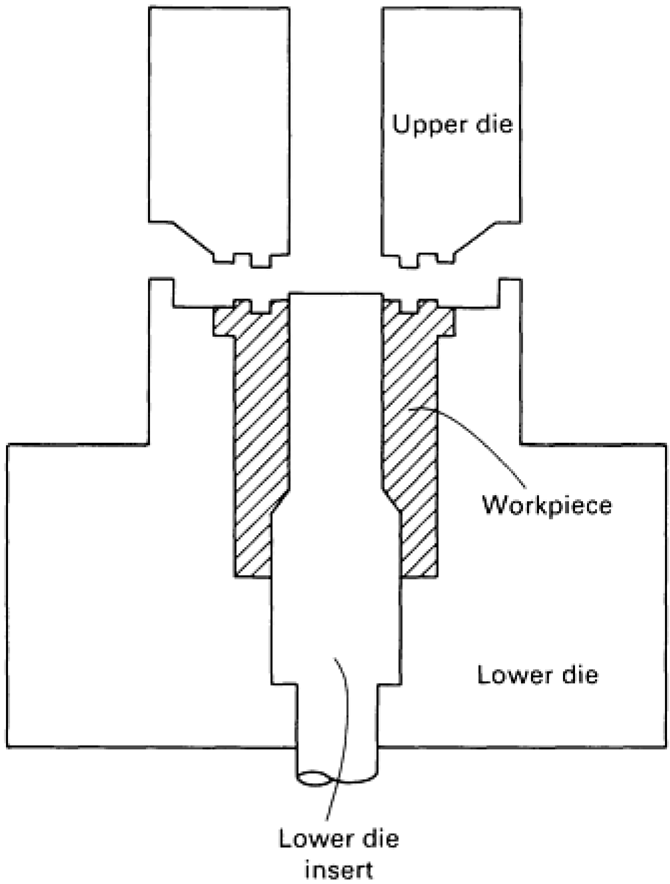

Fig. 6 Schematic of rotary forging setup for the forming of a copper alloy seal fitting used in high-pressure piping.

The machine used to produce these fittings is a rotating-die forge in which both dies rotate only about their own axis. The upper die is motor driven, while the lower die merely follows the rotation of the upper die after contact is made. The dies are constructed of A2 tool steel heat treated to a hardness of 58 to 62 HRC. The expected life of these dies is approximately 20,000 pieces.

In conventional processing, these fittings would be machined from 75 mm (3 in.) solid bar stock. This results in a large amount of wasted material, and machining time is approximately 17 min per piece. The tube stock used for rotary forging is more expensive than bar stock, but material waste is minimal. In addition, rotary forging requires only 20 s per piece, with an additional 3 to 4 min per piece needed for subsequent machining to final form.

Introduction

COINING is a closed-die forging operation, usually performed cold, in which all surfaces of the workpiece are confined or restrained, resulting in a well-defined imprint of the die on the workpiece. It is also a restriking operation (called, depending on the purpose, sizing or bottom or corner setting) used to sharpen or change a radius or profile. Ordinarily, coining entails the following steps:

- *Preliminary Workpiece Preparation.* Full contact between the blank and die surfaces, which is necessary for coining, usually requires some preliminary metal redistribution by other processes, such as forging or extrusion, because only a small amount of metal redistribution can take place in the coining dies in single-station coining. In progressive-die operations, coining is done as in single-station dies, but it is preceded by other operations such as blanking, drawing, piercing, and bending. Coining is often the final operation in a progressive-die sequence, although blanking or trimming, or both, frequently follow coining
- *Development of Detail in the Workpiece.* In coining dies, the prepared blank is loaded above the compressive yield strength and is held in this condition during coining. Dwell time under load is important for the development of dimensions in sizing and embossing; it is also necessary for the reproduction of fine detail, as in engraving
- *Trimming.* Flash that develops during coining and any hangers used to carry the blank through coining, especially in progressive-die coining, must be trimmed from the piece

Applicability

In coining, the surface of the workpiece copies the surface detail in the dies with dimensional accuracy that is seldom obtained by any other process. It is because of this that the process is used for coin minting.

Decorative items, such as patterned tableware, medallions, and metal buttons are also produced by coining. When articles with a design and a polished surface are required, coining is the only practical production method to use. Also, coining is well suited to the manufacture of extremely small items, such as interlocking-fastener elements.

Dimensional accuracy equal to that available only with the very best machining practice can often be obtained in coining. Many automotive components are sized by coining. Sizing is usually done on semifinished products, and provides significant savings in material and labor costs relative to machining.

Workpiece Size. Practical limits on workpiece size are mainly imposed by available press capacities and properties of the die material. For example, work metal with a compressive yield strength of 690 MPa (100 ksi) loaded in a press of 22 MN (2500 tonf) capacity can be coined in a maximum surface area of 0.032 m^2 (50 $in.^2$) . As the yield strength increases, the area that can be coined using the same press decreases proportionately. However, an increase in strength of the workpiece must be limited so that plastic failure of the die does not take place.

Hammers and Presses

In coining, the workpiece is squeezed between the dies so that the entire surface area is simultaneously loaded above the yield strength. To achieve the desired deformation of metal, the load determined from the compressive yield strength must be increased three to five times. Because of the area loading requirement and the great stress needed to ensure metal movement, press loading for coining is very severe, frequently approaching the capacity of the equipment used, with consequent danger of overloading.

Some coining equipment, such as drop hammers, cannot be readily overloaded, but presses (especially mechanical presses) can be severely overloaded. This is most likely to happen if more than one blank is fed to the coining dies at a time. Such overloading can break the press and the dies, and it will certainly shorten the life of the dies.

Overloading may be prevented by the use of overload release devices, and many presses are equipped with such devices. However, the usual means for preventing overloading in presses is careful control of workpiece thickness, which must be sufficient to allow acceptable coining, but not enough to lead to press overloading. Such thickness control, combined with blank-feeding procedures designed to minimize double blanking, is normally adequate to prevent overloading.

Coining may be satisfactorily undertaken in any type of press that has the required capacity. Metal movement, however, is accomplished during a relatively short portion of the stroke, so that a coining load is required only during a small portion of the press cycle.

Drop hammers, and knuckle-type and eccentric-driven mechanical presses are extensively used in coining. High-speed hydraulic presses also are well adapted for coining, especially when progressive dies are used. Large-capacity hydraulic presses are ideal for coining and sizing operations on large workpieces. On the other hand, when it is feasible to coin large numbers of small, connected parts, as in a continuous strip of work metal, roll coining is the most economical method.

Drop Hammers. Gravity drop hammers with ram weights in the range of 410 to 910 kg (900 to 2000 lb) are extensively used in the tableware industry. Board hammers can be used, although pneumatic-lift hammers predominate for this type of coining. In producing tableware, reproduction of detail and finish are more important than dimensional control.

Capacities of drop hammers are determined by ram weight and drop height, and coining pressures are stated in terms of these two quantities. Ram weight is usually selected in relation to the thickness and area of the blank. Drop height and the number of blows are determined by the complexity of the detail that is to be developed in the workpiece.

Mechanical presses with capacities ranging from a few tons to several hundred tons are widely used in coining. The larger presses are usually of the knuckle type, with production rates up to about 7500 pieces per hour. Small, specially built eccentric-driven presses are used for high-production coining of tiny parts.

Mechanical presses are well adapted for controlling size. Also, one-stroke sizing is generally preferred to a process requiring multiple blows, because there is less likelihood of fracturing the work metal.

Crank-driven mechanical presses have been successfully used in progressive-die coining. For these processes, coining usually follows combinations of piercing, forming, and blanking.

Hydraulic presses are extensively used for sizing operations, especially for workpieces with large surfaces to be coined. Spacers are required for maintaining close tolerances on the final dimensions of the part being sized. Hydraulic presses are sometimes favored because they are readily equipped with limiting devices that prevent overloading and possible die breakage.

Smaller hydraulic presses (about 70 kN, or 8 tonf, capacity) can be operated at speeds of up to 250 strokes per minute. These small high-speed presses are extensively used with progressive dies.

Capacity required for a coining operation, for open-die forming, or for sizing can be determined either by measuring in a compression machine the forces necessary to cause metal movement or by measuring the compressive yield strength and multiplying three to five times this value by the coined area of the part.

Strip of closely controlled thickness used in high-speed coining machines is frequently produced by rolling from round wire. The strain history and consequent strain-hardening behavior of progressively flattened round wire are usually not known. Also, because interaction between die and workpiece changes continuously with deformation, the loads required to flatten round wire are difficult to calculate and should be measured.

Lubricants

Whenever possible, coining without a lubricant is to be preferred. If entrapped in the coining dies, lubricants can cause flaws in the workpieces. For example, under conditions of constrained plastic flow, an entrapped lubricant will be loaded in hydrostatic compression and will interfere with the transfer of die detail to the workpiece. In many coining operations, however, because of work metal composition or the severity of coining, or both, the use of some lubricant is mandatory to prevent galling or seizing of the dies and the work metal.

No lubricant is used for coining teaspoons, medallions, or similar items from sterling silver. Some type of lubricant is ordinarily used for coining copper and aluminum and their alloys and for coining stainless, alloy, and carbon steels. When coining intricate designs, such as the design on the handles of stainless steel teaspoons, the lubricant must be used sparingly. A film of soap solution is usually sufficient. Excessive amounts of lubricant adversely affect workpiece finish and interfere with transfer of the design.

When coining items that do not require transfer of intricate detail, the type and amount of lubricant are less critical. A mixture of 50% oleum spirits and 50% medium-viscosity machine oil has been successful for prevention of galling and seizing for a large variety of coining operations. When coining involves maximum metal movement and high pressure, a commercial deep-drawing compound is sometimes used.

Die Materials

Coining dies may fail by wear, deformation due to compression, or cracking. With low coining pressures and soft work metal, wear failures predominate. With some combinations of die metal and work metal, dies may fail by adhesion (wear caused by metal pickup).

Failure of dies from deformation or cracking is usually caused by coining extremely intricate designs, attempts to coin large areas that confine the metal and build up excessive pressure, or coining of oversize slugs.

Constraints due to the pattern being produced may limit die life and cause premature cracking. If the obverse and reverse artwork of a decorative medal are not aligned properly, metal flow will be restricted and the die will not fill properly. As a result, excess tonnage (pressure) must be used to obtain fill, which sharply reduces die life. Stress raisers such as straight lines and sharp edges, which often are present in designs for decorative medals, also reduce die life unless the tonnage can be lowered. Low tonnage requirements often can be achieved by striking softer blanks, provided the blank is not so soft that a fin is extruded on coining.

Dies for Decorative Coining

Selection of tool steels for fabrication of dies used for striking high-quality coins and medals requires consideration of several important properties and characteristics. Among these are machinability, hardenability, distortion in hardening, hardness, wear resistance, and toughness. In dies used for decorative coining, materials that can be through hardened to produce a combination of good wear resistance, high hardness, and high toughness are preferred.

A smooth, polished background surface on the die is required for striking proof-type coins and medals. Massive undissolved carbides or nonmetallic inclusions make it more difficult to obtain this smooth background. Special processing and inspection should be required for tool steels to be used for coining dies (particularly in large sections), because any such imperfections can be troublesome. The stringent controls ordinarily applied to tool steels may not be sufficient to ensure that the required die surface condition will be obtainable.

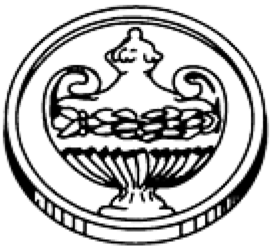
Typical Die Materials. For dies up to 50 mm (2 in.) in diameter, consumable-electrode vacuum-melted or electroslag remelted 52100 steel provides the clean microstructure necessary for the development of critical polished die surfaces. When heat treated to a hardness of 59 to 61 HRC, 52100 steel provides optimum die life. This steel is also suitable for photochemical etching, a process used in place of mechanical die sinking for engraving many low-relief dies. L6 tool steel at a hardness of 58 to 60 HRC is suitable for dies up to 102 mm (4 in.) in diameter. It can be through hardened, has enough toughness for long-life applications, and is suitable for photochemical etching of low-relief patterns. Air-hardening tool steels are preferred for coining and embossing dies greater than 102 mm (4 in.) in diameter. One of the chief reasons for choosing air-hardening tool steels is their low degree of distortion during heat treatment. Tool steel A6 is a nondeforming, deep-hardening material that is often used for large dies that must be hardened to 59 to 61 HRC. Air-hardening hot-work steels such as H13 are used at a hardness of 52 to 54 HRC for applications requiring especially high toughness.

For dies containing high-relief impressions, the lowest die cost is obtained by machining the impressions directly into the dies when the die life is anticipated to outlast the number of pieces to be coined. For longer runs that require two or more identical dies, it is less expensive to produce the impressions by hubbing. Hubbing is done by cutting the pattern into a male master plug (hub), hardening this hub, and pressing the hardened hub into a die block to make the coining impression. Highly alloyed tool steels are relatively difficult to hub. When coining dies are made from these steels, it may be necessary to form the impression by hot hubbing or by hubbing in several stages with intermediate anneals between stages.

Table 1 gives typical materials used to make the punches and dies for coining small pieces such as the 13 mm (½ in.) diam emblem shown in the accompanying sketch. The choice of tool material often depends less on the alloy to be coined than on the way the tools are made and the type of stamping equipment to be used.

Table 1 Typical materials for dies used to coin small emblems

Type of tool	Tool material[a] for striking a total quantity of:		
	1000	**10,000**	100,000
Machined dies for use on drop hammers	W1	W1	**O1[b], A2**
Machined dies for use on presses	O1	O1, A2	**O1, A2**
Hubbed dies for use on drop hammers	W1	W1	**W1[c]**
Hubbed dies for use on presses	O1	O1, A2	**A2, D2[d]**



(a) For coining the emblem from aluminum, copper, gold, or silver alloys, or from low-carbon, alloy, or stainless steel.

(b) O1 recommended only for coining low-carbon steel and alloys of copper, gold, or silver.

(c) The average life of W1 dies in coining alloys of copper, gold, or silver softer than 60 HRB would be about 40,000 ± 10,000 pieces. Life of W1 dies in coining harder materials would be about half as great; therefore, more than one set of dies would be needed for 100,000 parts or more.

(d) Hot hubbed

Tool steels O1 and A2 are alternative choices for machined dies in production quantities up to about 100,000 pieces. The small additional cost of A2 is often justified because A2 gives longer life, especially when aluminum alloys, alloy steels, stainless steels, or heat-resistant alloys are being coined.

Production of coins and medallions frequently involves quantities much greater than 100,000 pieces. Coins are usually produced on high-speed mechanical presses using dies containing impressions that have relatively low relief above the background plane. Dies for this type of operation must be easily hubbed, inexpensive, wear resistant, and made of nondeforming materials. Tool steel W1 is often selected for small dies, and 52100 is used for either small or large dies. Average die life can be expected to range from 200,000 to more than 1,000,000 strikes, depending on the type of coinage alloy and on coin diameter.

Dies for Coining Silverware. Probably the greatest amount of industrial coining is done with drop hammers in the silverware industry. Water-hardening steels such as W1 are almost always used for making such coining dies, whether the product is made of silver, a copper alloy, or stainless steel. Water-hardening grades are selected because die blocks made of these steels can be repeatedly reused. After a die block fails--either by shallow cracking of the hardened shell or by wear of the high points of the impressed pattern--the block is annealed, the impression is machined off, and a new impression is hubbed before the die is re-hardened. Dies made of deep-hardening tool steels such as O1, A2, and D2 are not reused (as are W1 dies), because they fail by deep cracking.

For ordinary designs requiring close reproduction of dimensions, dies may be made of A2 or of the high-carbon high-chromium steels D2, D3, and D4, to obtain greater compression resistance. For coining designs with deep configurations and either coarse or sharp details, where dies usually fail by cracking, a deep-hardening carbon tool steel may be used at lower hardness, or O1, S5, or S6 may be selected. In some instances, it may be desirable to select an air-hardening type such as A2, which provides improved dimensional stability and wear resistance. A hot-work steel such as H11, H12, or H13 may prove to be best when extreme toughness is the predominant requirement. When die failure occurs by rapid wear, a higher-hardness steel or a more highly alloyed wear-resistant steel such as A2 may solve the problem.

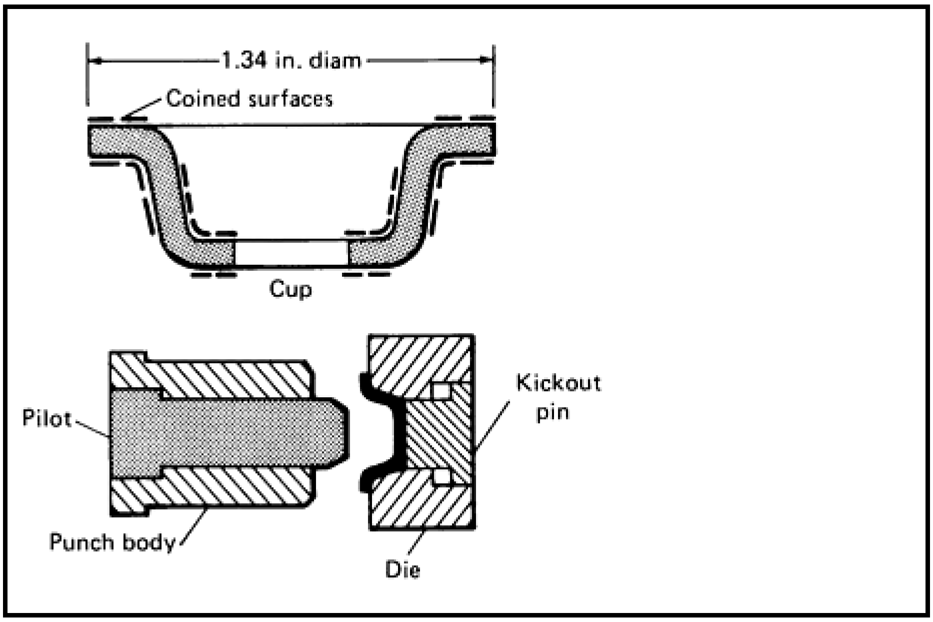
For articles coined on drop hammers from AISI 300 series austenitic stainless steels, it has sometimes been found advantageous to use steels of the S1, S5, S6, and L6 types, oil quenched and tempered to 57 and 59 HRC. Because the carbon contents of these grades are between 0.50 and 0.70%, they are less resistant to wear than are W1, A2, or D2, but are tougher and more resistant to chipping and splitting. If necessary, the wear resistance of S5 tool steel dies can be slightly improved by carburizing to a depth of 0.13 to 0.25 mm (0.005 to 0.010 in.).

Coining in Progressive Dies

Tool steels recommended for coining a cup-shape part to final dimensions in the last stages of progressive stamping are shown in Table 2. This press coining operation involves partial confinement of the entire cup within the die. This produces high radial die pressures and thus requires pressed-in inserts on long runs, to prevent die cracking. Quantities up to about 10,000 can be made with the steels given in Table 2 without danger of failure by cracking; the D2 steel listed for quantities greater than 10,000 pieces is used in the form of an insert pressed into the die plate.

Table 2 Typical tool steels for coining a preformed cup to final size on a press

Metal to be coined	Die material for total quantity of:		
	1000	**10,000**	100,000
Aluminum and copper alloys	W1	W1	**D2**
Low-carbon steel	W1	O1	**D2**
Stainless steel, heat-resisting alloys, and alloy steels	O1	A2	**D2**



(a) For quantities over 10,000, the materials are given for die inserts. All selections shown are for machined dies. The same material would be used for the punch, except that O1 should be substituted for W1 in applications in which W1 might crack during heat treating.

The punch material can be the same as the die material, except that O1 should be substituted for W1 in applications in which W1 might crack during quenching.

The coining illustrated in the sketch accompanying Table 2 is typical of the coining stage for articles stamped from strip material through progressive forming operations employing die and punch inserts for each stage. Frequently, the inserts are near, or even below, the minimum size that provides the amount of die stock required by good practice. Dies often cannot be any larger or they will not fit in the overall space available, as shown in the sketch in Table 2. In such instances, hot-work steels give better life than do W1, O1, A2, or S2. The separate pieces of the punch body and pilot in the tooling setup illustrated in Table 2 might be made of H12, at 49 to 52 HRC--a compromise between lower hardnesses that result in scoring deterioration and higher hardnesses that lead to failure by splitting. Scoring of the pilot part of the punch is best prevented by hard chromium plating 0.008 to 0.01 mm (0.0003 to 0.0004 in.) thick that has been baked at least 3 h at 150 to 200 °C (300 to 400 °F) to minimize hydrogen embrittlement.

In the coining die, type H12 hot-work tool steel at 45 to 48 HRC would probably be more resistant to splitting stresses than any of the cold-coining die steels. For the kickout pin, an L6 tool steel at a hardness of 40 to 45 HRC is recommended.

Tool steels H11, H12, H13, H20, and H21 at or near their full hardness of 50 to 54 HRC often perform well in coining dies having circular grooves, beads, thin sections, or any configuration that demands improved resistance to breakage and that can tolerate some sacrifice of wear resistance.

Working Hardnesses

The normal working hardnesses of the tool steels listed in Tables 1 and 2 are:

W1	**59-61 HRC**
O1	**58-60 HRC**
A2	**56-58 HRC**
D2	**56-58 HRC**

D2 might be used at 60 to 62 HRC for coining small aluminum parts.

Other Die Materials

Powder Metallurgy (P/M) Steels. The application of hot isostatic processing to powder metallurgy (P/M) production of high-speed steels and special high-alloy steels has expanded the range of tool steel grades available for long-run coining dies. Dramatic increases in toughness and grindability have been achieved. Type M4 is an excellent example. When made by P/M processing, M4 has approximately twice the toughness and two to three times the grindability of conventionally processed M4. Consequently, P/M M4 heat treated to 63 to 64 HRC has better toughness, wear resistance, and compressive strength than conventionally processed D2 at 62 HRC.

Cemented carbides are occasionally used to make coining dies, but generally only for light coining of small pieces in very large production quantities. The successful application of cemented carbides for this service depends to a great extent on the design of the die (or die insert), and to an even greater extent on the design of the hardened tool steel supporting and backup members that surround the carbide dies or inserts. It is most important that the supporting and backup members counteract any tensile stresses imposed on the carbide by the coining operation and that they ensure minimum movement of the die parts.

For light-load applications with minimal shock or impact loading, cemented tungsten carbide containing at least 13% cobalt is used. For applications involving greater shock loading, higher cobalt contents (up to 25%) are required.

Coinability of Metals

Limits to coining are established mainly by the unit loads that the coining dies will withstand in compression before deforming. Deformation of the dies results in dimensions that are out of tolerance in the work-piece as well as premature die failure.

In coining, deformation of the work metal is accomplished largely in a compression strain cycle, which leads to a progressive increase in compression flow strength as deformation progresses. This deformation cycle results in a product that has good bearing properties and wear resistance in service, but in the coining operation it can raise the yield strength to a level that approaches the maximum permissible die load, and the coining action stops.

Deformation strengthens the workpiece. It also increases the area of contact between the die and workpiece. As this contact area increases, radial displacement of the metal becomes increasingly difficult. Significant radial displacement is practical only for relatively soft metals such as sterling silver.

In general, if significant metal movement is required, this should be effected before coining by processes such as rolling or machining. To allow preliminary deformation to take place readily, the metal being coined should be soft and should have a low rate of strain hardening. If a metal lacks these characteristics, it can still be coined if first softened by annealing.

Steels and Irons. Steels that are most easily coined include carbon and alloy grades with carbon content up to about 0.30%. Coinability decreases as carbon or alloy content increases. Steels with carbon content higher than about 0.30% are not often coined, because they are likely to crack. Leaded steels usually coin as well as their nonleaded counterparts. However, other free-machining grades, such as those containing substantial amounts of sulfur, are not recommended for coining because they are susceptible to cracking. When steels are annealed for coining, full annealing is recommended. Process annealing is likely to result in excessive grain growth, which impairs the coined finish. A grain size no coarser than ASTM No. 6 is recommended.

Malleable iron castings are frequently sized by coining. The amount of coining that is practical mainly depends on the hardness.

Stainless steels of types 301, 302, 304, 305, 410, and 430 are those generally preferred for coining. Free-machining type 303Se (selenium-bearing) is sometimes coined.

For tableware, types 301 and 430 have been extensively used in coining of spoons and forks. Type 302 has also been used for such items. Type 305 coins well, but is not widely used because the stock costs more than types 301 and 302.

Stainless steels are relatively hard to coin and are consequently preferred in the soft annealed condition, in the hardness range of 75 to 85 HRB. For type 301 or similar austenitic stainless steels, the variation in nickel content permitted by the composition specifications significantly influences the strain-hardening characteristics of the steel. The low-nickel compositions work harden more than do the high-nickel compositions. For example, in low-nickel and high-nickel lots of type 301 stainless steel, the hardnesses after graded rolling to form a teaspoon bowl were, respectively, 45 and 40 HRC. Harder metal leads to shortened life of the blanking die.

The surface roughness of a well-finished piece of coined stainless steel is about 0.02 to 0.1 μm (1 to 4 μin.); this must be developed in the coining operation, because no major finishing can be done after coining without damage to design details. For functional parts, in which the item is coined only for sizing, surface finish may be less important. In general, however, the surface of the blank must be free from seams, pits, or scratches.

Copper, silver, gold, and their alloys have excellent coinability and are widely used in coin and medallion manufacture. These metals were the first to be minted, and the process of coining developed while working them.

The pure metals are sufficiently soft and coinable to allow extreme deformation in coining, but even after such deformation they are too soft to wear well. As a consequence, important coining metals are prepared by alloying; thus, a relatively wide range of hardness is obtainable.

Composite metals are being coined, principally in the minting of coins. Pressures for coining composites are slightly modified, in accordance with the bulk properties of the metal laminates used, but otherwise the coining operation is unaffected.

Coinability ratings of metals and alloys are difficult to establish on a quantitative basis, although the conditions under which a ductile metal will not coin can be stated in terms of the compressive loads that the die system can exert on the workpiece.

For simple die contours, coining loads can be determined readily, but for complex, incised die contours, coining behavior is a function of both the strength and deformation characteristics of the metal. The relations are so complex that stress calculations alone are not meaningful, and decorative items are coined in sequences that are established largely by experience. In addition, the coinability of a metal is frequently established by the difficulty encountered in preparing the blank for coining. Therefore, it is evident that a number of somewhat arbitrary factors enter into a determination of the coinability of a possible series of metals for a given item. This is especially true for tableware, which is required to be both decorative and useful.

Production Practice

Although coining operations are done as a part of many metalworking processes, by convention the operations narrowly designated as coining processes are of fairly limited scope. The range of coining processes is illustrated by the following examples. In these examples, coining processes fall into two broad categories. In the first category, the objective is the reproduction of ornate detail with a prescribed surface finish. In the second category, the objective is the close size control of an element, again with a prescribed surface finish.

Tableware. Most tableware is coined in single-station dies after extensive preparation of blanks. Each coined item must bear a reproduced ornate design and a polished finish.

Table knives may be made with flat or graded-thickness blades and solid or hollow handles. Flat blades are made by contour blanking followed by coining to develop the cutting edge and a desired surface finish. These blades are then soldered into handles. A stainless steel blade will be blanked, rolled to a graded thickness, outline blanked in one or more stages, and then coined. Type 410 stainless steel hardens to a point that it will not move in the coining operation. Therefore, blades made from type 410 stainless steel are usually heated to permit successful coining.

Sheet metal blanks for hollow handles are manually fed to a coining die mounted in a drop hammer. The blank is coined into an ornamented and polished knife half-handle, and then trimmed. Matched half-handles are soldered together, and the blade is soldered or cemented to the handle, as in the following example.

Example 1: Production of a Nickel Silver Knife Handle by Forming and Coining in a Drop Hammer.

Figure 1 shows the sequence of shapes in the production of a hollow handle for a table knife formed and coined in a 410 kg (900 lb) pneumatic drop hammer. The work metal was 0.81 mm (0.032 in.) thick copper alloy C75700 (nickel silver, 65-12) annealed to a hardness of 35 to 45 HRB; blank size was 25 by 230 mm (1 by 9 in.).

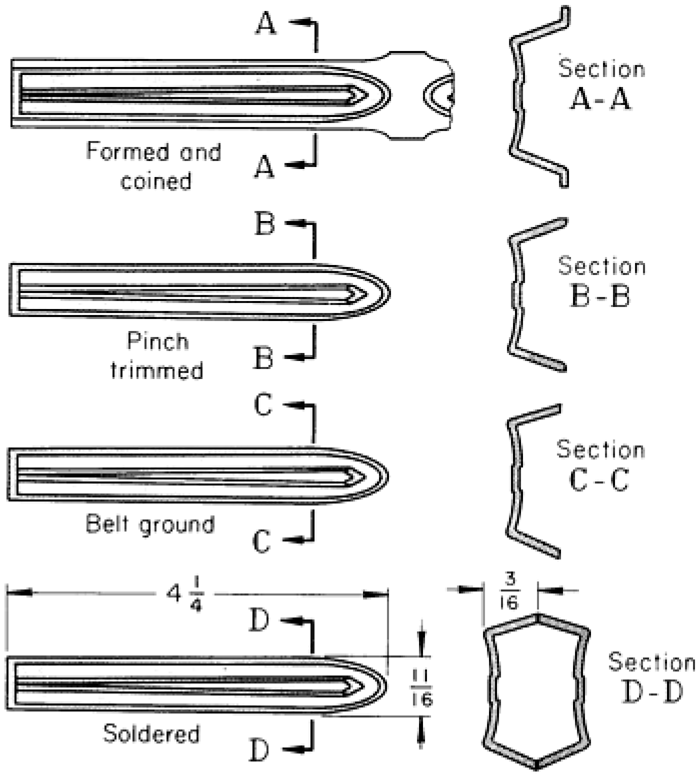


Fig. 1 Production of a hollow copper alloy C75700 knife handle by forming and coining. Dimensions given in inches.

Two workpieces were formed and coined simultaneously from one blank, in two blows of the drop hammer. The two-cavity die permitted easy loading and unloading of parts and also provided symmetry to prevent shifting of the punch. A volatile, fatty oil-base lubricant was applied to the blank by rollers.

The formed and coined halves were separated by slitting with a rotating cutter made of T1 tool steel, and the flange was removed in a pinch-trim operation. After belt grinding to deburr and provide a smooth, flat surface, the half handles were fluxed along the edges and soldered together. The soldered handles were then pickled, washed, and finished by a light emery on the soldered seams, and then were silver plated. The handle and blade were assembled and finish buffed.

Coins and medallions are produced by closed-die coining, in which a prepared blank is compressed between the coining dies while it is retained and positioned between the dies by a ring or collar. The volume of metal in the workpiece is equal to the volume of the die space when the die is closed. The volume of metal cannot exceed the closed-die space without developing excessive loads that may break the die and press. The simplest means of ensuring volume control in a coin blank is by carefully controlling the weight, which is easily measured and converted to volume.

In general, coins are needed in large quantities (about 300,000 before die dressing). To facilitate production and minimize die wear, the detail incorporated into the coin design is in low relief. The coin should have good wear resistance, which is achieved by the compressive working of the metal during coining. Wear of the coin face is prevented by raising the edge of the coin, which is usually serrated to have a so-called milled edge. This edge detail is machined into the retaining ring and is transferred to the expanding workpiece during coining. A typical procedure for coin manufacture is as follows:

- Coin disks are blanked from sheet of prescribed thickness and surface finish
- The disks are barrel tumbled to deburr, to develop a suitable surface finish, and to control weight
- The disks are edge rolled
- The disks are fed, one at a time, to the coining station for coining
- The coins are ejected from the retaining ring. This may be done by movement of the upper or lower die rather than by use of a conventional ejector

The steps employed to manufacture coins may also be used for medallions, with some added steps. Usually the processing of medallions does not require edging operations, but if the design details are in high relief, the full development of details may require restriking. Coined blanks are usually annealed before restriking. The blank must be reinserted into the coining dies in its initial position and then restruck. The use of this method for the manufacture of a medallion is described in the following example.

Example 2: Coining of Sterling Silver Alloy Medallions.

Medallions made from sterling silver alloy (92.5Ag-7.5Cu) and weighing 28 g (1 oz) (±1%) were made by coining, using the die setup illustrated in Fig. 2. Disks were blanked from strip and barrel finished. Following the first coining operation, the workpiece was annealed at 690 °C (1275 °F), repositioned in the die, and restruck. The single-station tooling consisted of the upper and lower incised O1 tool steel dies (60 HRC) and a retaining ring. After coining without lubrication, the medallion was manually removed from the retaining ring, because of the low production requirements (48 pieces per hour). Coining was done in a 3.6 MN (400 tonf) knuckle-type mechanical press.

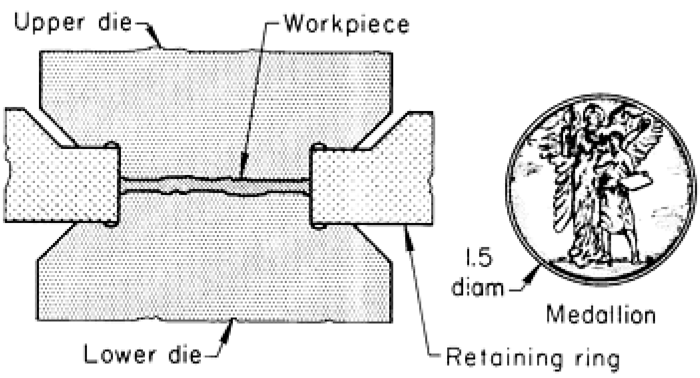

Fig. 2 Die setup used to produce sterling silver medallions by coining and restriking. Dimensions given in inches.

Minute parts are frequently produced in volume by coining in high-speed presses. For such operations, it is difficult to obtain commercial flat stock to the tolerances required, so it is common practice to prepare strip by rolling wire of the required material on precision rolls. The strip thus prepared is coiled and fed to the coining die as needed.

Also, in the manufacture of small, precise parts, the transfer of the workpiece into and out of the coining station is an important operation. To accomplish this, progressive-die tooling is used. The manufacture of a metal interlocking-fastener element can be done as described in the following example. In this example, strip was of a copper alloy; however, aluminum alloy has also been used for the same application.

Example 3: Coining Interlocking-Fastener Elements in a Progressive Die.

The interlocking-fastener element shown in Fig. 3 was manufactured from a precision-rolled, lubricated, flat strip of copper alloy C22600 (jewelry bronze; Cu-12.5Zn) 4.57 mm (0.180 in.) wide.

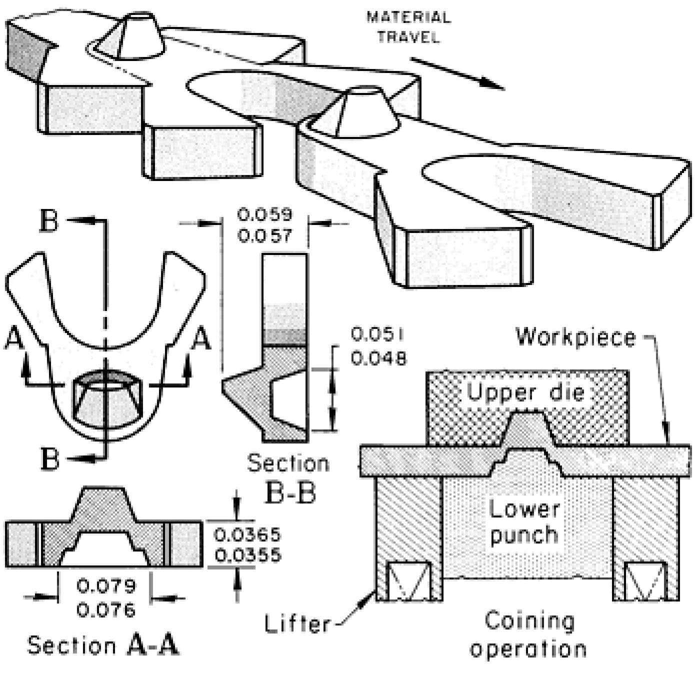

Fig. 3 Copper alloy C22600 interlocking-fastener element produced by coining and notching in a progressive die. Dimensions given in inches.

A special high-speed eccentric-shaft mechanical press with a 4.8 MM ($\frac{3}{16}$ in.) stroke was used. Tooling consisted of a D2 steel progressive die (59 to 61 HRC) that had edge-notching and coining stations. A ratchet-type roll feed was used. The coining portion of the die consisted of an upper die and a lower punch, with a spring-loaded stock lifter. The element was made at a production rate of 120,000 pieces per hour by notching, coining, and blanking, and then was attached to a tape.

Recesses, or mounting and locating features, are coined into high-production parts in a variety of products. Countersinks for screw heads and offsets for mating parts are regularly produced by coining. Often, one piece will have several mounting or assembly details coined into its face, as in the following example.

Example 4: Assembly and Mounting Details Coined Into a Mounting Plate.

The mounting recess for an oval post and the countersink for locating the end of a spring were coined into a mounting plate that was part of an automobile door lock (Fig. 4). The oval was coined to a depth of 1.27 mm (0.050 in.) in the third station of a six-station progressive die.

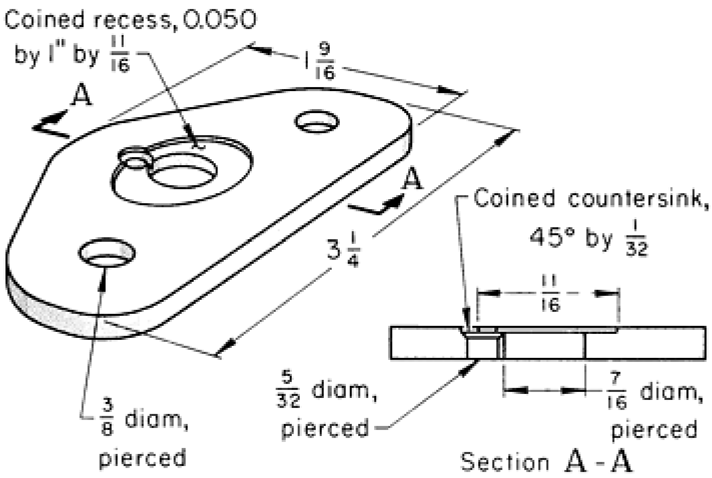

Fig. 4 1010 steel mounting plate with assembly and mounting features coined into its face. Dimensions given in inches.

The plate, as shown in Fig. 4, was made of 1010 hot-rolled steel 4.75 mm (0.187 in.) thick. The first station of the progressive die pierced the two end holes, which were then used as pilot holes for the other stations.

The location of these two holes took into consideration the growth in length of the part during coining. The second station pierced the center hole and the hole for the spring. The recess and the countersink were coined in the third station; the fourth station repierced the center hole. The plate was flattened in the fifth station and blanked in the sixth station. Later, the two end holes were countersunk, and the oval post was assembled to the oval recess. Production rate was 7500 plates per hour; annual production was five million pieces.

The dies were made of air-hardening and oil-hardening tool steels and had a life of 250,000 pieces before reconditioning was required. The piercing punch for the small hole had a life of about 50,000 pieces and could be changed without removing the die from the press.

Roll coining may be used when large numbers of very small items are to be produced and when the coining die is a repetitive single-station die that can be placed on a small roll. This method of coining is an advantage when coining parts in a strip, because the roll serves as both the feed control mechanism and the coining station. This procedure eliminates problems that develop in handling a continuous strip in a press. In press coining, the strip must be brought to a full stop during a prescribed portion of the press stroke.

Roll coining has been used for producing small parts to close dimensional tolerances. In the following example, multiple dies on rolls, together with the method of stock feeding used with roll coining dies, gave rates of production that were unattainable in presses.

Example 5: Roll Coining of Small Interlocking-Fastener Elements From Round Wire.

Copper alloy C22600 (jewelry bronze; Cu-12.5Zn) wire was fed into coining rolls to form elements of an interlocking-fastener strip (Fig. 5).

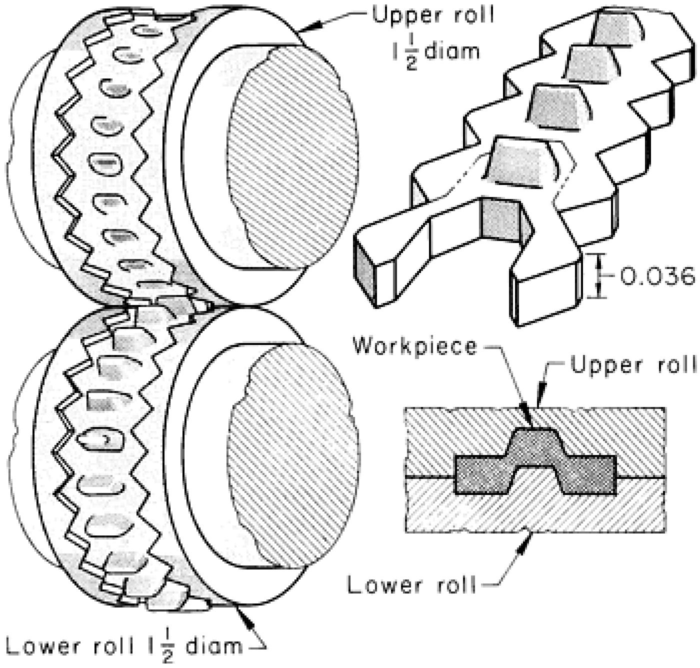

Fig. 5 Copper alloy C22600 interlocking-fastener element produced on coining rolls. Dimensions given in inches.

The rolls illustrated in Fig. 5 were geared together so that the male and female forms hubbed into the roll peripheries were accurately matched. Roll peripheries were a whole-number multiple of the lengths of the article coined. Diameters were kept as small as possible to minimize the expense of replacement of the rolls if premature failure occurred. The rolls enclosed a coining space nominally equal in cross section to that of the wire fed into them. This wire was forged and coined to fill the section presented in the roll space, to give the configuration shown in Fig. 5.

Sizing to close dimensional tolerances on several nonparallel surfaces can be readily achieved in the manufacture of small parts, such as the interlocking-fastener elements discussed in Examples 3 and 5. For large workpieces, ingenuity may be required to develop a coining process for sizing--ingenuity in the design of tooling to minimize the effect of distortion in the press, and ingenuity in the preparation of the workpiece to ensure a minimum of metal flow during coining.

For the flange-sizing operation in the following example, no surface finish requirement was specified because of the conditions under which the surfaces of the workpiece and the dies made contact. However, the finish of the surfaces coined was refined to 1 to 1.1 μm (40 to 45 μin.) from the typical shot-blasted finish of 9 to 10 μm (350 to 400 μin.).

The coining die setup described in the next example was designed to ensure control of thickness and parallelism.

Example 6: Sizing an Automobile Front-Wheel Hub by Coining.

The die setup illustrated in Fig. 6 was used to coin flanges of forged 1030 or 1130 steel front-wheel hubs using single-station tooling in an 18 MN (2000 tonf) knuckle-type mechanical press with a six-station feed table. Tolerances on the coined flange were: thickness within 0.127 mm (±0.005 in.) and parallelism within 0.10 mm (0.004 in.). To maintain these tolerances, the as-forged flange thickness could be not more than 1.40 mm (0.055 in.) greater than the coined dimension and had to be parallel within (0.43 mm) 0.017 in. The flange was coined to tolerances by centering the forged hub on the lower ring-shaped die. The top die, with a cavity depth equal to the specified flange thickness, was positioned over the wheel hub, and the coining load was applied. The top die was brought into contact with the lower die and, because the bearing surfaces of the upper and lower dies were parallel, the required parallelism was developed in the flange surfaces as the thickness was brought to the specified dimension.

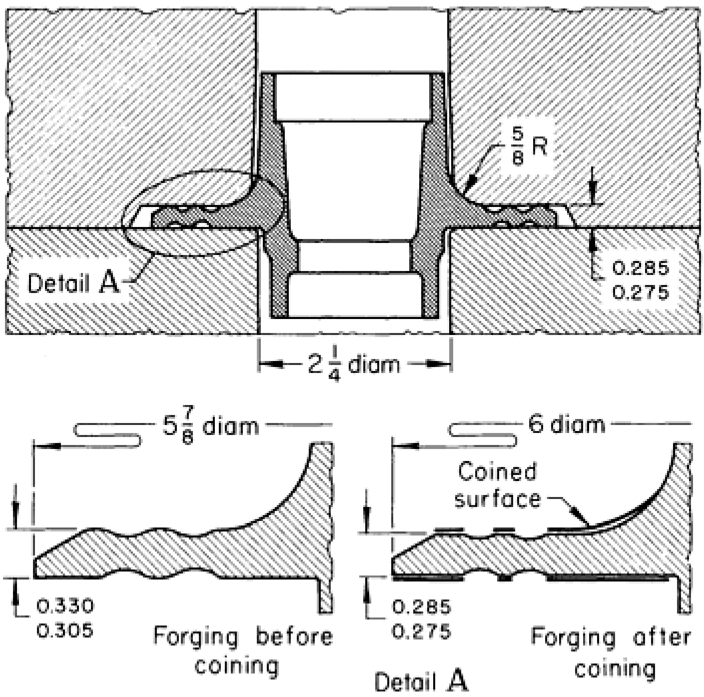

Fig. 6 Coining the flange on a forged 1030 or 1130 steel wheel hub to final size, at less cost than sizing the flange by machining. Dimensions given in inches.

Coining Versus Machining. In general, sizing by coining may be desirable when parallel surfaces are required in a workpiece, even if the workpiece is so large that maximum press capacities are required. However, sizing operations on nonparallel surfaces are feasible only if the work metal can be moved by the sizing-die surface without distorting the dies. Such metal movement is possible if the width of the metal being coined is about the same as the thickness. (For very soft metals, this movement is usually possible to a pronounced degree, but a sizing operation is of little significance for such materials.) In general, gross movement of the metal should not be required, and machining or forging should be used to bring the workpiece to approximate dimensions before sizing is attempted. When this is done, sizing by coining can produce workpieces having dimensional tolerances that are acceptable in good machining practice, often with significant savings in material and labor costs.

Coining

Processing Problems and Solutions

Establishment of a suitable blank preparation sequence is required to give the desired results from coining operations. Blank preparation may simply consist of annealing the blanks before or after coining, or both, followed by restriking to permit transfer of die detail to the workpiece.

Faulty coining may occur because die surfaces are not clean. Directing a jet of air across the die to remove loose dirt can eliminate some causes of incomplete detail in coined parts. Regular and frequent inspection of finished parts and dies is necessary to ensure that dies have not picked up stock or lubricant that can damage the surfaces of subsequently coined pieces.

Another frequent source of trouble in coining is faulty die alignment. Coining dies must be aligned to the degree of precision expected in the coined item.

Excessive tool breakage from die overloading is a common problem in coining, and it is difficult to suggest steps to eliminate it. In the manufacture of tableware, tool breakage is accepted, because replacement of tools is inexpensive and inspection procedures are adequate to prevent the buildup of large numbers of rejected items. When this approach to the problem is undesirable, the alternative is to establish the nature and magnitude of the overload and to relieve it by changing die design or process variables.

Control of Dimensions, Finish, and Weight

The quality of coined items is judged by various criteria, depending on end use. For decorative items, surface finish and transfer of detail are usually the primary objectives. For functional items, such as machinery components, dimensional accuracy and consistency are usually the most important factors.

Weight in coining sterling silver or other precious metals is important, mainly for economic reasons, and must be controlled. Controlling the weight of a blank is also a convenient way to control the volume of metal in a blank.

Dimensional Tolerances. Sizing is used to maintain dimensions to close tolerances and to refine the surface finish. In the following example, coining was used to hold the flange thickness to a total variation of 0.25 mm (0.010 in.). The same coining operation also controlled parallelism between the same two surfaces (see Example 6).

Coining was used to form the steel cam described in the example. To hold the dimensions to the specified tolerance, the part was annealed and coined again.

Example 7: Intermediate Annealing Before Coining to Dimension.

The breaker cam shown in Fig. 7 was made of 3.25/3.18 mm (0.128/0.125 in.) thick 1010 cold-rolled special-killed steel. Strips 86 mm (3⅜ in.) wide and 2.4 m (96 in.) long with a maximum hardness of 65 HRB and a No. 2 bright finish were purchased.

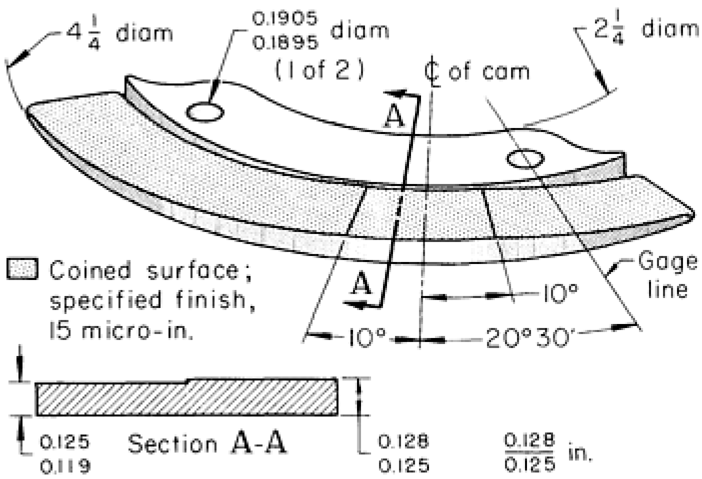

Fig. 7 Cold-rolled 1010 steel breaker cam that was given an intermediate anneal before being coined to final dimensions. Dimensions given in inches.

Cold working the cam surface by coining made it necessary to anneal the parts before flattening and restriking. The part contour and dimensions were extremely difficult to maintain. The surface finish was 0.4 μm (15 μin.). A pack anneal was used to minimize distortion and scale. The sequence of operations to make the part was:

- Shear strips to 1.2 m (48 in.) lengths
- Coin cam contour, pierce, and blank in a progressive die. High point on the cam was 3.12 to 3.15 mm (0.123 to 0.124 in.) thick
- Pack anneal at 900 to 925 °C (1650 to 1700 °F). The part had to be free of heat checks and scale
- Restrike to flatten and coin to 3.09 ± 0.076 mm (0.122 ± 0.003 in.) at the high point. Gage point (at 20.5° on open side) was 0.292 ± 0.0127 mm (0.0115 ± 0.0005 in.) below the high point on the cam

- Ream holes to 4.81 to 4.84 mm (0.1895 to 0.1905 in.) diam
- Case harden 0.020 mm (0.0008 in.) deep for wear-resistant surface (73 to 77 HR15-N)
- Wash and clean after case hardening
- Inspect dimensions and flatness

The cam was made in four lots of 2500 for a total of 10,000 per year. A 1.8 MN (200 tonf) mechanical press operating at 18 strokes per minute was used for the coining operations. The lubricant was an equal-parts mixture of mineral oil and an extreme-pressure chlorinated oil.

The die was made of D2 tool steel and had a life of 50,000 pieces between sharpenings for the cutting elements. The coining dies required more frequent attention because of the tolerance and finish requirements.

Other methods of making the part were machining and powder metallurgy. Parts machined to the required tolerances cost four times as much as coined parts. A powder metallurgy part did not meet the wear-resistance requirements.

Surface Finish. Tableware, coins, medallions, and many other coined items require an excellent surface finish. To achieve this, the dies must have an excellent surface, and the finish on the blank also must be good. Dies are carefully matched, tooled, stoned, and polished by hand. Polishing is done by wood sticks, lard oil, and various grits of emery. Typical surface finishing of sterling silver, before and after coining, when using the above practice, is illustrated in the following example.

Example 8: Effect of Die Finish on Finish of Coined Sterling Silver Fork.

Seven surface finish readings taken in the fork portion of uncoined sterling silver blanks showed an average surface roughness of 0.28 μm (11 μin.) (upper sketch of Fig. 8). When coining with dies that were not hand polished, the average finish in the fork section was reduced to 0.2 μm (9 μin.).

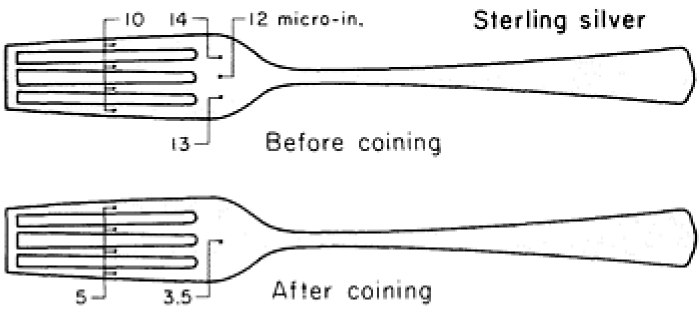

Fig. 8 Surface finish (in micro-inches) of a sterling silver fork before and after coining with hand-stoned and polished dies.

Dies were hand stoned and polished before a production run of 4000 forks. Workpiece surface finish improved to an average of 0.1 μm (5 μin.), as shown in Fig. 8 (lower sketch). To maintain this finish, hand polishing of the dies after each 1000 piece run was required. Coining was done in a 540 kg (1200 lb) air lift gravity drop hammer using a drop height of 610 mm (24 in.). Production rate was 500 pieces per hour.

Weight of the blanks for items coined from precious metals is often specified to close tolerances. These metals are soft and can be coined to intricate detail. However, the volume of metal placed in the die must be carefully controlled so that the metal can completely fill the design but not overload the die and press. A convenient method of controlling the volume of metal in a blank is to specify the weight, thickness, width, and length of the blank to close tolerances.

Not only is sterling silver flatware inspected for perfection of design detail and surface finish, but the blank is periodically checked for weight, which usually is held to ±1%.

Powder Forging

W. Brian James, Michael J. McDermott, and Robert A. Powell, Hoeganaes Corporation

Introduction

POWDER FORGING is a process in which unsintered, presintered, or sintered powder metal preforms are hot formed in confined dies. The process is sometimes called P/M (powder metallurgy) forging, P/M hot forming, or is simply referred to by the acronym P/F. When the preform has been sintered, the process is often referred to as "sinter forging."

Powder forging is a natural extension of the conventional press and sinter (P/M) process, which has long been recognized as an effective technology for producing a great variety of parts to net or near-net shape. Figure 1 illustrates the powder forging process. In essence, a porous preform is densified by hot forging with a single blow. Forging is carried out in heated, totally enclosed dies, and virtually no flash is generated. This contrasts with the forging of wrought steels, in which multiple blows are often necessary to form a forging from bar stock and considerable material is wasted in the form of flash.

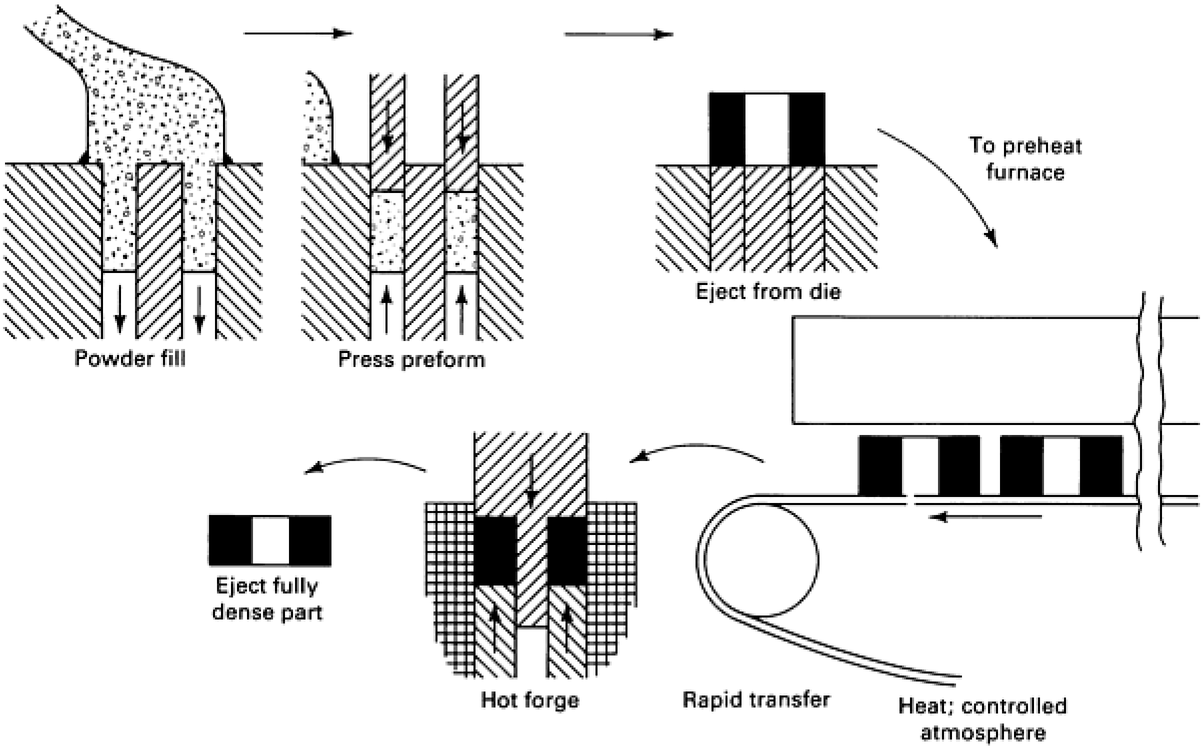

Fig. 1 The powder forging process.

The shape, quantity, and distribution of porosity in P/M and P/F parts strongly influence their mechanical performance. The effect of density on the mechanical properties of as-sintered iron and powder forged low-alloy steel is illustrated in Fig. 2. Powder forging, therefore, is a deformation processing technology aimed at increasing the density of P/M parts and thus their performance characteristics.

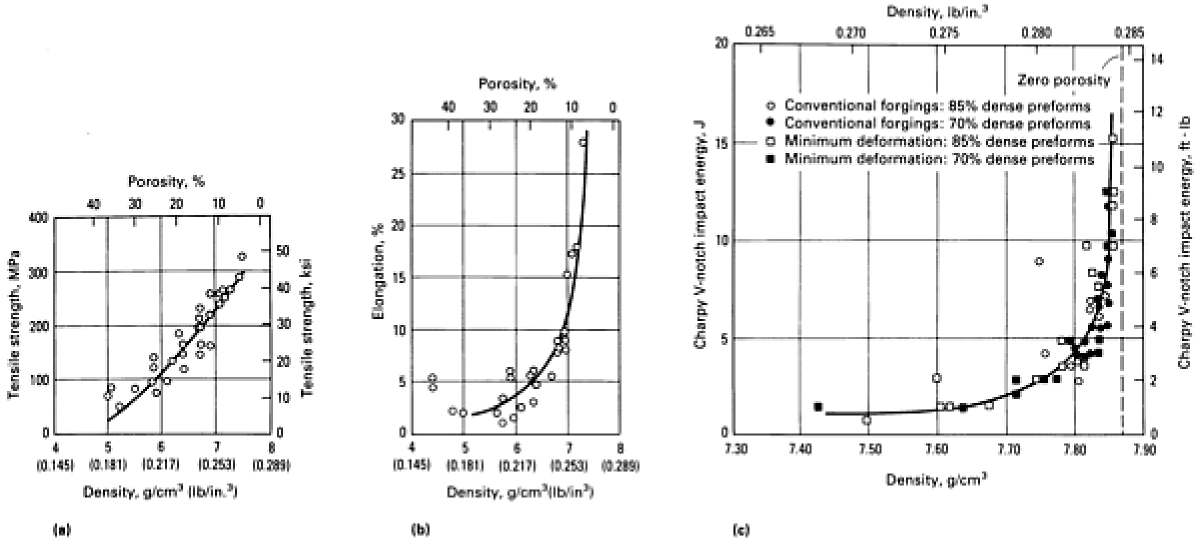

Fig. 2 Effect of density on mechanical properties. (a) and (b) As-sintered iron. Source: Ref 1. (c) Powder forged low-alloy steel. Source: Ref 2.

There are two basic forms of powder forging:

- Hot upsetting, in which the preform experiences a significant amount of lateral material flow
- Hot re-pressing, in which material flow during densification is mainly in the direction of pressing. This form of densification is sometimes referred to as hot restriking, or hot coining

These two deformation modes and the stress conditions they impose on pores are illustrated in Fig. 3.

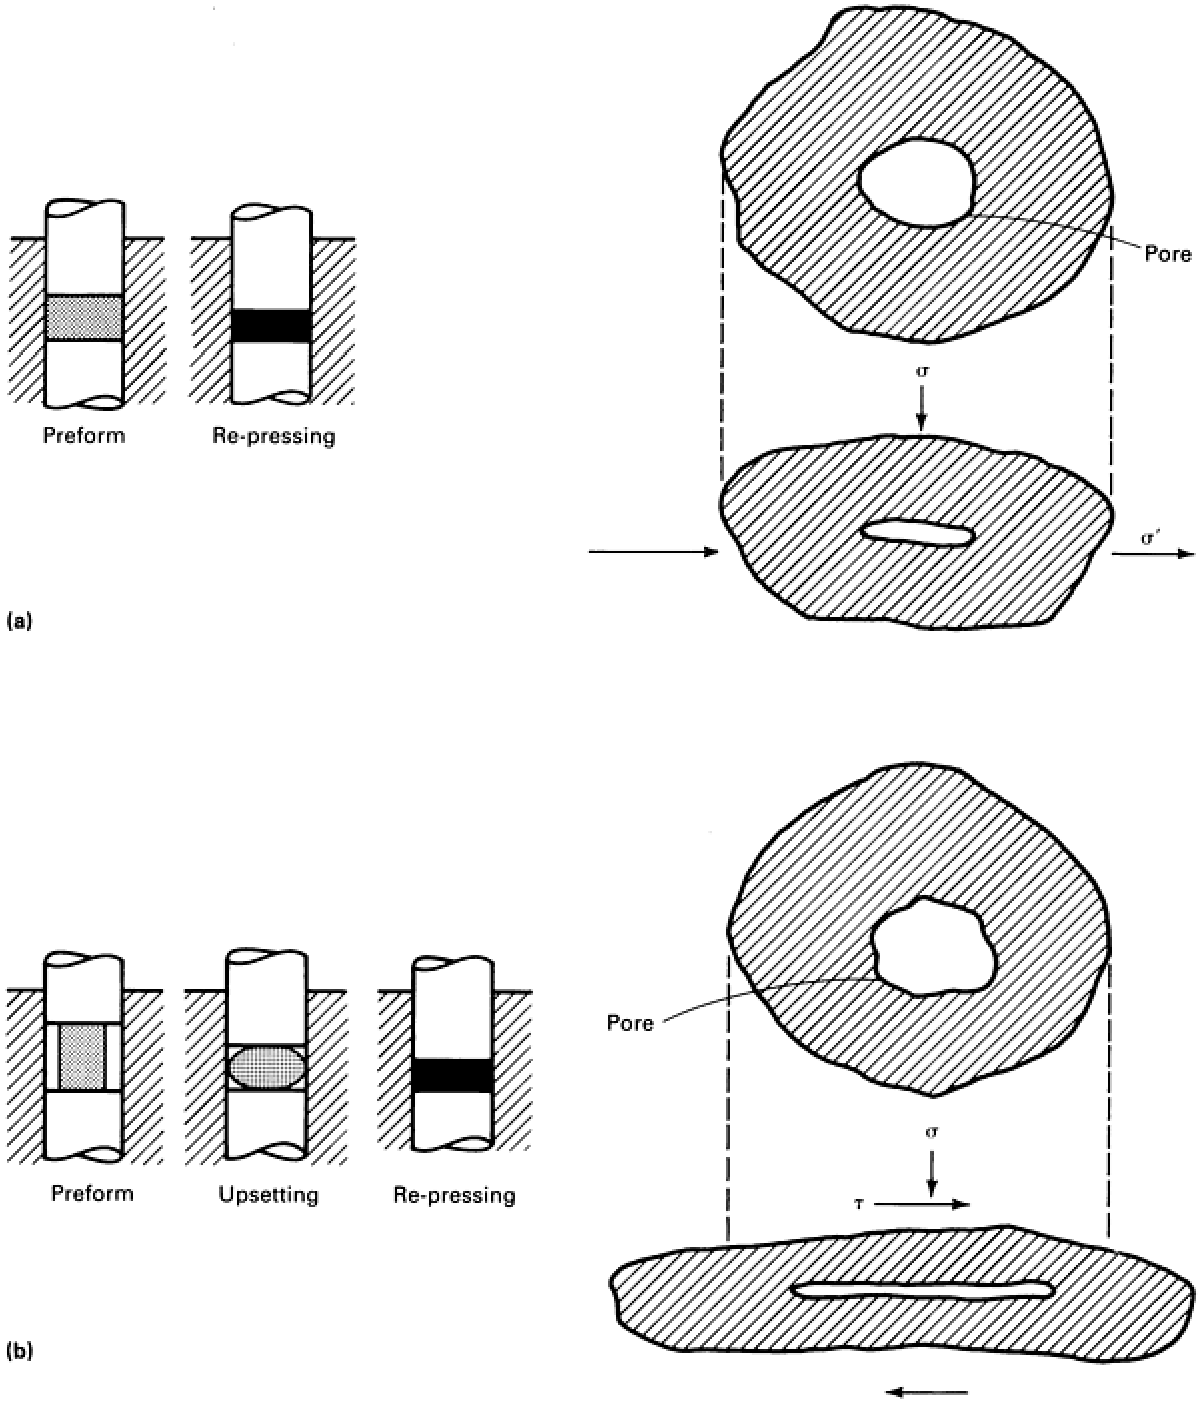

Fig. 3 Forging modes and stress conditions on pores for (a) re-pressing and (b) upsetting. Source: Ref 3.

In hot upset powder forging, the extensive unconstrained lateral flow of material results in a stress state around the pores that is a combination of normal and shear stresses. A spherical pore becomes flattened and elongated in the direction of lateral flow. The sliding motion due to shear stresses breaks up any residual interparticle oxide films and leads to strong metallurgical bonding across collapsed pore interfaces. This enhances dynamic properties such as fracture toughness and fatigue strength.

The stress state during hot re-press powder forging consists of a small difference between vertical and horizontal stresses, which results in very little material movement in the horizontal direction and thus limited lateral flow. As densification proceeds, the stress state approaches a pure hydrostatic condition. A typical pore simply flattens, and the opposite sides of the pore are brought together under pressure. Hot re-press forging requires higher forging pressures than does hot upset forging for comparable densification. The decreased interparticle movement compared with upsetting reduces the tendency to break up any residual interparticle oxide films and may result in lower ductility and toughness.

While powder forged parts are primarily used in automotive applications where they compete with cast and wrought products, parts have also been developed for military and off-road equipment.

The economics of powder forging have been reviewed by a number of authors (Ref 4, 5, 6, 7, 8, 9). Some of the case histories included in the section "Applications of Powder-Forged Parts" in this article also compare the cost of powder forging with that of alternative forming technologies.

The discussion of powder forging in this article is limited to ferrous alloys. Information on the forging of aluminum, nickel-base, and titanium powders is available in the articles "Forging of Aluminum Alloys," "Forging of Nickel-Base Alloys," and "Forging of Titanium Alloys" in this Volume. Detailed information on all aspects of powder metallurgy is available in *Powder Metal Technologies and Applications,* Volume 7 of the *ASM Handbook.*

Material Considerations

The initial production steps of powder forging (preforming and sintering) are identical to those of the conventional press and sinter P/M process. Certain defined physical characteristics and properties are required in the powders used in these processes. In general, powders are classified by particle shape, particle size, apparent density, flow, chemistry, green strength, and compressibility. More information on testing of powders is available in the Section "Metal Powder Production and Characterization" in *Powder Metal Technologies and Applications*, Volume 7 of the *ASM Handbook.*

Powder Characteristics. Shape, size distribution, apparent density, flow, and composition are important characteristics for both conventional P/M and powder forging processes. The shape of the particles is important in relation to the ability of the particles to interlock when compacted. Irregular particle shapes such as those produced by water atomization are typically used. In P/M parts, surface finish is related to the particle size distribution of the powder. In powder forging, however, the surface finish is directly related to the finish of the forging tools. This being the case, it might be considered possible to use coarser powders for powder forging (Ref 10). Unfortunately, the potential for deeper surface oxide penetration is greater when the proportion of coarser particles is increased. Typical pressing grades are -80 mesh with a median particle size of about 75 μm (0.003 in.). The apparent density and flow are important to maintain fast and accurate die filling. The chemistry affects the final alloy produced as well as the compressibility.

Green strength and compressibility are more critical in P/M than they are in P/F applications. Although there is a need to maintain edge integrity in P/F preforms, there are rarely thin, delicate sections that require high green strength. Because P/F preforms do not require high densities (typically 6.2 to 6.8 g/cm^3, or 0.22 to 0.25 lb/in.^{3}), the compressibility obtainable with prealloyed powders is sufficient. However, carbon is not prealloyed because it has an extremely detrimental effect on compressibility (Fig. 4).

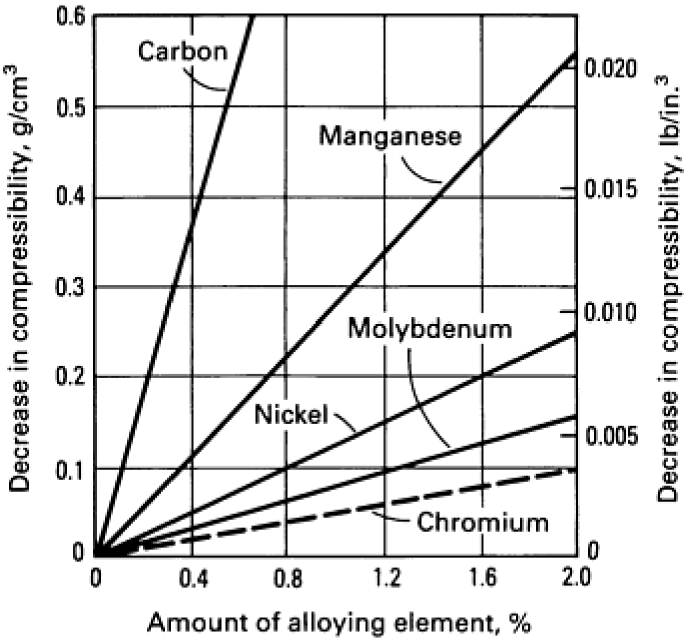

Fig. 4 Effect of alloying elements on the compressibility of iron powder. Source: Ref 10.

Alloy Development. Several investigators have shown that forged conventional elemental powder mixes result in poor mechanical properties, such as fatigue resistance, impact resistance, and ductility (Ref 11, 12). This is almost entirely due to the chemical and metallurgical heterogeneity that exists in materials made by this method. To overcome this, very long diffusion times or higher processing temperatures are required to fully homogenize the material, particularly when elements such as nickel are used. Samples forged from prealloyed powder have also been shown to have better hardenability than samples forged from admixed powders (Ref 13). Fully prealloyed powders have therefore been produced by several manufacturers. Each particle in these powders is uniform in composition, thereby alleviating the necessity for extensive alloy diffusion.

Powder purity and the precise nature and form of impurities are also extremely important. In a conventional powder metal part, virtually all properties are considerably lower than those of equivalent wrought materials. The effect of inclusions is overshadowed by the effect of the porosity. For a powder forging at full density, as in a conventional forging, the dominant effect of residual porosity on properties is replaced by the form and nature of impurity inclusions.

The two principal requirements for powder forged materials are an ability to develop an appropriate hardenability to guarantee strength and to control fatigue performance by microstructural features such as inclusions.

Hardenability. Manganese, chromium, and molybdenum are very efficient promoters of hardenability, whereas nickel is not. In terms of their basic cost, nickel and molybdenum are relatively expensive alloying additions compared with chromium and manganese. On this basis, it would appear that chromium/manganese-base alloys would be the most cost-effective materials for powder forging. However, this is not necessarily the case, because these materials are highly susceptible to oxidation during the atomization process. In addition, during subsequent powder processing, high temperatures are required to reduce the oxides of chromium and manganese, and special care must be taken to prevent reoxidation during handling and forging. If the elements become oxidized, they do not contribute to hardenability. Nickel and molybdenum have the advantage that their oxides are reduced at conventional sintering temperatures. Alloy design is therefore a compromise and the majority of atomized prealloyed powders in commercial use are nickel/molybdenum based, with manganese present in limited quantities. The compositions of three commercial powder metallurgy steels are listed below.

Alloy	Composition, wt %[(a)]		
	Mn	**Ni**	Mo
P/F-4600	0.10-0.25	1.75-1.90	**0.50-0.60**
P/F-2000	0.25-0.35	0.40-0.50	**0.55-0.65**

(a) All compositions contain balance of iron.

The higher cost of nickel and molybdenum along with the higher cost of powder compared with conventional wrought materials is often offset by the higher material utilization inherent in the powder forging process.

More recently, P/F parts have been produced from iron powders (0.10 to 0.25% Mn) with copper and/or graphite additions for parts that do not require the heat-treating response or high strength properties achieved through the use of the low-alloy steels. Detailed descriptions of alloy development for powder forging applications have been published previously (Ref 14, 15).

Inclusion Assessment. Because the properties of material powder forged to near full density are strongly influenced by the composition, size distribution, and location of nonmetallic inclusions (Ref 16, 17, 18), a method has been developed for assessing the inclusion content of powders intended for P/F applications (Ref 19, 20, 21, 22). Samples of powders intended for forging applications are re-press powder forged under closely controlled laboratory conditions. The resulting compacts are sectioned and prepared for metallographic examination. The inclusion assessment technique involves the use of automatic image analysis equipment. The automated approach is preferred because it is not sensitive to operator subjectivity and can be used routinely to obtain a wider range of data on a reproducible basis.

In essence, an image analyzer consists of a good-quality metallurgical microscope, a video camera, a display console, a keyboard, a microprocessor, and a printer. The video image is assessed in terms of its gray-level characteristics, black and white being extremes on the available scale. The detection level can also be set to differentiate between oxides and sulfides.

Compared with wrought steels, only a limited amount of material flow is present in powder forged components. Inclusion stringers common to wrought steel are therefore not found in powder forged materials. Figure 5(a) illustrates an inclusion type encountered in powder forged low-alloy steels. The fragmented nature of these inclusions makes size determination by image analysis more complex than would be the case with the solid exogenous inclusion shown in Fig. 5(b). Basic image analysis techniques tend to count the inclusion shown in Fig. 5(a) as numerous small particles rather than as a single larger entity. Amendment of the detected video image is required to classify such inclusions; the method used is discussed in Ref 22.

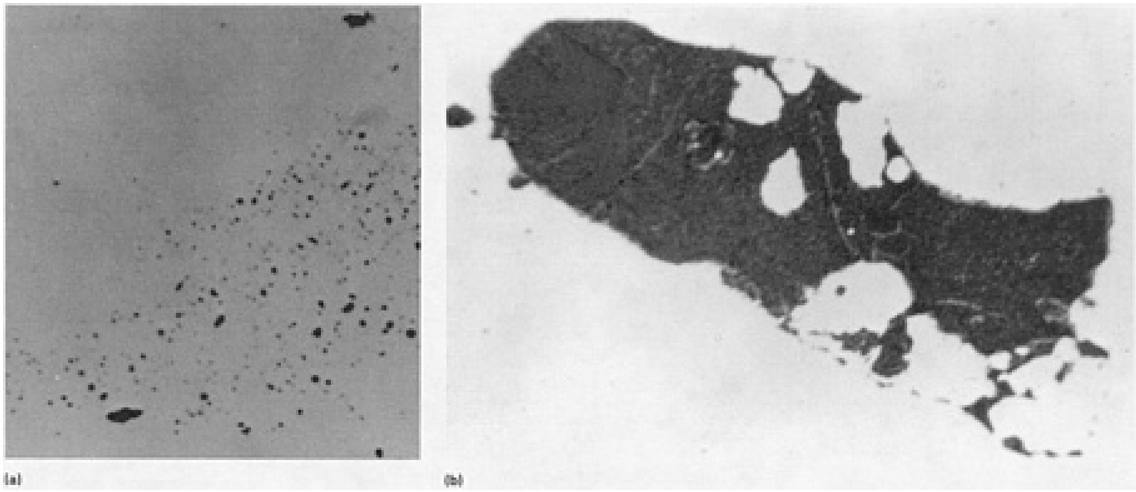

Fig. 5 Two types of inclusions. (a) "Spotty particle" oxide inclusion. 800×. (b) Exogenous slag inclusion. 590×. Source: Ref 21.

Iron Powder Contamination. Water-atomized low-alloy steel powders are generally produced and processed in a plant that also manufactures pure iron powders. In the early days of alloy development when alloy powder production was limited, procedures were developed to minimize cross-contamination of powders. Considerable care is still taken to prevent cross-contamination, and iron powder contamination of low-alloy powders is typically less than 1%. Studies have shown that for "through hardening" applications, up to 3% iron powder contamination has little effect on the strength and ductility of powder forged material (Ref 23, 24).

The compact used for inclusion assessment may also be used to measure the amount of iron powder particles present. The sample is lightly pre-etched with 2% nital. Primary etching is with an aqueous solution of sodium thiosulfate and potassium metabisulfite. This procedure darkens the iron particles and leaves the low-alloy matrix very light (Fig. 6).

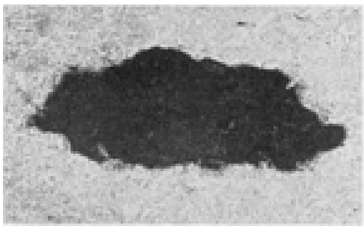

Fig. 6 Iron powder contamination of water-atomized low-alloy steel powder. Source: Ref 21.

The etched samples are viewed on a light microscope at a magnification of 100×. The total number of points of a 252-point grid that intersect iron particles for ten discrete fields is divided by the total number of points in the ten fields (2520) to determine the percentage of iron contamination.

Powder Forging

W. Brian James, Michael J. McDermott, and Robert A. Powell, Hoeganaes Corporation

Process Considerations

Development of a viable powder forging system requires consideration of many process parameters. The mechanical, metallurgical, and economic outcomes depend to a large extent on operating conditions, such as temperature, pressure, flow/feed rates, atmospheres, and lubrication systems. Equally important consideration must be given to the types of processing equipment, such as presses, furnaces, dies, and robotics, and to secondary operations, in order to obtain the process conditions that are most efficient. This efficiency is maintained by optimizing the process line layout. Examples of effective equipment layouts for preforming, sintering, reheating, forging, and controlled cooling have been reviewed in the literature (Ref 4, 25). Figure 7 shows a few of the many possible operational layouts. Each of these process stages is reviewed in the following sections.

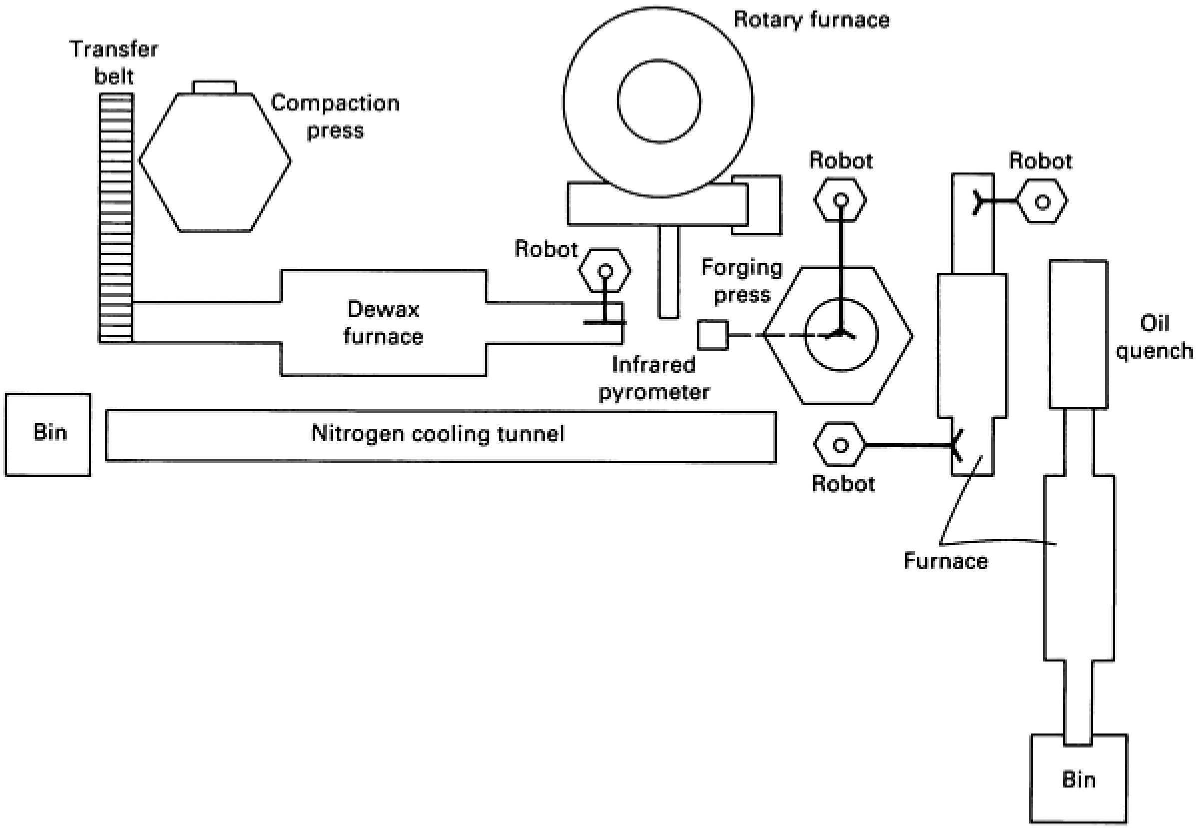

Fig. 7 A powder forging process line. Source: Ref 26.

Preforming. Preforms are manufactured from admixtures of metal powders, lubricants, and graphite. Compaction is predominantly accomplished in conventional P/M presses that use closed dies. In order to avoid the necessity of thermally removing the lubricant, preforms can be compacted without admixed lubricants in an isostatic press. However, even though they produce uniform weight and density distributions, the pressure and rate limitations of high-production isostatic presses (414 MPa, or 60 ksi, pressure and 120 cycles per hour) have severely restricted their commercial use for compacting P/F preforms.

Control of weight distribution within preforms is essential to produce full density and thus maximize performance in the critical regions of the forged component. Excessive weight in any region of the preform may cause overload stresses that could lead to tool breakage.

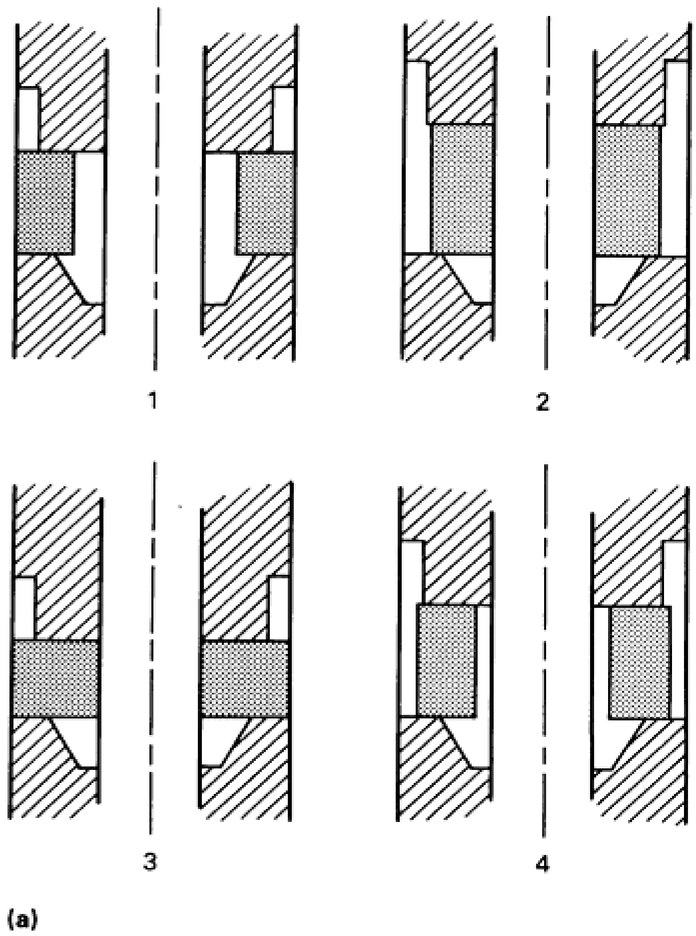
Successful preform designs have been developed by an iterative trial and error procedure, using prior experience to determine the initial shape. More recently, computer-aided design (CAD) has been used for preform design (Ref 27, 28, 29, 30).

Preform design is intimately related to the design and dimensions of the forging tooling, the type of forging press, and the forging process parameters. Among the variables to be considered for the preforming tools are:

- Temperature, that is, preform temperature, die temperature, and, when applicable, core rod temperature
- Ejection temperature of the forged part
- Lubrication conditions--influence on compaction/ejection forces and tooling temperatures
- Transfer time and handling of the preform from the preheat furnace to the forging die cavity

Correct preform design not only entails having the right amount of material in the various regions of the preform but also is concerned with material flow between the regions and prevention of potential fractures and defects.

An example of the effect of preform geometry on forging behavior can be taken from the work of C.L. Downey and H.A. Kuhn (Ref 31). Figure 8(a) shows four possible preforms that could be forged to produce the axisymmetric part having the cup and hub sections shown in Fig. 8(b).



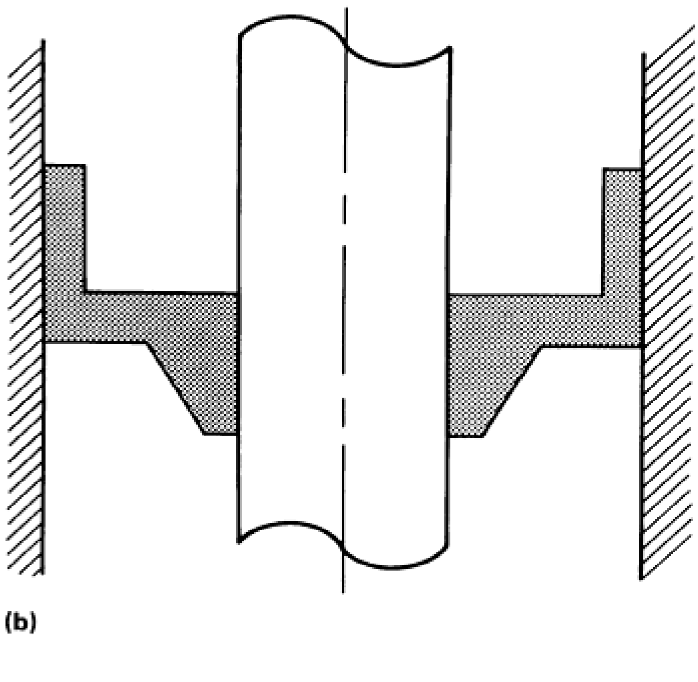


Fig. 8 (a) Possible configurations for the ring preform for forging the part shown in (b). See text for details. (b) Cross section of the part under consideration for powder forging. Source: Ref 31.

Preform geometries 2 and 4 in Fig. 8(a) result in defective forgings due to cracking at the outer rim as metal flows around the upper punch radius. This occurs because the deforming preform is expanding in diameter as the metal flows around the corner, even though there is axial compression to help compensate for the circumferential tension. This type of cracking can be avoided by using a preform that fills the die with no clearance at the outside diameter, as in preforms 1 and 3.

Preform 3 can be rejected because it is similar to hub extrusion, and this may lead to cracking at the top surface of the hub. Allowing some clearance between the bore diameter of the preform and the mandrel eliminates this type of crack.

Preform 1 overcomes these problems. Use of this preform has resulted in defect-free parts, while the expected cracking occurred-with use of the other preforms (Ref 31).

Sintering and Reheating. Preforms may be forged directly from the sintering furnace; sintered, reheated, and forged; or sintered after the forging process. The basic requirements for sintering in a ferrous powder forging system are: lubricant removal, oxide reduction, carbon diffusion, development of particle contacts, and heat for hot densification. Oxide reduction and carbon diffusion are the most important aspects of the sintering operations. For most ferrous powder forging alloys, sintering takes place at about 1120 °C (2050 °F) in a protective reducing atmosphere with a carbon potential to prevent decarburization. The time required for sintering depends upon the number of sintering stages for delubrication, diffusion of carbon, reduction of oxides, and the type of sintering equipment used. Typical P/M sintering has been commonly performed at 1120 °C (2050 °F) for 20 to 30 min; these conditions may be required to help diffuse elements such as copper and nickel. In the prealloyed systems used for powder forging, only the diffusion of carbon is usually required. It has been shown that the time required to diffuse carbon and reduce the oxides is about 3 min at 1120 °C (2050 °F) (Ref 32, 33, 34). This is illustrated in Fig. 9. Increases in temperature will of course reduce the time required for sintering by improving oxide reduction and increasing carbon diffusion. Chromium-manganese steels have been limited in their use because of the higher temperatures required to reduce their oxides and the greater care needed to prevent reoxidation.

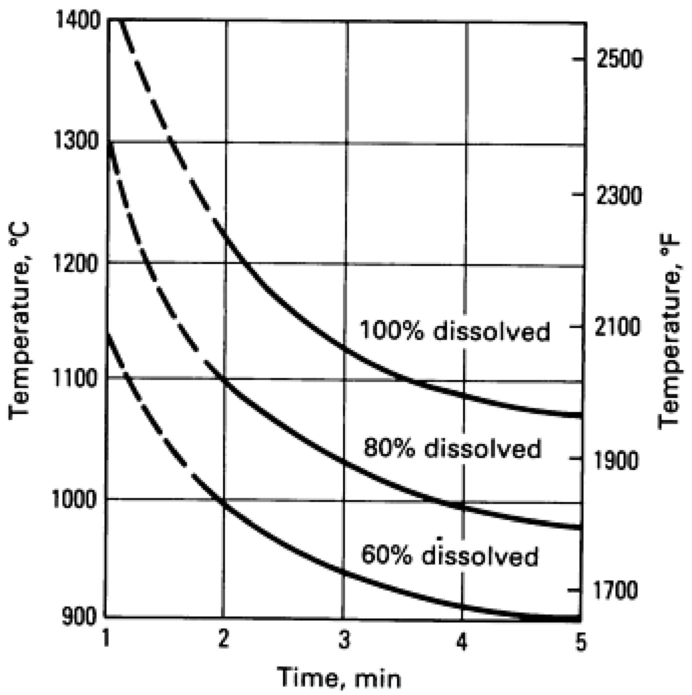

Fig. 9 Carbon dissolution as a function of time and temperature. Data are for an iron-graphite alloy at a density of 6.2 to 6.3 g/cm^3 (0.224 to 0.228 lb/in.^{3}). Source: Ref 34, Ref 8.

Any of the furnaces used for sintering P/M parts, such as vacuum, pusher, belt, rotary hearth, walking beam, roller hearth, and batch/box, may be used for sintering or reheating P/F preforms. Delubrication can be accomplished in any of these types of furnaces or in separate delubrication furnaces before entering the sintering furnace. Typically, belt, rotary hearth, and batch/box furnaces have been used for sintering and reheating preforms. However, the choice of sintering furnace largely depends upon the following conditions:

- Material being forged
- Size and weight of parts
- Forging process route (sinter/reheat versus sinter/forge)
- Forging temperature
- Atmosphere capabilities
- Delubrication capabilities
- Furnace loading capabilities/sintering rate
- Sintering time
- Robotics

The sintered preforms may be forged directly from the sintering furnace, stabilized at lower temperatures and forged, or cooled to room temperature, reheated, and forged. All cooling, temperature stabilization, and reheating must occur under protective atmosphere to prevent oxidation.

Induction furnaces are often used to reheat axisymmetric preforms to the forging temperature because of the short time required to heat the material. Difficulties may be encountered in obtaining uniform heating throughout asymmetric shapes because of the variation in section thickness.

Powder forging involves removing heated preforms from a furnace, usually by robotic manipulators, and locating them in the die cavity for forging at high pressures (690 to 965 MPa, or 100 to 140 ksi). Preforms may be graphite coated to prevent oxidation during reheating and transfer to the forging die. These dies are typically made from hot-work steels such as AISI H13 or H21. Lubrication of the die and punches is usually accomplished by spraying a water-graphite suspension into the cavity (Ref 35, 36, 37).

The forging presses commonly used in conventional forging (Ref 38, 39, 40, 41), including hammers, high-energy-rate forming (HERF) machines, mechanical presses, hydraulic presses, and screw presses, have been evaluated for use in powder forging (Ref 8, 42). The essential characteristics that differentiate presses are: contact time, stroke velocity, available energy and load, stiffness, and guide accuracy. Mechanical crank presses are the most widely used because of their short, fast strokes; short contact times; and guide accuracy. Hydraulic presses have also been used for applications in the 7.7 g/cm^3 (0.28 lb/in.^{3}) density range, and screw presses are starting to be used because of their lower cost and short contact times. More information on forging equipment is available in the articles "Hammers and Presses for Forging" and "Selection of Forging Equipment" in this Volume.

Metal Flow in Powder Forging. Some of the problems encountered in powder forging, and their probable causes, are described in Table 1. These problems are related to the aforementioned sintering and reheating equipment and to the deformation processing described below.

Table 1 Common powder forging problems and their probable causes

Forging problem	Probable causes
Surface oxidation	**Extensive transfer time from furnace**
Surface decarburization	**Overly high forging temperature**
	Entrapped liquid/graphite coating during reheat
	Excessive die lubrication (water)

	Oxidation during sintering or reheating
Surface porosity	**Excessive contact time**
	Low forging temperature
Tool wear	**Low preform temperatures**
	High or low tool temperature
	Excessive contact time
Poor tolerances	**Temperature variations in tools and preforms**
Excessive flash/tool jamming	**Excessive preform temperature**
	High preform weight/incorrect distribution
	Improper tool design
Excessive forging loads	**Low preform temperature**
	High preform weight
Low densities	**Oxidation**
	Low forging temperature/pressure
	Low preform weight
	Die chill
Cracks,laps	**Improper tool or preform design**
Improper die fill	**Improper preform weight distribution/material flow**

Draft angles, which facilitate forging and ejection in conventional forging, are eliminated in powder forged parts. This means that greater ejection forces--on the order of 15 to 20% of press capacity as a minimum--are required for the powder forging of simple shapes. However, the elimination of draft angles permits P/F parts to be forged more closely to net shape. Figure 10 illustrates the ejection forces required for a P/F gear as a function of residual porosity (Fig. 10a) and preform temperature (Fig. 10b). To be suitable for powder forging, standard forging presses must be modified to have stronger ejection systems.

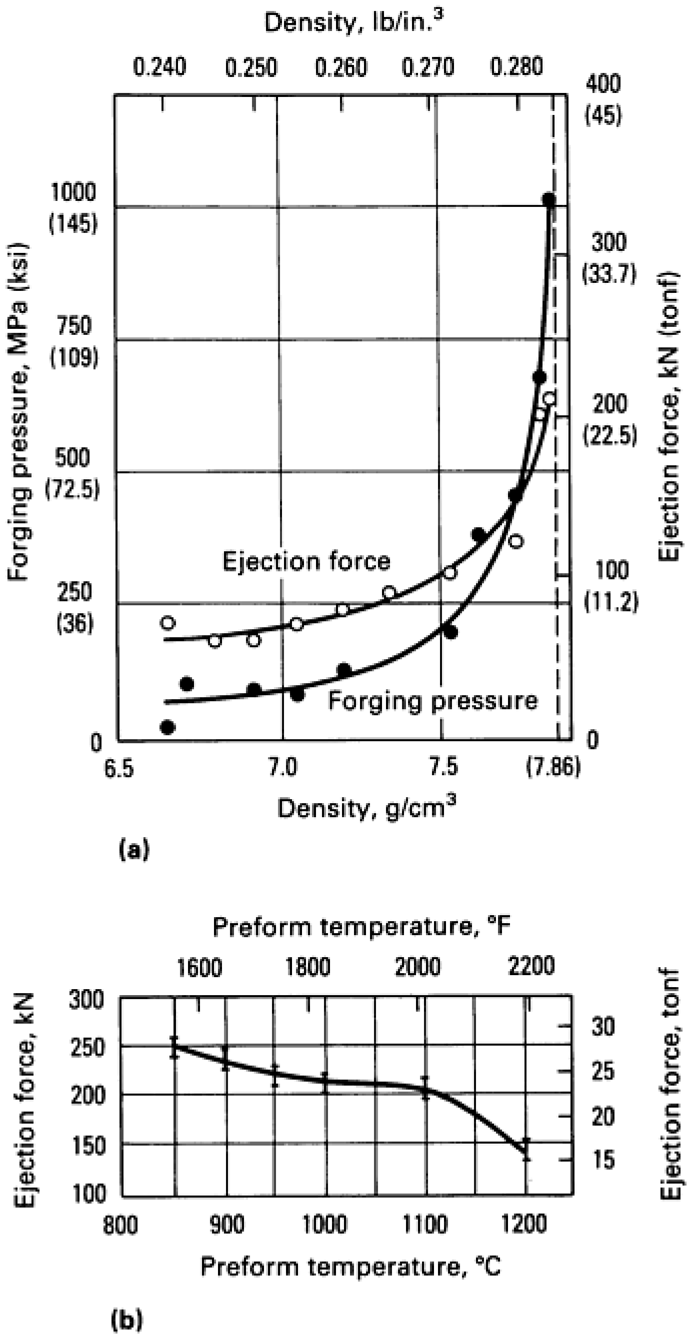

Fig. 10 (a) Forging pressure and ejection force as functions of density for the P/F-4600 powder forged gear shown in Fig. 12. Preform temperature: 1100 °C (2010 °F). (b) Ejection force after forging as a function of preform temperature for a powder forged gear. Forging pressure ranged from 650 to 1000 MPa (94 to 145 ksi).

The deformation behavior of sintered, porous materials differs from that of wrought materials because porous materials densify during the forming operation. As a consequence, a porous preform will appear to have a higher rate of work hardening than its wrought counterpart. The work-hardening exponent, *m*, can be defined in terms of the true stress-true strain diagram:

$$\sigma = K\epsilon^m \qquad \textbf{(Eq 1)}$$

where σ is true stress, ϵ is true strain, and K is a proportionality constant. An empirical relationship between m and density ρ for a ferrous preform has been shown (Ref 44):

$$m = 0.31\rho^{-1.91} \quad \textbf{(Eq 2)}$$

where ρ is expressed as a fraction of the density of pore-free material. The value of m for pore-free pure iron is 0.31, and any excess over this value for porous iron is due to geometric work hardening.

A further consequence of the densification of porous preforms during deformation is reflected in Poisson's ratio for the porous material. Poisson's ratio is a measure of the lateral flow behavior of a material; for compression of a cylinder, it is expressed as diametral strain ϵ_d divided by height strain $-\epsilon_z$. For a pore-free material, Poisson's ratio for plastic deformation ν is 0.5. This is a direct result of the fact that the volume of the material remains constant during deformation. For example, equating the volume of a cylinder before and after deformation (Ref 44):

$$H_0[\pi D_0^2)/4] = H_f[(\pi D_f^2)/4] \quad \textbf{(Eq 3)}$$

where H_0 and H_f are initial and final cylinder heights, respectively, and D_0 and D_f are initial and final cylinder diameters, respectively. Dividing by $H_f D_0^2$ yields:

$$H_0/H_f = (D_f/D_0)^2 \quad \textbf{(Eq 4)}$$

and taking logarithms

$$\ln (H_0/H_f) = \ln (D_f/D_0)^2 = 2 \ln (D_f/D_0) \quad \textbf{(Eq 5)}$$

or

$$-\epsilon_z = 2\epsilon_d \quad \textbf{(Eq 6)}$$

and, from the definition of Poisson's ratio:

$$\nu = \frac{-\epsilon_d}{\epsilon_z} = 0.5 \quad \textbf{(Eq 7)}$$

During compressive deformation of a sintered metal powder preform, some material flows into the pores, and there is a volume decrease. For a given reduction in height, the diameter of a sintered P/M cylinder will expand less than that of an identical cylinder of a pore-free material. Poisson's ratio for a P/M preform will therefore be less than 0.5 and will be a function of the pore volume fraction. H.A. Kuhn (Ref 45) has established an empirical relationship between Poisson's ratio and part density:

$$\nu = 0.5\,\rho^a \quad \textbf{(Eq 8)}$$

The best fit to experimental data is obtained with the exponent a = 1.92 for room-temperature deformation and a = 2.0 for hot deformation. The slight difference in this exponent may be due to work hardening (Ref 44).

In deformation processing of materials, plasticity theory is useful for calculating forming pressures and stress distributions. The above mentioned idiosyncrasies in the deformation behavior of sintered, porous materials have been taken into account in the development of a plasticity theory for porous materials. This has been of benefit in applying workability analysis to porous preforms (Ref 31, 44, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59).

A typical workability line is shown in Fig. 11, which also indicates the way processing variables affect the location of the line. The line has a slope of -0.5, and workability improves as the plane strain intercept (y-axis intercept) value increases. For a given material, workability can be improved through either temperature adjustment or a change in preform density. Figure 12(b) to (e) show the effects of temperature and pressure on the densification and forming of the powder forged gear shown in Fig. 12(a) (Ref 61). While Fig. 12(b) to (e) indicate that higher temperatures reduce the forging pressures required, Fig. 13 illustrates a region of forging pressure at lower temperatures that is comparable to that for higher-temperature forging. The ability to forge at lower temperatures may be beneficial in extending the life of the forging dies.

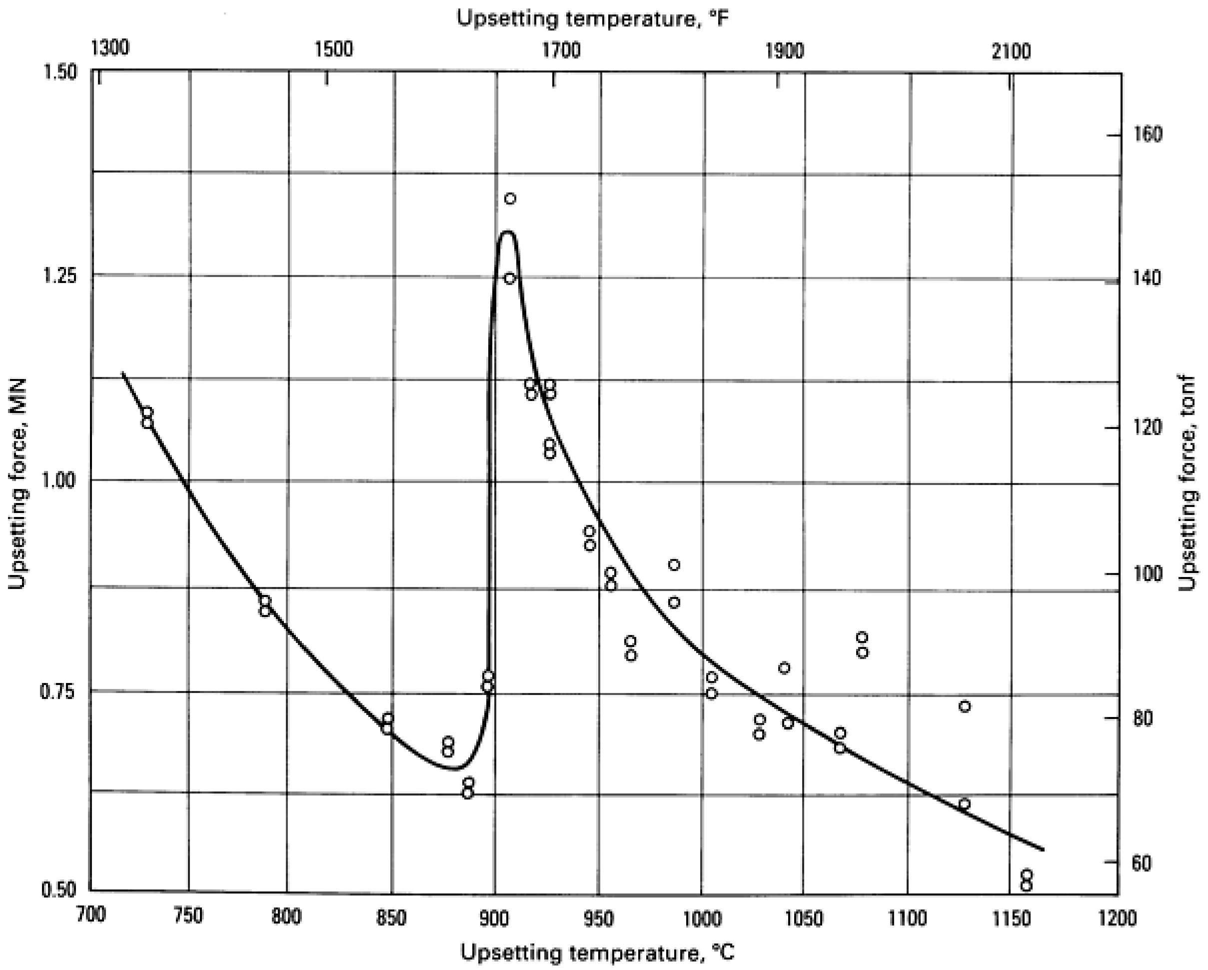

Fig. 13 Force required for a 50% reduction in height of water-atomized iron powder preforms as a function of deformation temperature. Source: Ref 62.

The data presented in Fig. 13 relate to a pure iron with no added graphite. The dramatic increase in the force required for densification around 900 °C (1650 °F) is due to the phase transformation from body-centered cubic (bcc) α iron to face-centered cubic (fcc) austenite. In this temperature range, the flow stress of austenite is higher than that of ferrite. However, although materials are fully austenitic at conventional forging temperatures (1000 to 1130 °C, or 1830 to 2065 °F), the flow stress of austenite at 1100 °C (2010 °F) is less than that of ferrite at 850 °C (1560 °F).

A similar low flow stress regime has been observed for prealloyed material (Fig. 14). However, depending on the amount of solution of graphite, the dip in the flow stress versus temperature curve becomes less pronounced and eventually is no longer observed. The presence of carbon in solution alters the phase distribution, and the observed flow stress depends on the relative proportions of ferrite and austenite in the microstructure.

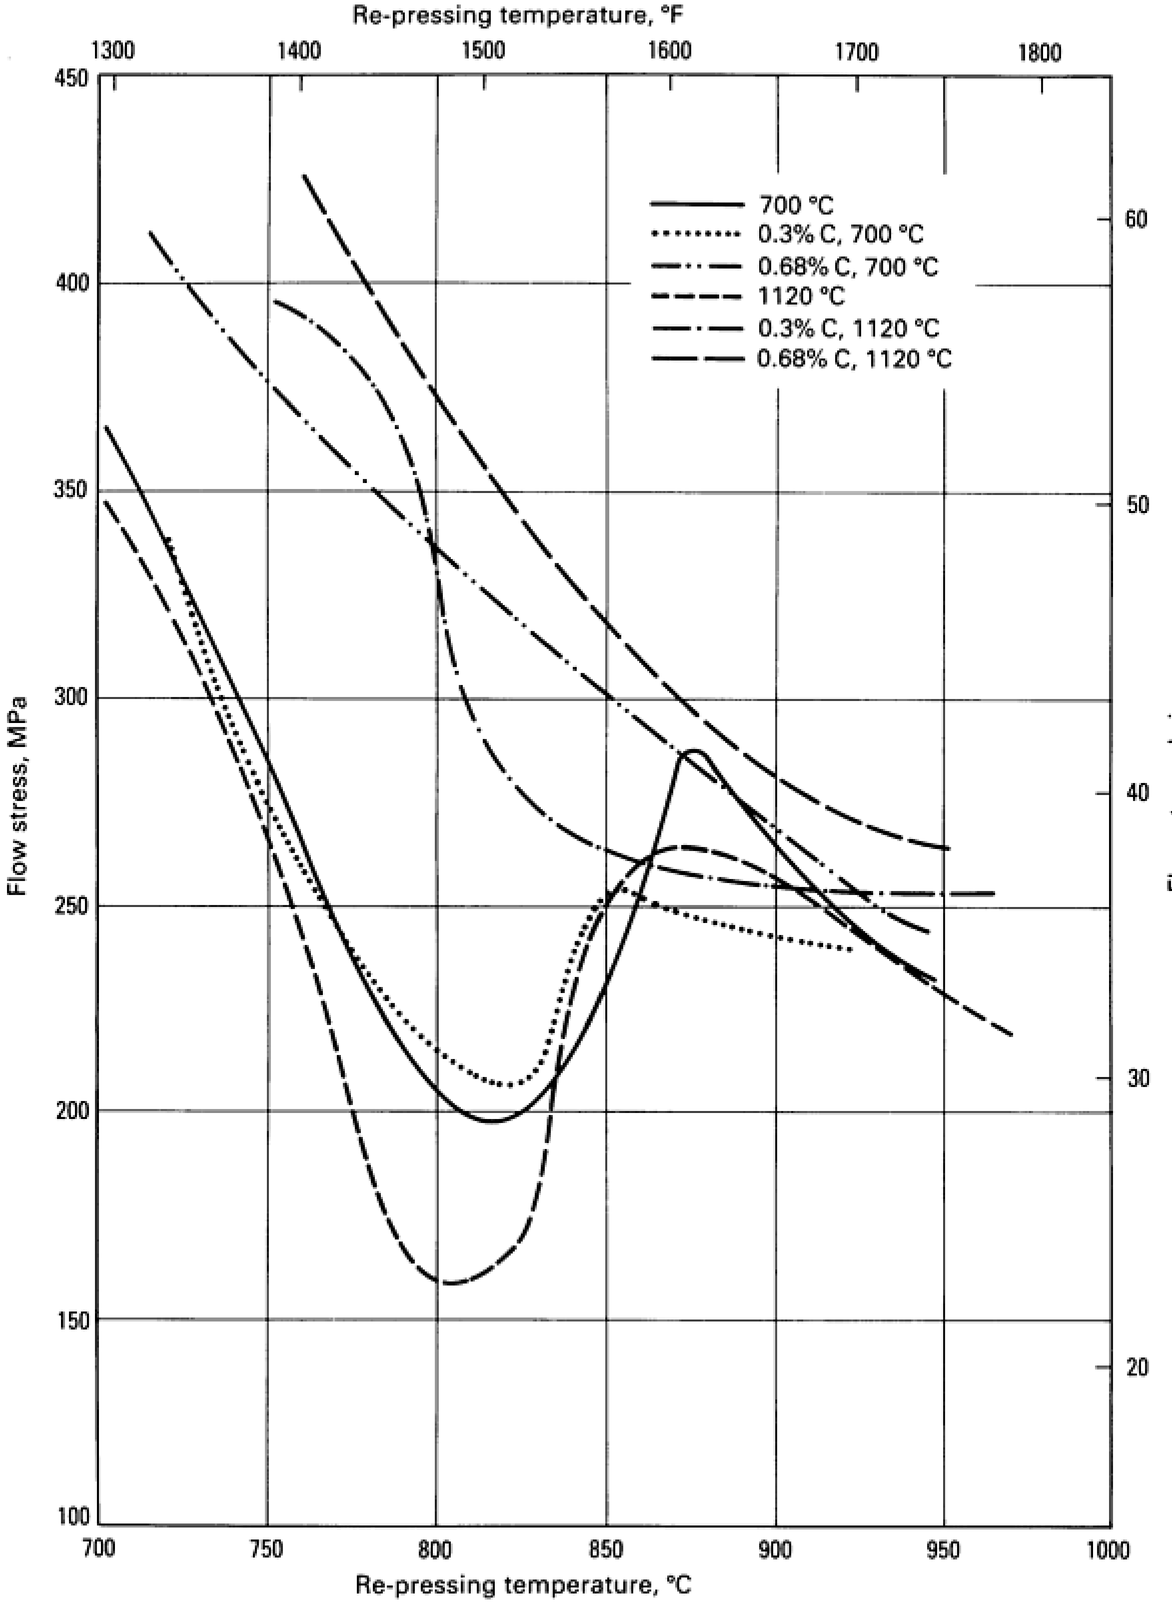

Fig. 14 Influence of hot re-pressing temperature on flow stress for P/F-4600 at various carbon contents and presintering temperatures. Data are for density of 7.4 g/cm^3 (0.267 lb/in.^{3}). Source: Ref 63, 64.

In order to take any advantage of the low flow stress, the thermomechanical processing of preforms that contain added graphite must therefore be such that the graphite does not go into solution. Even under such conditions, in the data reported by Q. Jiazhong, O. Grinder, and Y. Nilsson (Ref 65), the mechanical properties of low temperature forged material are considerably inferior to those of material forged at higher temperatures (Table 2). The low-temperature forging resulted in incomplete densification, and this degraded the mechanical properties. G. Bockstiegel and H. Olsen observed a similar dependence of forged density on preform temperature (Ref 66). They pointed out that the presence of free graphite might impede densification. During subsequent heat treatment, when the graphite goes into solution, it could leave fine porosity, which would degrade the mechanical properties of the material.

Table 2 Tensile and impact properties of P/F-4600 hot re-pressed at two temperatures

Metal flow can cause surface fractures. These are generally associated with contact between the deforming preform and the forging tooling. Surface fracture problems may be avoided by changing the preform geometry or the lubrication conditions.

Frictional constraint at the interface between the preform and the forging die generates undesirable stress states in the preform that can lead to fracture. The types of fracture encountered in powder forging are:

- Free-surface fracture
- Die contact surface fracture
- Internal fracture

Production of metallurgically sound forgings requires the prediction and elimination of fracture. An excellent review of the subject is given in Ref 44, 47, 57, and 58.

Tool Design. In order to produce sound forged components, the forging tooling must be designed to take into account:

- Preform temperature
- Die temperature
- Forging pressure
- The elastic strain of the die
- The elastic/plastic strain of the forging
- The temperature of the part upon ejection
- The elastic strain of the forging upon ejection
- The contraction of the forging during cooling
- Tool wear

Specified part dimensional tolerances can only be met when the above parameters have been taken into account. However, there is still some flexibility in the control of forged part dimensions even after die dimensions have been selected. Higher preform ejection temperatures result in greater shrinkage during cooling. Increases in die temperature expand the die cavity and thus increase the size of the forged part. Therefore, if the forgings are undersize for a given set of forging conditions, a lower preform preheat temperature and/or a higher die preheat temperature can be used to produce larger parts. On the other hand, if the forged parts are oversize, the preform preheat temperature could be raised and/or the die temperature lowered to bring the parts to the desired size.

Secondary Operations. In general, the secondary operations applied to conventional components such as plating and peening, may be applied to powder forged components. The most commonly used secondary operations involve deburring, heat treating, and machining.

The powder forged components may require deburring or machining to remove limited amounts of flash formed between the punches and the die. This operation is considerably less extensive than that required for wrought forgings.

The heat treatment of P/M products is the same as that required for conventionally processed materials of similar composition. The most common heat-treating practices involve treatments such as carburizing, quench-and-temper cycles, or continuous-cooling transformations.

The amount of machining required for P/F components is generally less than the amount required for conventional forgings because of the improved dimensional tolerances, shown in Table 3. Standard machining operations may be used to achieve final dimensions and surface finish (Ref 67). One of the main economic benefits of powder forging is the reduced amount of machining required, as illustrated in Fig. 15.

Table 3 Comparison of powder forging with competitive processes

Process	**Range of weights**		**Height-to-diameter ratio**	**Shape**	**Material use, %**	**Surface roughness µm**	**Quantity required for economical production[(a)]**	Cost per unit[(b)]
	kg	**lb**						
Powder forging	0.1-5	0.22-11	1	No large variations in cross section; openings limited	100	5-15	20,000	**200**
Precision forging	0.3-5	0.66-11	2	Any; openings limited	80-90	10-20	20,000	**200**
Cold forging	0.01-35	0.022-77	Not limited	Mostly rotational symmetry	95-100	1-10	5,000	**150**
Precision casting	0.1-10	0.22-22	Not limited	Any; no limits on openings	70-90	10-30	2,000	**100**

Sintering	0.01-5	0.022-11	1	No large variations in cross section; openings limited	100	1-30	5,000	**100**

(a) For 0.5 kg (1.1 lb) parts.

(b) Sintering = 100%

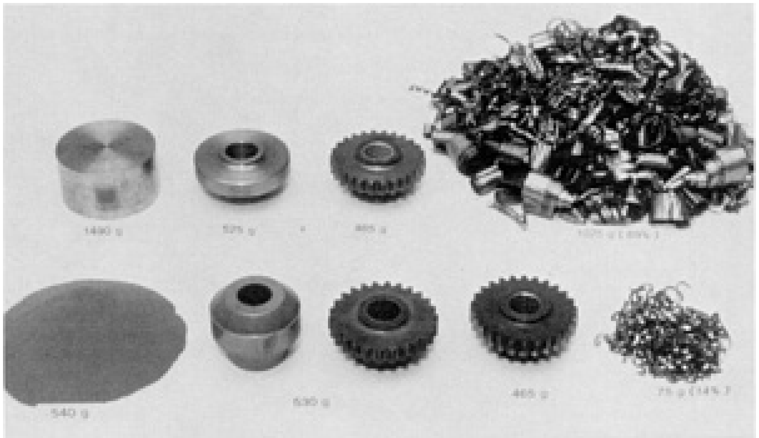

Fig. 15 Comparison of material use for a conventionally forged reverse idler gear (top) and the equivalent powder forged part (bottom). Material yield in conventional forging is 31%; that for powder forging is 86%. 1 lb = 453.6 g. Source: Ref 61.

In general, pore-free P/F materials machine as readily as conventional forgings processed to achieve identical composition, structure, and hardness. Difficulties are encountered, however, if P/F components are machined with the same cutting speeds, feed rates, and tool types as conventional components. These differences in machinability have been related to inclusion types and microporosity (Ref 16, 68). These studies conclude that P/F materials can exhibit equal or greater machinability than wrought steels. Improved machinability can be accomplished by the addition of solid lubricants such as manganese sulfide.

However, the presence of microporosity and low-density noncritical areas in P/F components leads to reduced machinability. The machinability behavior for these areas is similar to that of conventional P/M materials (Ref 69). The overall machinability of a powder forged component may be said to depend on the amount, type, size, shape, and dispersion of inclusions and/or porosity, as well as on the alloy and heat-treated structure.

Mechanical Properties

Wrought steel bar stock undergoes extensive deformation during cogging and rolling of the original ingot. This creates inclusion stringers and leads to planes of weakness, which affect the ductile failure of the material. The mechanical properties of wrought steels vary considerably according to the direction test pieces are cut from the wrought billet. Powder forged materials, on the other hand, undergo relatively little material deformation, and their mechanical properties have been shown to be relatively isotropic (Ref 70). The directionality of properties in wrought steel is illustrated in Table 4.

Table 4 Comparison of transverse and longitudinal mechanical properties of wrought steels

Material	Specimen orientation	Ultimate tensile strength		Yield strength, 0.2% offset		Impact energy		Fatigue endurance limit		Elongation, %	Reduction of area, %

Data on 5046 and 4340 are from Ref 71; data on 8620 are from Ref 72; data on EN-16 are from Ref 73.

(a) Composition of EN-16: Fe-1.7Mn-0.27Mo.

Mechanical properties of powder forged materials are usually intermediate to the transverse and longitudinal properties of wrought steels. The rotating-bending fatigue properties of powder forged material also have been shown to fall between the longitudinal and transverse properties of wrought steel of the same tensile strength (Ref 74). This is illustrated in Fig. 16.

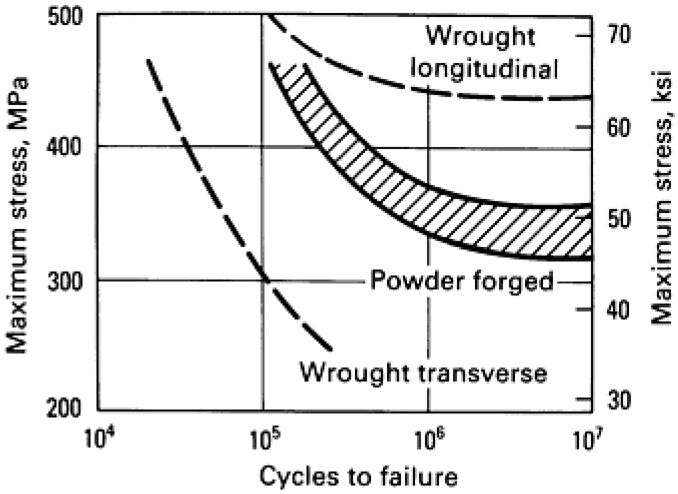

Fig. 16 Comparison of fatigue resistance of powder forged and wrought materials. Source: Ref 74.

While the performance of machined laboratory test pieces follows the intermediate trend described above, in the case of actual components, powder forged parts have been shown to have superior fatigue resistance (Fig. 17). This has generally been attributed not only to the relative mechanical property isotropy of powder forgings but also to their better surface finish and finer grain size.

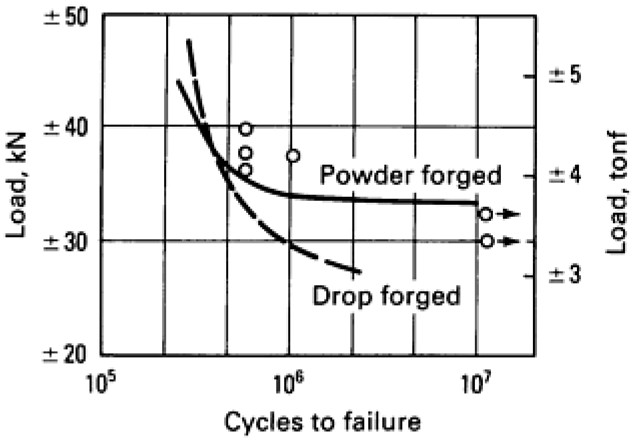

Fig. 17 Fatigue curves for powder forged and drop forged connecting rods. Source: Ref 75.

The present section reviews the mechanical properties of powder forged materials. The data presented represent results obtained on machined standard laboratory test pieces. Data will be reported for four primary materials. The first two material systems are based on prealloyed powders (P/F-4600 and P/F-2000). The third material based on an iron-copper-carbon alloy, was used by Toyota in 1981 to make P/F connecting rods; Ford Motor Company introduced powder forged rods with a similar chemistry in 1986. Mechanical property data are therefore presented for copper and graphite powders mixed with an iron powder base to produce materials that generally contain 2% Cu. Some powder forged components are made from plain carbon steel. This is the fourth and final material for which mechanical property data are presented.

Forging Mode. It is well known that the forging mode has a major effect on the mechanical properties of components. With this in mind, the mechanical property data reported in this section were obtained on specimens that were either hot upset or hot re-press forged. The forging modes used to produce billets for mechanical property testing are shown in Fig. 18.

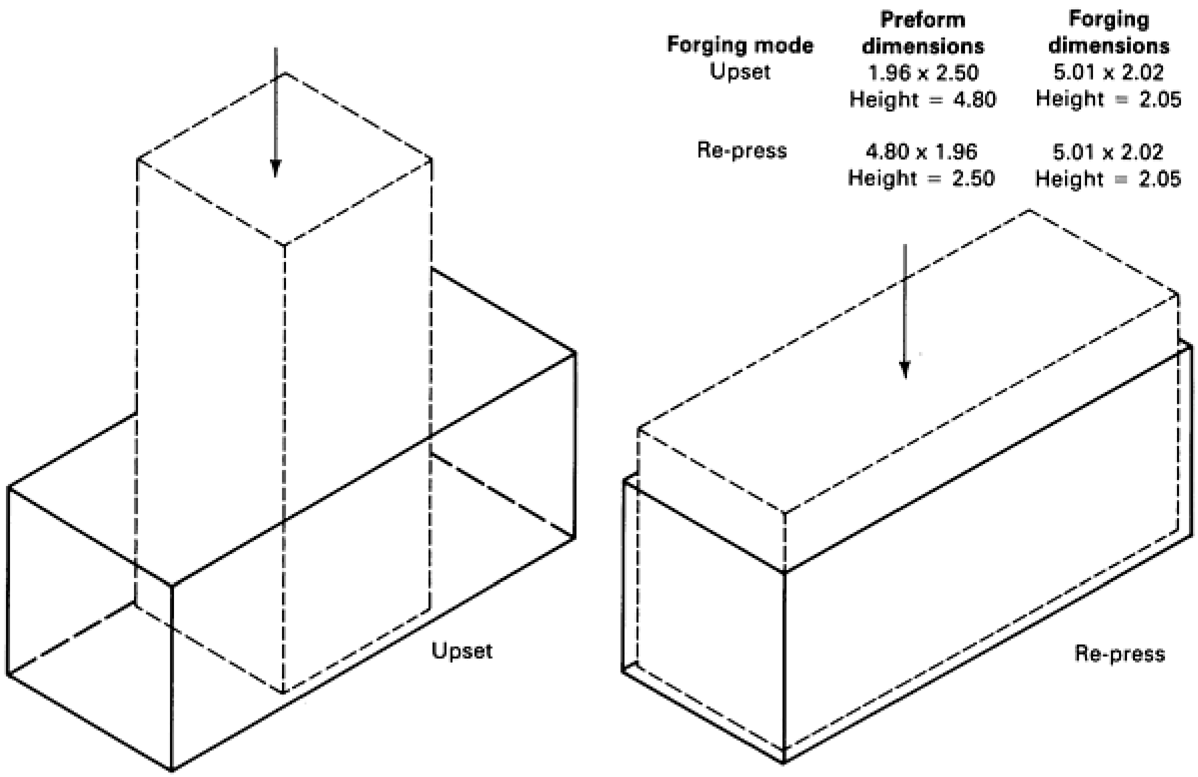

Fig. 18 Forging modes used in production of billets for mechanical testing. Dimensions, given in inches, are average values.

Longitudinal test specimens 10 mm (0.4 in.) in diameter (for tensile and fatigue testing) and 10.8 × 10.8 mm (0.425 × 0.425 in.) square (for impact testing) were then cut from the forged billets. These specimen sizes represent comparable 10 mm (0.4 in.) diam ruling sections used for heat treatment and were the section sizes used unless otherwise noted.

Heat Treatments. There were three heat treatments used in developing the properties of the prealloyed powder forged materials: case carburizing, blank carburizing, and through-hardening (quenching and tempering).

Case carburizing was applied to materials with a nominal core carbon content of 0.20 to 0.25%. Blank carburizing is intended to produce a microstructure similar to that found in the core of case carburized samples. At the 0.20 to 0.25% C level, this results in a core hardness of 45 to 55 HRC.

Quenching and tempering was applied to achieve through hardened microstructures over a range of forged carbon contents. A low-temperature temper or stress relief at 175 °C (350 °F) resulted in core hardnesses in the range of 55 to 65 HRC for materials with carbon contents of 0.4% and above. In addition, higher-temperature tempers were designed to achieve core hardnesses of 45 to 55 HRC and 25 to 30 HRC in these higher-carbon samples. Details of these heat treatments are given below.

Case Carburizing. Specimens were austenitized for 8 h at 955 °C (1750 °F) in an endothermic gas atmosphere with a dew point of -11 °C (+12 °F). They were then cooled to 830 °C (1525 °F) and stabilized at temperature in an endothermic gas atmosphere with a dew point of +2 °C (+35 °F). The specimens were quenched in a fast quench rate oil with agitation at a temperature of 65 °C (150 °F). They were then stress relieved at 175 °C (350 °F) for 2 h. This heat treatment resulted in a case depth of about 1.52 mm (0.060 in.), with a 1.0% carbon content in the case and a nominal core carbon of 0.25%.

Blank Carburizing. The forged samples were austenitized for 2 h at 955 °C (1750 °F) in a dissociated ammonia and methane atmosphere. They were quenched with agitation in a fast quench rate oil at 65 °C (150 °F). The samples were reaustenitized at 845 °C (1550 °F) for 30 min in a dissociated ammonia and methane atmosphere, followed by oil quenching with agitation in oil held at 65 °C (150 °F). They were then stress relieved at 175 °C (350 °F) for 2 h in a nitrogen atmosphere.

Through-Hardening. This quench and temper heat treatment consisted of austenitizing the specimens for 1 h at 955 °C (1750 °F) in a dissociated ammonia and methane atmosphere, followed by quenching with agitation in a fast quench rate oil at 65 °C (150 °F). The specimens were reaustenitized at 845 °C (1550 °F) for 30 min in a dissociated ammonia and methane atmosphere, followed by quenching with agitation in oil at 65 °C (150 °F). They were stress relieved for 1 h at 175 °C (350 °F) in a nitrogen atmosphere or tempered at the various temperatures listed in the tables. This procedure resulted in a uniform microstructure throughout the cross section.

Hardenability. Jominy hardenability curves are presented in Fig. 19 for the P/F-4600, P/F-2000, and iron-copper-carbon alloys. Testing was carried out according to ASTM A 255. Specimens were machined from upset forged billets that had been sintered at 1120 °C (2050 °F) in dissociated ammonia.

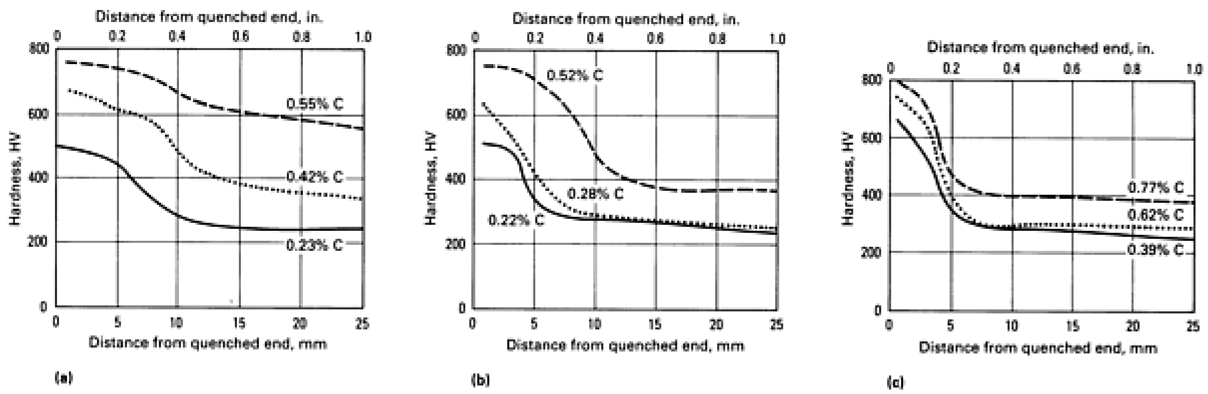

Fig. 19 Jominy hardenability curves for (a) P/F-4600, (b) P/F-2000, and (c) iron-copper-carbon materials at various forged-carbon levels. Vickers hardness was determined at a 30 kgf load.

Tempering Response. Tempering curves (core hardness versus carbon content and tempering temperature) are presented in Fig. 20 for P/F-2000 and P/F-4600. The curves for P/F-4600 cover ruling sections of 10 mm (0.40 in.) to 25.4 mm (1.0 in.).

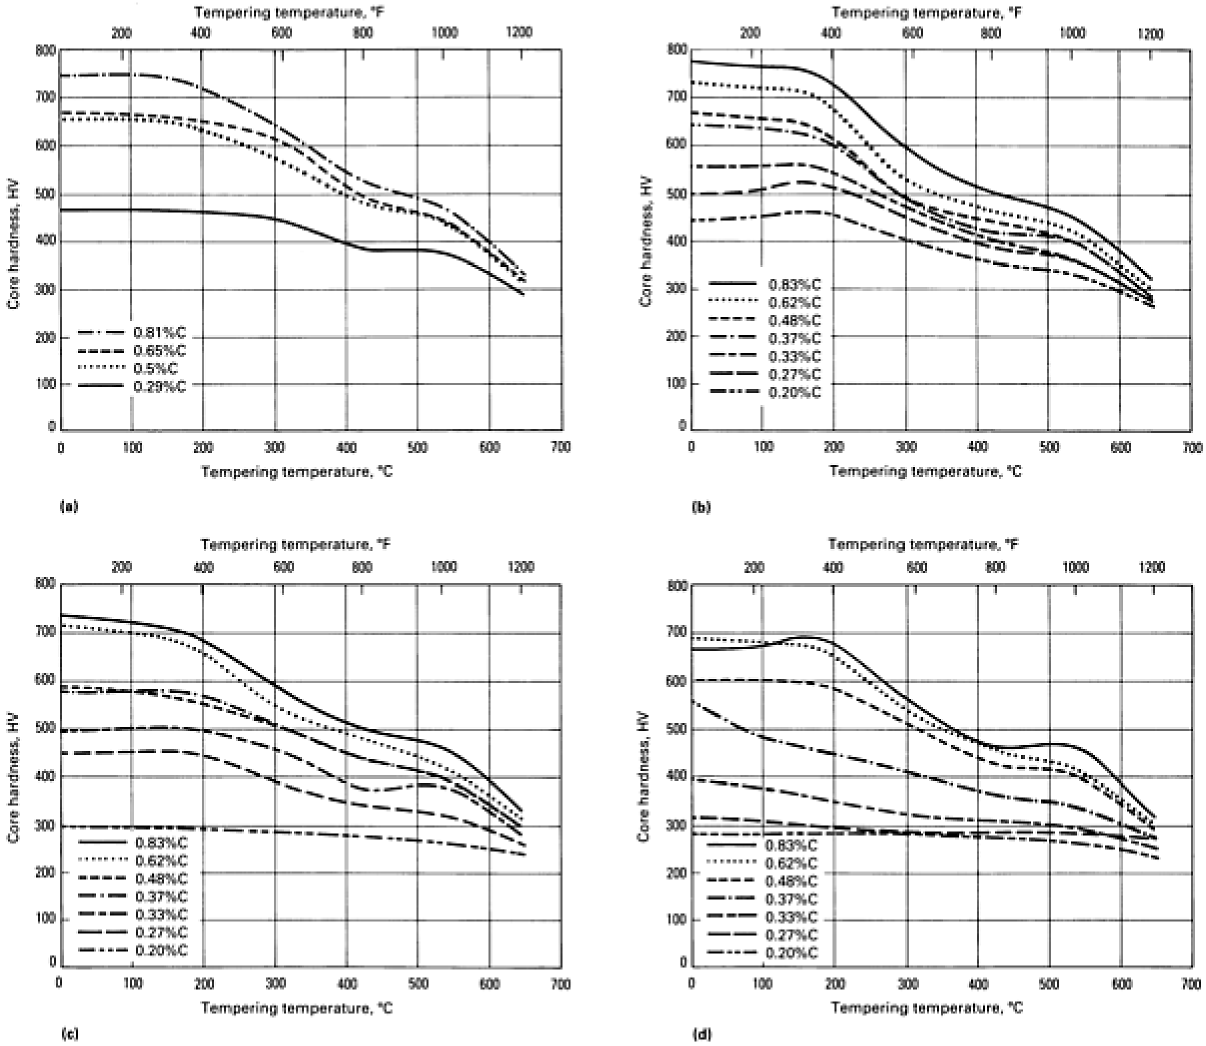

Fig. 20 Effect of tempering temperature and carbon content on the core hardness of (a) P/F-2000 for a ruling section of 10 mm (0.40 in.), and of P/F-4600 materials for ruling sections of (b) 10 mm (0.40 in.), (c) 19 mm (0.75 in.), and (d) 25.4 mm (1.0 in.).

Tensile, Impact, and Fatigue Properties. Tensile properties were determined on test pieces with a gage length of 25.4 mm (1 in.) and a gage diameter of 6.35 mm (0.25 in.). Testing was carried out according to ASTM E 8 using a crosshead speed of 0.5 mm/min (0.02 in./min). Room-temperature impact testing was carried out on standard Charpy V-notch specimens according to ASTM E 23. Rotating-bending fatigue (RBF) testing was performed using single-load, cantilever, rotating fatigue testers. Dimensions of the RBF test specimen are shown in Fig. 21.

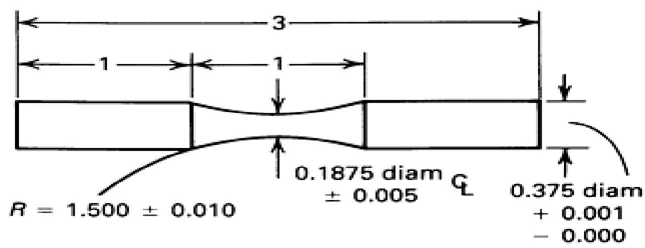

Fig. 21 Dimensions (in inches) of RBF test specimens.

The tensile, impact, and fatigue data for the various materials are summarized in Tables 5, 6, 7 and Fig. 22 and 23.

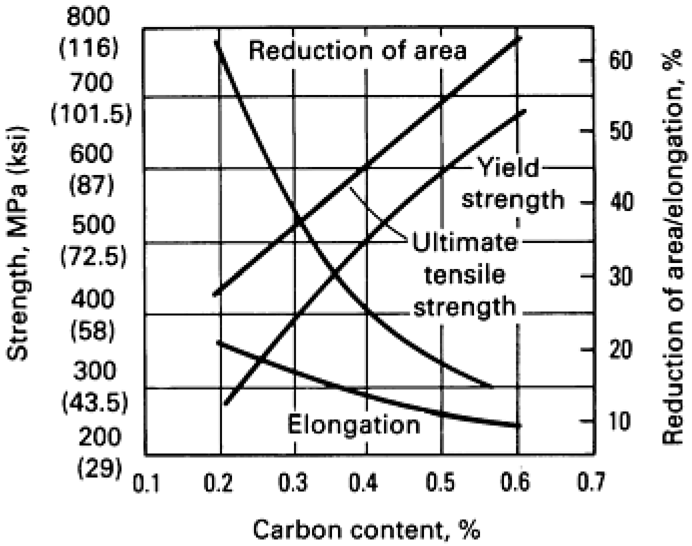

Fig. 22 Mechanical properties versus carbon content for iron-carbon alloys. Source: Ref 76.

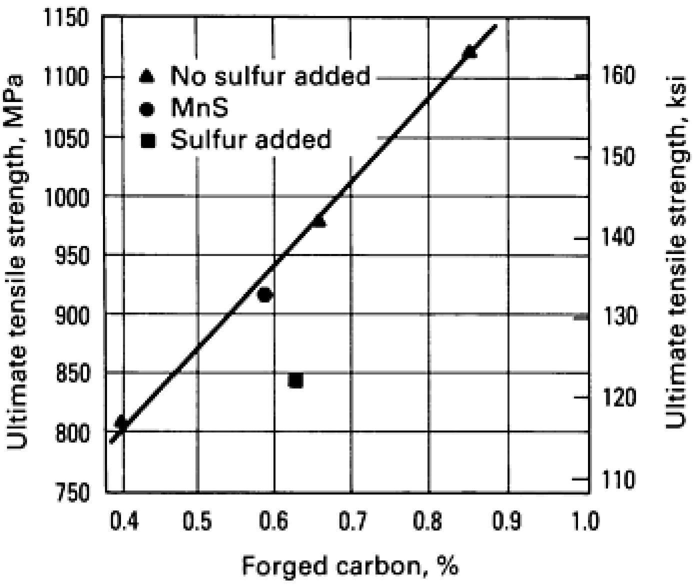

Fig. 23 Effect of sulfur and carbon on the ultimate tensile strength of iron-copper-carbon alloys. Samples were upset forged and forced-air cooled.

The iron-copper-carbon alloys were either still-air cooled or forced-air cooled from the austenitizing temperature of 845 °C (1550 °F). Cooling rates for these treatments are shown in Fig. 24. The austenitizing temperature influences core hardness. These iron-copper-carbon alloys are often used with manganese sulfide additions for enhanced machinability. The tensile, impact, and fatigue properties for a sample with a 0.35% manganese sulfide addition are compared with a material without sulfide additions in Table 8. The results obtained for a sulfurized powder sample are included for comparison. The tensile properties for iron-copper-carbon alloys with a range of forged carbon content are summarized in Fig. 23. Data from the samples with manganese sulfide and sulfurized powders are included for comparison. The manganese sulfide addition had little influence on tensile strength, whereas the sulfurization process degraded tensile properties.

Table 8 Mechanical property and fatigue data for iron-copper-carbon alloys with sulfur additions

Compressive Yield Strength. The 0.2% offset compressive yield strengths for P/F-4600 at various forged carbon levels and after different heat treatments are summarized in Table 9. A comparison of 0.2% offset tensile yield strength with the compressive yield strength for P/F-4600 with a range of carbon contents is given in Fig. 25 for samples stress relieved at 175 °C (350 °F).

various carbon levels

Rolling-Contact Fatigue. Powder forged materials have been used in bearing applications. Rolling-contact fatigue testing is an accelerated bearing test used to rank materials with respect to potential performance in bearing applications. Rolling-contact fatigue testing of both case carburized and through hardened P/F-4600 and P/F-2000 materials was carried out using ball/rod testers according to the procedure described in Ref 77. Weibull analysis data are summarized in Table 10.

Effect of Porosity on Mechanical Properties. The mechanical property data summarized in the previous sections are related to either hot re-press or hot upset forged pore-free material. The general effect of density on mechanical properties was illustrated in Fig. 2, and the properties of material incompletely densified because of forging at 870 °C (1600 °F) were presented in Table 2. The tensile and impact properties of P/F-4600 with two levels of residual porosity are summarized in Fig. 26 and 27. In one instance, the material was at a density of 7.84 g/cm^3 (0.283 lb/in.^{3}) and had a background of very fine porosity (Ref 78). The other series of samples had been purposely forged to a density of 7.7 g/cm^3 (0.278 lb/in.^{3}) (Ref 79). The performance of these materials is compared with that for pore-free samples at two levels of core hardness: 25 to 30 HRC (Fig. 26) and 45 to 50 HRC (Fig. 27). At the lower hardness, porosity has no effect on tensile strength, but even fine microporosity significantly reduces tensile ductility and impact strength. Tensile ductility at the higher core hardness is slightly influenced by the fine microporosity, and is significantly reduced for the material with a density of 7.7 g/cm^3 (0.278 lb/in.^{3}). The presence of porosity diminishes impact performance.

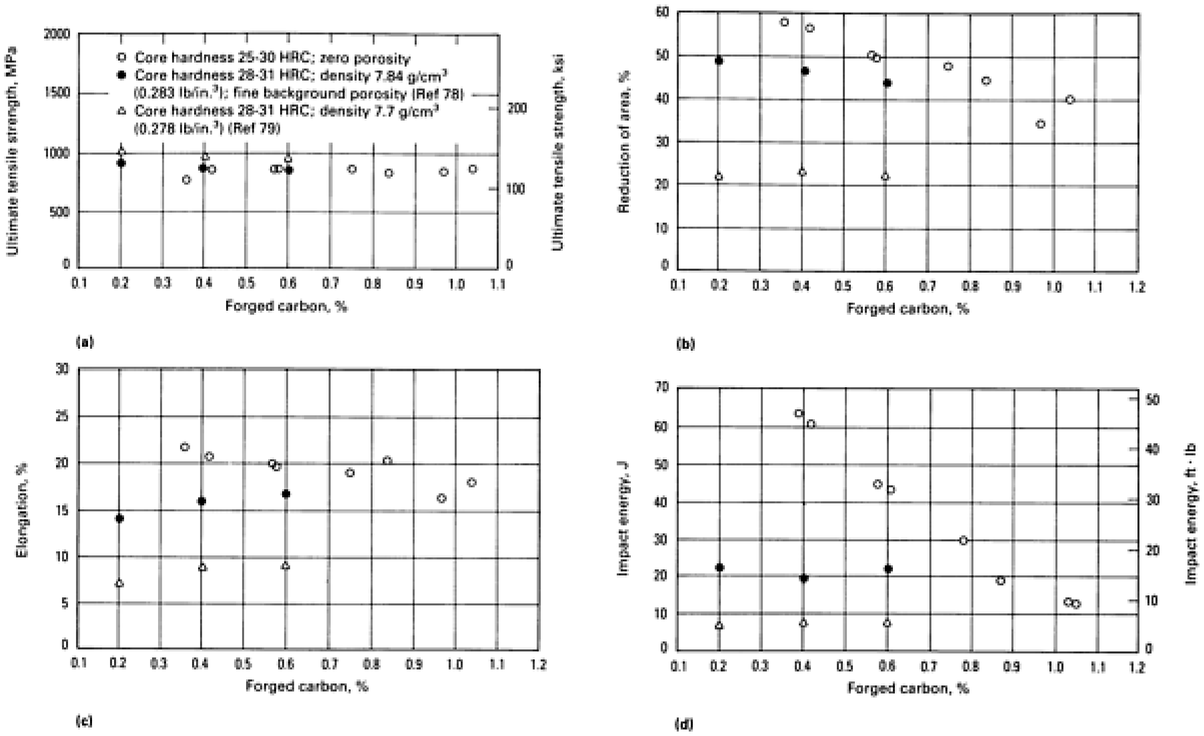

Fig. 26 Influence of density on the tensile and impact properties of P/F-4600 materials with core hardnesses of 25 to 30 HRC and 28 to 31 HRC. (a) Ultimate tensile strength. (b) Percent reduction of area. (c) Percent elongation. (d) Room-temperature impact energy. See also Fig. 27.

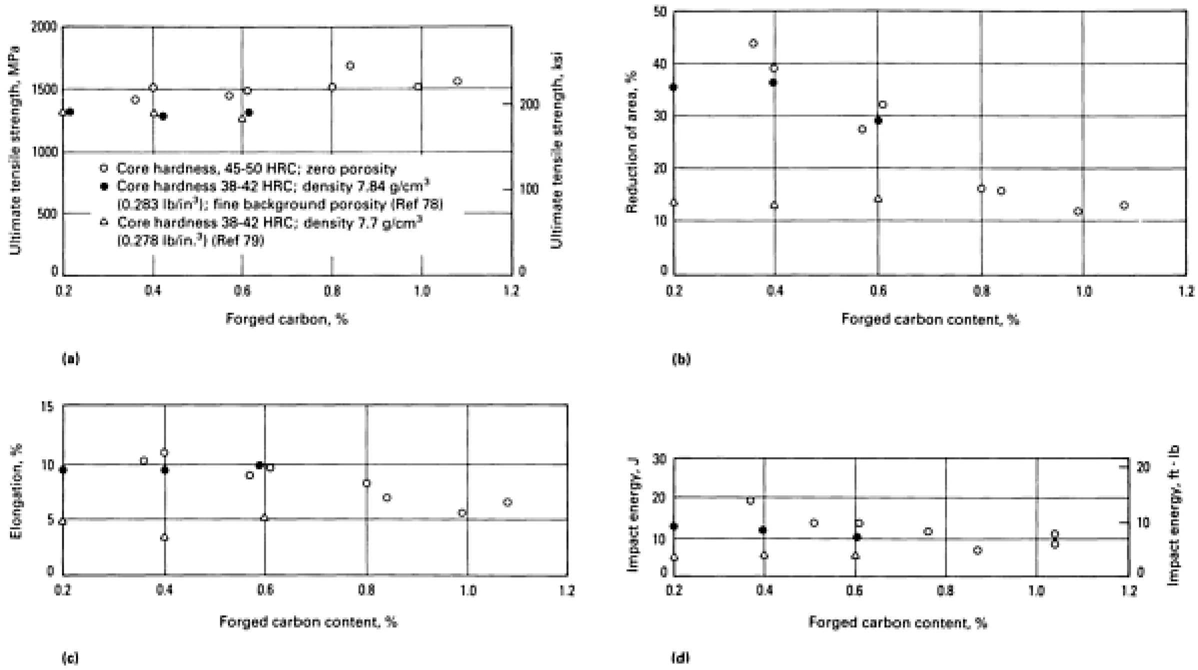

Fig. 27 Influence of density on the tensile and impact properties of P/F-4600 materials with core hardnesses of 38 to 42 HRC and 45 to 50 HRC. (a) Ultimate tensile strength. (b) Percent reduction of area. (c) Percent

elongation. (d) Room-temperature impact energy. See also Fig. 26.

Powder Forging

W. Brian James, Michael J. McDermott, and Robert A. Powell, Hoeganaes Corporation

Quality Assurance for P/F Parts

Many of the quality assurance tests applied to wrought parts are similar to those used for powder forged parts. Among the parameters specified are: part dimensions, surface finish, magnetic particle inspection, composition, density, metallographic analysis, and nondestructive testing. These are discussed below.

Part Dimensions and Surface Finish. Typical tolerances for powder forged parts are summarized in Table 11. The as-forged surface finish of a powder forged part is directly related to the surface finish of the forging tool. Surface finish is generally better than 0.8 μm (32 μin.), which is better than that obtained on wrought forged parts. This good surface finish is beneficial to the fatigue performance of P/F parts.

Table 11 Typical tolerances for powder forged parts

Dimension or characteristic	Description	Typical tolerance		Minimum tolerance		
		mm/mm	in./in.	mm	in.	

a	Linear dimension perpendicular to the press axis	0.0025	0.0025	0.08	0.003	b	Linear dimensions parallel to the press axis	±0.25	±0.10	0.20	0.008	
c	Concentricity of holes to external dimensions	. . .	. . .	0.10	0.004	
d	**Surface finish**	. . .	. . .	**Normally better than 0.8 μm (32 μin.)**		

Source: Ref 80

Magnetic particle inspection is used to detect surface blemishes such as cracks and laps.

Composition. Parts are generally designed to a specified composition. The forged carbon and oxygen contents are of particular interest. The specified carbon level is required to achieve the desired heat treatment response, and forged oxygen levels have a significant influence on dynamic properties (Fig. 28).

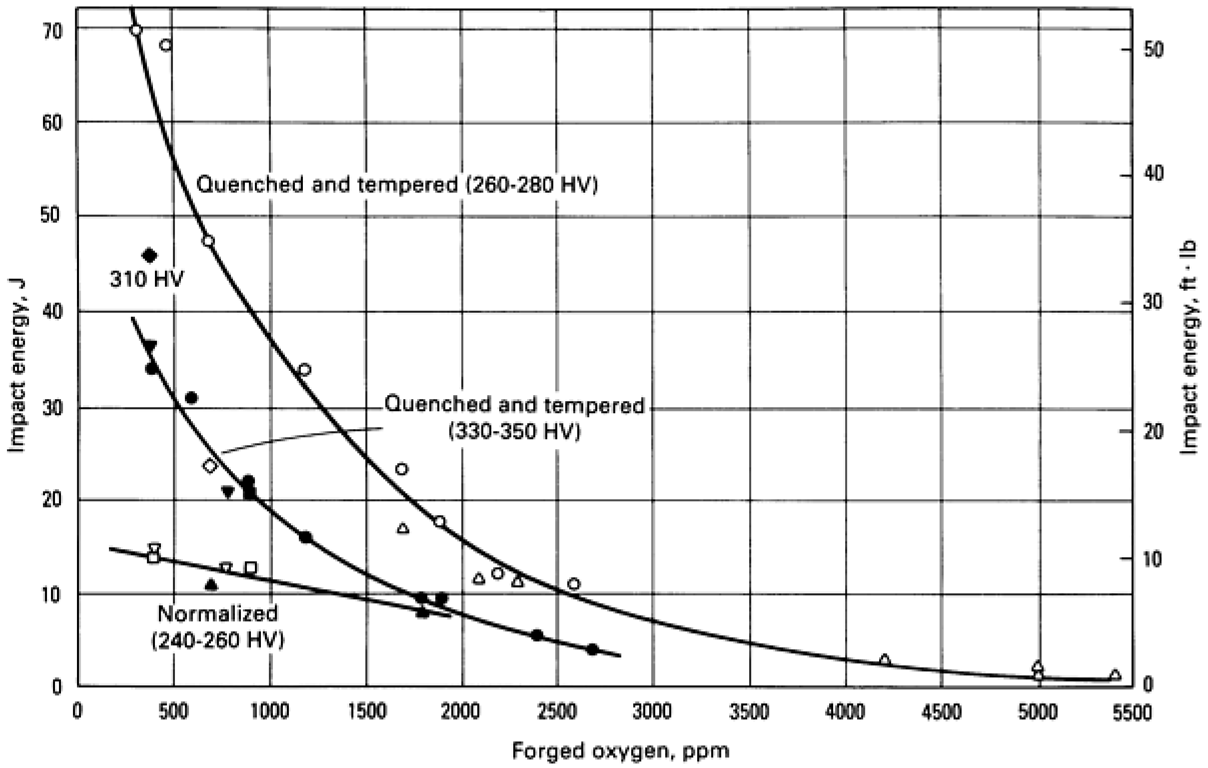

Fig. 28 Room-temperature impact energy as a function of forged oxygen content for various powder forged alloys. Heat treatments and hardnesses are indicated on the curves. Source: Ref 81.

Density. Sectional density measurements are taken to ensure that sufficient densification has been achieved in critical areas. Displacement density checks are generally supplemented by microstructural examination to assess the residual porosity level. For a given level of porosity, the measured density will depend on the exact chemistry, thermomechanical condition, and microstructure of the sample. Parts may be specified to have a higher density in particular regions than is necessary in less critical sections of the same component.

Metallographic Analysis. Powder forged parts are subjected to extensive metallographic evaluation. The primary parameters of interest include those discussed below.

The extent of surface decarburization permitted in a forged part will generally be specified. The depth of decarburization may be estimated by metallographic examination, but is best quantified using microhardness measurements as described in ASTM E 1077.

Surface finger oxides are defined as oxides that follow prior particle boundaries into the forged part from the surface and cannot be removed by physical means such as rotary tumbling. An example of surface finger oxides is shown in Fig. 29. Metallographic techniques are used to determine the maximum depth of surface finger oxide penetration.

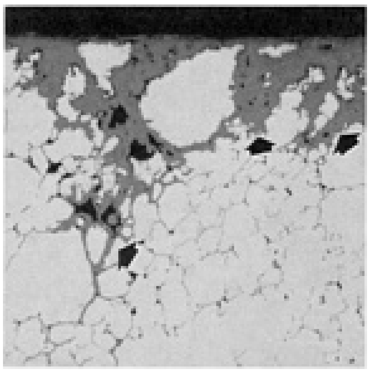

Fig. 29 Surface finger oxides (arrows at upper right) and interparticle oxide networks (arrow near lower left) in a powder forged material.

Interparticle oxides follow prior particle boundaries. They may sometimes form a continuous three-dimensional network but more often will, in a two-dimensional plane of polish, appear to be discontinuous. An example is presented in Fig. 29.

Most parts have what may be defined as functionally critical areas. The fabricator and end-user decide upon the maximum permissible depth of surface finger oxide penetration and whether oxide networks can be tolerated in critical regions. These decisions are then specified on the part drawing or in the purchase agreement.

The microstructure of a powder forged part depends on the thermal treatment applied after the forged part has been ejected from the die cavity. Most parts are carburized, quenched and stress relieved, or quenched and tempered. Other heat treatments used on wrought steels may also be applied to powder forged materials.

Iron powder contamination in low-alloy powder forged parts can be quantified by means of the etching procedure described in the section "Material Considerations" in this article.

The nonmetallic inclusion level in a powder forged part may also be quantified using the image analysis technique described in the section "Material Considerations." However, if the section of a component selected for inclusion assessment is not pore-free, image analysis procedures are not applicable (pores and oxide inclusions have similar gray level characteristics for feature detection). In fact, the presence of porosity makes it difficult for even visual quantitative determination of inclusion size.

Nondestructive Testing. Although metallographic assessment of powder forged parts is common, it is also useful to have a nondestructive method for evaluating the microstructural integrity of components. It has been demonstrated that this can be achieved with a magnetic bridge comparator.

Magnetic bridge sorting can be used to compare the eddy currents developed within a forging placed in a coil that carries an alternating current with the eddy currents produced in a randomly selected reference sample from the same forging batch (Ref 21). Differences are indicated by the displacement of a light spot from its balanced position in the center of the measuring screen of the system. If the part being tested is similar to the reference sample, the light spot returns to the center of the screen. The screen can be arbitrarily divided into a number of zones, as illustrated in Fig. 30. Testing of randomly selected samples can then be used to establish a typical frequency distribution of components within a forged batch relative to the reference sample.

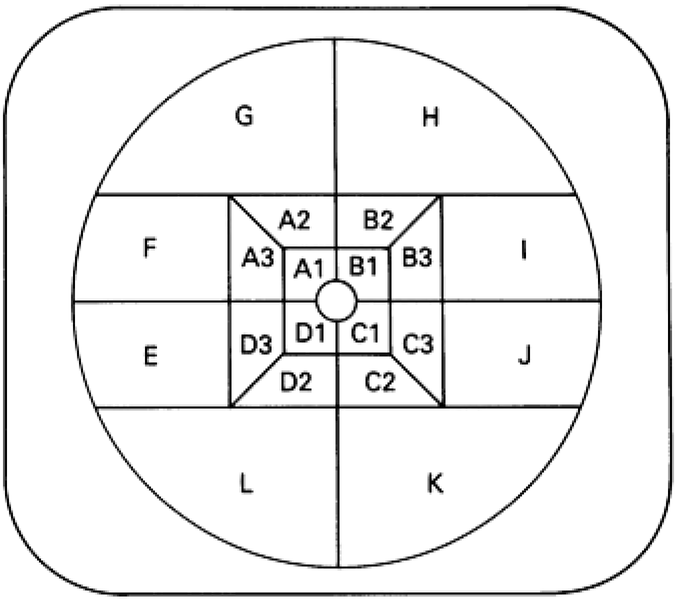

Fig. 30 Sorting grid categories arbitrarily assigned to the measuring screen of the magnetic bridge comparator. See text for details.

Once the frequency distribution has been established for a limited number of components within a forging batch, selected components that are representative of several zones on the screen are subjected to metallographic examination. Limited metallographic testing thus can be used to check the metallurgical integrity of parts from various zones.

Once acceptable zones have been defined, the entire forging batch can be assessed by means of the magnetic bridge. Components in unacceptable categories are automatically rejected. Experience with this technique minimizes the number of parts requiring sectioning for metallographic examination. Core hardness, surface decarburization, surface oxide penetration, and porosity can also be evaluated using this technique.

Magnetic bridge sorting, an adaptation of the technique used to test drop forged parts, enables potentially defective components to be eliminated from a batch of forgings. It also can be used to provide 100% inspection of the metallurgical integrity of a forging batch.

Applications of Powder Forged Parts

Previous sections in this article compared powder forging and drop forging and illustrated the range of mechanical property performance that can be achieved in powder forged material. The various approaches to the powder forging process were reviewed, as was the influence of process parameters on the metallurgical integrity of the forged parts. The present section concentrates on examples of powder forged components and highlights some of the reasons for selecting powder forged parts over those made by competing forming methods.

Example 1: Converter Clutch Cam.

The automotive industry is the principal user of powder forged parts, and components for automatic transmissions represent the major area of application. One of the earliest powder forgings used in such an application is the converter clutch cam (Fig. 31). The primary reason powder forging was chosen over competitive processes was that it reduced manufacturing costs by 58%, compared with the conventional process of machining a forged gear blank. This cost saving resulted from substantially lower machining cost and lower total energy use.

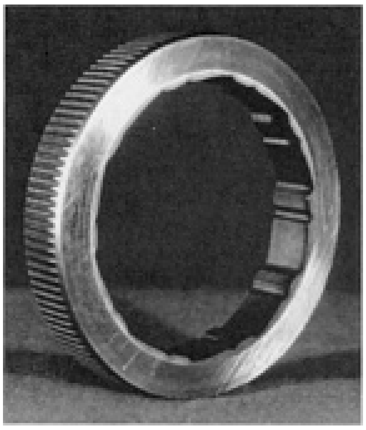

Fig. 31 Powder forged converter clutch cam used in an automotive automatic transmission. Courtesy of Precision Forged Products Division, Federal Mogul Corporation.

Powder forged cams are made from a water-atomized steel powder (P/F 2000) containing 0.6% Mo, 0.5% Ni, 0.3% Mn, and 0.3% graphite. Preforms weighing 0.33 kg (0.73 lb) are compacted to a density of 6.8 g/cm^3 (0.246 lb/in.^{3}). The preforms are sintered at 1120 °C (2050 °F) in an endothermic gas atmosphere with a +2 °C (+35 °F) dewpoint. The sintered preforms are graphite coated before being induction heated and forged to near full density (less than 0.2% porosity) using both axial and lateral flow. After forging, the face of the converter clutch cam is ground, carburized to a depth of 1.78 mm (0.070 in.), and surface hardened by means of induction. The part requires a high density to withstand the high Hertzian stress the inner cam surface experiences in service. Machining requires only one step on the P/F cam; seven machining operations were required for the conventionally processed part. Production of P/F cams began in 1971. Since then, well over 30 million P/F converter clutch cams have been made without a single service failure.

Example 2: Inner Cam/Race.

A part that illustrates the complex shapes that can be formed on both the inner and outer surfaces of a powder forged component is the inner cam/race shown in Fig. 32 (Ref 82). The part is the central member in an automotive automatic transmission torque converter centrifugal lock-up clutch.

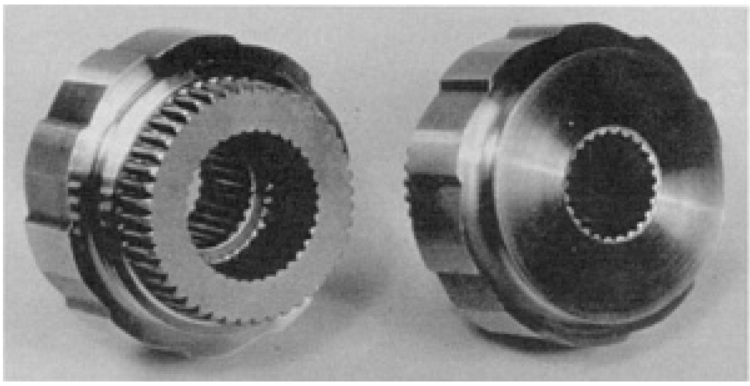

Fig. 32 Powder forged inner cam/race for an automotive automatic transmission. Courtesy of Precision Forged Products Division, Federal Mogul Corporation.

The inner cam/race is forged to a minimum density of 7.82 g/cm^3 (0.283 lb/in.^{3}) from a P/F-4662 material. The part has a minimum quenched and stress-relieved hardness of 58 HRC and a tensile strength of 2070 MPa (300 ksi). The application imposes high stresses on the cams and splines.

Example 3: Internal Ring Gear.

The powder forged internal ring gear shown in Fig. 33 is used in automatic transmissions for trucks with a maximum gross vehicle weight of 22,700 kg (50,000 lb) (Ref 83). The gear transmits 1355 N · m (1000 ft · lb) of torque through the gear and spline teeth.

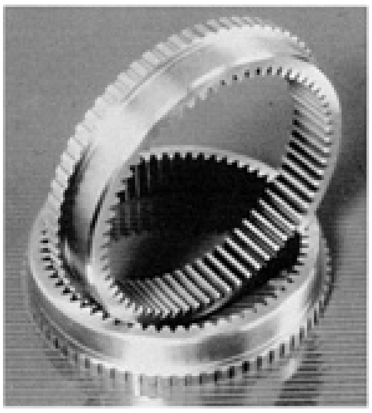

Fig. 33 Powder forged internal ring gear used in automatic transmission for trucks of up to 22,700 kg (50,000 lb) gross vehicle weight. Courtesy of Precision Forged Products Division, Federal Mogul Corporation.

Originally, the gear was produced by forging an AISI 5140M tubing blank. The conventionally forged blank required rough machining, gear tooth shaping, spline machining, core heat treating, carburizing, and deburring. The only secondary operations required on the powder forged part are surface grinding, hard turning, shot blasting, and vibratory tumbling.

The P/F-4618 ring gear is produced to a minimum density of 7.82 g/cm^3 (0.283 lb/in.^{3}). The part is selectively carburized using a proprietary process (Ref 84, 85, 86) and quench hardened. Minimum surface hardness is 57 HRC (2070 MPa, or 300 ksi, ultimate tensile strength), while the core hardness is 25 HRC (825 MPa, or 120 ksi, ultimate tensile strength). The internal gear teeth are produced to AGMA Class 7 tolerances.

Example 4: Powder Forged Tapered Bearing Race.

The use of powder forging for production of tapered roller bearing races has resulted in considerable cost savings. The economy of the P/F process results from material savings, elimination of machining, energy savings from the elimination of subsequent carburizing, and raw material inventory reduction.

In some cases, up to 80% of the material is lost to machining when a bearing race is produced from bar stock. Material savings resulting from powder forging average 50% on bearing cup and cone production. In the example shown in Fig. 34, a material savings of 1.25 kg (2.74 lb) is realized using powder forging; nearly 62% of the feedstock is wasted when this component is machined from hot rolled tube stock.

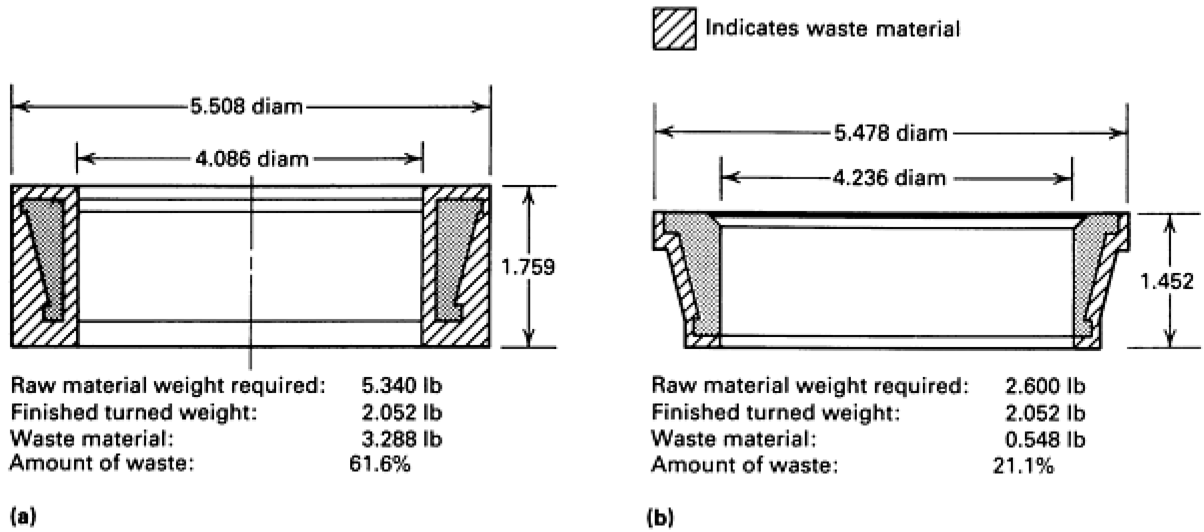

Fig. 34 Raw material utilization in the production of a tapered roller bearing race. (a) Produced from hot rolled tube stock. (b) Powder forged from preform. Source: Ref 87.

In addition to the cost savings, the fatigue life of powder forged cups and cones was found to be greater than that of similar cups produced from wrought bearing steels (Fig. 35).

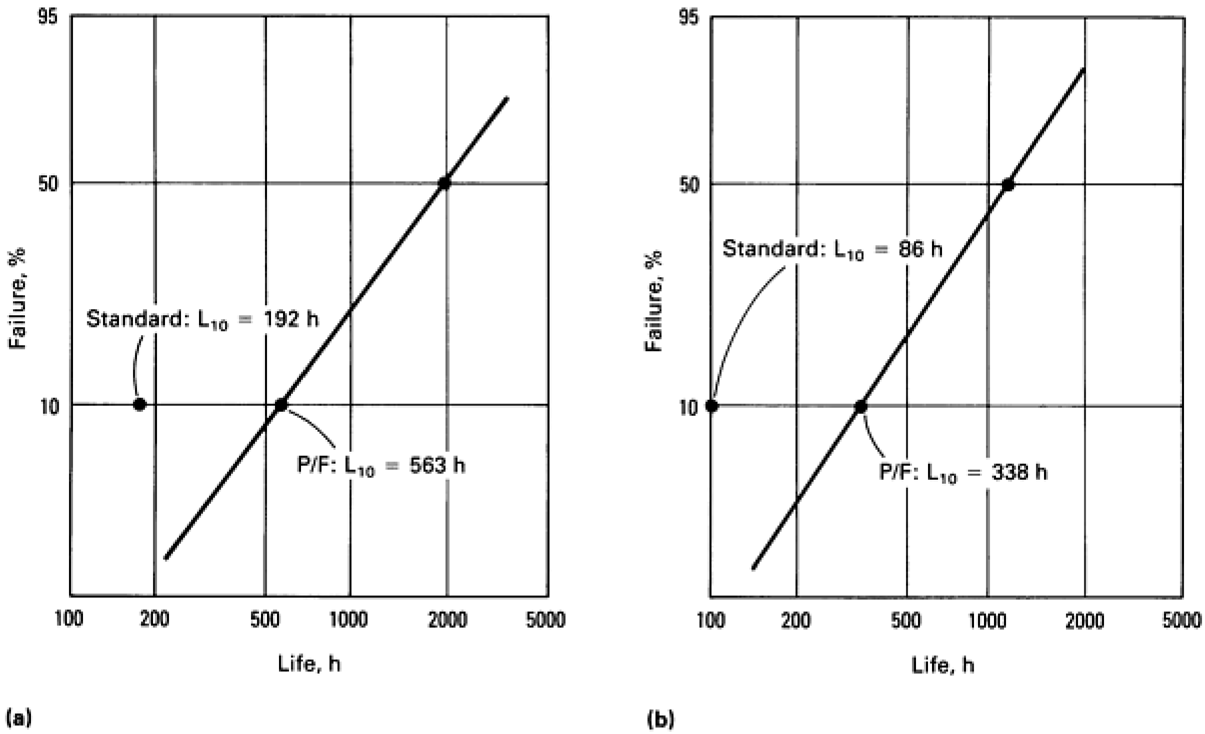

Fig. 35 Weibull plots of L_{10} life of P/F bearing races compared with L_{10} of wrought and machined races. (a) Cups. (b) Cones. Source: Ref 88.

Example 5: Powder Forged Connecting Rods.

Connecting rods were among the components selected for a number of powder forging development programs in the 1960s (Ref 5, 7, 18, 89, 90, 91, 92, 93). However, it was not until 1976 that the first powder forged connecting rod was produced commercially. This was the connecting rod for the Porsche 928 V-8 engine (Fig. 36a).

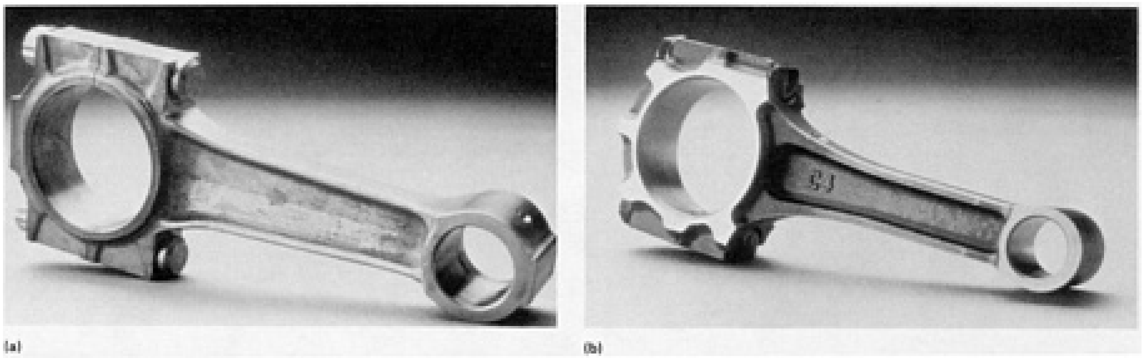

Fig. 36 Powder forged connecting rods. (a) Rod for Porsche 928 V-8 engine. Note reduced size of balance pads. Courtesy of Powder Forging Division, GKN Forgings. (b) Rod for Toyota 1.9 L engine; balance pads are completely eliminated.

The powder forged connecting rod for the Porsche 928 engine was made from a water-atomized low-alloy steel powder (0.3 to 0.4% Mn, 0.1 to 0.25% Cr, 0.2 to 0.3% Ni, and 0.25 to 0.35% Mo) to which graphite was added to give a forged carbon content of 0.35 to 0.45%. The forgings were oil quenched and tempered to a core hardness of 28 HRC (ultimate tensile strength of 835 to 960 MPa, or 121 to 139 ksi), followed by shot peening to a surface finish of 11 to 13 on the Almen scale.

The preform was designed such that the powder forged component had less than 0.2% porosity in the critical web region. The powder forged connecting rod had considerably better fatigue properties than did conventional drop forged rods. Its weight control was good enough to allow a reduction in the size of the balance pads (Fig. 36a), resulting in about a 10% weight saving (it weighed ~1 kg, or 2 lb). Powder forged connecting rods are currently used in both the Porsche 928 and 944 engines.

The first high-volume commercialization of powder forged connecting rods was in the 1.9 L Toyota Camry engine. In this design, the balance pads were completely eliminated (Fig. 36b). Despite the publication of the results of development trials in 1972 (Ref 91), it was not until the summer of 1981 that production rods were introduced (Ref 9, 93).

Toyota selected a copper steel (Fe-0.55C-2Cu) based on a water-atomized iron powder to replace conventional forgings, which had been made from a quenched and tempered 10L55 free-machining steel. The preform, which has a preshaped partial I-beam web section, has an average green density of 6.5 g/cm^3 (0.235 lb/in.^{3}). The preform shape is such that forging is predominantly in the re-pressing mode. However, some lateral flow does take place where required in critical regions, such as the web.

Preforms are sintered for 20 min at 1150 °C (2100 °F) in an endothermic gas atmosphere in a specially designed rotary hearth furnace. During sintering, the preforms are supported on flat, ceramic plates. The preforms are allowed to stabilize at about 1010 °C (1850 °F) before closed-die forging.

Exposure of the preform to the atmosphere during transfer to the forging dies is limited to 4 to 5 s. The forging tooling is illustrated in Fig. 37. An ion nitriding treatment is applied to the punches and dies in the regions at which forging deformation occurs (Ref 9). The connecting rods are forged at the rate of 10 per minute, and tool lives of over 100,000 pieces have been reported (Ref 94).

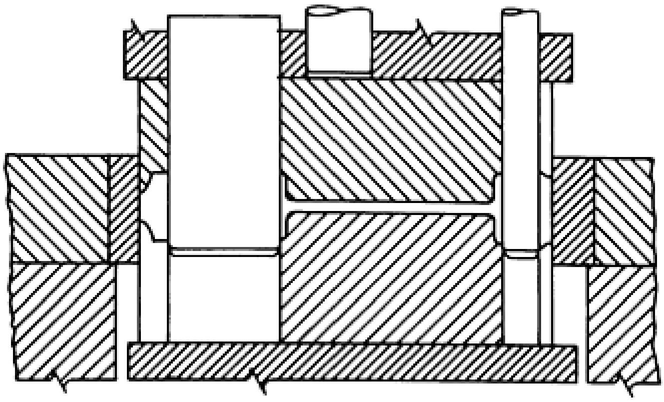

Fig. 37 Tooling used for powder forging of the Toyota connecting rod. Source: Ref 93.

The forged rods are subjected to a thermal treatment after forging. This results in a ferrite/pearlite microstructure with a core hardness of 240 to 300 HV (30 kgf load). Subsequent operations include burr removal, shot peening, straightening, sizing, magnetic particle inspection, and finish machining.

Savings in material and energy are substantial for the powder forged rods (Ref 9). Billet weight for conventional forging is 1.2 kg (2.65 lb); the powder forging preform weighs 0.7 kg (1.54 lb) and requires little machining. In addition to the benefits in process economics, the variability in fatigue performance for the powder forged rods is reported to be half that of conventionally forged parts (Ref 93).

Ford Motor Company has recently introduced powder forged connecting rods in the 1.9 L four-cylinder engine used in the Ford Escort and Mercury Lynx models. Ford has also announced plans to use powder forged rods in its modular engine, which is scheduled for production in 1992 (Ref 94).

Introduction

CARBON AND ALLOY STEELS are by far the most commonly forged materials, and are readily forged into a wide variety of shapes using hot-, warm-, or cold-forging processes and standard equipment (see the Sections "Forging Processes" and "Forging Equipment and Dies" in this Volume). Despite the large number of available compositions, all of the materials in this category exhibit essentially similar forging characteristics. Exceptions to this are steels containing free-machining additives such as sulfides; these materials are more difficult to forge than are nonfree machining grades.

Generally, the hot forgeability of carbon and alloy steels improves as deformation rate increases. The improvement in workability has been primarily attributed to the increased heat of deformation generated at high deformation rates.

Selection of forging temperatures for carbon and alloy steels is based on carbon content, alloy composition, the temperature range for optimum plasticity, and the amount of reduction required to forge the workpiece. Of these factors, carbon content has the most influence on upper-limit forging temperatures. Table 1 lists the typical hot forging temperatures for a variety of carbon and alloy steels; it can be seen that, in general, forging temperatures decrease with increasing carbon and alloy content.

Table 1 Typical forging temperatures for various carbon and alloy steels

Steel	Major alloying elements	Typical forging temperature	
		°C	°F
Carbon steels			
1010	. . .	1315	2400
1015	. . .	1315	2400
1020	. . .	1290	2350
1030	. . .	1290	2350
1040	. . .	1260	2300
1050	. . .	1260	2300
1060	. . .	1180	2160
1070	. . .	1150	2100
1080	. . .	1205	2200

1095	. . .	1175	2150
Alloy steels			
4130	Chromium, molybdenum	1205	2200
4140	Chromium, molybdenum	1230	2250
4320	Nickel, chromium, molybdenum	1230	2250
4340	Nickel, chromium, molybdenum	1290	2350
4615	Nickel, molybdenum	1205	2200
5160	Chromium	1205	2200
6150	Chromium, vanadium	1215	2220
8620	Nickel, chromium, molybdenum	1230	2250
9310	Nickel, chromium, molybdenum	1230	2250

Source: Ref 1

Steels have been forged in quantity since near the beginning of the Industrial Revolution. Despite (or perhaps because of) this long history, the forging of steels is an intuitive, empirical process, and literature on the subject is relatively scarce. This article will attempt to present forgeability data for carbon and alloy steels whenever possible, and to provide some general guidelines for the forging of these materials. The thermomechanical processing of high-strength low-alloy (microalloyed) forging steels also will be discussed.

Hot Forging Behavior

The hot forging of carbon and alloy steels into intricate shapes is rarely limited by forgeability aspects with the exception of the free-machining grades mentioned earlier. Section thickness, shape complexity, and forging size are limited primarily by the cooling that occurs when the heated workpiece comes into contact with the cold dies. For this reason equipment that has relatively short die contact times, such as hammers, is often preferred for forging intricate shapes in steel.

Forgeability

Hot-Twist Testing. One common means of measuring the forgeability of steels is the hot-twist test. As the name implies, this test involves twisting of heated bar specimens to fracture at a number of different temperatures selected to cover the possible hot working temperature range of the test material. The number of twists to fracture, as well as the torque required to maintain twisting at a constant rate, are reported. The temperature at which the number of twists is the greatest, if such a maximum exists, is assumed to be the optimal hot working temperature of the test material. Figure 1 shows forgeabilities of several carbon steels as determined by hot-twist testing. More information on the hot-twist test is available in Ref 2, 3, and 4.

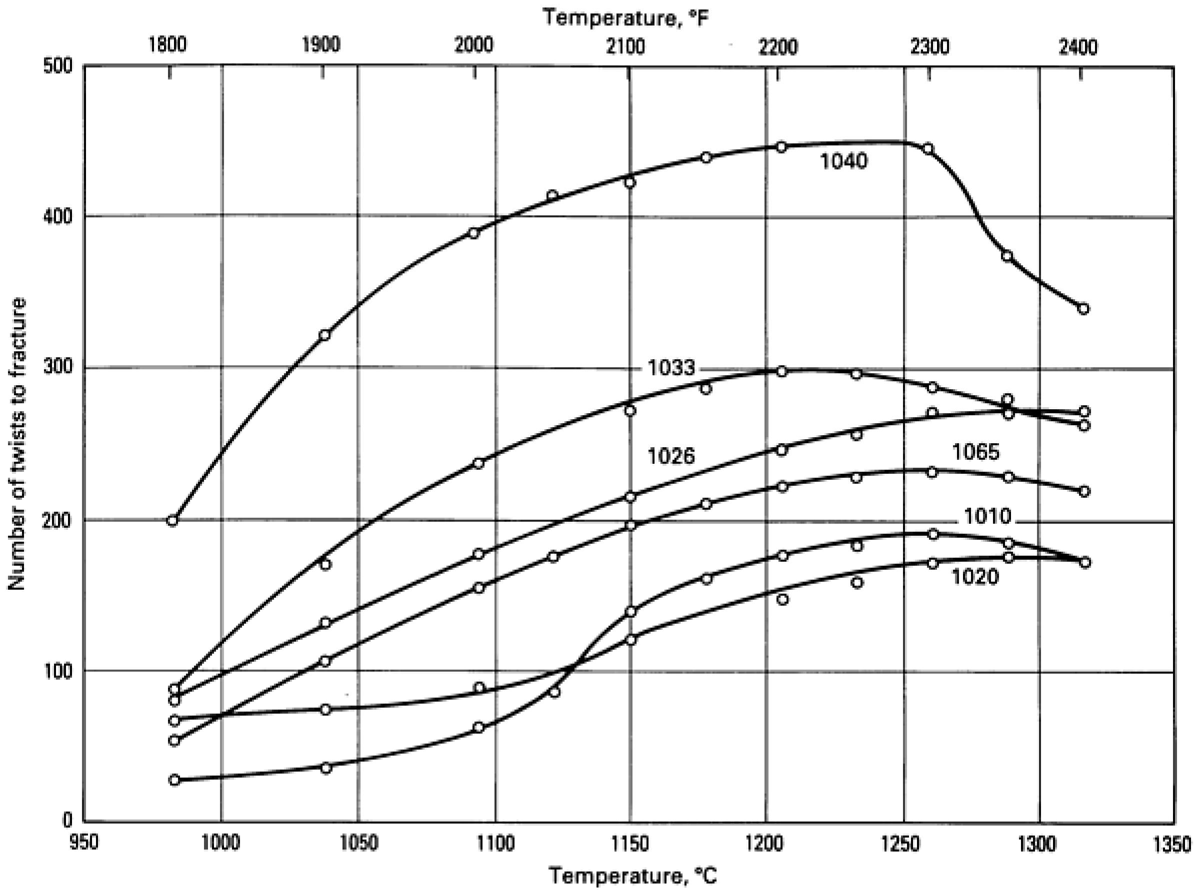

Fig. 1 Forgeabilities of various carbon steels as determined using hot-twist testing. Source: Ref 2.

Other Forgeability Tests. Numerous other tests are used to evaluate the forgeability of steels, including:

- *The wedge-forging test,* in which a wedge-shape specimen is forged between flat dies and the vertical deformation that causes cracking is established
- *The side-pressing test,* which consists of compressing a cylindrical bar specimen between flat, parallel dies with the axis of the cylinder parallel to the dies. The ends of the cylinder are unconstrained, and forgeability is measured by the amount of deformation obtained before cracking
- *The upset test,* in which a cylinder is compressed between flat dies and the surface strains at fracture at the equator of the cylinder are measured
- *The notched-bar upset test,* which is similar to the upset test except that axial notches are machined into the test specimen to introduce high local stress levels. These higher stresses may be more indicative of the stresses experienced during actual forging operations than those produced in the standard upset test
- *The hot tensile test,* which often uses a special test apparatus to vary both strain rates and temperatures over a wide range

More detailed information on these test procedures, as well as other techniques used to evaluate the bulk workability of materials, is available in the articles in the Section "Evaluation of Workability" in this Volume and in Ref 5 and 6.

Effect of Strain Rate on Forgeability. As previously stated, the forgeability of steels generally increases with increasing strain rate. This effect has been shown for low-carbon steel in hot-twist testing (Fig. 2), where the number of twists to failure increases with increasing twisting rate. It is believed that this improvement in forgeability at higher strain rates is due to the increased heat of deformation produced at higher strain rates. Excessive temperature increases from heat of deformation, however, may lead to incipient melting, which can lower forgeability and mechanical properties.

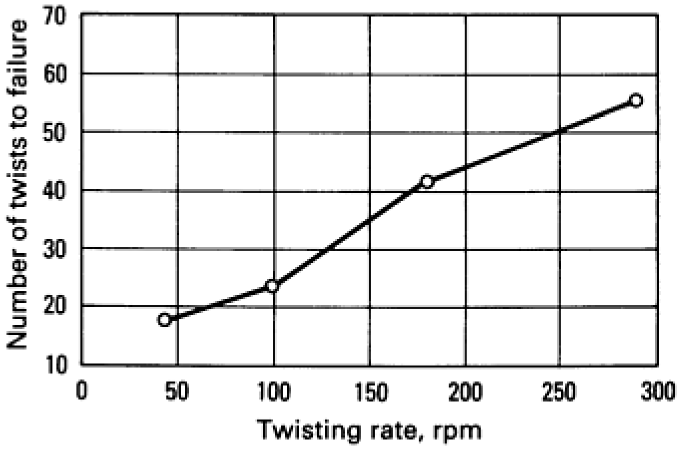

Fig. 2 Influence of deformation rate on hot-twist characteristics of low-carbon steels at 1095 °C (2000 °F). Source: Ref 7.

Flow Stress and Forging Pressure

Flow stresses and forging pressures can be obtained from torque curves generated in hot-twist tests or from hot-compression or tension testing. Figure 3 shows torque versus temperature curves for several carbon and alloy steels obtained from hot-twist testing. These data show that the relative forging pressure requirements for this group of alloys do not vary widely at normal hot-forging temperatures. A curve for AISI type 304 stainless steel is included to illustrate the effect of higher-alloy content on flow strength.

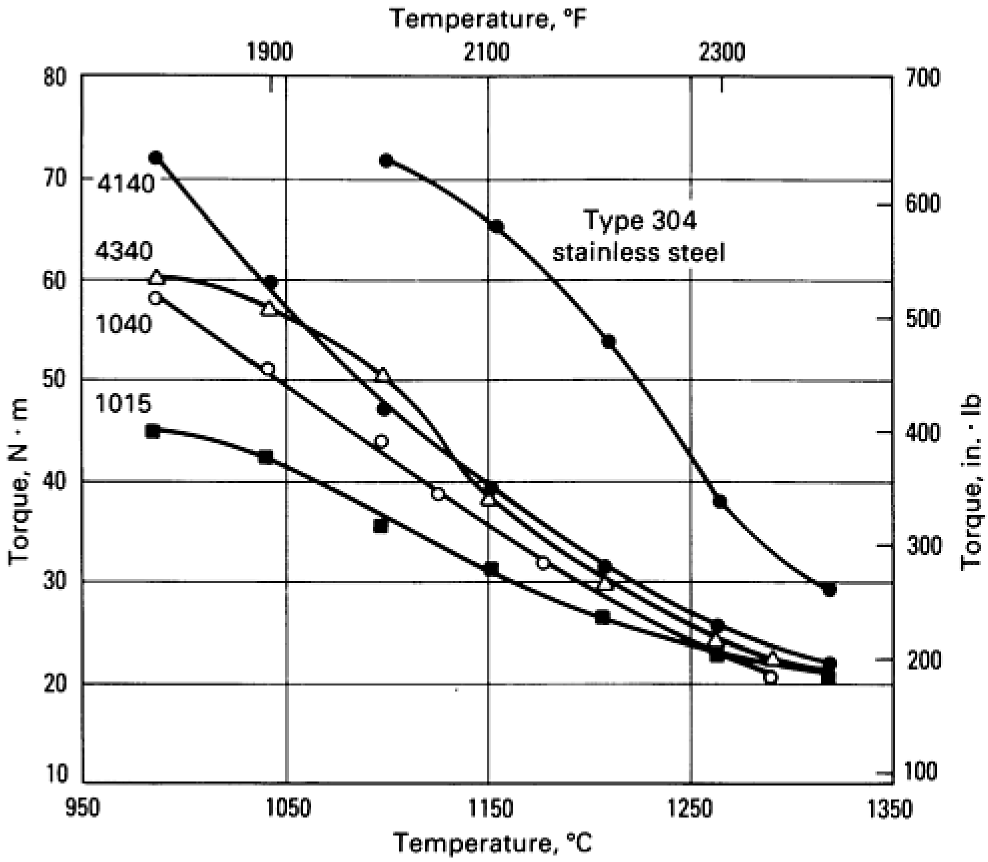

Fig. 3 Deformation resistance versus temperature for various carbon and alloy steels. Source: Ref 7.

Figure 4 shows actual forging pressure measurements for 1020 and 4340 steels and AISI A6 tool steel for reductions of 10 and 50%. Forging pressures for 1020 and 4340 vary only slightly at identical temperatures and strain rates. Considerably greater pressures are required for the more highly-alloyed A6 material, and this alloy also exhibits a more significant increase in forging pressure with increasing reduction.

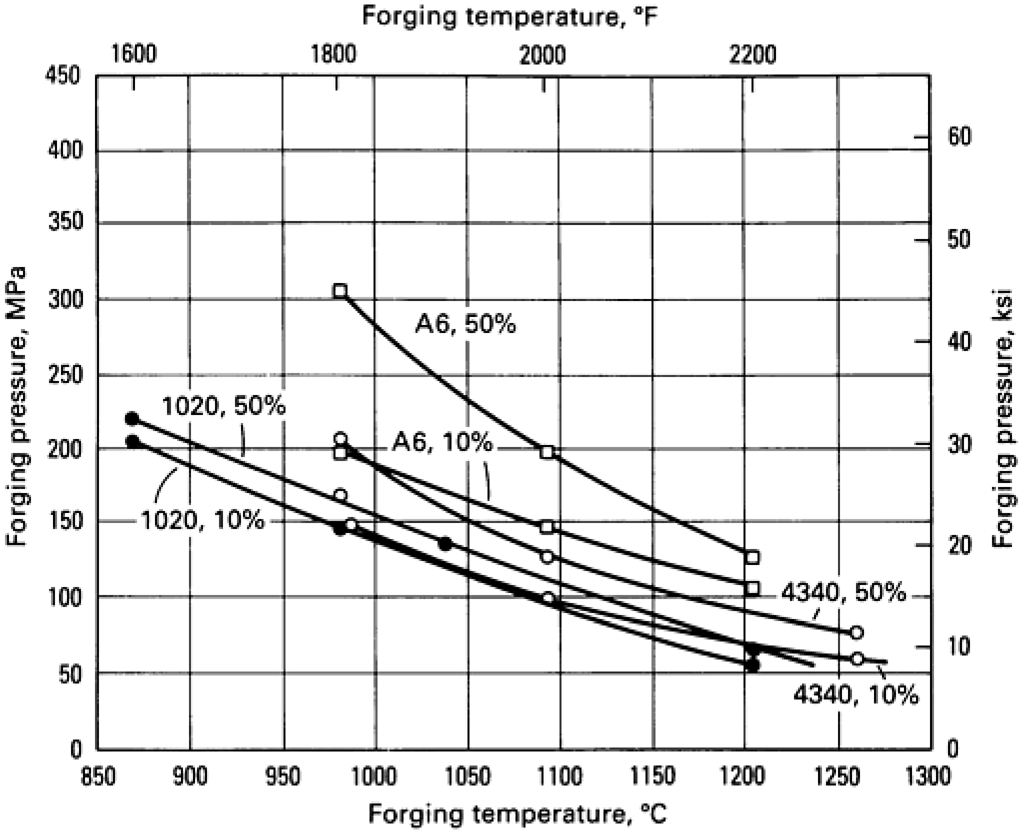

Fig. 4 Forging pressure versus temperature for three steels. Data are shown for reductions of 10 and 50%. Strain rate was constant at 0.7 s^{-1}. Source: Ref 9.

Effect of Strain Rate on Forging Pressure. Forging pressures required for a given steel increase with increasing strain rate. Studies of low-carbon steel (Ref 8) indicate that the influence of strain rate is more pronounced at higher forging temperatures. This effect is illustrated in Fig. 5, which gives stress-strain curves for a low-carbon steel forged at various temperatures and strain rates.

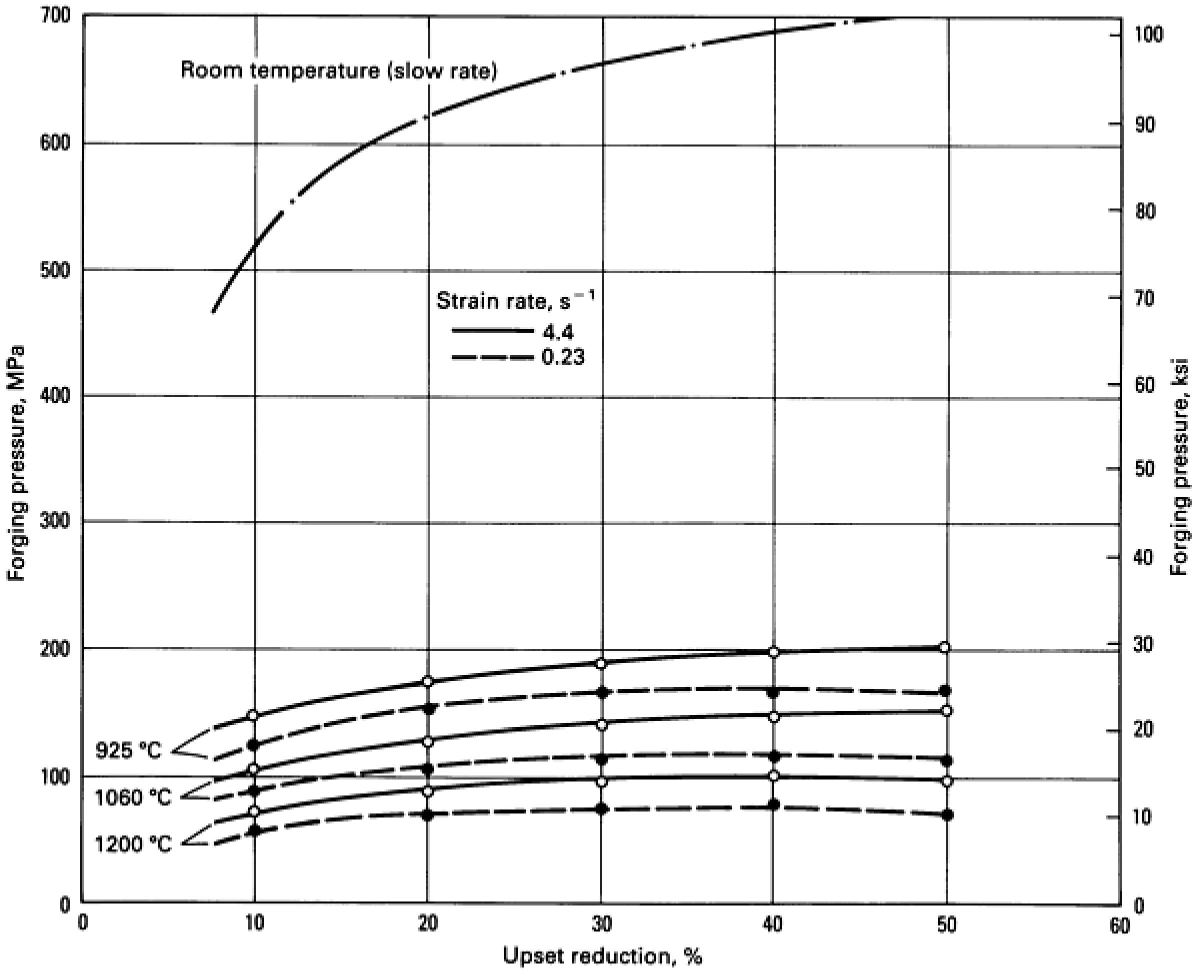

Fig. 5 Forging pressure for low-carbon steel upset at various temperatures and two strain rates. Source: Ref 8.

Similar effects have been observed in alloy steels. Figure 6 shows the forging pressures required upset 4340 steel at several temperatures and strain rates.

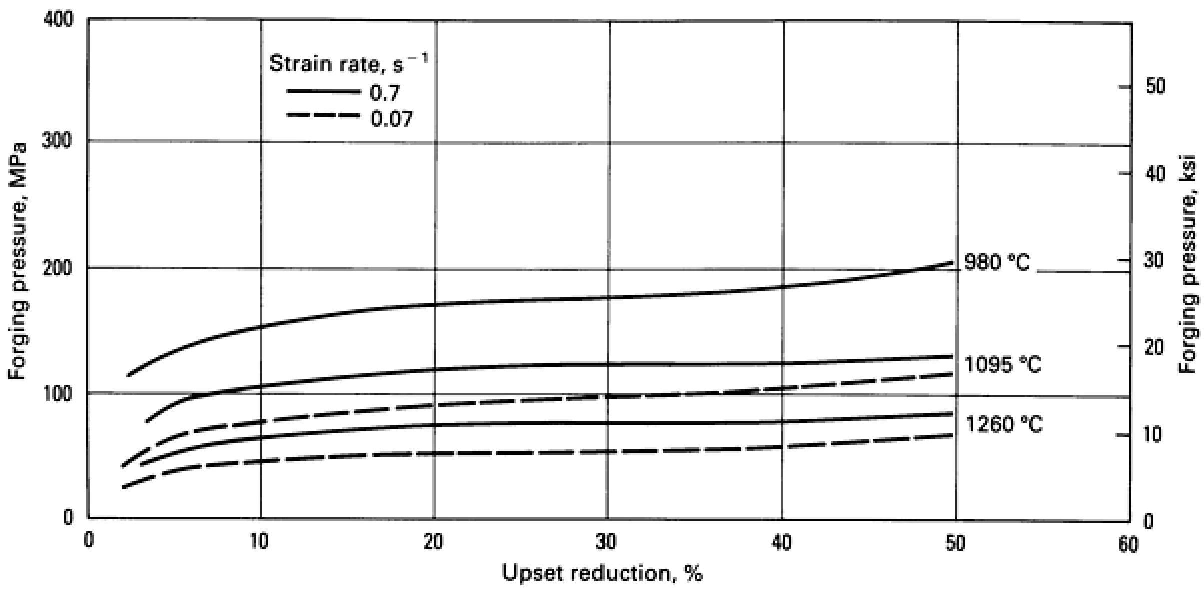

Fig. 6 Forging pressure for AISI 4340 steel upset at various temperatures and two strain rates. Source: Ref 9.

Effects of Forging on Properties

The shaping of a complex configuration from a carbon or alloy steel bar or billet requires first that the steel be "arranged" into a suitable starting shape (preformed) and then that it be caused to flow into the final part configuration. This rearrangement of the metal has little effect on hardness and strength of the steel, but certain mechanical properties, such as ductility, impact strength, and fatigue strength, are enhanced. This improvement in properties is thought to take place because forging:

- Breaks up segregation, heals porosity, and aids homogenization
- Produces a fibrous grain structure (Fig. 7) that enhances mechanical properties parallel to the grain flow
- Reduces as-cast grain size

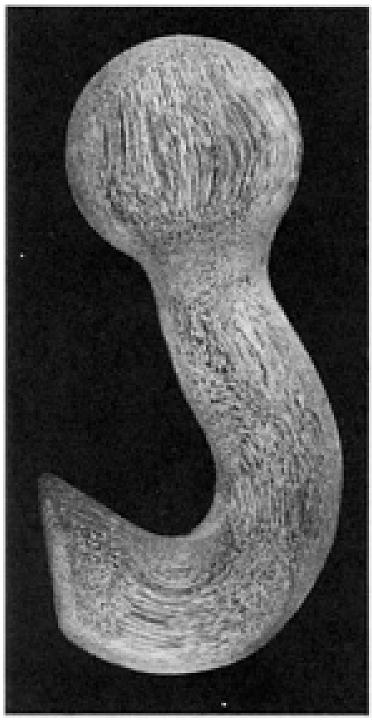

Fig. 7 4140 steel forged hook showing fibrous structure (flow lines) resulting from hot forging. Etched using 50% hot aqueous HCl. 0.5×

Typical improvements in ductility and impact strength of heat-treated steels as a function of forging reduction are shown in Fig. 8 and 9. These data illustrate that maximum improvement in each case occurs in the direction of maximum elongation.Toughness and ductility reach maximums after a certain amount of reduction, after which further reduction is of little value.

The typical longitudinal mechanical properties of low- and medium-carbon steel forgings in the annealed, normalized, and quenched and tempered conditions are listed in Table 2. As might be expected, strength increases with increasing carbon content, while ductility decreases.

(a) Rotating beam test at 10^7 endurance limit.

It should be recognized that closed-die forgings for the most part are made from wrought billets that have received considerable prior working. Open-die forgings, however, may be made from either wrought billets or as-cast ingots. Metal flows in various directions during closed-die forging. For example, in the forging of a rib and web shape such as an airframe component, nearly all metal flow is in the transverse direction. Such transverse flow improves ductility in that direction with little or no reduction in longitudinal ductility. Transverse ductility could conceivably equal or surpass longitudinal ductility if forging reductions were large enough and if metal flow were primarily in the transverse direction.

Similar effects are observed in the upsetting of wrought billets. In this case, however, the original longitudinal axis of the material is shortened by upsetting, and lateral displacement of metal is in the radial direction. When upset reductions exceed about 50%, ductility in the radial direction usually exceeds that in the axial direction (Fig. 10).

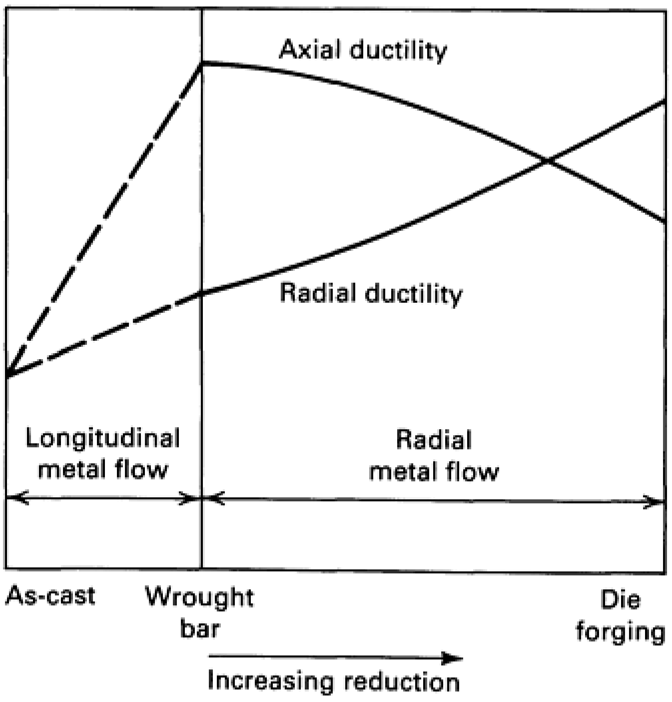

Fig. 10 Typical influence of upset reduction on axial and radial ductility of forged steels.

Forging Lubricants (Ref 14)

For many years, oil-graphite mixtures were the most commonly used lubricants for forging carbon and alloy steels. Recent advances in lubricant technology, however, have resulted in new types of lubricants, including water/graphite mixtures and water-base synthetic lubricants. Each of the commonly used lubricants has advantages and limitations (Table 3) that must be balanced against process requirements.

Table 3 Advantages and limitations of the principal lubricants used in the hot forging of steels

Type of lubricant	**Advantages**	Limitations

Water-base micro-graphite	Eliminates smoke and fire; provides die cooling; is easily extended with water	**Must be applied by spraying for best results**
Water-base synthetic	Eliminates smoke and fire; is cleaner than oils or water-base graphite; aids die cooling; is easily diluted, and needs no agitation after initial mixing; reduces clogging of spray equipment; does not transfer dark pigment to part	**Must be sprayed; lacks the lubricity of graphite for severe forging operations**
Oil-base graphite	**Fluid film lends itself to either spray or swab application; has good performance over a wide temperature range (up to 540 °C, or 1000 °F)**	**Generates smoke, fire, and noxious odors; explosive nature may shorten die life; has potentially serious health and safety implications for workers**

Source: Ref 14

Selection Criteria. Lubricant selection for forging is based on several factors, including forging temperature, die temperature, forging equipment, method of lubricant application, complexity of the part being forged, and environmental and safety considerations. At normal hot-forging temperatures for carbon and alloy steels, water-base graphite lubricants are used almost exclusively, although some hammer shops may still employ oil-base graphite.

The most common warm-forming temperature range for carbon and alloy steels is 540 to 870 °C (1000 to 1500 °F). Because of the severity of forging conditions at these temperatures, billet coatings are often used in conjunction with die lubricants. The billet coatings used include graphite in a fluid carrier or water-base coatings used in conjunction with phosphate conversion coating of the workpiece.

For still lower forging temperatures (less than about 400 °C, or 750 °F), molybdenum disulfide has a greater load-carrying capacity than does graphite. Molybdenum disulfide can either be applied in solid form or dispersed in a fluid carrier. More information on lubricant chemistry, application, and selection is available in Ref 14.

Forging of Carbon and Alloy Steels

Steels for Forging

Carbon and alloy steel ingots, blooms, billets, and slabs for forging are hot rolled or cast to approximate cross sectional dimensions; therefore, straightness, camber, twist, and flatness tolerances do not apply. Semifinished steel products for forging are produced to either specified piece weights or specified lengths.

Surface Conditioning. Semifinished steel products for forging can be conditioned by scarfing, chipping, or grinding to remove or minimize surface imperfections. It should be kept in mind that, regardless of surface conditioning, the product is still likely to contain some surface imperfections.

Weight tolerances for billets, blooms, and slabs are often ±5% for individual pieces or for lots weighing less than 18 Mg (20 tons). Lots weighing more than that are frequently subject to weight tolerances of ±2.5%.

Cutting. Semifinished steel products for forging are generally cut to length by hot shearing. Depending on the steel composition, hot sawing or flame cutting may also be used.

Quality, as the term is applied to semifinished steel products for forging, is dependent on many different factors, including the degree of internal soundness, relative uniformity of chemical composition, and relative freedom from surface imperfections.

Forging quality semifinished steel is used in hot forging applications that may involve subsequent heat treatment or machining operations. Such applications require relatively close control of chemical composition and steel manufacture. Forging-quality carbon and alloy steel products are produced to the guidelines described in Ref 15.

Powder metallurgy (P/M) steels are also forged from both sintered preforms and green (unsintered) preforms. Detailed information on the forging of P/M steels and the properties of the resulting products is available in the article "Powder Forging" in this Volume.

Heat Treatment of Carbon and Alloy Steel Forgings (Ref 16)

Usually steel forgings are specified by the purchaser in one of four principal conditions: as forged with no further thermal processing; heat treated for machinability; heat treated for final mechanical/physical properties; or specially heat treated to enhance dimensional stability, particularly in more complex part configurations.

As Forged. Although the vast majority of steel forgings are heat treated before use, a large tonnage of low-carbon steel (0.10 to 0.25% C) is used in the as-forged condition. In such forgings, machinability is good, and little is gained in terms of strength by heat treatment. In fact, a number of widely used ASTM and federal specifications permit this economic option. It is also interesting to note that, compared to the properties produced by normalizing, strength and machinability are slightly better, which is most likely attributable to the fact that grain size is somewhat coarser than in the normalized condition.

Heat Treated for Machinability. When a finished machined component must be produced from a roughly dimensioned forging, machinability becomes a vital consideration to optimize tool life, increase productivity, or both. The purchase specification or forging drawing may specify the heat treatment. However, when specifications give only maximum hardness or microstructural specifications, the most economical and effective thermal cycle must be selected. Available heat treatments include full anneal, spheroidize anneal, subcritical anneal, normalize, or normalize and temper. The heat treatment chosen depends on the steel composition and the machine operations to be performed. Some steel grades are inherently soft, others become quite hard in cooling from the finishing temperature after hot forging. Some type of annealing is usually required or specified to improve machinability.

Heat Treated to Final Physical Properties. Normalizing or normalizing and tempering may produce the required minimum hardness and minimum ultimate tensile strength. However, for most steels, a hardening (austenitize) and quenching (in oil, water, or some other medium, depending on section size and hardenability) cycle is employed, followed by tempering to produce the proper hardness, strength, ductility, and impact properties. For steel forgings to be heat treated above the 1034 MPa (150 ksi) strength level and having section size variations, it is general practice to normalize before austenitizing to produce a uniform grain size and minimize internal residual stresses. In some instances, it is common practice to use the heat for forging as the austenitizing cycle and to quench at the forge unit. The forging is then tempered to complete the heat treat cycle. Although there are obvious limitations to this procedure, definite economies are possible when the procedure is applicable (usually for symmetrical shapes of carbon steels that require little final machining).

Special heat treatments are sometimes used to control dimensional distortion, relieve residual stresses before or after machining operations, avoid quench cracking, or prevent thermal shock or surface (case) hardening. Although most of the heat-treating cycles discussed above can apply, very specific treatments may be required. Such treatments usually apply to complex forging configurations with adjacent differences in section thickness, or to very high hardenability steels and alloys. When stability of critically dimensioned finished parts permits only light machining of the forging after heat treatment to final properties, special treatments are available, including marquenching (martempering), stress relieving, and multiple tempering.

Many applications, such as crankshafts, camshafts, gears, forged rolls, rings, certain bearings, and other machinery components, require increased surface hardness for wear resistance. The important surfaces are usually hardened after machining by flame or induction hardening, carburizing, carbonitriding, or nitriding. These processes are listed in the approximate order of increasing cost and decreasing maximum temperature. The latter consideration is important in that dimensional distortion usually decreases with decreasing temperature. This is particularly true of nitriding, which is usually performed below the tempering temperature for the steel used in the forging. Detailed information on heat treatment practices for carbon and alloy steels is available in *Heat Treating*, Volume 4 of the *ASM Handbook.*

Microalloyed Forging Steels

Microalloying--the use of small amounts of elements such as vanadium and niobium to strengthen steels--has been in practice since the 1960s to control the microstructure and properties of low-carbon steels (Ref 17). Most of the early developments were related to plate and sheet products in which microalloy precipitation, controlled rolling, and modern steelmaking technology combined to increase strength significantly relative to that of low-carbon steels.

The application of microalloying technology to forging steels has lagged behind that of flat-rolled products because of the different property requirements and thermomechanical processing of forging steels. Forging steels are commonly used in applications in which high strength, fatigue resistance, and wear resistance are required. These requirements are most often filled by medium-carbon steels. Thus, the development of microalloyed forging steels has centered around grades containing 0.30 to 0.50% C.

The driving force behind the development of microalloyed forging steels has been the need to reduce manufacturing costs. This is accomplished in these materials by means of a simplified thermomechanical treatment (that is, a controlled cooling following hot forging) that achieves the desired properties without the separate quenching and tempering treatments required by conventional carbon and alloy steels. In Fig. 11 the processing sequence for conventional (quenched and tempered) steels is compared with the microalloyed steel-forging process.

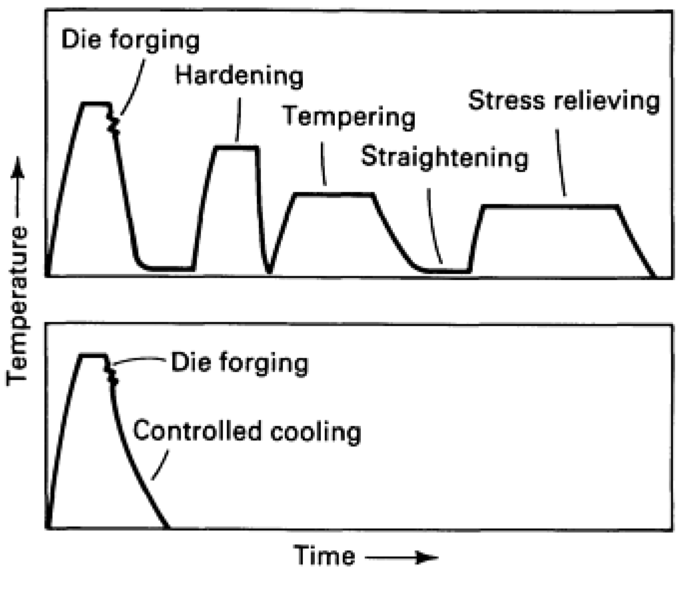

Fig. 11 Processing cycles for conventional (quenched and tempered; top) and microalloyed steels (bottom). Source: Ref 26.

Effects of Microalloying Elements (Ref 18)

Carbon. Most of the microalloyed steels developed for forging have carbon contents ranging from 0.30 to 0.50%, which is high enough to form a large amount of pearlite. The pearlite is responsible for substantial strengthening. This level of carbon also decreases the solubility of the microalloying constituents in austenite.

Niobium, Vanadium, and Titanium. Formation of carbonitride precipitates is the other major strengthening mechanism of microalloyed forging steels. Vanadium, in amounts ranging from 0.05 to 0.2%, is the most common microalloying addition used in forging steels. Niobium and titanium enhance strength and toughness by providing control of austenite grain size. Often niobium is used in combination with vanadium to obtain the benefits of austenite grain size control (from niobium) and carbonitride precipitation (from vanadium).

Manganese is used in relatively large amounts (1.4 to 1.5%) in many microalloyed forging steels. It tends to reduce the cementite plate thickness while maintaining the interlamellar spacing of pearlite developed (Ref 19); thus, high manganese levels require lower carbon contents to retain the large amounts of pearlite required for high hardness. Manganese also provides substantial solid solution strengthening, enhances the solubility of vanadium carbonitrides, and lowers the solvus temperature for these phases.

The silicon content of most commercial microalloyed forging steels is about 0.30%; some grades contain up to 0.70% (Ref 20). Higher silicon contents are associated with significantly higher toughness, apparently because of an increased amount of ferrite relative to that formed in ferrite-pearlite steels with lower silicon contents.

Sulfur. Many microalloyed forging steels, particularly those destined for use in automotive forgings in which machinability is critical, have relatively high sulfur contents. The higher sulfur contents contribute to their machinability, which is comparable to that of quenched and tempered steels (Ref 21, 22).

Aluminum and Nitrogen. As in hardenable fine-grain steels, aluminum is important for austenite grain size control in microalloyed steels (Ref 19). The mechanism of aluminum grain size control is the formation of aluminum nitride particles. It has been shown that nitrogen is the major interstitial component of vanadium carbonitride (Ref 23). For this reason, moderate to high nitrogen contents are required in vanadium-containing microalloyed steels to promote effective precipitate strengthening.

Controlled Forging (Ref 24)

The concept of grain size control has been used for many years in the production of flat-rolled products. Particularly in plate rolling, the ability to increase austenite recrystallization temperature using small niobium additions is well known; the process used to produce these steels is usually referred to as controlled rolling (see the article "Flat, Bar, and Shape Rolling" in this Volume).

The benefits of austenite grain size control are not, of course, limited to flat-rolled products. Although the higher finishing temperatures required for rolling of bars limit the usefulness of this approach to microstructural control, finishing temperatures for microalloyed bar steels must nonetheless be controlled. It has been shown that, although strength is not significantly affected by finishing temperature, toughness of vanadium-containing microalloyed steels decreases with increasing finishing temperature (Ref 25, 26). This effect is shown in Fig. 12, which compares Charpy V-notch impact strength for a microalloyed 1541 steel finished at three temperatures. This detrimental effect of a high finishing temperature on impact toughness also carries over to forging operations, that is, the lower the finish temperature in forging, the higher the resulting toughness, and vice versa. After extensive testing, the investigators in Ref 26 recommended that finishing temperature for forging be reduced to near 1000 °C (1800 °F). Such treatment resulted in impact properties equal to or better than those of hot-rolled bar (Ref 26). The same investigators concluded that rapid induction preheating was beneficial for microalloyed forging steels, and that cost savings of 10% (for standard microalloyed forgings) to 20% (for resulfurized grades) were possible.

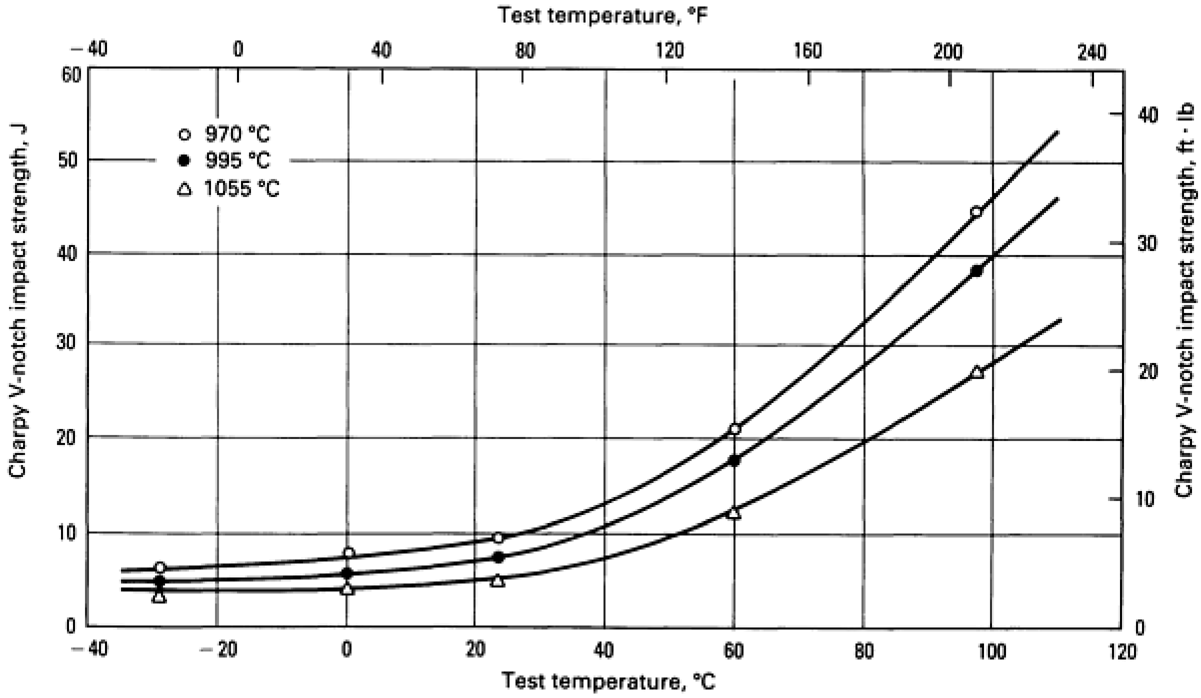

Fig. 12 Effect of hot finishing temperature on impact strength of microalloyed 1541 steel (AISI 1541 plus 0.10% V). Source: Ref 25.

Lower finishing temperatures, however, take their toll in terms of higher required forging pressures (and thus higher machine capacities needed) and increased die wear. The improved toughness resulting from lower finishing temperatures, as well as any cost savings that may be achieved as a result of the elimination of heat treatment, must be weighed against the cost increases caused by these factors.

Microalloyed Cold Heading Steels

Steels used in the production of high-strength fasteners by cold heading were previously produced from quenched and tempered alloy steels. To obtain sufficient strength with adequate ductility required six processing steps. Recent developments have led to the use of microalloyed niobium-boron steels that require no heat treatment (Ref 27). These steels make use of niobium and boron additions to develop bainitic structures with high work-hardening rates. In most cases they use the deformation of cold heading to achieve the required strength levels without heat treatment. Table 4 lists the compositions and selected properties of these materials.

Table 4 Compositions and selected properties of three microalloyed cold heading steels

Steel	**Nominal composition, %**	**Yield strength**		**Ultimate tensile strength**		**Elongation, %**	Reduction of area, %
		MPa	**ksi**	**MPa**	**ksi**		
Grade 1	Fe-0.20C-1.2Mn-25-50 ppm B	350	51	600	87	35	**68**

Forging of Stainless Steel

Revised by Thomas Harris and Eugene Priebe, Armco Inc.

Introduction

STAINLESS STEELS, based on forging pressure and load requirements, are considerably more difficult to forge than carbon or low-alloy steels, primarily because of the greater strength of stainless steels at elevated temperatures and the limitations on the maximum temperatures at which stainless steels can be forged without incurring microstructural damage. Forging load requirements and forgeability vary widely among stainless steels of different types and compositions; the most difficult alloys to forge are those with the greatest strength at elevated temperatures.

Forging Methods

Open-die, closed-die, upset and roll forging, and ring rolling are among the methods used to forge stainless steel. As in the forging of other metals, two of these methods are sometimes used in sequence to produce a desired shape.

Open-die forging (hand forging) is often used for smaller quantities for which the cost of closed dies cannot be justified and in cases in which delivery requirements dictate shortened lead times. Generally, products include round bars, blanks, hubs, disks, thick-wall rings, and square or rectangular blocks or slabs in virtually all stainless grades. Forged stainless steel round bar can also be produced to close tolerances on radial forge machines.

Although massive forgings are normally associated with open-die forging, most stainless steel open-die forgings are produced in the range of 10 to 900 kg (25 to 2000 lb). Additional information on product types is available in the article "Open-Die Forging" in this Volume.

Closed-die forging is extensively applied to stainless steel in order to produce blocker-type, conventional, and close-tolerance forgings. Selection from the above closed-die types invariably depends on quantity and the cost of the finished part. Additional information on these types of products is available in the article "Closed-Die Forging in Hammers and Presses" in this Volume.

Upset forging is sometimes the only suitable forging process when a large amount of stock is needed in a specific location of the workpiece. For many applications, hot upset forging is used as a preforming operation to reduce the number of operations, to save metal, or both when the forgings are to be completed in closed dies.

The rules that apply to the hot upset forging of carbon and alloy steels are also applicable to stainless steel; that is, the unsupported length should never be more than $2\frac{1}{2}$ times the diameter (or, for a square, the distance across flats) for single-blow upsetting. Beyond this length, the unsupported stock may buckle or bend, forcing metal to one side and preventing the formation of a concentric forging. Exceeding this limitation also causes grain flow to be erratic and nonuniform around the axis of the forging and encourages splitting of the upset on its outside edges. The size of an upset produced in one blow also should not exceed $2\frac{1}{2}$ diameters (or, for a square, $2\frac{1}{2}$ times the distance across flats). This varies to some extent, depending on the thickness of the upset. For extremely thin upsets, the maximum size may be only two diameters, or even less. Without reheating and multiple blows, it is not possible to produce an upset in stainless steel that is as thin or with corner radii as small as that which can be produced when a more forgeable metal such as carbon steel is being upset (see the article "Hot Upset Forging" in this Volume).

Roll forging can be used to forge specific products, such as tapered shafts. It is also used as a stock-gathering operation prior to forging in closed dies. Details on this process are available in the article "Roll Forging" in this Volume.

Ring rolling is used to produce some ringlike parts from stainless steel at lower cost than by closed-die forging. The techniques used are essentially the same as those for the ring rolling of carbon or alloy steel (see the article "Ring Rolling" in this Volume). More power is required to roll stainless steel, and it is more difficult to fill corners. A large ring mill capable of rolling carbon steel rings with a face height of 2 m (80 in.) can roll stainless steel rings up to about 1.25 m (50 in.) in height. Because stainless steel is more costly than carbon or alloy steel, the savings that result from using ring rolling are proportionately greater for stainless steel.

Ingot Breakdown

In discussing the forgeability of the stainless steels, it is critical to understand the types of primary mill practices available to the user of semifinished billet or bloom product.

Primary Forging and Ingot Breakdown. Most stainless steel ingots destined for the forge shop are melted by the electric furnace argon oxygen decarburization process. They will usually weigh between 900 and 13,500 kg (2000 to 30,000 lb), depending on the shop and the size of the finished piece. Common ingot shapes are round, octagonal, or fluted; less common ingot shapes include squares. Until recently, all of these ingots would have been top poured. Increasing numbers of producers are switching to the bottom-poured ingot process. This process is slightly more expensive to implement in the melt shop, but it more than pays for itself in extended mold life and greatly improved ingot surface.

Some stainless steel grades used in the aircraft and aerospace industries are double melted. The first melt is done with the electric furnace and argon oxygen decarburization, and these "electrodes" are then remelted by a vacuum arc remelting (VAR) or electroslag remelting (ESR) process. This remelting under a vacuum (VAR) or a slag (ESR) tends to give a much cleaner product with better hot workability. For severe forging applications, the use of remelt steels can sometimes be a critical factor in producing acceptable parts. These double-melted ingots are round in shape and will vary in diameter from 450 to 900 mm (18 to 36 in.), and in some cases, they weigh in excess of 11,000 kg (25,000 lb). The breakdown of ingots is usually done on large hydraulic presses (13,500 kN, or 1500 tonf). A few shops, however, still use large hammers, and the four-hammer radial forging machine is being increasingly used for ingot breakdown.

Heating is the single most critical step in the initial forging of ingots. The size of the ingot and the grade of the stainless steel will dictate the practice necessary to reduce thermal shock and to avoid unacceptable segregation levels. It is essential to have accurate and programmable control of the furnaces used to heat stainless steel ingots and large blooms.

Primary forging or breakdown of an ingot is usually achieved using flat dies. However, some forgers work the ingot down as a round using "V" or swage dies. Because of the high hot hardness of stainless steel and the narrow range of working temperatures for these alloys, light reductions, or saddening (an operation in which an ingot is given a succession of light reductions in a press or rolling-mill or under a hammer in order to break down the skin and overcome the initial fragility due to a coarse crystalline structure preparatory to reheating prior to heavier reductions), is the preferred initial step in the forging of the entire surface of the ingot.

After the initial saddening of the ingot surface is complete, normal reductions of 50 to 100 mm (2 to 4 in.) can be taken. If the chemistry of the heat is in accordance with specifications and if heating practices have been followed and minimum forging temperatures observed, no problems should be encountered in making the bloom and other semifinished product.

If surface tears occur, the forging should be stopped, and the workpiece conditioned. Some forgers use hot powder scarfing, but this presents environmental problems. The most common method is to grind out the defect. The ferritic, austenitic, and nitrogen-strengthened austenitic stainless steels can be air cooled, ground, and reheated for reforging. The martensitic and precipitation-hardening grades must be slow cooled and overaged before grinding and reheating. The ingot surface is important, and many producers find it advantageous to grind the ingots before forging to ensure good starting surfaces.

Billet and Bloom Product. Forgers buy bars, billets, or blooms of stainless steel for subsequent forging on hammers and presses. Forged stainless steel billet and bloom products tend to have better internal integrity than rolled product, especially with larger-diameter sections (>180 mm, or 7 in.). Correctly conditioned billet and bloom product should yield acceptable finished forgings if good heating practices are followed and if attention is paid to the minimum temperature requirements. Special consideration must be given to sharp corners and thin sections, because these tend to cool off very rapidly. Precautions should be taken when forging precipitation-hardening or nitrogen-strengthened austenitic grades.

Revised by Thomas Harris and Eugene Priebe, Armco Inc.

Forgeability

Closed-Die Forgeability. The relative forging characteristics of stainless steels can be most easily depicted through examples of closed-die forgings. The forgeability trends these examples establish can be interpreted in light of the grade, type of part, and forging method to be used.

Stainless steels of the 300 and 400 series can be forged into any of the hypothetical parts illustrated in Fig. 1. However, the forging of stainless steel into shapes equivalent to part 3 in severity may be prohibited by shortened die life (20 to 35% of that obtained in forging such a shape from carbon or low-alloy steel) and by the resulting high cost. For a given shape, die life is shorter in forging stainless steel than in forging carbon or low-alloy steel.

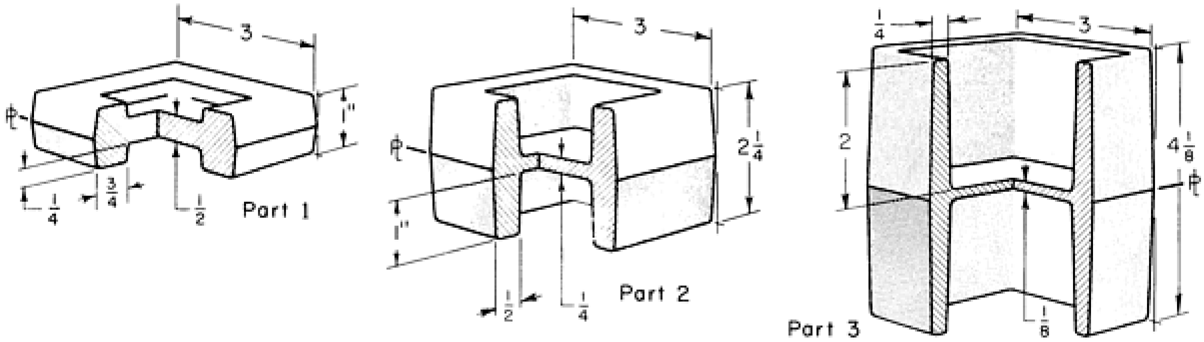

Fig. 1 Three degrees of forging severity. Dimensions given in inches.

Forgings of mild severity, such as part 1 in Fig. 1, can be produced economically from any stainless steel with a single heating and about five blows. Forgings approximating the severity of part 2 can be produced from any stainless steel with a single heating and about ten blows. For any type of stainless steel, die life in the forging of part 1 will be about twice that in the forging of part 2.

Part 3 represents the maximum severity for forging all stainless steels and especially those with high strength at elevated temperature; namely, types 309, 310, 314, 316, 317, 321, and 347. Straight-chromium types 403, 405, 410, 416, 420, 430, 431, and 440 are the easiest to forge into a severe shape such as part 3 (although type 440, because of its high carbon content, would be the least practical). Types 201, 301, 302, 303, and 304 are intermediate between the two previous groups.

One forge shop has reported that part 3 would be practical and economical to produce in the higher-strength alloys if the center web were increased from 3 to 6 mm ($\frac{1}{8}$ to $\frac{1}{4}$ in.) and if all fillets and radii were increased in size. It could then be forged with 15 to 20 blows and 1 reheating, dividing the number of blows about equally between the first heat and the reheat.

Hot Upsetting. Forgings of the severity represented by hypothetical parts 4, 5, and 6 in Fig. 2 can be hot upset in one blow from any stainless steel. However, the conditions are similar to those encountered in hot die forging. First, with a stainless steel, die wear in the upsetting of part 6 will be several times as great as in the upsetting of part 4. Second, die wear for the forming of any shape will increase as the elevated-temperature strength of the alloy increases. Therefore, type 410, with about the lowest strength at high temperature, would be the most economical stainless steel for forming any of the parts, particularly part 6. Conversely, type 310 would be the least economical.

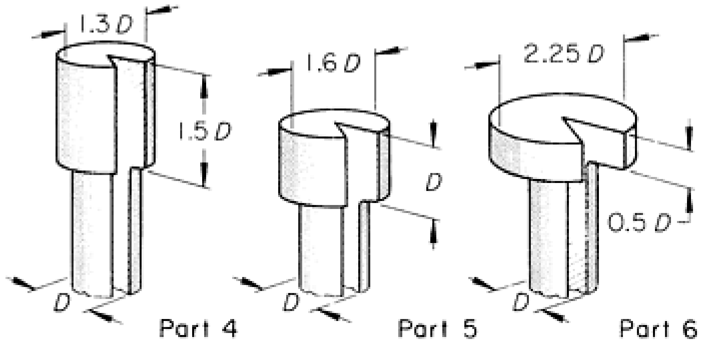

Fig. 2 Three degrees of upsetting severity.

Upset Reduction Versus Forging Pressure. The effect of percentage of upset reduction (upset height versus original height) on forging pressure for low-carbon steel and for type 304 stainless steel at various temperatures is illustrated in Fig. 3. Temperature has a marked effect on the pressure required for any given percentage of upset, and at any given forging temperature and percentage of upset, type 304 stainless requires at least twice the pressure required for 1020 steel.

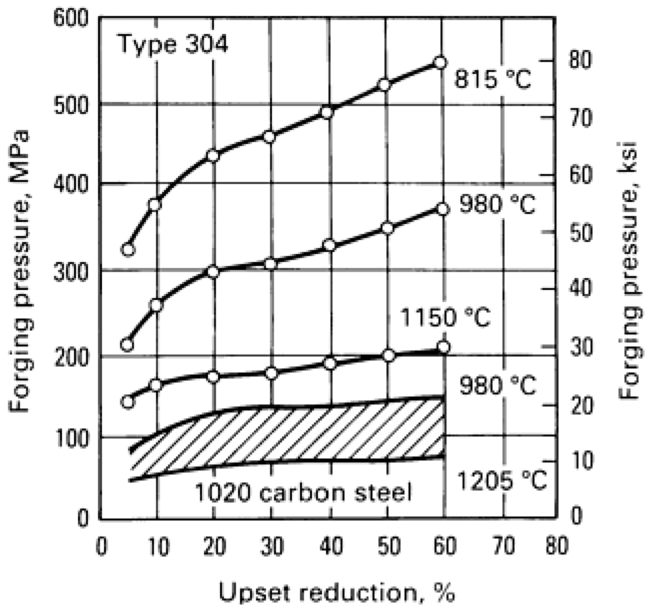

Fig. 3 Effect of upset reduction on forging pressure for various temperatures. Source: Ref 1.

The effects of temperature on forging pressure are further emphasized in Fig. 4(a). These data, based on an upset reduction of 10%, show that at 760 °C (1400 °F) type 304 stainless steel requires only half as much pressure as A-286 (an iron-base heat-resistant alloy), although the curves for forging pressure for the two metals converge at 1100 °C (2000 °F). However, at a forging temperature of 1100 °C (2000 °F), the pressure required for a 10% upset reduction on type 304 is more than twice that required for a carbon steel (1020) and about 60% more than that required for 4340 alloy steel. Differences in forgeability, based on percentage of upset reduction and forging pressure for type 304 stainless steel, 1020, and 4340 at the same temperature (980 °C, or 1800 °F), are plotted in Fig. 4(b).

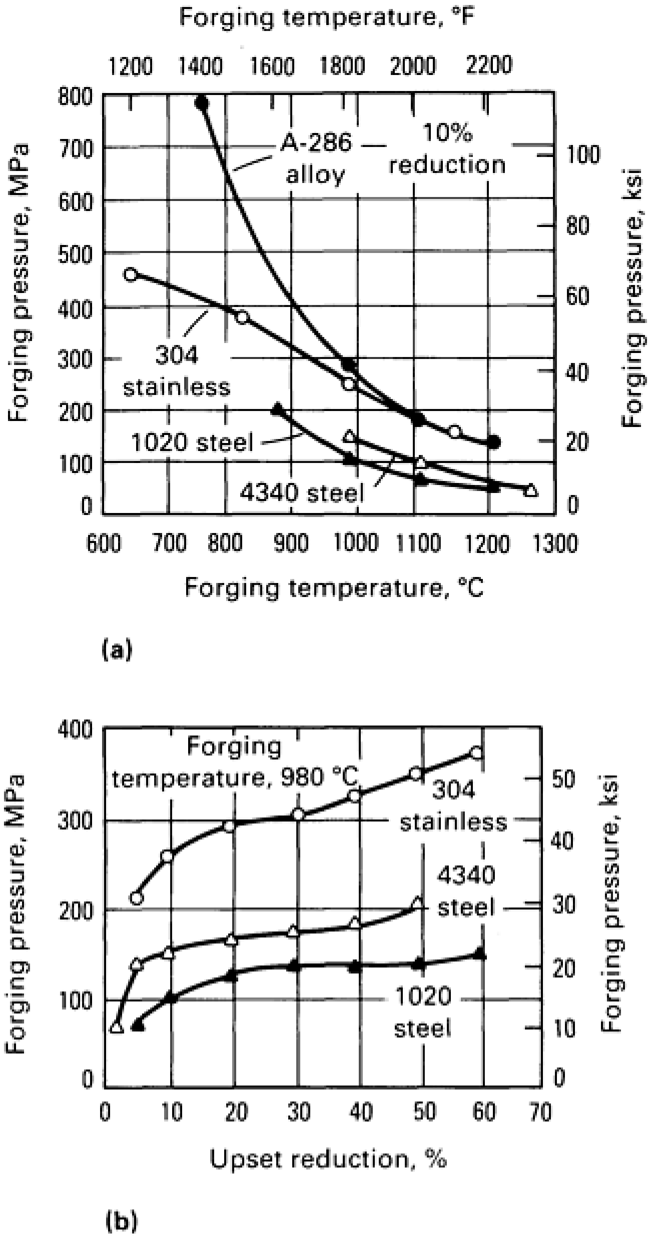

Fig. 4 Forging pressure required for upsetting versus (a) forging temperature and (b) percentage of upset reduction. Source: Ref 2.

Forging of Stainless Steel

Revised by Thomas Harris and Eugene Priebe, Armco Inc.

Austenitic Stainless Steels

The austenitic stainless steels are more difficult to forge than the straight-chromium types, but are less susceptible to surface defects. Most of the austenitic stainless steels can be forged over a wide range of temperatures above 930 °C (1700 °F), and because they do not undergo major phase transformation at elevated temperature, they can be forged at higher temperatures than the martensitic types (Table 1). Exceptions to the above statements occur when the composition of the austenitic stainless steel promotes the formation of δ-ferrite, as in the case of the 309S, 310S, or 314 grades. At temperatures above 1100 °C (2000 °F), these steels, depending on their composition, may form appreciable amounts of δ-ferrite. Figure 5 depicts these compositional effects in terms of nickel equivalent (austenitic-forming elements) and chromium equivalent. Delta-ferrite formation adversely affects forgeability, and compensation for the amount of ferrite present can be accomplished with forging temperature restrictions.

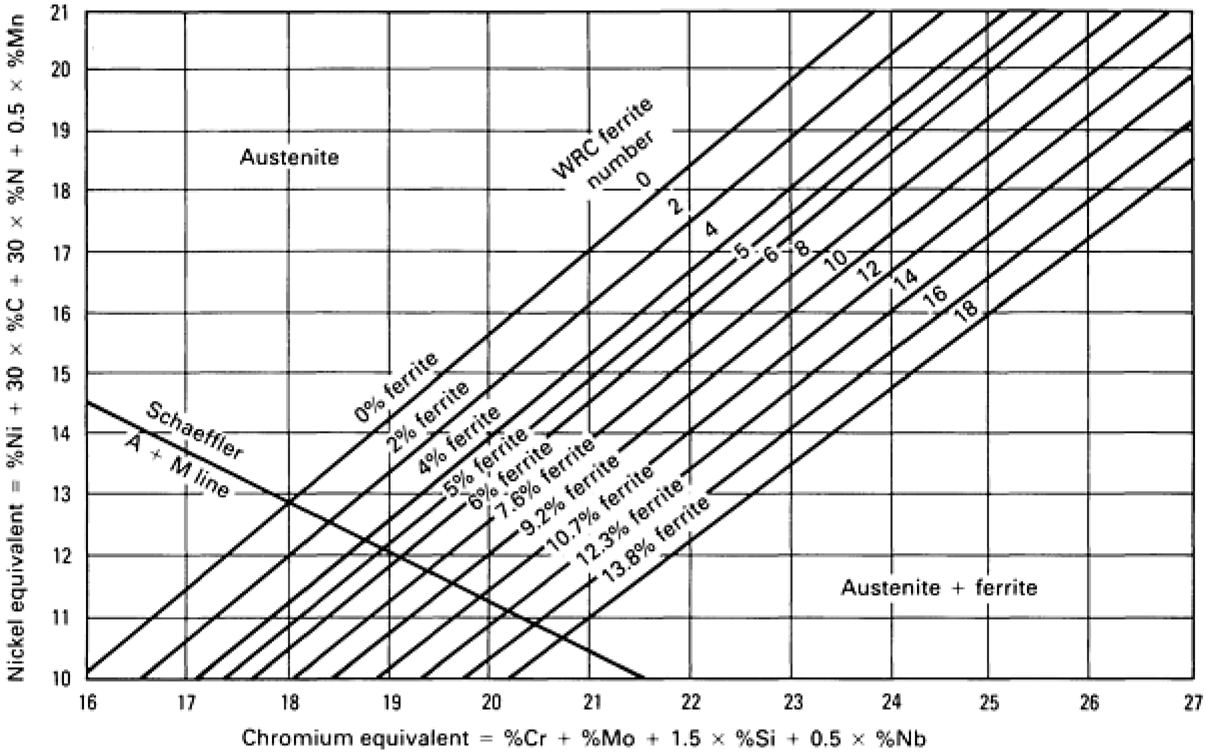

Fig. 5 Schaeffler (constitution) diagram used to predict the amount of δ-ferrite that will be obtained during elevated-temperature forging or welding of austenitic/ferritic stainless steels. A, austenite; M, martensite. WRC, Welding Research Council. Source: Ref 4.

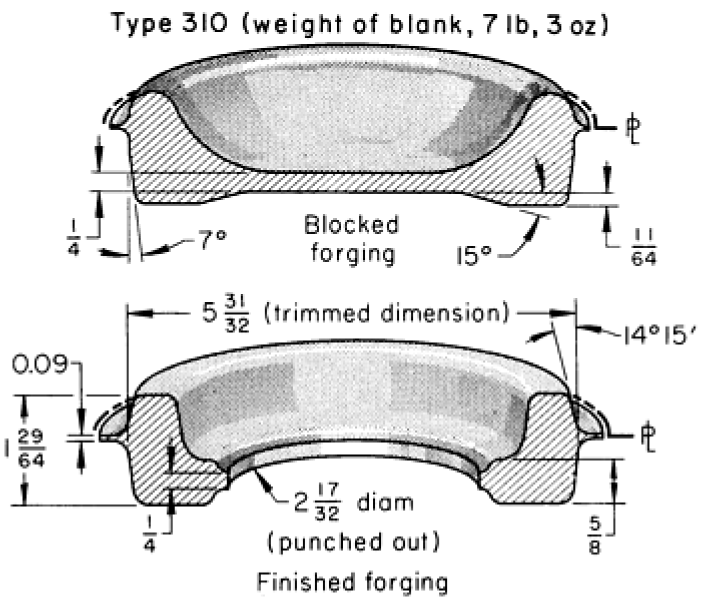
Equally important restrictions in forging the austenitic stainless steels apply to the finishing temperatures. All but the stabilized types (321, 347, 348) and the extralow-carbon types should be finished at temperatures above the sensitizing range (~815 to 480 °C, or 1500 to 900 °F) and cooled rapidly from 870 °C (1600 °F) to a black heat. The highly alloyed grades, such as 309, 310, and 314, are also limited with regard to finishing temperature, because of their susceptibility at lower temperatures to hot tearing and σ formation. A final annealing by cooling rapidly from about 1065 °C (1950 °F) is generally advised for nonstabilized austenitic stainless steel forgings in order to retain the chromium carbides in solid solution.

Finishing temperatures for austenitic stainless steels become more critical where section sizes increase and ultrasonic testing requirements are specified. During ultrasonic examination, coarse-grain austenitic stainless steels frequently display sweep noise that can be excessive due to a coarse-grain micro-structure. The degree of sound attenuation normally increases with section size and may become too great to permit detection of discontinuities. Careful control of forging conditions, including final forge reductions of at least 5%, can assist in the improvement of ultrasonic penetrability.

A typical procedure for the hammer forging of one of the more difficult-to-forge austenitic steels (type 310) is given in the following example.

Example 1: Forging a Ringlike Part From Type 310 Steel.

The ringlike part shown in Fig. 6 was forged in a 13,500 N (3000 lbf) steam hammer by upsetting a piece of round bar and completing the shape in one blocking and one finishing impression. Because of its small size and symmetrical shape, the workpiece could be handled rapidly and completed without reheating. The effect of forging severity, however, is reflected in the short die life. Die life and other forging details are given in the table in Fig. 6.



Sequence of operations
Upset on flat portion of die to approximately 115 mm (4 $\frac{1}{2}$ in.) in diameter. Forge in blocker impression. Forge in finisher impression. Hot trim (900 to 925 °C, or 1650 to 1700 °F) and punch out center. Air cool. Clean (shot blast)

Processing conditions	
Blank preparation	**Cold sawing**
Stock size	**90 mm (3 $\frac{1}{2}$ in.) in diameter**
Blank weight	**3.25 kg (7 lb, 3 oz)**
Heating method	**Gas-fired, slot-front box furnace**
Heating time	**1 h**

Atmosphere	**Slightly oxidizing**
Die material	**6G at 388-429 HB[(a)]**
Die life, total	**507-2067 forgings[(b)]**
Die lubricant	**Graphite-oil**
Production rate	**50 forgings per hour[(c)]**

(a) Inserts at this hardness were used in die blocks of the same material, but softer (341-375 HB).

(b) Average life was 1004 forgings. Life to rework and total life were the same, because worn die inserts were not reworked.

(c) Based on a 50 min working hour

Fig. 6 Typical procedure for forging a ringlike part from an austenitic stainless steel. Dimensions given in inches.

The stabilized or extralow-carbon austenitic stainless steels, which are not susceptible to sensitization, are sometimes strain hardened by small reductions at temperatures well below the forging temperature. Strain hardening is usually accomplished at 535 to 650 °C (1000 to 1200 °F) (referred to as warm working or hot-cold working). When minimum hardness is required, the forgings are solution annealed.

Sulfur or selenium can be added to austenitic stainless steel to improve machinability. Selenium, however, is preferred because harmful stringers are less likely to exist. Type 321, stabilized with titanium, may also contain stringers of segregate that will open as surface ruptures when the steel is forged. Type 347, stabilized with niobium, is less susceptible to stringer segregation and is the stabilized grade that is usually specified for forgings.

When heating the austenitic stainless steels, it is especially desirable that a slightly oxidizing furnace atmosphere be maintained. A carburizing atmosphere or an excessively oxidizing atmosphere will impair corrosion resistance, either by harmful carbon pickup or by chromium depletion. In types 309 and 310, chromium depletion can be especially severe.

Nitrogen-strengthened austenitic stainless steels are iron-base alloys containing chromium and manganese. Varying amounts of nickel, molybdenum, niobium, vanadium, and/or silicon are also added to achieve specific properties. Nitrogen-strengthened austenitic stainless steels provide high strength, excellent cryogenic properties and corrosion resistance, low magnetic permeability (even after cold work or subzero temperature), and higher elevated-temperature strengths as compared to the 300 series stainless steels. These alloys are summarized as follows:

- UNS S24100 (Nitronic 32) ASTM XM-28. High work hardening while remaining nonmagnetic plus twice the yield strength of type 304 with equivalent corrosion resistance
- UNS S24000 (Nitronic 33) ASTM XM-29. Twice the yield strength of type 304, low magnetic permeability after severe cold work, high resistance to wear and galling as compared to standard austenitic stainless steels, and good cryogenic properties
- UNS S21904 (Nitronic 40) ASTM XM-11. Twice the yield strength of type 304 with good corrosion resistance, low magnetic permeability after severe cold working, and good cryogenic properties
- UNS S20910 (Nitronic 50)ASTM XM-19. Corrosion resistance greater than type 316L with twice the

yield strength, good elevated and cryogenic properties, and low magnetic permeability after severe cold work

- UNS S21800 (Nitronic 60). Galling resistance with the corrosion resistance equal to that of type 304 and with twice the yield strength, good oxidation resistance, and cryogenic properties

A forgeability comparison, as defined by dynamic hot hardness, is provided in Fig. 7.

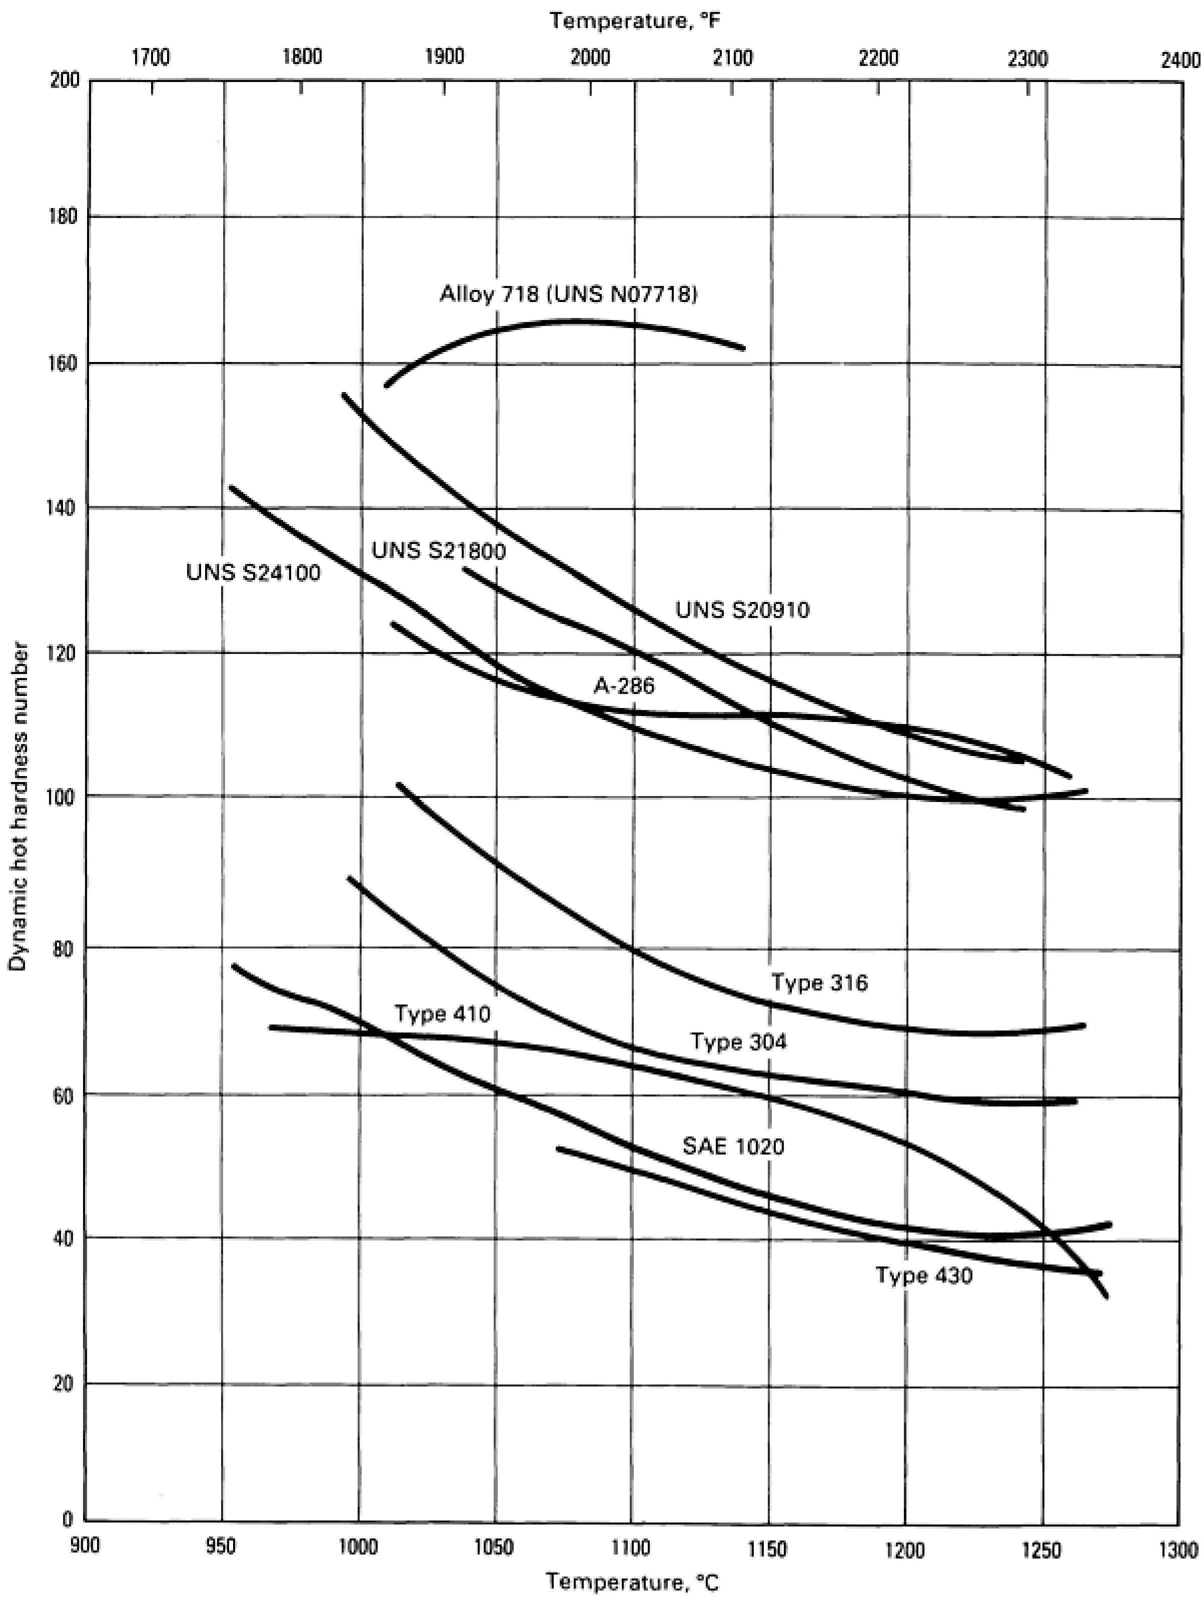


Fig. 7 Comparative dynamic hot hardness versus temperature (forgeability) for various ferrous alloys.

Martensitic Stainless Steels

Martensitic stainless steels have high hardenability to the extent that they are generally air hardened. Therefore, precautions must be taken in cooling forgings of martensitic steels, especially those with high carbon content, in order to prevent cracking. The martensitic alloys are generally cooled slowly to about 590 °C (1100 °F), either by burying in an insulating medium or by temperature equalizing in a furnace. Direct water sprays, such as might be employed to cool dies, should be avoided, because they would cause cracking of the forging.

Forgings of the martensitic steels are often tempered in order to soften them for machining. They are later quench hardened and tempered.

Maximum forging temperatures for these steels are low enough to avoid the formation of δ-ferrite. If δ-ferrite stringers are present at forging temperatures, cracking is likely to occur. Delta-ferrite usually forms at temperatures from 1095 to 1260 °C (2000 to 2300 °F). Care must be exercised so as not to exceed this temperature during forging and to avoid rapid metal movement that might result in local overheating. Surface decarburization, which promotes ferrite formation, must be minimized.

The δ-ferrite formation temperature decreases with increasing chromium content, and small amounts of δ-ferrite reduce forgeability significantly. As the δ-ferrite increases above about 15% (Fig. 5), forgeability improves gradually until the structure becomes entirely ferritic. Finishing temperatures are limited by the allotropic transformation, which begins near 815 °C (1500 °F). However, forging of these steels is usually stopped at about 925 °C (1700 °F), because the metal is difficult to deform at lower temperatures.

Sulfur or selenium can be added to type 410 to improve machinability. These elements can cause forging problems, particularly when they form surface stringers that open and form cracks. This can sometimes be overcome by adjusting the forging temperature or the procedure. With sulfur additions, it may be impossible to eliminate all cracking of this type. Therefore, selenium additions are preferred.

Revised by Thomas Harris and Eugene Priebe, Armco Inc.

Ferritic Stainless Steels

The ferritic straight-chromium stainless steels exhibit virtually no increase in hardness upon quenching. They will work harden during forging; the degree of work hardening depends on the temperature and the amount of metal flow. Cooling from the forging temperature is not critical.

The ferritic stainless steels have a broad range of forgeability, which is restricted somewhat at higher temperature because of grain growth and structural weakness but is closely restricted in finishing temperature only for type 405. Type 405 requires special consideration because of the grain-boundary weakness resulting from the development of a small amount of austenite. The other ferritic stainless steels are commonly finished at any temperature down to 705 °C (1300 °F). For type 446, the final 10% reduction should be made below 870 °C (1600 °F) to achieve grain refinement and room-temperature ductility. Annealing after forging is recommended for ferritic steels.

Precipitation-Hardening Stainless Steels

The semiaustenitic and martensitic precipitation-hardening stainless steels can be heat treated to high hardness through a combination of martensite transformation and precipitation. They are the most difficult to forge and will crack if temperature schedules are not accurately maintained. The forging range is narrow, and the steel must be reheated if the temperature falls below 980 °C (1800 °F). They have the least plasticity (greatest stiffness) at forging temperature of any of the classes and are subject to grain growth and δ-ferrite formation. Heavier equipment and a greater number of blows are required to achieve metal flow equivalent to that of the other types.

During trimming, the forgings must be kept hot enough to prevent the formation of flash-line cracks. To avoid these cracks, it is often necessary to reheat the forgings slightly between the finish-forging and trimming operations. Cooling, especially the cooling of the martensitic grades, must be controlled to avoid cracking.

Forging of Stainless Steel

Revised by Thomas Harris and Eugene Priebe, Armco Inc.

Forging Equipment

Stainless steels are generally forged with the same types of hammers, presses, upsetters, and rolling machines used to forge carbon and alloy steels. Descriptions of these machines are provided in the articles "Hammers and Presses for Forging," "Hot Upset Forging," "Roll Forging," and "Ring Rolling" in this Volume.

Hammers. Simple board-type gravity-drop hammers are not extensively used for the forging of stainless steel, because of their low capacity and because greater control is obtained with other types of equipment. Power-drop hammers (steam or air) are widely used for open-die forgings, as well as for all types of large and small closed-die forgings. The service life of the die is usually longer in hammers than in hydraulic presses; in a hammer, the hot workpiece is in contact with the dies (particularly the upper die) for a shorter length of time. Hammers cost less than presses of equivalent capacity and are generally more flexible than presses in the variety of functions they can fulfill.

Presses. Mechanical presses are extensively used for small forgings; they are used less often for forgings weighing as much as 45 kg (100 lb) each and are seldom used for forgings weighing more than 70 kg (150 lb). Mechanical presses cost more than hammers of equivalent capacity, but they require less operator skill and can produce forgings at a higher rate than hammers.

Hydraulic presses can be used for all steps in the forging of stainless steel. However, they are more often used to complete intricate forgings after preforming in other types of equipment. Die life is usually shorter in a hydraulic press than in a hammer; in a press, the work metal contacts the dies for a longer period of time. However, there is less danger of local overheating of the metal in hydraulic presses, because their action is slower than that of hammers.

Radial Forging Machines. Another tool that is increasing in use is the radial forging machine. This is a precision four-hammer forging machine that is capable of forging all grades of stainless steel into round, rectangular, square, and octagonal shapes. Different cross sections on the same piece are possible including the forging of complicated step-down shafts.

The machine uses four axial symmetrical hammers, which are in opposing pairs and are electromechanically controlled by a pre-programmed processor, that simultaneously deliver 200 blows per minute to the work. Two hydraulically controlled manipulators, one in each side of the hammer box, rotate and position the workpiece during forging.

Each hammer delivers up to approximately 9000 kN (1000 tonf) of force per blow, depending on the size of the machine. As a result of the counter-blow configuration, the workpiece receives enough energy so that isothermal reductions are possible, an advantage in the forging of grades with narrow hot-working ranges. The piece loses very little temperature during forging and sometimes actually increases in temperature. Therefore, everything is finished in one heat. The feed and rotation motions of the chuck head are synchronized with the hammers to prevent twisting or stretching during forging.

In operation, the manipulator or chuck head on the entry side of the hammer box positions the workpiece between the four hammers and supports it until the length is increased so as to be grasped by the manipulator or chuck head at the exit side. Forging then continues in a back and forth mode until the desired finished cross section is achieved. At the end of each forging pass, the trailing manipulator relinquishes its grip so that the end receives the same reduction as the rest of the workpiece. This results in uniformity in mechanical properties as well as dimensions. In general, experience with the radial forging machine indicates an oversize of 0.015 times the cold-finish dimension and typical tolerances for hot-forged products to be approximately one-half the ASTM A 484 or one-fourth the DIN 7527 standards.

Forging of Stainless Steel

Revised by Thomas Harris and Eugene Priebe, Armco Inc.

Dies

In most applications, dies designed for the forging of a given shape from carbon or alloy steel can be used to forge the same shape from stainless steel. However, because of the greater force used in forging stainless steel, more strength is required in the die. Therefore, the die cannot be resunk as many times for the forging of stainless steel, because it may break. When a die is initially designed for the forging of stainless steel, a thicker die block is ordinarily used in order to obtain a greater number of resinkings and therefore a longer total life. Die practice for the forging of stainless steel varies considerably among different plants, depending on whether forging is done in hammers or presses and on the number of forgings produced from other metals in proportion to the number forged from stainless steel.

Multiple-cavity dies for small forgings (less than about 10 kg, or 25 lb) are more commonly used in hammers and less commonly used in presses. If multiple-cavity dies are used, the cavities are usually separate inserts, because some cavities have longer service lives than others. With this practice, individual inserts can be changed as required. Larger forgings (more than about 10 kg, or 25 lb) are usually produced in single-cavity dies, regardless of whether a hammer or a press is used.

In forge plants in which carbon and alloy steels comprise the major portion of the metals forged, the usual practice is to use the same die system (single-cavity versus multiple-cavity) for stainless steel, accepting the fact that die life will be shorter. This approach is generally more economical than using a separate die practice for a relatively small tonnage of forgings.

Practice is likely to be entirely different in shops in which most of the forgings produced are from stainless steel or from some other difficult-to-forge metal, such as heat-resistant alloys. For example, in one plant in which mechanical presses are used almost exclusively, most of the dies are of the single-cavity design. Tolerances are always close, so practice is the same regardless of the quantity to be produced. A die is made with a finishing cavity, and after it is worn to the extent that it can no longer produce forgings to specified tolerances, the cavity is recut for a semifinishing, or blocker, cavity. When it can no longer be used as a blocker die, its useful life is over because resinking would result in a thin die block.

Die Materials. In shops in which die practice is the same for stainless steel as for carbon and alloy steels, die materials are also the same (see the article "Dies and Die Materials for Hot Forging" in this Volume). In shops in which special consideration is given to dies for stainless steel, small dies (for forgings weighing less than 9 kg, or 20 lb) are made solid from hot-work tool steel, such as H11, H12, or H13. For large dies, regardless of whether they are single or multiple impression, common practice is to make the body of the block from a conventional die block low-alloy steel, such as 6G or 6F2 (see the article "Dies and Die Materials for Hot Forging" in this Volume). Inserts are of H11, H12, or H13 hot-work tool steel (or sometimes H26, where it has proved a better choice). In many specialty applications, nickel- and cobalt-base superalloys are fabricated for die inserts on conventional hot-work tool steel dies. Welded inlays of these alloys are also being used in critical areas for improved wear resistance and much higher hot strength.

Gripper dies and heading tools used for the hot upsetting of stainless steel are made from one of the hot-work tool steels. Small tools are machined from solid tool steel. Larger tools are made by inserting hot-work tool steels into bodies of a lower-alloy steel, such as 6G or 6F2.

Roll dies for roll forging are usually of the same material used for the roll forging of carbon or alloy steels. A typical die steel composition is Fe-0.75C-0.70Mn-0.35Si-0.90Cr-0.30Mo.

Die hardness depends mainly on the severity of the forging and on whether a hammer or a press is used. Die wear decreases rapidly as die hardness increases, but some wear resistance must always be sacrificed for the sake of toughness and to avoid breaking the dies.

Most solid dies (without inserts) made from such steels as 6G and 6F2 for use in a hammer are in the hardness range of 36.6 to 40.4 HRC. This range is suitable for forgings as severe as part 3 in Fig. 1. If severity is no greater than that of part 1 in Fig. 1, die hardness can be safely increased to the next level (41.8 to 45.7 HRC). If forging is done in a press, the dies can be safely operated at higher hardnesses for the same degree of forging severity. For example, dies for forgings of maximum severity would be 41.8 to 45.7 HRC, and dies for minimum severity would be 47.2 to 50.3 HRC.

Inserts or solid dies made from hot-work tool steel are usually heat treated to 40 to 47 HRC for use in hammers. For forgings of maximum severity (part 3, Fig. 1), hardness near the low end of the range is used. For minimum severity (part 1, Fig. 1), die hardness will be near the high end of the range. Adjustment in die hardness for different degrees of forging severity is usually also needed for forging in presses, although a higher hardness range (usually 47 to 55 HRC) can be safely used.

The hardness of gripper-die inserts for upset forging is usually 44 to 48 HRC. For the heading tools, hardness is 48 to 52 HRC.

Roll-forging dies are usually heat treated to 50 to 55 HRC. Rolls for ring rolling, when made from hot-work tool steel, are usually operated in the hardness range of 40 to 50 HRC.

Die Life. Because of the differences in forgeability among stainless steels, die life will vary considerably, depending on the composition of the metal being forged and the composition and hardness of the die material. Other conditions being equal, the forging of types 309, 310, and 314 stainless steel and the precipitation-hardening alloys results in the shortest die life. The longest die life is obtained when forging lower-carbon ferritic and martensitic steels. Die life in forging type 304 stainless steel is usually intermediate. However, die life in forging any stainless steel is short compared to the die life obtained in forging the same shape from carbon or alloy steel.

Example 2: Die Life in the Upset Forging of Type 304 versus 4340 versus 9310.

The 100 mm (4 in.) upset shown in Fig. 8 was, at different times, produced from three different metals in the same 150 mm (6 in.) upsetter and in the same gripper dies (H12 hot-work tool steel at 44 HRC). From the bar chart shown in Fig. 8, the effect of work metal composition on die life is obvious. Die life for upsetting type 304 stainless steel was less than one-fifth the die life for upsetting the low-carbon alloy steel (9310) and less than one-third that for upsetting 4340.

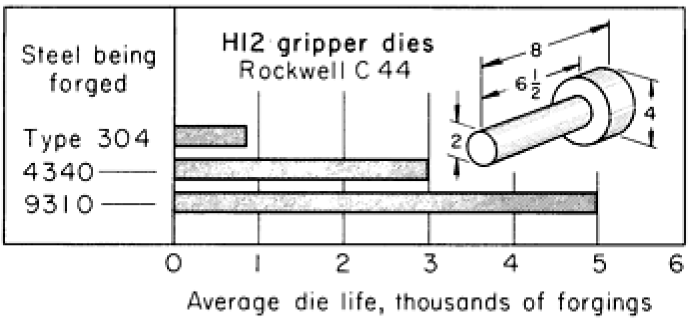

Fig. 8 Effect of steel being forged on the life of gripper dies in upsetting. Dimensions given in inches.

Example 3: Effect of Forging Severity on Die Life.

The effect of the forging shape (severity) on die life for forging type 431 stainless steel is shown in Fig. 9. When forging to the relatively mild severity of shape A, the range of life for five dies was 6000 to 10,000 forgings, with an average of 8000. When forging severity was increased to that of shape B, the life of three dies ranged from approximately 700 to 2200 forgings, with an average of 1400.

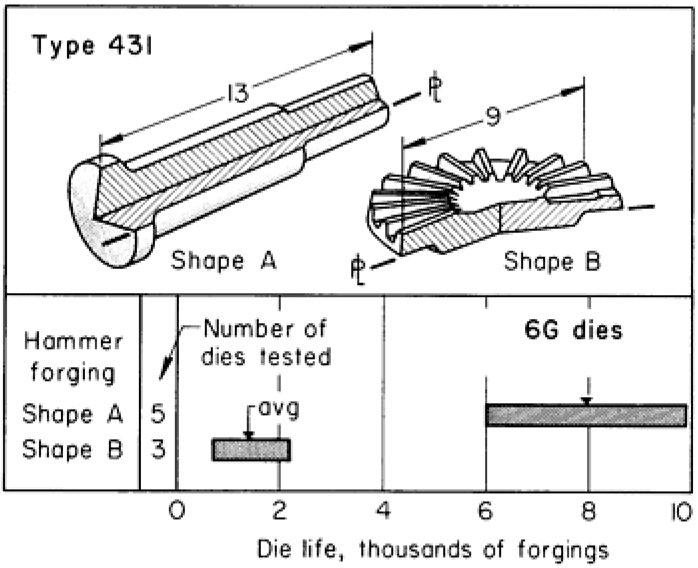

Fig. 9 Effect of severity of forging on die life. Dies: 341-375 HB. Dimensions given in inches.

Shapes A and B were both forged in the same hammer. Tool material and hardness were also the same for both shapes (6G die block steel at 341 to 375 HB).

Forging of Stainless Steel

Revised by Thomas Harris and Eugene Priebe, Armco Inc.

Heating for Forging

Recommended forging temperatures for most of the standard stainless steels are listed in Table 1. The thermal conductivity of stainless steels is lower than that of carbon or low-alloy steels. Therefore, stainless steels take longer to reach the forging temperature. However, they should not be soaked at the forging temperature, but should be forged as soon as possible after reaching it. The exact time required for heating stock of a given thickness to the established forging temperature depends on the type of furnace used. Time and stock thickness relationships for three types of furnaces are shown in Fig. 10.

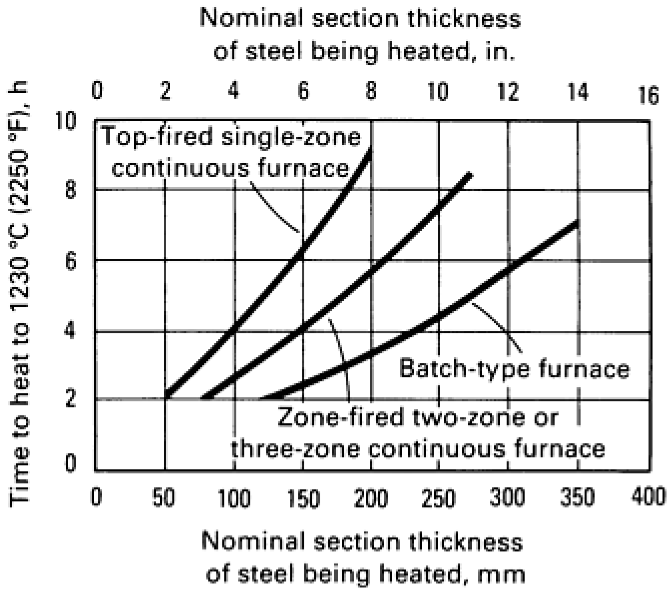

Fig. 10 Effect of section thickness on time for heating stainless steel in various types of furnaces. Source: Ref 5.

The preheating of forging stock will be dictated by the grade, size, and condition of the stock to be forged. Austenitic and ferritic grades, for example, are generally considered safe from thermal shock and can be charged directly into hot furnaces. Certain martensitic grades and precipitation-hardening grades should be preheated, with the preheat temperatures in the range of 650 to 925 °C (1200 to 1700 °F), depending on section size and the condition of the material.

Section sizes larger than 150 × 150 mm (6 × 6 in.) require consideration, because the rapid heating of larger sections will result in differential expansion that could locally exceed the tensile strength of the interior of the section. The resulting internal crack, frequently termed klink, will often open transversely upon further reductions. Generally, the greater the ability of the stainless grade to be hardened to high hardness levels, the more susceptible it is to thermal shock.

The physical condition of the stainless steel must also be taken into consideration. Cast material (that is, ingot or continuous cast) will be more susceptible to thermal shock than semiwrought or wrought product.

Equipment. Gas-fired and electric furnaces are used with equal success for heating the stock. Gas-fired furnaces are more widely used, because heating costs are usually lower. The gas employed should be essentially free from hydrogen sulfide and other sulfur-bearing contaminants. Oil-fired furnaces are widely used for heating the 400-series stainless steels and the 18-8 varieties, but because of the danger of contamination from sulfur in the oil, they are considered unsafe for heating the high-nickel grades. Trace amounts of vanadium present in the fuel oil can also cause surface problems because the resulting vanadium oxide will fuse with the high chrome scale.

Although not absolutely necessary, heating of stainless steel is preferably done in a protective atmosphere. When gas heating is used, an acceptable protective atmosphere can usually be obtained by adjusting the fuel-to-air ratio. When the furnace is heated by electricity, the protective atmosphere (if used) must be separately generated. Induction heating is most often used to heat local portions of the stock for upsetting.

Temperature control within ±5 °C (10 °F) is achieved by the use of various types of instruments. A recording instrument is preferred, because it enables the operator to observe the behavior of the furnace throughout the heating cycle.

It is recommended that the temperature of the pieces of forging stock be checked occasionally with an optical or probe-type pyrometer as the pieces are removed from the furnace. This practice not only provides a check on the accuracy of the furnace controls but also ensures that the stock is reaching the furnace temperature.

Control of Cooling Rate. Cooling from the forging operations should also be considered in terms of grade and size. Austenitic grades are usually quenched from the forge. This is done to minimize the formation of intergranular chromium carbides and to facilitate cutting and machining after forging. Because martensitic grades are characterized by high hardenability, special precautions are taken in cooling them from forging temperatures. Common practice is to place hot forgings in insulating materials for slow cooling. For parts that have either heavy sections or large variation in section, it is often desirable to charge the forged parts into an annealing furnace immediately after forging.

In particular, the higher-carbon grades, such as 440A, 440B, and 440C, and the modified 420 types, such as UNS 41800 (ASTM A565, Grade 615), must be carefully slow cooled after forging. These steels often require furnace-controlled interrupted cooling cycles to ensure against cracks. A suitable cycle consists of air cooling the forgings to temperatures at which the martensite transformation is partially complete (between 150 and 250 °C, or 300 and 500 °F), then reheating the forgings in a furnace at a temperature of about 650 °C (1200 °F) before final cooling to room temperature. This procedure also prevents the formation of excessive grain-boundary carbides, which sometimes develop during continuous slow cooling.

The control cooling of 17-4 PH, 15-5 PH, and PH 13-8 Mo grades after forging must also be considered. These grades are austenitic upon cooling from forging or solution-treating temperatures until a temperature of approximately 120 to 150 °C (250 to 300 °F) is reached. At this temperature, transformation to martensite begins; this transformation is not complete until the piece has reached approximately 30 °C (90 °F) for 17-4 PH and 15-5 PH and 15 °C (60 °F) for PH 13-8 Mo. Cooling in this transformation range should be as uniform as possible throughout the cross section of the piece to prevent thermal cracking.

Upon completion of the forging of precipitation hardening grades, sections less than 75 mm (3 in.) in thickness should be air cooled to between 30 and 15 °C (90 and 60 °F) before any further processing. Intricate forgings should first be equalized for a short period of time (30 min to 1 h, depending on size) in the temperature range of 1040 °C (1900 °F) to the forging temperature. The part can then be allowed to air cool to between 30 and 15 °C (90 and 60 °F). This equalization relieves forging stresses and improves temperature uniformity on the part. Nonuniformity in cooling may promote cracking. Forgings that are more than 75 mm (3 in.) in section, after equalizing, should be air cooled until dull red or black, covered immediately and completely on all sides with a light gage metal cover (do not use galvanized) or thin ceramic thermal sheeting, then allowed to cool undisturbed to between 30 and 15 °C (90 and 60 °F). Cooling should be done in areas that are free from drafts and away from furnaces where temperatures in the surrounding area are above 30 °C (90 °F). The covered, cooling steel should not be placed too near other large forged sections that have been cooled or are practically cooled, because this can interfere with the uniformity of the cooling.

Furnace cooling of 17-4 PH and 15-5 PH large or intricate sections may be desirable in cold weather. This extends the cooling time considerably, but if necessary, the heated forgings should be air cooled to approximately 315 to 370 °C (600 to 700 °F), charged into a furnace, and equalized at that temperature. The furnace is then shut off, and the furnace and forgings should be allowed to cool to room temperature.

Revised by Thomas Harris and Eugene Priebe, Armco Inc.

Heating of Dies

Dies are always heated for the forging of stainless steel. Large dies are heated in ovens; small dies, by burners of various design.

There is no close agreement among forge shops on the maximum die temperature that should be maintained, although it is generally agreed that 150 °C (300 °F) should be the minimum temperature. A range of 150 to 205 °C (300 to 400 °F) is common. Dies are sometimes heated to 315 °C (600 °F). Die temperature is determined by means of temperature-sensitive crayons or surface pyrometers.

Die Lubrication

Dies should be lubricated before each blow. For forging in shallow impressions, a spray of colloidal graphite in kerosene or in low-viscosity mineral oil is usually adequate. Ordinarily, dies are sprayed manually, but in press forging, automatic sprays timed with the press stroke are sometimes used. For deeper cavities, however, it is often necessary to use a supplemental spray (usually manual) to reach the deep areas of the cavity or to swab the cavity with a conventional forging oil. Forging oils are usually mixtures of oil and graphite; the oil should be free of lead and sulfur. Forging oils are often purchased as greases and are then diluted with mineral oil to the desired viscosity. Any volatile lubricant should be used sparingly. With even a slight excess, vapor explosions are likely, and greater amounts can cause explosions that will eject the workpiece, possibly injuring personnel.

Glass is sometimes used as a lubricant or billet coating in press forging. The glass is applied by dipping the heated forging in molten glass or by sprinkling the forging with glass frit. Glass is an excellent lubricant, but its viscosity must be compatible with the forging temperature used. For optimal results, the viscosity of the glass should be maintained at 10 Pa · s (100 cP). Therefore, when different forging temperatures are used, a variety of glass compositions must be stocked. Another disadvantage of glass is that it will accumulate in deep cavities, solidify, and impair metal flow. Therefore, the use of glass is generally confined to shallow forgings that require maximum lateral flow.

Forging of Stainless Steel

Revised by Thomas Harris and Eugene Priebe, Armco Inc.

Trimming

When production quantities justify the cost of tools, forgings are trimmed in dies. Hot trimming is preferred for all types of stainless steel, because less power is required and because there is less danger of cracking than in cold trimming. The precipitation-hardening stainless steels must be hot trimmed to prevent flash-line cracks, which can penetrate the forging.

It is often practical to hot trim immediately after the forging operation, before the workpiece temperature falls below a red heat. Less often, forgings are reheated to 900 to 950 °C (1650 to 1750 °F) and then trimmed.

Tool Materials. Punches for the hot trimming of closed-die forgings are often made of 6G or 6F2 die block steel at 41.8 to 45.7 HRC, and the blades are made of a high-alloy tool steel, such as D2, at 58 to 60 HRC (compositions of tool steels are given in the article "Dies and Die Materials for Hot Forging" in this Volume). In some forge shops, both punches and blades for hot trimming are made of a carbon or low-alloy steel (usually with less than 0.30% C) and then hard faced, generally with a cobalt-base alloy (a typical composition is Co-1.10C-30Cr-3Ni-4.50W).

Upset forgings can be hot trimmed in a final pass in the upsetter or in a separate press. For trimming in the upsetter, H11 tool steel at 46 to 50 HRC has performed successfully on a variety of forgings with a normal flash thickness. For the trimming of heavy flash in the upsetter, H21 at 50 to 52 HRC is recommended. Tools for hot trimming in a separate press are usually made of a 0.30% C carbon or low-alloy steel and are hard faced with a cobalt-base alloy (a typical composition is Co-1.10C-30Cr-3Ni-4.50W).

Forging of Stainless Steel

Revised by Thomas Harris and Eugene Priebe, Armco Inc.

Cleaning

Stainless steels do not form as much scale as carbon or alloy steels, especially when a protective atmosphere is provided during heating. However, the scale that does form is tightly adherent, hard, and abrasive. It must be removed prior to machining, or tool life will be severely impaired.

Mechanical or chemical methods, or a combination of both, can be used to remove scale. Abrasive blast cleaning is an efficient method and is applicable to forgings of various sizes and shapes in large or small quantities. When surfaces will not be machined or passivated, blasting must be done with only silica sand; the use of steel grit or shot will contaminate the surfaces and impair corrosion resistance.

Abrasive blast cleaning is usually followed by acid pickling. The forgings are then thoroughly washed in water.

Barrel finishing (tumbling) is sometimes used for descaling. Acid pickling is recommended after tumbling.

Wire brushing is sometimes used for removing scale from a few forgings. Brushes with stainless steel wire must be used unless the forgings will be machined or passivated.

Salt bath descaling followed by acid cleaning and brightening is an efficient method of removing scale. A typical procedure is detailed in Table 2. Additional information on scale removal is available in the articles "Classification and Selection of Cleaning Processes" and "Surface Engineering of Stainless Steels" in *Surface Engineering*, Volume 5 of the *ASM Handbook.*

Table 2 Cycle for sodium hydride (reducing) descaling of annealed stainless steel forgings

Operation sequence	**Bath composition**	**Bath temperature, °C (°F)**	Treatment time, min
Descale	1.5 to 2.0% NaH	400-425 (750-800)	**20**
Quench	Water (circulated in tank)	Cold	**1-3**
Acid clean	10% H_2SO_4	65 (145)	**20**
Acid brighten	10% HNO_3-2% HF	65 (145)	**30**
Rinse	Water (high-pressure spray)	Ambient	**2**
Rinse	**Water**	**80 (175)**	**1-2**

Forging of Heat-Resistant Alloys

Revised by S.K. Srivastava, Haynes International, Inc.

Introduction

THE FORGING INDUSTRY has incorporated numerous technological innovations during the last two decades. The use of computer-aided design, manufacture, and engineering is particularly significant in the forging of heat-resistant alloys because of the premium placed on higher quality and lower cost. On one hand, the thrust of alloy development has been to increase the service temperature, which means lower forgeability of the alloys. On the other hand, near-net shape manufacturing demands even closer control on the final shape. Machining of these alloys is difficult and expensive and can sometimes amount to 40% of the cost of production. The complexity of these demands makes computers more relevant to the portion of the forging industry concerned with heat-resistant alloys. Computers can analyze and simulate the forging process, predict material flow, optimize the energy consumption, and perform design and manufacturing functions. More information on the use of computers in the modeling of the forging process is available in the Section "Computer-Aided Process Design for Bulk Forming" in this Volume.

Forgings of heat-resistant alloys are widely used in the power, chemical, and nuclear industries; as structural components for aircraft and missiles; and for gas-turbine and jet-engine components such as shafts, blades, couplings, and vanes. Because of their greater strength at elevated temperatures, these alloys are more difficult to forge than most metals. Heat-resistant alloys are more difficult to forge than stainless steels (see the article "Forging of Stainless Steel" in this Volume). Generally, these alloys can be grouped into two categories:

- Solid solution strengthened alloys such as Alloy X (UNS N06002)
- γ' strengthened alloys such as Waspaloy (UNS N07001)

The latter group is much more difficult to forge than the former.

Forging of Heat-Resistant Alloys

Revised by S.K. Srivastava, Haynes International, Inc.

Forging Methods

The three critical factors in any method of forging are reduction (strain), rate of reduction (strain rate), and temperature of the workpiece at any time during forging. Regardless of the method used, the forging of heat-resistant alloys should be done as part of total thermomechanical processing. In some cases, forgings are deliberately processed for better stress rupture, creep, and low-cycle fatigue life. Therefore, the objectives for the forgings are uniform grain refinement, controlled grain flow, and structurally sound components. These objectives often depend on melting practices, ingot-mold design, and ingot-billet breakdown practices. The soundness and uniformity of the forging billets must be ensured. In order to impart optimal work during each stage, it may even be necessary to include redundant work if work penetration in the subsequent processing sequence is not likely to be uniform.

Recrystallization must be achieved in each operation to obtain the desired grain size and flow characteristics. Recrystallization also helps to eliminate the grain- and twin-boundary carbides that tend to develop during static heating or cooling. Nonuniform distribution of inhomogeneities will likely lead to problems. Up to 80% of metal reduction accompanying recrystallization is usually completed over falling temperatures; the remaining 20% can be warm worked at lower temperatures for additional strengthening. The current trend in the forging of heat-resistant alloys is to lower the strain rate and to heat the dies. Faster strain rates lead to frictional heat buildup, nonuniform recrystallization, and metallurgical instabilities, and are also likely to cause radial-type ruptures, especially in high-γ' alloys such as Astroloy (UNS N13017) and U-700. Heat-resistant alloys can be forged by a variety of methods, and two or more of these methods are often used in sequence.

Open-die forging (hand or flat-die forging) can be used to produce preforms for relatively large parts, such as wheels and shafts for gas turbines. Many such preforms are completed in closed dies. Open-die forging is seldom used for producing forgings weighing less than 9 kg (20 lb). More information on forging with open dies is available in the article "Open-Die Forging" in this Volume.

Closed-die forging is widely used for forging heat-resistant alloys. The procedures, however, are generally different from those used for similar shapes from carbon or low-alloy steels (see the article "Closed-Die Forging in Hammers and Presses" in this Volume). For example, preforms made by open-die forging, upsetting, rolling, or extrusion are used to a greater extent for the closed-die forging of heat-resistant alloys than for steel. Because of the greater difficulties encountered in forging heat-resistant alloys as compared to forging similar sizes and shapes from steel, diemaking is also different (see the section "Dies" in this article).

Upset forging is commonly applied to heat-resistant alloys--sometimes as the only forging operation but more often to produce preforms (as for turbine buckets and blades). In the upset forging of heat-resistant alloys, the maximum unsupported length of upset is about two diameters. Additional information is available in the article "Hot Upset Forging" in this Volume.

Extrusion is also used to produce preforms for subsequent forging in closed dies, and it often competes with upsetting. Whether the preform is produced by extruding a slug or by forming an upset on the end of a smaller cross section depends mainly on the equipment available. Information on the extrusion process for heat-resistant alloys is available in the article "Conventional Hot Extrusion" in this Volume.

Roll forging is sometimes used to produce preforms for subsequent forging in closed dies. The rolling techniques used for preforming heat-resistant alloys are basically the same as those employed for preforming steel (see the article "Roll Forging" in this Volume). Roll forging saves material and decreases the number of closed-die operations required.

Ring rolling is sometimes used to save material when producing annular parts from hollow billets. The general method used for heat-resistant alloys is essentially the same as that for steel and is described in the article "Ring Rolling" in this Volume. Heat-resistant alloys with forgeability ratings of 1 or 2 (see Table 1) can be ring rolled using the same procedures as those carbon and low-alloy steels. Alloys with forgeability ratings of 3, 4, and 5 require more steps in ring rolling as well as supplemental heating with auxiliary torches.

Table 1 Forging temperatures and forgeability ratings for heat-resistant alloys

(a) Lower temperatures are often used for specific forgings to conform to appropriate specifications or to achieve structural uniformity.

(b) Based on the considerations stated in the section "Forging Alloys" in this article. 1, most forgeable; 5, least forgeable.

Isothermal forging and hot-die forging of heat-resistant alloys offer a number of advantages. Closer tolerances than those possible in conventional forging processes can be achieved, resulting in reduced material and machining costs. Because die chilling is not a problem in isothermal or hot-die forging, lower strain rates (hydraulic presses) can be used. This lowers the flow stress of the work material; therefore, forging pressure is reduced, and larger parts can be forged in existing hydraulic presses. Additional information is available in the article "Isothermal and Hot-Die Forging" in this Volume, and a specific type of isothermal forging process is briefly discussed in the section "Powder Alloys" in this article.

Revised by S.K. Srivastava, Haynes International, Inc.

Forging Alloys

Table 1 lists the most commonly forged heat-resistant alloys, and their forging temperatures and forgeability ratings.

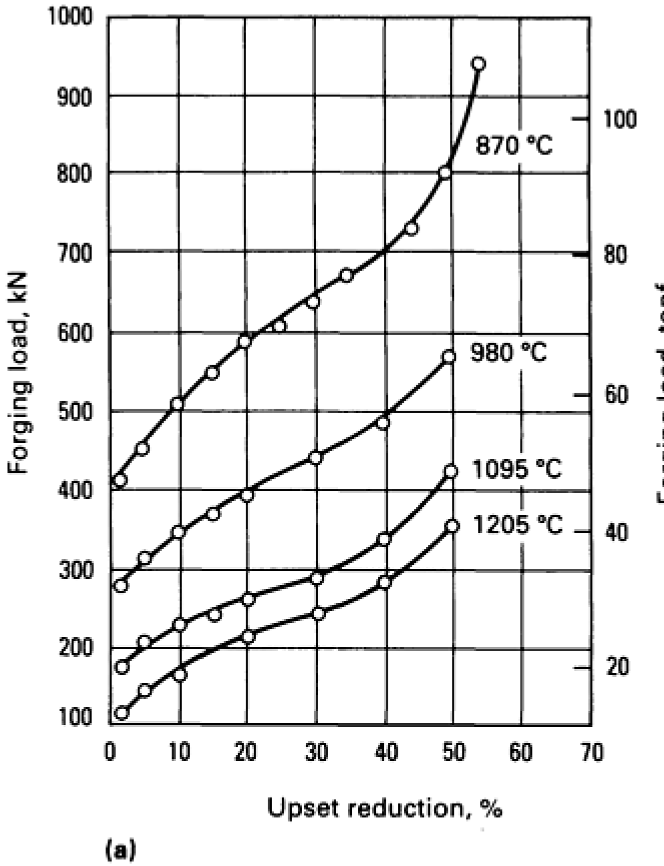
General Characteristics. The two basic material characteristics that greatly influence the forging behavior of heat-resistant alloys are flow stress and ductility. Because these alloys were designed to resist deformation at high temperatures, it is not surprising that they are very difficult to hot work; ductility is limited, and the flow stress is high. Further, any alloying addition that improves the service qualities usually decreases workability. These alloys are usually worked with the precipitates dissolved; the higher concentration of dissolved alloying elements (40 to 50% total) gives rise to higher flow stress, higher recrystallization temperature, and lower solidus temperature, thus narrowing the useful temperature range for hot forming. Where ductility is defined as the amount of strain to fracture, the ductility of these alloys is influenced by the deformation temperature, strain rate, prior history of the material, composition, degree of segregation, cleanliness, and the stress state imposed by the deformation process.

Temperature limits for forging nickel-base heat-resistant alloys are largely determined by melting and precipitation reactions. As with all heat-resistant alloys, an intermediate temperature region of low ductility is likely to be encountered in attempts to forge metals near a temperature between regimes of low- and high-temperature deformation. The region of low ductility often occurs at temperatures around 0.5 of the melting point as measured on the Kelvin scale. The dividing temperature has a physical basis. At hot-working temperatures, self-diffusion rates are high enough for recovery and recrystallization to counteract the effects of strain hardening.

Iron-Base Alloys. Stock for forgings of the iron-base alloys is generally furnished as press-forged squares or hot-rolled rounds, depending on size. As-cast ingots are sometimes used.

The inclusion content of the alloys has a significant effect on their forgeability. Alloys containing titanium and aluminum can develop nitride and carbonitride segregation, which later appears as stringers in wrought bars and affects forgeability. This type of segregation has been almost completely eliminated through the use of vacuum melting. Therefore, iron-base alloys can be forged into a greater variety of shapes with greater reductions, approaching the forgeability of AISI type 304 stainless steel.

Temperature has an important effect on forgeability. The optimal temperature range for forging A-286 and similar iron-base alloys is narrow. The forgeability of A-286, based on the forging load required for various upset reductions at four forging temperatures, is shown in Fig. 1(a). Figure 1(b) shows that, on the basis of forging pressure, A-286 is considerably more difficult to forge than 1020 steel, even though A-286 is among the most forgeable of the heat-resistant alloys (Table 1). For example, as shown in Fig. 1(b), 1020 steel at 1205 °C (2200 °F) requires only about 69 MPa (10 ksi) for an upset reduction of 30%, but for the same reduction at the same temperature, A-286 requires approximately 172 MPa (25 ksi).



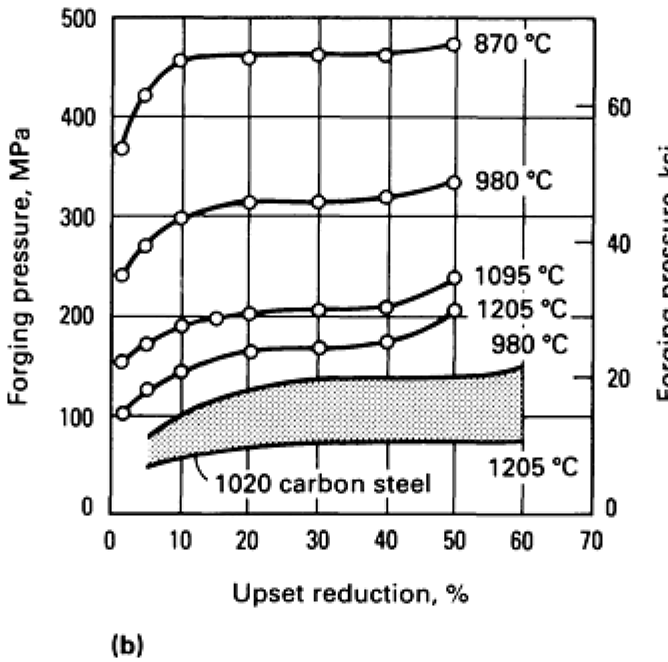


Fig. 1 Effect of upset reduction at four temperatures on forging load in the forging of A-286 (a), and the forging pressure for A-286 compared with that for 1020 steel (b). Source: Ref 1.

Forging pressures increase somewhat for greater upset reductions at normal forging temperatures. As shown in Fig. 2, the pressure for a 20% upset reduction of A-286 at 1095 °C (2000 °F) is about 193 MPa (28 ksi), but for an upset reduction of 50% the pressure increases to about 241 MPa (35 ksi). Figure 2 also shows that forging pressure is up to 10 or 12 times greater than the tensile strength of the alloy at forging temperature.

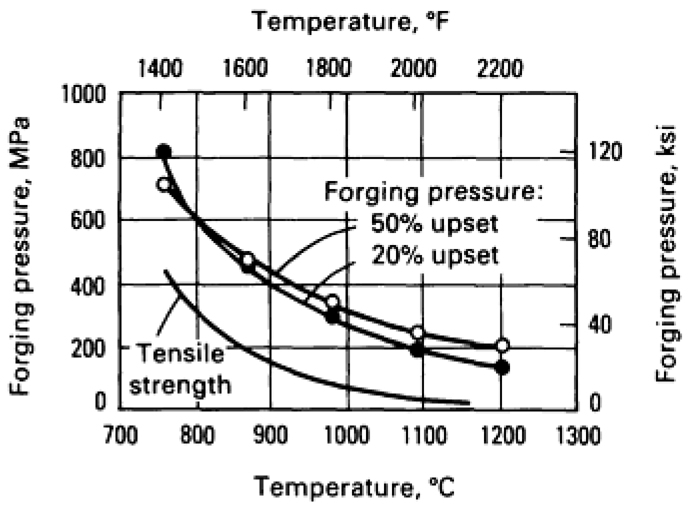

Fig. 2 Forging pressure versus temperature for A-286. Also shown is the effect of increasing temperature on the tensile strength of the material. Upset strain rate: 0.7 s^{-1}. Source: Ref 2.

Strain rates also influence forging pressures. Figure 3 shows that as strain rate increases, more energy is required in presses and hammers.

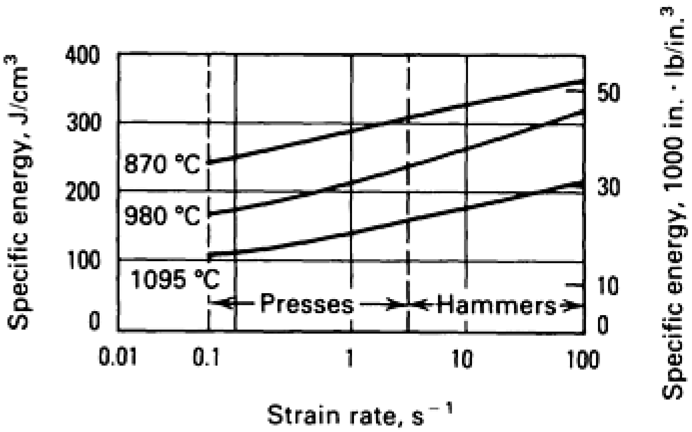

Fig. 3 Specific energy versus strain rate in the press and hammer forging of A-286 at three temperatures. Source: Ref 2.

Nickel-base alloys initially consisted of relatively simple nickel-chromium alloys hardened by small additions of titanium and aluminum for service to 760 °C (1400 °F). With the development of production vacuum-melting techniques, workable alloys can be produced that contain relatively large amounts of titanium, aluminum, zirconium, niobium, and other reactive elements. Nitrogen and oxygen levels are reduced by vacuum melting, which eliminates most of the nitrides and oxides that contribute to poor forgeability. Therefore, current nickel-base alloys consist of numerous compositions containing larger amounts of hardening elements.

The nickel-base alloys are available in various cogged billet and bar sizes for forging. The alloys are ordinarily melted by one of the following methods:

- Air melting, followed by vacuum induction melting or vacuum consumable-electrode arc melting
- Vacuum induction melting followed by vacuum consumable-electrode arc melting

- Consumable-electrode arc melting under slag

Compared with ordinary arc-melting techniques, these three melting procedures have produced marked improvements in forgeability by reducing the levels of segregation. However, most ingots made on a production basis still contain enough segregation to influence forgeability. Ingots produced by vacuum induction melting solidify progressively toward the center and take longer to freeze than ingots manufactured by other methods; therefore, the alloying elements and impurities concentrate at the center. The segregation is generally less in ingots produced by consumable-electrode arc melting.

As shown in Table 1, the nickel-base alloys are, in general, less forgeable than the iron-base alloys; almost all of the nickel-base alloys require more force for producing a given shape. Astroloy (UNS N13017) and Alloy U-700 are the two most difficult-to-forge nickel-base alloys. For a given percentage of upset reduction at a forging temperature of 1095 °C (2000 °F), these alloys require about twice the specific energy needed for the iron-base A-286.

In the forgeability ratings listed in Table 1, Astroloy and U-700 alloys have about one-fifth the forgeability of Alloy 600 (UNS N06600). However, these ratings reflect only a relative ability to withstand deformation without failure; they do not indicate the energy or pressure needed for forging, nor can the ratings be related to low-alloy steels and other alloys that are considerably more forgeable.

The forging of nickel-base alloys requires close control over metallurgical and operational conditions. Particular attention must be given to control of the work metal temperature. Figure 4 shows ductility (measured by percentage of reduction in area) versus temperature curves for several nickel-base alloys. Data on transfer time, soaking time, finishing temperature, and percentage of reduction should be recorded. Critical parts are usually numbered, and precise records are kept. These records are useful in determining the cause of defective forgings, and they permit metallurgical analysis so that defects can be avoided in future products.

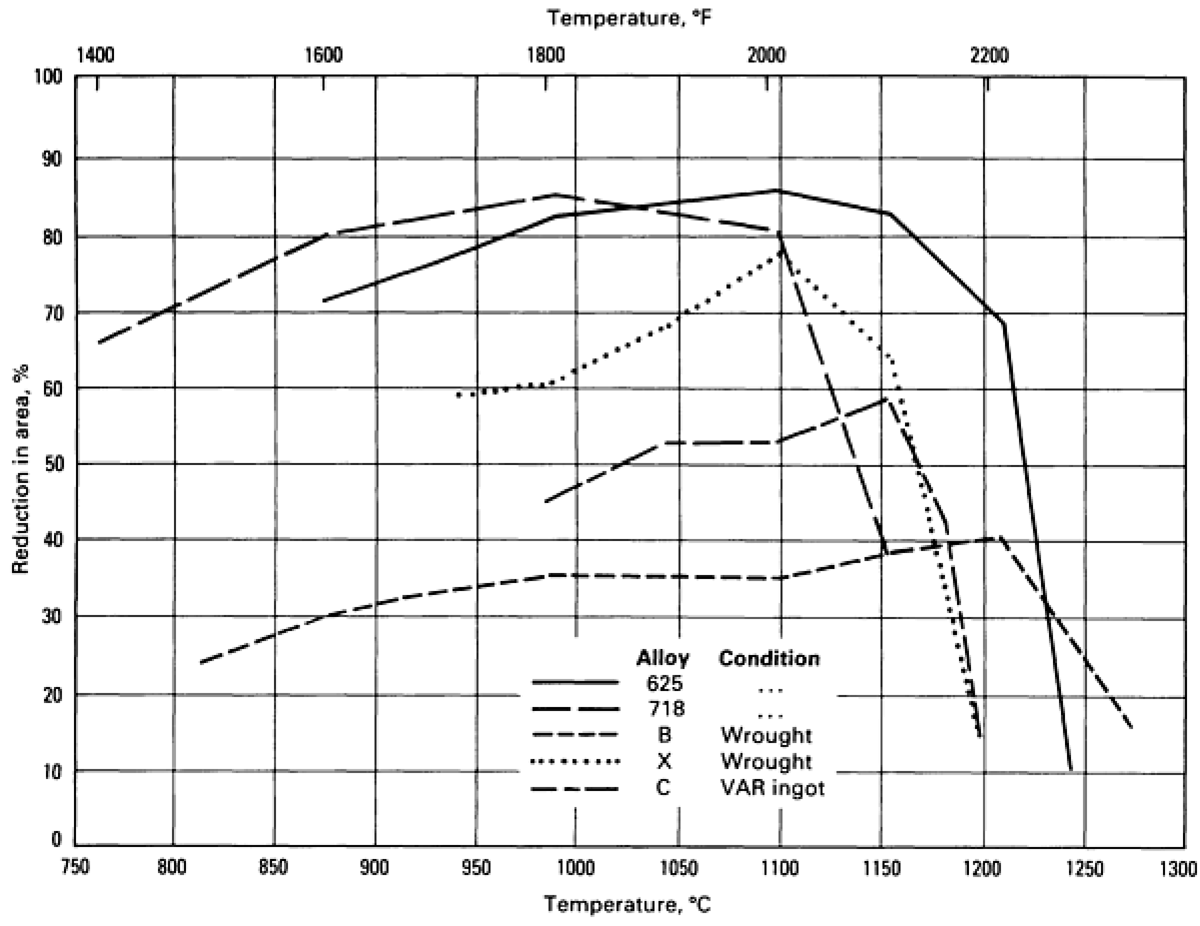

Fig. 4 Ductility (measured by percentage of reduction in area) versus temperature for several nickel-base heat-

resistant alloys. Source: Ref 3, 4, 5, 6, 7, 8, and 9.

The nickel-base alloys are sensitive to minor variations in composition, which can cause large variations in forgeability, grain size, and final properties. In one case, wide heat-to-heat variations in grain size occurred in parts forged from Alloy 901 (UNS N09901) in the same sets of dies. For some parts, optimal forging temperatures had to be determined for each incoming heat of material by making sample forgings and examining them after heat treatment for variations in grain size and other properties.

In the forging of nickel-base alloys, the forging techniques developed for one shape usually must be modified when another shape is forged from the same alloy; therefore, development time is often necessary for establishing suitable forging and heat-treating cycles. This is especially true for such alloys as Waspaloy (UNS N07001), Alloy 41 (UNS N07041), U-500 (UNS N07500), and U-700.

Cobalt-Base Alloys. Many of the cobalt-base alloys cannot be successfully forged because they ordinarily contain more carbon than the iron-base alloys and therefore greater quantities of hard carbides, which impair forgeability.

The two cobalt-base alloys listed in Table 1 are forgeable. The strength of these alloys at elevated temperatures, including the temperatures at which they are forged, is considerably higher than that for iron-base alloys; consequently, the pressures required in forging them are several times greater than those for the iron-base alloys.

Even when forged at its maximum forging temperature, Alloy-25 work hardens; therefore, forging pressure must be increased with greater reductions. Accordingly, this alloy generally requires frequent reheating during forging to promote recrystallization and to lower the forging pressure for subsequent steps.

Forging conditions (temperature and reduction) have a significant effect on the grain size of cobalt-base alloys. Because low ductility, notch brittleness, and low fatigue strength are associated with coarse grains, close control of forging and of final heat treatment is important.

Cobalt-base alloys are susceptible to grain growth when heated above about 1175 °C (2150 °F). They heat slowly and require a long soaking time for temperature uniformity. Forging temperatures and reductions, therefore, depend on the forging operation and the part design.

The alloys are usually forged with small reductions in initial breakdown operations. The reductions are selected to impart sufficient strain to the metal so that recrystallization (and usually grain refinement) will occur during subsequent reheating. Because the cross section of a partly forged section has been reduced, less time is required to reach temperature uniformity in reheating. Consequently, because reheating time is shorter, the reheating temperature may sometimes be increased 30 to 85 °C (50 to 150 °F) above the initial forging temperature without harmful effects. However, if the part receives only small reductions in subsequent forging steps, forging should be continued at the lower temperatures. These small reductions, in turn, must be in excess of about 5 to 15% to avoid abnormal grain growth during subsequent annealing. The forging temperatures given in Table 1 are usually satisfactory.

Powder Alloys. Some alloys, such as Alloy IN-100 and Alloy 95, contain very high proportions of γ', and their cast ingots cannot be forged. Powders of these alloys, however, can be compacted by a number of techniques to produce billets having a very fine grain structure. Such billets can then be superplastically forged. Pratt and Whitney Aircraft has used its patented Gatorizing process to produce preforms for engine compressor and turbine disks with IN-100 billets. In Gatorizing, which is a type of isothermal forging process, both the workpiece and the dies are maintained at 1175 °C (2150 °F). Boron nitride is used as the lubricant. The process is done in vacuum in order to protect the heated dies from oxidation. The use of Gatorizing has led to substantial reductions in material use and finish machining.

Forging of Heat-Resistant Alloys

Revised by S.K. Srivastava, Haynes International, Inc.

Machines

The hammers, presses, upsetters, roll and ring forging machines, and rotary forging machines used in the forging of steel are also used in the forging of heat-resistant alloys, except that more power is needed for forging a given shape from a heat-resistant alloy than for steel. Detailed information on hammers and presses is available in the articles "Hammers and Presses for Forging" and "Selection of Forging Equipment" in this Volume.

Steam or air hammers are extensively used for producing preforms in open dies, particularly for forgings that weigh 45 kg (100 lb) or more. For smaller forgings, particularly for those weighing less than 9 kg (20 lb), preforms are more often produced in rolls, presses, or upsetters.

Steam hammers are also extensively used for producing large forgings (generally over 45 kg, or 100 lb, and up to about 910 kg, or 2000 lb) in closed dies. A distinct advantage of a power hammer for this type of work is the short time of contact between the dies and the hot work metal; therefore, less heat is transferred to the dies than in press forging. A disadvantage of hammer forging is that, because of the severe impact blows, temperature may be excessively increased locally in the metal being forged. As a result, localized grain growth can take place. Also, the very high strain rates experienced in hammer forging can be detrimental in forging of strain-rate sensitive materials.

Mechanical presses are most often used for producing closed-die forgings that weigh less than 9 kg (20 lb)--turbine buckets and blades, for example. Mechanical presses are used less often for forgings that weigh 9 to 45 kg (20 to 100 lb) and are seldom used for closed-die forgings weighing over 45 kg (100 lb). Mechanical presses are preferred for small forgings that require close tolerances because closer control of dimensions and longer die life can be obtained in presses than in hammers.

Hydraulic presses are used for producing large forgings (up to several tons) from heat-resistant alloys. One advantage of a hydraulic press is that the temperature throughout the metal being forged remains more nearly uniform than in hammer forging.

The main disadvantage of forging in a hydraulic press is the long die contact time with the hot workpiece. This causes cooling of the workpiece (cracks may occur in chilled regions) and buildup of heat in the dies.

Revised by S.K. Srivastava, Haynes International, Inc.

Dies

Because of the forces required for forging heat-resistant alloys, special attention must be given to die design, die material, and diemaking practice (see also the article "Dies and Die Materials for Hot Forging" in this Volume).

Die Design. Die cavities need not be different from those used to forge the same shape from steel. However, because of the greater forces required for forging heat-resistant alloys, more attention must be given to the strength of the die in order to prevent breakage; the original dies must be thicker or the number of resinkings will be fewer. For very deep dies, support rings must be used to prevent die breakage.

Iron-base alloys have been forged in dies previously used for producing the same shapes from steel. For forging some nickel-base alloys, however, the dies formerly used for steel are not used; these alloys require more rugged dies.

Die Material. Die life is a major problem in forging heat-resistant alloys, and dies often must be reworked after forging as few as 400 pieces. In contrast, if carbon steel were forged to the same shape, the dies would generally produce 10,000 to 20,000 forgings before major rework. The difference is due to the greater strength of heat-resistant alloys at high temperature and the closer tolerances that are usually required for heat-resistant alloy forgings. As a result, every effort is made through the selection of die material and hardness to prolong die life.

Most dies for forging in hammers and mechanical presses are made of hot-work tool steel such as AISI H11, H12, or H13. Optimal die life can be obtained by heat treating dies to as high a hardness as possible, although some hardness must be sacrificed to obtain toughness and to prevent the possibility of premature die breakage. For example, in forging turbine buckets in a mechanical press, the hardness of the bottom die may range from 47 to 56 HRC. For forgings of minimum severity, the bottom die is heat treated to 53 to 56 HRC. As severity increases, the hardness of the bottom die is decreased; 47 to 49 HRC is used for forgings of maximum severity.

The bottom die is always given primary consideration because it is in contact with the heated workpiece longer than the top die and is more likely to break from the wedging effect. The top die is operated at a lower temperature than the bottom die; therefore, it can be made from a die steel having greater wear resistance--but at some sacrifice of shock resistance.

When hydraulic presses are used, as in the forging of large turbine disks, it may be necessary to use heat-resistant alloys as the die material. If die temperatures do not exceed 595 °C (1100 °F), dies made from steels such as H11 or H13 are generally satisfactory. However, in hydraulic presses, it is not unusual for the dies, or parts of dies, to reach 925 °C (1700 °F). To resist such high temperatures, dies or die inserts are sometimes made from nickel-base alloys such as Alloy 41. Inserts are used in areas that are excessively heated during forging.

Isothermal forging requires strength and integrity of the dies at temperatures of the workpiece. In the superplastic forging of Alloy IN-100, TZM molybdenum alloy dies have been used. However, this requires either a vacuum or an inert atmosphere to prevent oxidation of the die.

Diemaking Practice. Multiple-cavity dies, such as those used in the forging of steel, are seldom used in the forging of heat-resistant alloys. Blocking, semifinishing, and finishing operations are performed separately in single-cavity dies, often in different hammers or presses and at different times. This procedure is used because:

- The heating range is usually quite narrow, so that there is time for only one operation before the workpiece is too cold
- Tolerances are usually close, so that all forging is best done in the center of the hammer or press
- Because of the short die life, a more economical diemaking and die reconditioning program can be established by using single-cavity dies

Almost without exception, the dies used for the forging of heat-resistant alloys are made of the same materials and by approximately the same practice without regard for the number of forgings to be produced. Parts forged from heat-resistant alloys are costly and are intended for critical end uses; therefore, no downgrading can be permitted in tooling. Further, tolerances are usually the same for both small and large numbers of forgings.

In addition, because heat-resistant alloys are difficult to forge and close dimensional tolerances are usually demanded, life of the finishing dies is short. The finishing die is often used until tolerances can no longer be met and is then recut for a semifinishing impression or for the blocker impression.

Forging of Heat-Resistant Alloys

Revised by S.K. Srivastava, Haynes International, Inc.

Preparation of Stock

Shearing is widely used for cutting small bars in preparing stock for forging. The maximum size of bar that can be sheared depends mainly on the available equipment. A cross section of approximately 25 mm (1 in.) is often the maximum size cut by shearing. For cutting thicker cross sections, an abrasive cutoff wheel is satisfactory and economical.

Because heat-resistant alloys are relatively hard, sheared surfaces are generally smooth without excessive distortion, provided shear blades are kept sharp. However, shear blades wear rapidly and often must be reconditioned after shearing 50 to 100 pieces.

Heating. Forging temperature varies widely, depending on the composition of the alloy being forged (Table 1) and to some extent on the heat treatment and end use. Forging-temperature ranges are relatively narrow, but temperatures can be increased for better forgeability if the end use permits. Excessively high forging temperatures cause grain growth in most heat-resistant alloys and adversely affect subsequent heat treatment. Therefore, when maximum properties are required for end use, forging temperatures must be precisely controlled. Lower forging temperatures are less likely to cause damage to the workpiece, but the additional forging blows required will shorten die life.

Atmosphere protection for heating the forging stock is desirable but not essential, because heat-resistant alloys have high resistance to oxidation at elevated temperature. Protective atmospheres provide cleaner surfaces on finished forgings and therefore minimize subsequent cleaning problems.

Electrically heated furnaces are often preferred for heating forging stock because their temperatures can be closely controlled and the possibility of contaminating the work metal is minimized. Fuel-fired furnaces are used less frequently than those heated by electrical resistance. If fuel-fired furnaces are used, the fuel must have extremely low sulfur content, especially when heating the nickel-base alloys, or contamination may occur.

Any type of pyrometric control that can maintain temperature within ±6 °C (±10 °F) is suitable for temperature control. Recording types are preferred because they allow the operator to observe the behavior of the furnace. As the pieces of stock are discharged from the furnace, periodic checks should be made with an optical pyrometer. This permits a quick comparison of work metal temperature with furnace temperature.

The time at temperature is less critical than the necessity for precise temperature control. Grain growth takes place slowly in heat-resistant alloys (unless the temperature is increased above the normal forging temperature), and oxidation is at a minimum; consequently, heating time is less critical than for carbon or alloy steel. In the event of a major breakdown in the equipment while at elevated temperature, the best practice is to remove heated stock from the furnace.

Reheating. Because of the narrow heating range, temperatures of the partly finished forgings must be checked carefully, and the workpieces must be reheated as required to keep them within the prescribed temperature range. This is one reason for using single-cavity dies. It is usually necessary to reheat the work after each forging operation, even when the operations immediately follow each other.

Revised by S.K. Srivastava, Haynes International, Inc.

Heating of Dies

Dies are always heated for the forging of heat-resistant alloys. The heating is usually done with various types of burners, although embedded elements are sometimes used. Optimal die temperature for conventional hot forging varies from 150 to 260 °C (300 to 500 °F); the lubricant used is an important limitation on maximum die temperature. Die temperature is controlled by the use of temperature-sensitive crayons or surface pyrometers.

Lubricants

Dies should be lubricated before each forging. For shallow impressions, a spray of colloidal graphite in water or in mineral oil is usually adequate. Dies are usually sprayed manually, although some installations include automatic sprays that are timed with the press stroke. Deeper cavities, however, may require the use of a supplemental spray (usually manually controlled) to ensure coverage of all surfaces, or they can be swabbed with a conventional forging oil. These oils are readily available as proprietary compounds.

Cooling Practice

Specific cooling procedures are rarely, if ever, needed after the forging of heat-resistant alloys. If forging temperatures are correctly maintained, the forgings can be cooled in still air, after which they will be in suitable condition for heat treating.

Heat Treatment

The heat treatment of wrought heat-resistant alloy forgings consists largely of solution annealing and precipitation-hardening treatments. Iron- and nickel-base heat-resistant alloys consist of a face-centered cubic (fcc) matrix at room and elevated temperatures. This phase is typically referred to as γ, or austenite, and is analogous to the high-temperature fcc phase formed during heat treatment of steels.

Alloying additions lead to the precipitation of various phases, including γ'[Ni_3(Al, Ti)], γ'', and various carbides such as MC (M = titanium, niobium, and so on), M_6C (M = molybdenum and/or tungsten), or $M_{23}C_6$ (M = chromium). In general, the primary strength of heat-resistant alloys is derived from the γ' and γ'' dispersion developed through heat treatment. In nickel-base alloys such as Waspaloy and Astroloy, aluminum and, to some degree, titanium combine with nickel to form γ'. In nickel-iron-base alloys, (for example, Alloy 718 and Alloy 901) and iron-base alloys (for example, A286), titanium, niobium, and, to a lesser extent, aluminum combine with nickel to form γ' or γ''. Further, the nickel-iron and iron-base alloys are all prone to the formation of other phases, such as those referred to as η(Ni_3Ti) and δ(Ni_3Nb).

The solution annealing and precipitation temperature regimes for several of the important superalloys are shown in the pseudo binary phase diagrams in Fig. 5. For both Waspaloy and Alloy 901, the solvus temperatures depend primarily on the aluminum and titanium contents, not on other alloying elements such as molybdenum and chromium, which provide solid-solution strength to the γ matrix.

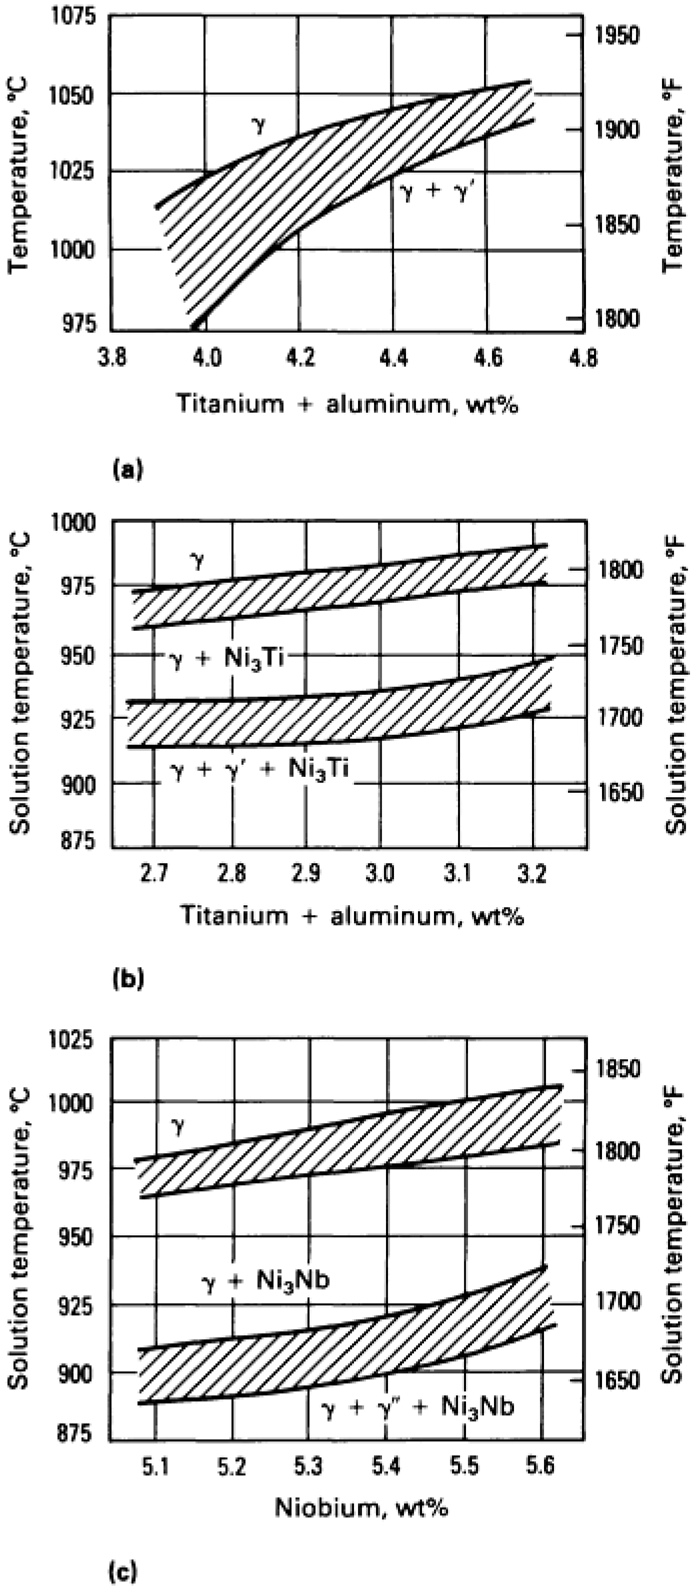

Fig. 5 Portions of pseudo binary phase diagrams for Waspaloy alloy held at temperature for 4 h and oil quenched (a), Alloy 901 held at solution temperature for 1 h and oil quenched (b), Alloy 718 held at solution temperature for 1 h and air cooled (c). Source: Ref 10.

Similarly, the solution and precipitation temperatures in Alloy 718 are strongly dependent on niobium content. It can also be seen in Fig. 5 that the heat treatment of the alloys must be carried out at very high temperatures. These temperatures are usually only several hundred degrees Fahrenheit below those at which incipient melting occurs. Therefore, the forging of these alloys is quite difficult. However, these same characteristics enable superalloy forgings to be used at very high temperatures that are often substantially above those at which high-strength quenched-and-tempered steels are appropriate. Heat treatments for several heat-resistant alloys are summarized in Table 2.

Table 2 Heat treatments for several wrought heat-resistant alloys

Alloy	**UNS designation**	Heat treatment	
		Solution treatment	Aging treatment
Waspaloy	N07001	Hold at 1080 °C (1975 °F) for 4 h; air cool.	**Hold at 840 °C (1550 °F) for 24 h and air cool; hold at 760 °C (1400 °F) for 16 h and air cool.**
Astroloy	N13017	Hold at 1175 °C (2150 °F) for 4 h and air cool; hold at 1080 °C (1975 °F) for 4 h and air cool.	**Hold at 840 °C (1550 °F) for 24 h and air cool; hold at 760 °C (1400 °F) for 16 h and air cool.**
Alloy 901	N09901	Hold at 1095 °C (2000 °F) for 2 h and water quench.	**Hold at 790 °C (1450 °F) for 2 h and air cool; hold at 720 °C (1325 °F) for 24 h and air cool.**
Alloy 718	N07718	Hold at 980 °C (1800 °F) for 1 h and air cool.	**Hold at 720 °C (1325 °F) for 8 h and furnace cool; hold at 620 °C (1150 °F) for 8 h and air cool.**
A-286	**S66286**	**Hold at 980 °C (1800 °F) for 1 h and air cool.**	**Hold at 720 °C (1525 °F) for 16 h and air cool.**

Surface Finish

Because heat-resistant alloys resist scaling, better surface finishes can be produced on forgings than are possible with most other forged metals. Die finish is a major factor affecting surface finish; to produce the best finish on forgings, all dies, new or reworked, must be carefully polished and stoned. The type of alloy forged and the amount of draft have only minor influence on final surface finish.

Forging of Refractory Metals

Introduction

REFRACTORY METALS are forged from as-cast ingots or from billets that have been previously broken down by forging or extrusion. Forgeability depends to some extent on the method used to work the ingot into a billet. The forging characteristics of refractory metals and alloys are listed in Table 1.

Table 1 Forging characteristics of refractory metals and alloys

(a) Minimum hot-working temperature is the lowest forging temperature at which alloys begin to recrystallize during forging.

(b) Based on breakdown forging and rolling experience

Niobium and Niobium Alloys

Niobium and several of its alloys, notably, Nb-1Zr and Nb-33Ta-1Zr, can be forged directly from the as-cast ingot. Most impression-die forging experience, however, has been with unalloyed niobium.

Unalloyed niobium and the two alloys mentioned above can be cold worked. Other alloys, such as Nb-15W-5Mo-1Zr, generally require initial hot working by extrusion to break down the coarse grain structure of as-cast ingots before finish forging.

The billets are usually heated in a gas furnace using a slightly oxidizing atmosphere. Niobium alloys tend to flow laterally during forging. This results in excessive flash that must be trimmed from forgings.

Niobium and its alloys can be protected from oxidation during hot working by dipping the billets in an Al-10Cr-2Si coating at 815 °C (1500 °F), then diffusing the coating in an inert atmosphere at 1040 °C (1900 °F). The resulting coating is about 0.05 to 0.1 mm (2 to 4 mils) thick and provides protection from atmospheric contamination at temperatures to 1425 °C (2600 °F). Glass frit coatings can also be applied to the workpiece before heating in a gas-fired furnace.

Molybdenum and Molybdenum Alloys

The forging behavior of molybdenum and molybdenum alloys depends on the preparation of the billet. Billets prepared by pressing and sintering can be forged directly. Large billets are open die forged or extruded before closed-die forging. Arc-cast billets are usually brittle in tension; they cannot be forged before extruding, except at extremely high temperatures. A minimum extrusion ratio for adequate forgeability is 4 to 1.

Workpieces subjected to large reductions usually exhibit anisotropy and will recrystallize at lower temperatures than parts given less reduction. Forging temperature and reduction must be carefully controlled to avoid premature recrystallization in service and the resulting loss in strength.

Gas- or oil-fired furnaces can be used to heat molybdenum and its alloys to approximately 1370 °C (2500 °F). Induction heating is required for higher forging temperatures. Above 760 °C (1400 °F), molybdenum forms a liquid oxide that volatilizes rapidly enough that surface contamination is rarely a problem. If metal losses are excessive, protective atmospheres such as argon, carbon monoxide, or hydrogen can be used during heating. The liquid oxide formed during heating also serves as a lubricant. Glass coatings are also used; in addition to providing lubrication, glass coatings reduce heat losses during forging. Molybdenum disulfide and colloidal graphite are suitable lubricants for small forgings.

Tantalum and Tantalum Alloys

Unalloyed tantalum and most of the single-phase alloys listed in Table 1 can be forged directly from cast ingots. However, breakdown operations are usually required in order to avoid laps, wrinkles, internal cracks, and other forging defects. The breakdown temperature is 1095 to 1315 °C (2000 to 2400 °F). After about 50% reduction, the forging temperature may be permitted to drop slightly below 1095 °C (2000 °F). Billets produced by powder metallurgy techniques do not lend themselves to direct forging and must be subjected to breakdown.

Most of the forging experience to date has been with the Ta-10W alloy. Billets are heated to 1150 to 1205 °C (2100 to 2200 °F) in gas-fired furnaces using an oxidizing atmosphere. Breakdown forging below 980 °C (1800 °F) or continued working below 815 °C (1500 °F) can cause internal cracking. Forgeability of the tantalum alloys decreases sharply as tungsten content exceeds about 12.5%. Interstitial elements such as carbon, oxygen, and nitrogen also have a deleterious effect on forgeability.

Two types of coatings--glasses and aluminides--have been successfully used to protect tantalum from oxidation during forging. A 0.076 mm (3 mil) thick coating of aluminum has provided protection for the Ta-10W alloy when it was heated in air at 1370 °C (2500 °F) for 30 min. Glass coatings are generally preferred for their lubricating properties. Various borosilicate glasses are available that can be used for forging operations carried out in the range of 1095 to 1315 °C (2000 to 2400 °F).

Tungsten and Tungsten Alloys

Tungsten-base materials, like the other refractory alloy systems, can be classified into two broad groups: unalloyed tungsten, and solid-solution or dispersion-strengthened alloys. These classifications are convenient because they group the alloys in terms of metallurgical behavior and applicable consolidation methods. Solid-solution alloys and unalloyed tungsten can be produced by powder metallurgy or conventional melting techniques; dispersion-strengthened alloys can be produced only by powder metallurgy methods.

The forgeability of tungsten alloys, like that of molybdenum alloys, is dependent on the consolidation technique used. Billet density, grain size, and interstitial content all affect forgeability.

Metallurgical principles in the forging of tungsten are much the same as those for molybdenum. Tungsten is usually forged in the hot/cold-working temperature range, in which hardness and strength increase with increasing reductions. Both systems exhibit increasing forgeability with decreasing grain size.

Tungsten requires considerably higher forging pressures than molybdenum; therefore, in-process annealing is often necessary in order to reduce the load requirements for subsequent forging operations. Because the need for lateral support during forging is greater for tungsten than for molybdenum, the design of preliminary forging tools is more critical. This is especially true for pressed and sintered billets, which have some porosity and are less than theoretical density.

Tungsten oxide, which becomes molten and volatilizes at forging temperatures, serves as an effective lubricant in the forging of tungsten. Mixtures of graphite and molybdenum disulfide are also used. Sprayed on the dies, these films provide lubricity and facilitate removal of the part from the dies. Glass coatings are also used, but they can accumulate in the dies and interfere with complete die filling.

Forging of Aluminum Alloys

G.W. Kuhlman, Aluminum Company of America

Introduction

ALUMINUM ALLOYS can be forged into a variety of shapes and types of forgings with a broad range of final part forging design criteria based on the intended application. Aluminum alloy forgings, particularly closed-die forgings, are usually produced to more highly refined final forging configurations than hot-forged carbon and/or alloy steels, reflecting differences in the high-temperature oxidation behavior of aluminum alloys during forging, the forging engineering approaches used for aluminum, and the higher material costs associated with aluminum alloys in comparison to carbon steels. For a given aluminum alloy forging shape, the pressure requirements in forging vary widely, depending primarily on the chemical composition of the alloy being forged, the forging process being employed, the forging strain rate, the type of forging being manufactured, the lubrication conditions, and the forging and die temperature.

Figure 1 compares the flow stresses of some commonly forged aluminum alloys at 350 to 370 °C (660 to 700 °F) and at a strain rate of 4 to 10 s^{-1} to 1025 carbon steel forged at an identical strain rate but at a forging temperature typically employed for this steel. Flow stress represents the low limit of forging pressure requirements; however, actual forging pressures are usually higher because of the other forging process factors outlined above. For some low-to-intermediate strength aluminum alloys, such as 1100 and 6061, flow stresses are lower than those of carbon steel. For high-strength alloys, particularly 7*xxx* series alloys such as 7075, 7010, 7049, and 7050, flow stresses, and therefore forging pressures, are considerably higher than those of carbon steels. Finally, other aluminum alloys, such as 2219, have flow stresses quite similar to those of carbon steels. As a class of alloys, however, aluminum alloys are generally considered to be more difficult to forge than carbon steels and many alloy steels. The chemical compositions, characteristics, and typical mechanical properties of all wrought aluminum alloys referred to in this article are reviewed in the article "Properties of Wrought Aluminum and Aluminum Alloys" in *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials*, Volume 2 of the *ASM Handbook.*

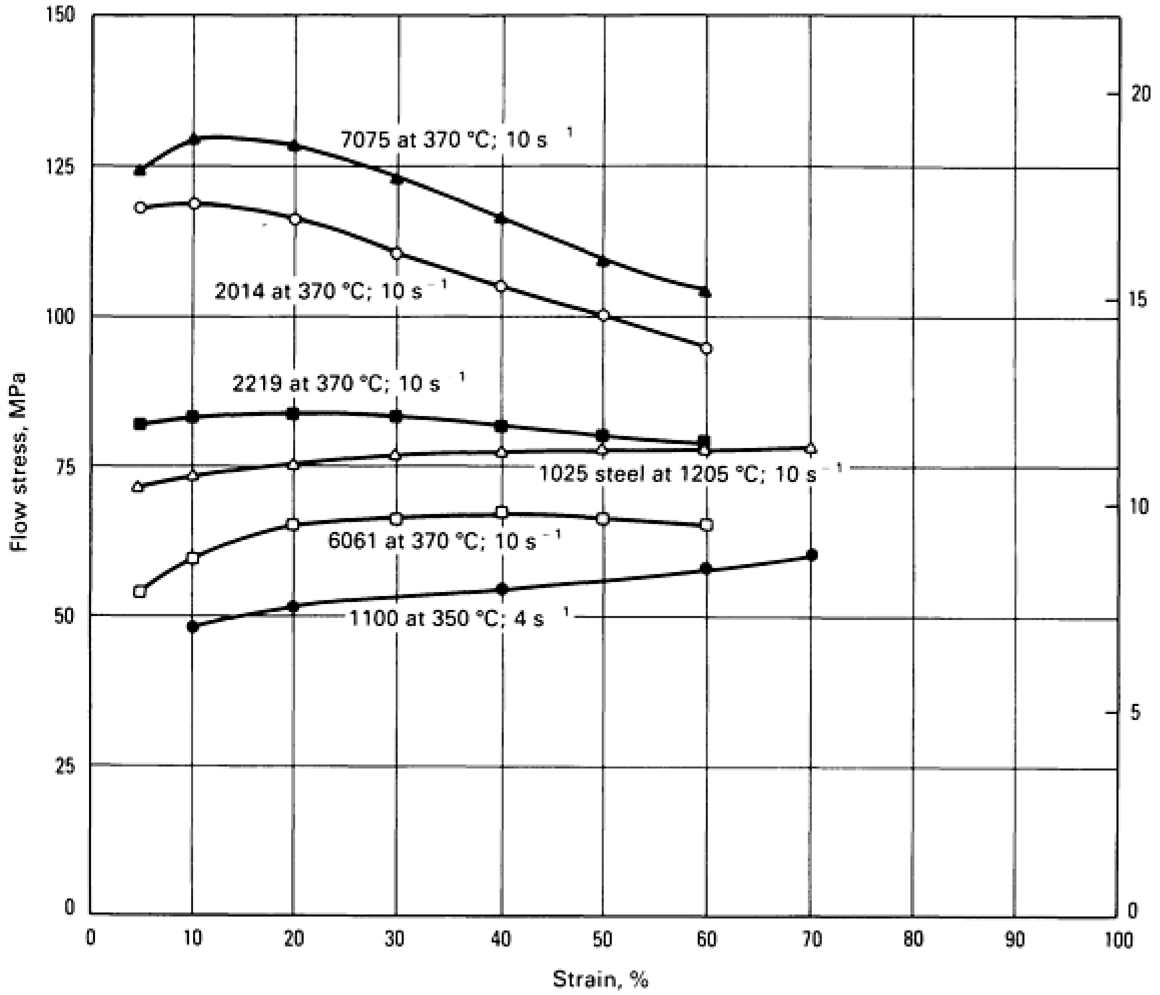

Fig. 1 Flow stresses of commonly forged aluminum alloys and of 1025 steel at typical forging temperatures and various levels of total strain.

Forging of Aluminum Alloys

G.W. Kuhlman, Aluminum Company of America

Forgeability

Compared to the nickel/cobalt-base alloys and titanium alloys, aluminum alloys are considerably more forgeable, particularly in conventional forging process technology, in which dies are heated to 540 °C (1000 °F) or less. Figure 2 illustrates the relative forgeability of ten aluminum alloys that constitute the bulk of aluminum alloy forging production. This arbitrary unit is principally based on the deformation per unit of energy absorbed in the range of forging temperatures typically employed for the alloys in question. Also considered in this index is the difficulty of achieving specific degrees of severity in deformation as well as the cracking tendency of the alloy under forging process conditions. There are wrought aluminum alloys, such as 1100 and 3003, whose forgeability would be rated significantly above those presented; however, these alloys have limited application in forging because they cannot be strengthened by heat treatment.

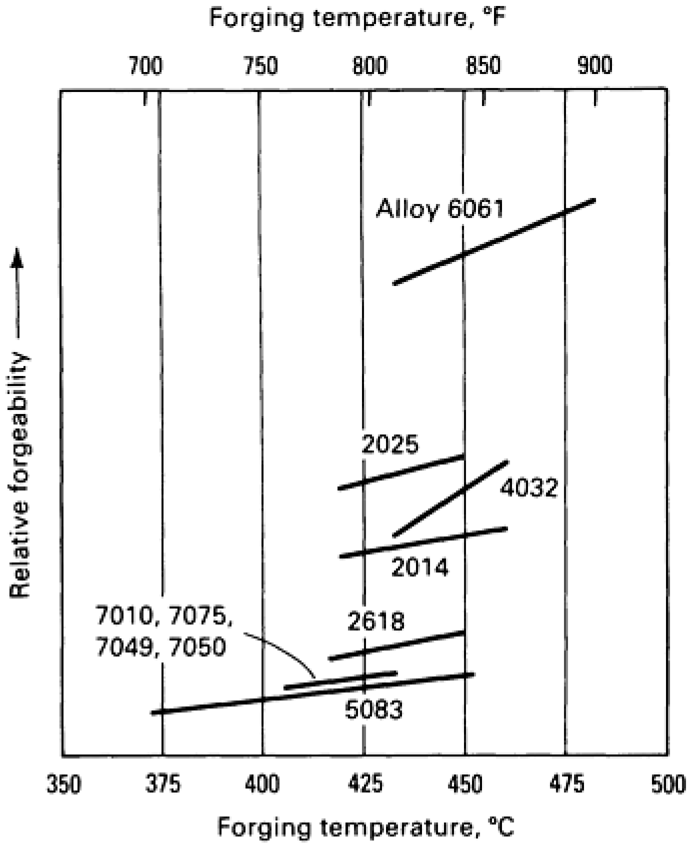

Fig. 2 Forgeability and forging temperatures of various aluminum alloys

Effect of Temperature. As shown in Fig. 2, the forgeability of all aluminum alloys improves with increasing metal temperature, and there is considerable variation in the effect of temperature for the alloys plotted. For example, the high-silicon alloy 4032 shows the greatest effect, while the high-strength Al-Zn-Mg-Cu 7*xxx* alloys display the least effect. Figure 3 shows the effect of temperature on flow stress at a strain rate of 10 s^{-1} for alloy 6061, a highly forgeable aluminum alloy. There is nearly a 50% increase in flow stress between the highest temperature (480 °C, or 900 °F, the top of the recommended forging range for 6061) and 370 °C (700 °F), which is below the minimum temperature recommended for 6061. For other, more difficult-to-forge alloys, such as the 2*xxx* and 7*xxx* series, the change in flow stress with temperature is even greater, indicating the principal reason for the relatively narrow metal temperature ranges.

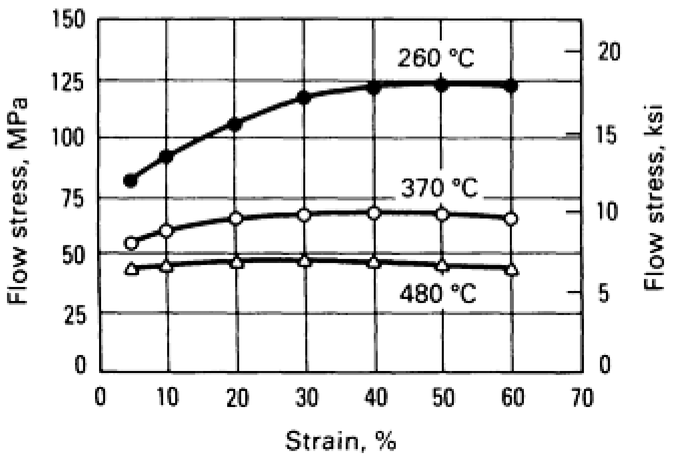

Fig. 3 Flow stress versus strain rate for alloy 6061 at three temperatures and a strain rate of 10 s^{-1}

The 15 aluminum alloys that are most commonly forged, as well as recommended temperature ranges, are listed in Table 1. All of these alloys are generally forged to the same severity, although some alloys may require more forging power and/or more forging operations than others. The forging temperature range for most alloys is relatively narrow (generally <55 °C, or 100 °F), and for no alloy is the range greater than 85 °C (155 °F). Obtaining and maintaining proper metal temperatures in the forging of aluminum alloys is critical to the success of the forging process. Die temperature and deformation rates play key roles in the actual forging temperature achieved.

Table 1 Recommended forging temperature ranges for aluminum alloys

Aluminum alloy	**Forging temperature range**	
	°C	**°F**
1100	315-405	600-760
2014	420-460	785-860
2025	420-450	785-840
2219	425-470	800-880
2618	410-455	770-850
3003	315-405	600-760
4032	415-460	780-860
5083	405-460	760-860
6061	430-480	810-900
7010	370-440	700-820
7039	380-440	720-820
7049	360-440	680-820
7050	360-440	680-820
7075	380-440	720-820

Effect of Deformation Rate. Aluminum alloy forgings are produced on a wide variety of forging equipment (see the section "Forging Equipment" in this article). The deformation or strain rate imparted to the deforming metal varies considerably, ranging from very fast (for example, $\geq$10 s^{-1} on equipment such as hammers, mechanical presses, and high-energy-rate machines) to relatively slow (for example, $\leq$0.1 s^{-1} on equipment such as hydraulic presses). Therefore, deformation or strain rate is also a critical element in the successful forging of given alloy.

Figure 4 presents the effect of two strain rates--10 s^{-1} and 0.1 s^{-1}--on the flow stresses of two aluminum alloys--6061 and 2014--at 370 °C (700 °F). It is clear that higher strain rates increase the flow stresses of aluminum alloys and that the increase in flow stress with increasing strain rate is greater for more difficult-to-forge alloys, such as the 2*xxx* and 7*xxx* series. For 6061, the more highly forgeable alloy, the increase in flow stress with the rapid strain rate is of the order of 70%; for 2014, the higher strain rate virtually doubles the flow stress. Although aluminum alloys are generally not considered to be as sensitive to strain rate as other materials, such as titanium and nickel/cobalt-base superalloys, selection of the strain rate in a given forging process or differences in deformation rates inherent in various types of equipment affect the forging pressure requirements, the severity of deformation possible, and therefore the sophistication of the forging part that can be produced.

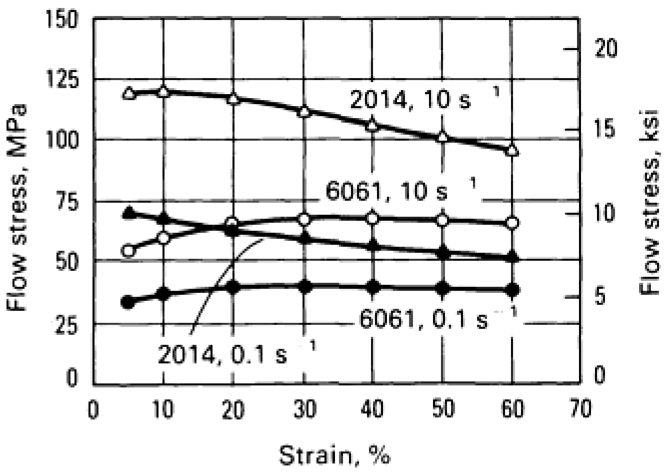

Fig. 4 Flow stress versus strain rate for alloys 2014 and 6061 at 370 °C (700 °F) and two different strain rates

Effect of Die Temperature. Unlike some forging processes for carbon and alloy steels, the dies used in virtually all hot-forging processes for aluminum alloys are heated in order to facilitate the forging process. Therefore, die temperature is another critical element in the forgeability and forging process optimization of this alloy class. Table 2 summarizes the die temperature ranges typically used for several aluminum forging processes. The criticality of die temperature in the optimization of the process depends on the forging equipment being employed, the alloy being forged, and the severity of the deformation or the sophistication of the forging design. For slower deformation processes, such as hydraulic press forging, die temperature frequently controls the actual metal temperature during deformation, and in fact, aluminum alloys forged in hydraulic presses are isothermally forged; that is, metal and dies are at the same temperature during deformation. Therefore, the die temperatures employed for hydraulic press forging exceed those typical of more rapid deformation processes, such as hammers and mechanical presses. Die heating techniques are discussed in the section "Heating of Dies" in this article.

Table 2 Die temperature ranges for the forging of aluminum alloys

Forging process/equipment	Die temperature	
	°C	°F
Open-die forging		

Ring rolling	95-205	**200-400**
Mandrel forging	95-205	**200-400**
Closed-die forging		
Hammers	95-150	**200-300**
Upsetters	150-260	**300-500**
Mechanical presses	150-260	**300-500**
Screw presses	150-260	**300-500**
Orbital (rotary) forging	150-260	**300-500**
Spin forging	150-315	**200-600**
Roll forging	95-205	**200-400**
Hydraulic presses	**315-430**	**600-800**

Forging of Aluminum Alloys

G.W. Kuhlman, Aluminum Company of America

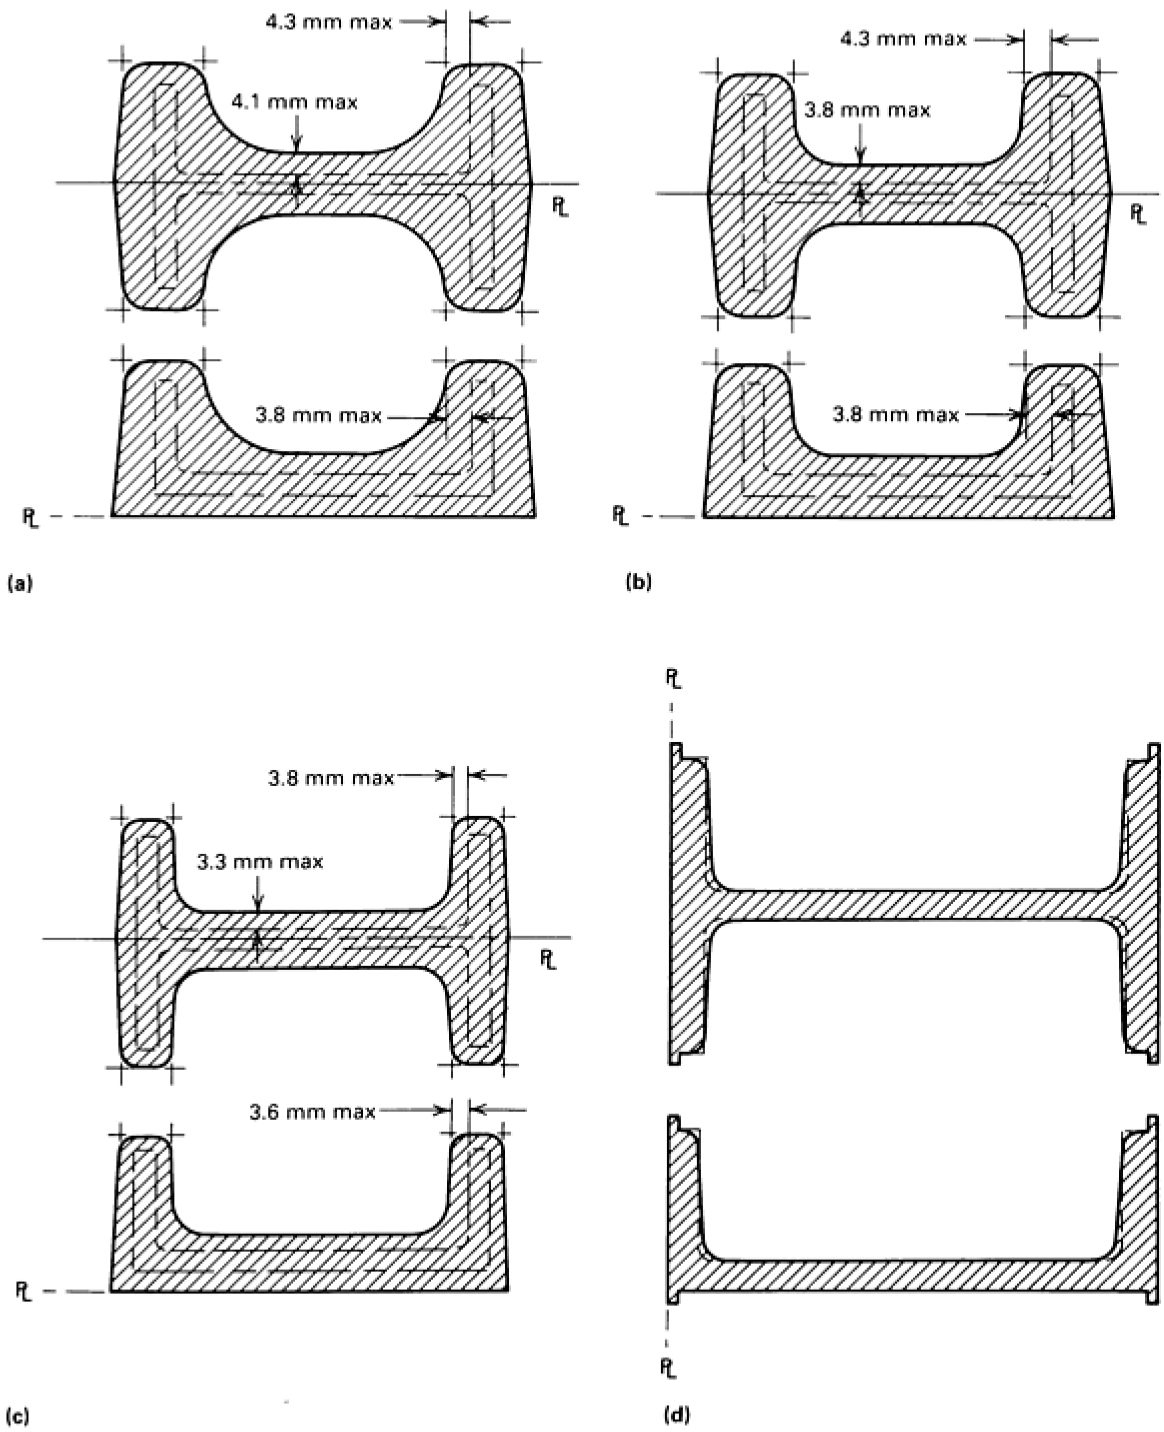
Forging Methods

Aluminum alloys are produced by all of the current forging methods available, including open-die (or hand) forging, closed-die forging, upsetting, roll forging, orbital (rotary) forging, spin forging, mandrel forging, ring rolling, and extrusion. Selection of the optimal forging method for a given forging shape is based on the desired forged shape, the sophistication of the forged-shape design, and cost. In many cases, two or more forging methods are combined in order to achieve the desired forging shape and to obtain a thoroughly wrought structure. For example, open-die forging frequently precedes closed-die forging in order to prework the alloy (especially when cast ingot forging stock is being employed) and in order to preshape (or preform) the metal to conform to the subsequent closed dies and to conserve input metal.

Open-die forging is frequently used to produce small quantities of aluminum alloy forgings when the construction of expensive closed dies is not justified or when such quantities are needed during the prototype fabrication stages of a forging application. The quantity that warrants the use of closed dies varies considerably, depending on the size and shape of the forging and on the application for the part. However, open-die forging is by no means confined to small or prototype quantities, and in some cases, it may be the most cost-effective method of aluminum forging manufacture. For example, as many as 2000 pieces of biscuit forgings have been produced in open dies when it was desired to obtain the properties of a forging but closed dies did not provide sufficient economic benefits.

Open-die forgings in aluminum alloys can be produced to a wide variety of shapes, ranging from simple rounds, squares, or rectangles to very complex contoured forgings (see the article "Open-Die Forging" in this Volume). In the past, the complexity and tolerances of the open-die forging of aluminum and other materials depended on the skill of the press-operator; however, with the advent of programmable computer-controlled open-die forging presses, it is possible to produce such shapes to overall thickness/width tolerances bands of 1.27 mm (0.050 in.). Because the open-die forging of aluminum alloys is also frequently implemented to produce preforms for closed-die forgings, these state-of-the-art forging machines also provide very precise preform shapes, improving the dimensional consistency and tolerances of the resulting closed-die forging and reducing closed-die forging cost through further input material conservation. More information on open-die forging is available in the article "Open-Die Forging" in this Volume.

Closed-Die Forging. Most aluminum alloy forgings are produced in closed dies. The four types of aluminum forgings shaped in closed dies are blocker-type (finish forging only), conventional (block and finish forging or finish forging only), high-definition (near-net shape), and precision (no draft, net shape). These closed-die forging types are illustrated in Fig. 5.



Characteristic	Tolerance, mm (in.)			
	Blocker-type	**Conventional**	**High-definition**	Precision
Die closure	+2.3, -1.5 (+0.09, -0.06)	+1.5, -0.8 (+0.06, -0.03)	+1.25, -0.5 (+0.05, -0.02)	**+0.8, -0.25 (+0.03, -0.01)**
Mismatch	0.5 (0.02)	0.5 (0.02)	0.25 (0.01)	**0.38 (0.015)**
Straightness	0.8 (0.03)	0.8 (0.03)	0.5 (0.02)	**0.4 (0.016)**
Flash extension	3 (0.12)	1.5 (0.06)	0.8 (0.03)	**0.8 (0.03)**
Length and width	±0.8 (±0.03)	±0.8 (±0.03)	±0.8 (±0.03)	**+0.5, -0.25 (+0.02, -0.01)**

Fig. 5 Types of aluminum closed-die forgings and tolerances for each. (a) Blocker-type. (b) Conventional. (c) High-definition. (d) Precision

Blocker-type forgings (Fig. 5a) are produced in relatively inexpensive, single sets of dies. In dimensions and forged details, they are less refined and require more machining than conventional or high-definition closed-die forgings. A blocker-type forging costs less than a comparable conventional or high-definition forging, but it requires more machining.

Conventional closed-die forgings (Fig. 5b) are the most common type of aluminum forging. They are produced with either a single set of finish dies or with block and finish dies, depending on the design criteria. These forgings have less machine stock and tighter tolerances than blocker-type forgings, but require additional cost (both for the dies and for fabrication) to produce.

High-Definition Forgings. With the advent of improved forging equipment and process control, as discussed below, high-definition near-net shape closed-die forgings (Fig. 5c) can be produced and offer forging design and tolerance enhancement over conventional or blocker-type forgings to effect further reduction in machining costs. High-definition forgings are produced with multiple die sets, consisting of one or more blocker dies and finish dies, and are frequently used with some as-forged surfaces remaining unmachined by the purchaser.

Precision forgings (Fig. 5d) represent the most sophisticated aluminum forging design produced. These forgings, for which the forger may combine forging and machining processes in the fabrication sequence, cost more than other aluminum forging types, but by definition require no subsequent machining by the purchaser and therefore may be very cost effective. Net shape aluminum forgings are produced in two-piece, three-piece through-die, and/or multiple-segment wrap-die systems to very restricted design and tolerances necessary for assembly. Net shape aluminum forgings are discussed more thoroughly in the section "Aluminum Alloy Precision Forgings" in this article and in the article "Precision Forging" in this Volume; more information on the closed-die forging process is available in the article "Closed-Die Forging in Hammers and Presses" in this Volume.

Upset forging can be accomplished in specialized forging equipment called upsetters (a form of mechanical press) or high-speed multiple-station formers and is frequently used to produce forging shapes that are characterized by surfaces of revolution, such as bolts, valves, gears, bearings, and pistons. Upset forging may be the sole process used for the shape, such as pistons, or it can be used as a preliminary operation to reduce the number of impressions, to reduce die wear, or to save metal when the products are finished in closed dies. Wheel and gear forgings are typical products for which upsetting is advantageously used in conjunction with closed-die forging. As a rule, in the upset forging of aluminum alloys, the unsupported length of forgings must not exceed three diameters for a round shape or three times the diagonal of the cross section for a rectangular shape. The article "Hot Upset Forging" in this Volume contains more information on upsetting.

Roll forging can be used as a preliminary preform operation to reduce metal input or to reduce the number of closed-die operations. In roll forging, the metal is formed between moving rolls, either or both containing a die cavity, and is most often used for parts, such as connecting rods, where volume is high and relatively restricted cross-sectional variations typify the part. Roll forging is discussed at length in the article "Roll Forging" in this Volume.

Orbital (rotary) forging is a variant of closed-die mechanical or hydraulic press forging in which one or both of the dies is caused to rotate, usually at an angle, leading to the incremental deformation of the workpiece. Orbital forging is used to produce parts with surfaces of revolution with both hot and cold aluminum alloy forging processes, and it provides highly refined close-tolerance final shapes. Additional information on orbital forging is available in the article "Rotary Forging" in this Volume.

Spin forging, a relatively new aluminum alloy forging technique, combines closed-die forging and computer numerically controlled (CNC) spin forgers to achieve close-tolerance axisymmetric hollow shapes such as those illustrated in Fig. 6 through the use of either hot- or cold-forging techniques. Because spin forging is accomplished over a mandrel, inside diameter contours are typically produced to net shape, requiring no subsequent machining. Outside diameter contours can be produced net or with very little subsequent machining and to much tighter out-of-round and concentricity tolerances than competing forging techniques, such as forward or reverse extrusion (see below), resulting in material savings. Parts with both ends open, one end closed, or both ends closed can also be produced.

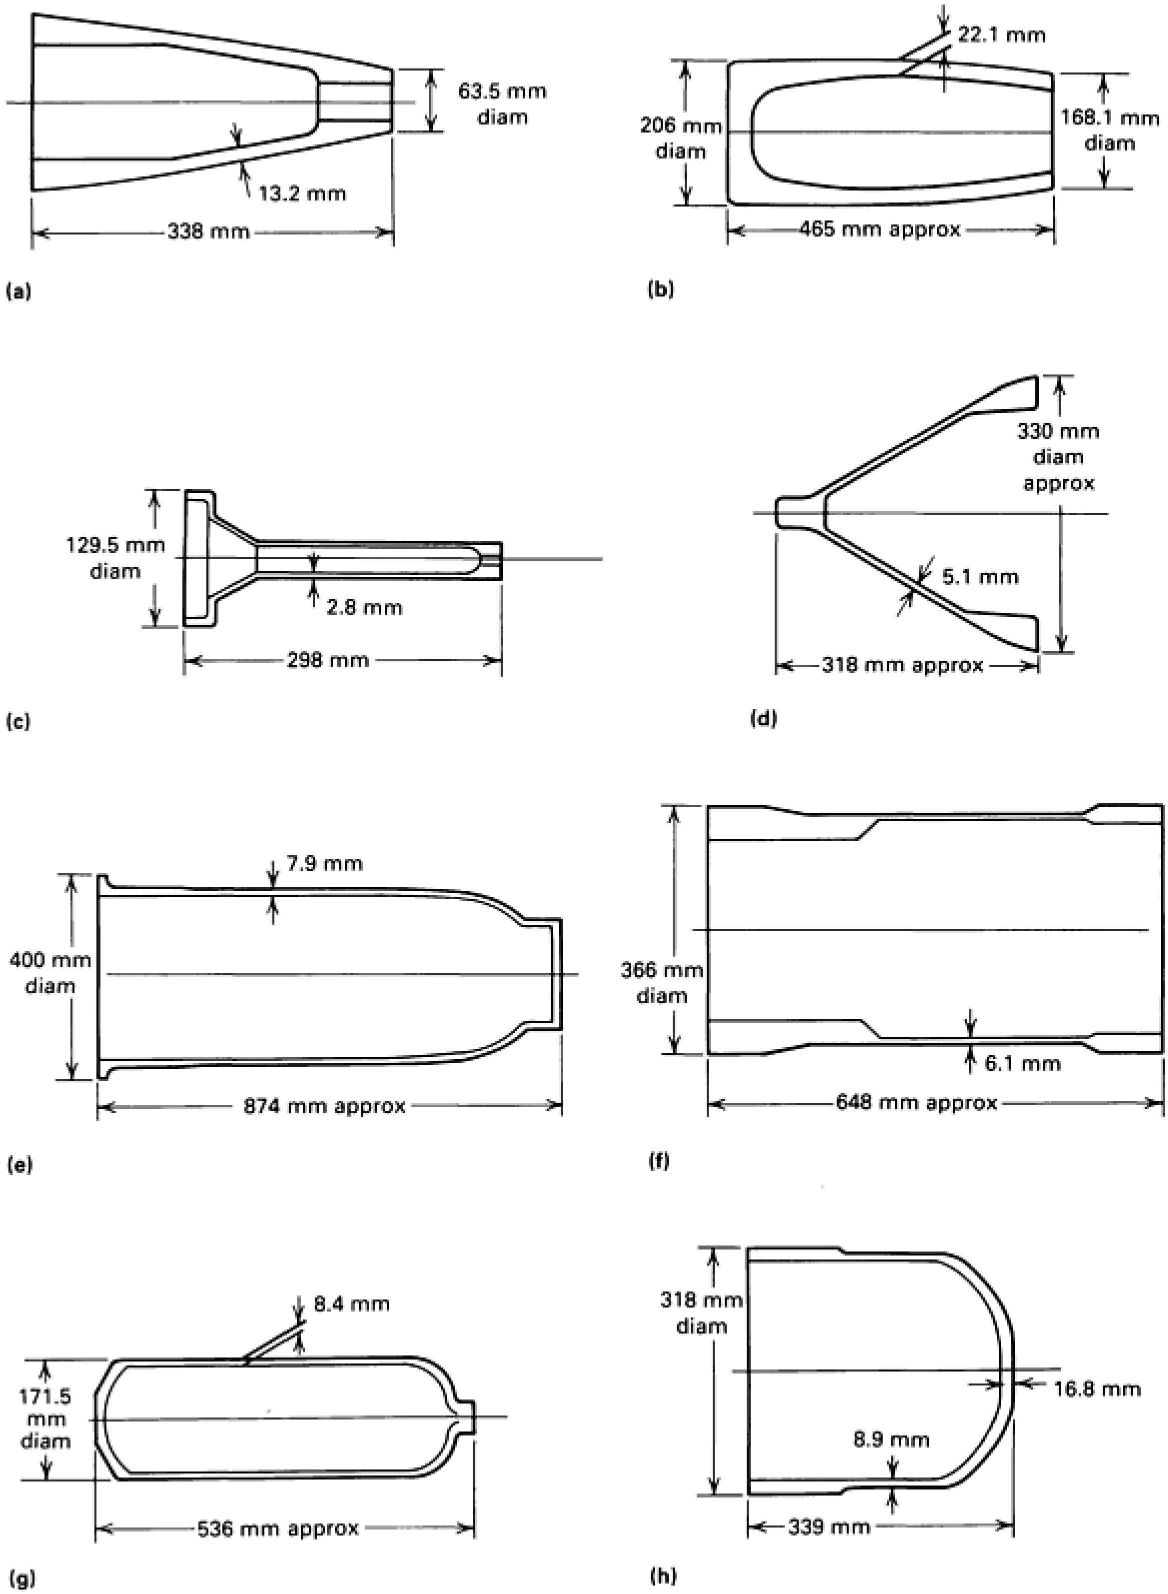


Fig. 6 Examples of spin-forged aluminum alloy shapes. (a) Ordnance ogive. (b) Ordnance center section. (c) Ordnance fuse. (d) Jet engine spinner. (e) Missile nose cone. (f) Missile center section. (g) Bottle. (h) Missile forward case.

Ring rolling is also used for aluminum alloys to produce annular shapes. The procedure used to ring roll aluminum alloys is essentially the same as that used for steel (see the article "Ring Rolling" in this Volume). Both rectangular and contoured cross section rolled rings, with or without subsequent machining by the forger, are produced in many aluminum alloys. The temperatures employed for the ring rolling of aluminum alloys are quite similar to those for other forging processes, although care must be taken to maintain metal temperature. The deformation achieved in the ring rolling of aluminum typically results in the predominant grain flow in the tangential or circumferential orientation. If predominant grain flow is desired in other directions, such as axial or radial, other ring-making processes, such as hollow-biscuit open-die forgings, mandrel forging, or reverse/forward extrusion, can be employed. The economy of ring rolling in aluminum alloys depends on the volume, size, and contour of the forging. For some ring parts, it may be more economical to produce the shape by mandrel forging or to cut rings from hollow extruded cylinders. Both techniques are discussed below.

Mandrel forging is used in aluminum alloys to produce axisymmetric, relatively simple, hollow ring or cylindrical shapes, in which the metal is incrementally forged, usually on a hammer or hydraulic press, over a mandrel. In the incremental forging process, the wall thickness of the preform is reduced, and this deformation enlarges the diameter of the piece. The mandrel forging of aluminum has been found to be economical for relatively low-volume part fabrication and/or in the fabrication of very large ring shapes (up to 3.3 m, or 130 in., in diameter). With control of the working history of the input material and the mandrel-forging process, mandrel-forged rings can be produced with either circumferential or axial-predominant grain orientations.

Reverse or forward extrusion, a variant of closed-die forging for aluminum, can be used to produce hollow, axisymmetric shapes in aluminum alloys with both ends open or with one end closed. The terminology of reverse or forward extrusion refers to the direction of metal movement in relation to the movement of the press head. In forward extrusion, the metal is extruded (typically downward) in the same direction as the press head. Conversely, for reverse extrusion, metal moves opposite the motion of the cross-head. Selection of forward versus reverse extrusion is usually based on part geometry and the opening restrictions of the press. Some presses are specifically equipped with openings in the upper cross-head to accommodate the fabrication of very long reverse extrusions, either solid or hollow. Extrusion as a metal deformation process also frequently plays an important role in the closed-die forging of aluminum alloy parts other than hollow shapes (such as wheels). More information on extrusion is available in the articles "Cold Extrusion" and "Conventional Hot Extrusion" in this Volume.

G.W. Kuhlman, Aluminum Company of America

Forging Equipment

Aluminum alloy forgings are produced on the full spectrum of forging equipment, ranging from hammers and presses to specialized forging machines. Selection of forging equipment for a given forging shape and type is based on the capabilities of the equipment, forging design sophistication, desired forging process, and cost. Additional information on the types of equipment used in the manufacture of forgings is available in the Section "Forging Equipment and Dies" in this Volume.

Hammers. Gravity- and power-drop hammers are used for both the open-die and closed-die forging of aluminum alloys because of the relatively low fabrication costs associated with such equipment, although the power requirements for aluminum frequently exceed those for steel. Hammers deform the metal with high deformation speeds; therefore, control of the length of the stroke and of the force and speed of the blows is particularly useful in forging aluminum alloys, because of their sensitivity to strain rate and their exothermic nature under rapid deformation processes. Power-drop hammers are used to manufacture closed-die forgings if an applied draft of about 5 to 7° can be tolerated. Hammers are frequently used as a preliminary operation for subsequent closed-die forging by other forging processes, and for some products, such as forged aluminum propellers, power-assisted hammers are the optimal forging process equipment because of their capacity for conserving input material and their ability to produce a finished blade that has essentially net airfoil contours.

Mechanical and Screw Presses. Both mechanical and screw presses are extensively used for the closed-die forging of aluminum alloys. They are best adapted to aluminum forgings of moderate size, high volume (cost consideration), and relatively modest shape that do not require extensive open-die preforming. In forging aluminum alloys on mechanical or screw presses, multiple-die cavities, frequently within the same die block, and multiple forging stages, frequently without reheating, are used to enhance the deformation process, to increase the part design sophistication, and to improve tolerance control. The automotive rear knuckle suspension component shown in Fig. 7 illustrates the complexity of the high-volume aluminum alloy forging producible on a mechanical press.

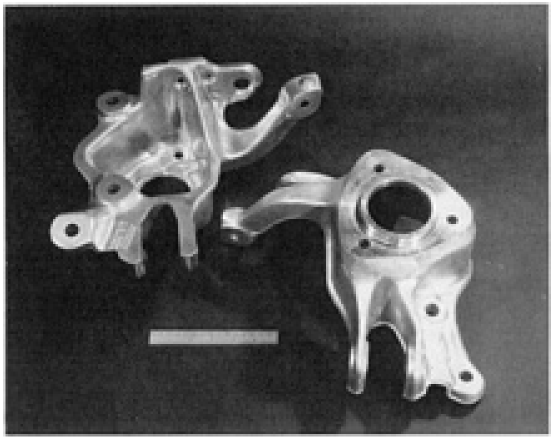

Fig. 7 Complex aluminum alloy automotive suspension components forged on a mechanical press.

Mechanical and screw presses combine impact with a squeezing action that is more compatible with the flow characteristics of aluminum alloys than hammers. Screw presses differ from mechanical presses in that the former have a degree of strain rate control that can be exploited to enhance the deformation control of aluminum alloys. State-of-the-art mechanical and screw presses have press load and operation monitoring and press control systems. These systems, combined with automated handling and supporting equipment, such as reheat furnaces and trim presses, can be used to achieve full forging process automation and highly repeatable and precise forging conditions in order to enhance the uniformity of the resulting aluminum alloy forgings. Typically, the minimum applied draft for mechanical or screw press forged aluminum alloys is 3°; however, both press types have been used to manufacture precision, net shape aluminum alloy forgings with draft angles of 1°. Screw presses are particularly well suited to the manufacture of the highly twisted, close-tolerance aluminum blades used in turbine engines.

Hydraulic Presses. Although the fastest hydraulic presses are slower acting than mechanical or screw presses, hydraulic presses are frequently best suited to producing either very large aluminum closed-die forgings (Fig. 8) or very intricate aluminum alloy forgings. The deformation achieved in a hydraulic press is more controlled than that typical of mechanical and screw presses or hammers. Therefore, hydraulic presses are particularly well adapted to the fabrication of conventional, high-definition, and precision no-draft, net shape aluminum alloy forgings in which slow or controlled strain rates minimize the resistance of the aluminum alloy to deformation, reduce pressure requirements, and facilitate achieving the desired shape.

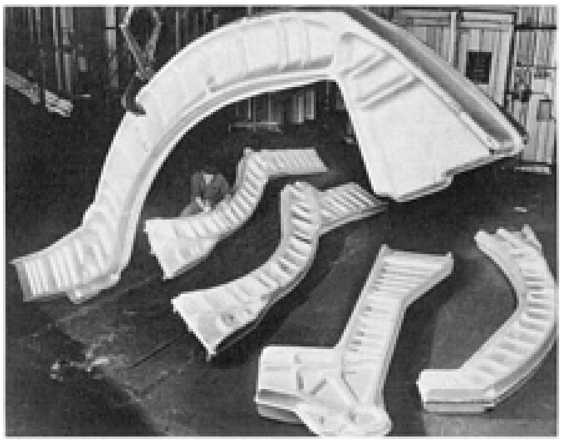

Fig. 8 Examples of very large blocker-type aluminum alloy airframe forgings.

State-of-the-art hydraulic presses, including very large machines of up to 445 MN (50,000 tonf), include speed and pressure controls and programmable modes of operation. With organization into press cells, automatic handling and lubrication, die heating and supporting equipment, such presses provide a high degree of forging process automation and forging process control to achieve process optimization and improved product uniformity. The minimum applied draft angle for high-definition hydraulic press forged aluminum alloys is 3°; for hydraulic press forged precision, net shape aluminum forgings, the minimum draft angle is 0 to 0.5° on outside contours and 0.5 to 1° on inside contours.

G.W. Kuhlman, Aluminum Company of America

Die Materials, Design, and Manufacture

For the closed-die forging of aluminum alloys, die materials selection, die design, and manufacturing are critical elements in the overall aluminum forging process, because the dies are a major element of the final cost of such forgings. Further, forging process parameters are affected by die design, and the dimensional integrity of the finished forging is in large part controlled by the die cavity. Therefore, the forging of aluminum alloys requires the use of dies specifically designed for aluminum for the following reasons:

- The deformation behavior of aluminum alloys differs from that of other materials; therefore, the intermediate and final cavity die design must optimize metal flow under given forging process conditions and provide for the fabrication of defect-free final parts
- Allowances for shrinkage in aluminum alloys are typically greater than those for steels and other materials
- Temperature control of the dies used to forge aluminum alloys is critical; therefore, the methods used for heating and maintaining die temperatures during forging must be considered in the design

Die Materials. The die materials used in the closed-die forging of aluminum alloys are identical to those employed in forging steels except that, because of the forces applied in aluminum alloy forging and the sophistication of the parts produced, such materials are typically used at lower hardness levels in order to improve their toughness. Available die materials were primarily designed for the forging of steels and are not necessarily optimized for the demands of aluminum alloy forgings. However, with advanced steelmaking technology, such as argon oxygen decarburization refining, vacuum degassing, and ladle metallurgy, the transverse ductility and fracture toughness of available standard and proprietary die steel grades have been improved dramatically. As a result, the performance of these grades in the forging of aluminum alloys has also improved dramatically.

Although die wear is less significant with aluminum alloy forgings than with steel and other high-temperature materials, high-volume aluminum alloy forgings can present die wear problems in cases in which die blocks have reduced hardness in order to provide improved toughness. Therefore, higher-hardness die inserts and/or surface treatments are often used to improve wear characteristics in order to maintain die cavity integrity. The surface treatments employed include carburizing, nitriding, carbonitriding, and surface alloying using a variety of state-of-the-art techniques.

Beyond die wear, the most common cause of die failure in aluminum forging dies is associated with die checking or die cracking, which, if left unheeded, can lead to eventual catastrophic loss of the die. Such die checking usually occurs at stress raisers inherent in the die cavity. Improved-toughness die steels, improved die-sinking techniques (see below), improved die design (see below), and lower-hardness die blocks serve to reduce the incidence of die checking in the forging of aluminum alloys. Further, forging dies for aluminum alloys are routinely repair welded using metal inert gas, tungsten inert gas, or other welding techniques.

For hot upsetting, both gripper dies and heading tools are usually made of 6G and 6F2 at a hardness of 42 to 46 HRC. Grades 6G or 6F2, or their proprietary variants, are the most widely used die materials in all closed-die forging processes for aluminum. If the quantities to be forged are large enough to justify the added cost or if the forging process and the part are particularly demanding, hot-work tool steels such as H11, H12, H13, or their proprietary variants are employed, usually at 44 to 50 HRC.

Die Design. A key element in the cost control of dies for aluminum forging and in the successful fabrication of aluminum alloy forgings is die design and die system engineering. Closed dies for aluminum forgings are manufactured either as stand-alone die blocks or as inserts into die holder systems, usually to reduce the overall cost of the dies for a given forging. Die holder systems may be universal, covering a wide range of potential die sizes, or may be constructed to handle families or parts of similar overall geometries. The design of aluminum forging dies is highly intensive in engineering skills and is based upon extensive empirical knowledge and experience. A complete compendium of aluminum forging design principles and practices is available in Ref 1.

Because aluminum alloy forging design is engineering intensive, the advent of computer-aided design (CAD) hardware and software has had an extensive impact on aluminum alloy die design. A detailed discussion of CAD technology is available in the Section "Computer-Aided Process Design for Bulk Forming" in this Volume. Computer-aided design techniques for aluminum forging parts and dies are fully institutionalized within the forging industry such that many aluminum alloy forgings, particularly high-definition and precision forgings, are designed with this technique. The CAD databases created are then used, as discussed below, with computer-aided manufacturing (CAM) to produce dies, to direct the forging process, and to assist in final part verification and quality control. Both public domain and proprietary CAD design software packages are used to design the finished forging from the machined part, including the dies, and to design the critical blocker and preform shapes needed to produce the finish shape, including the dies.

Beyond computer-aided design, heuristic techniques such as artificial intelligence are being used to commit the extensive aluminum forging design knowledge and experience into expert systems in order to enhance the design process. Complementing the expert systems is current research and development for aluminum alloys into powerful finite-element deformation-modeling techniques that, when fully developed, will further aid the designer in his task and will permit evaluation, verification, and optimization of forging part and die design on a computer before committing the design to any costly die sinking or part fabrication.

Die Manufacture. Aluminum alloy forging dies are produced by a number of machining techniques, including hand sinking, copy milling from a model, electrodischarge machining (EDM), and CNC direct sinking. With the availability of CAD data bases, CAM-driven CNC direct die sinking and EDM die sinking are at the leading edge of the state-of-the-art in aluminum alloy die sinking. These techniques serve to reduce the cost of the dies and, perhaps more important, to increase the accuracy of the dies by as much as 50% compared to the other techniques. For example, standard die-sinking tolerances are ±0.1 mm (±0.005 in.), but with CAM-driven CNC/EDM sinking, tolerances are reduced to ±0.07 mm (±0.003 in.) on complex dies. The finish on dies used for the forging of aluminum alloys is more critical than that on dies used for steel. Therefore, cavities are highly polished, frequently with automated equipment, by a variety of techniques in order to obtain an acceptable finish and to remove the disturbed surface layer resulting from such die-sinking techniques as electrodischarge machining.

Processing of Aluminum Alloy Forgings

The common elements in the manufacture of any aluminum alloy forging include preparation of the forging stock, preheating stock, die heating, lubrication, the forging process, trimming, forming and repair, cleaning, heat treatment, and inspection. The critical aspects of each of these elements are reviewed below.

Preparation of Forging Stock. Aluminum alloy forgings are typically produced from cast or wrought stock; forged or rolled bar, extruded bar, or plate are the primary examples. Selection of forging stock type for a given forging shape is based on the required forging processes, forging shape, mechanical property requirements, and cost. Sawing and shearing are the two methods most frequently used to cut aluminum alloy forging stock into lengths for forging. Abrasive cutoff can be used, but it is slower than sawing.

Sawing with a circular or band saw having carbide-tipped blades is the fastest and generally the most satisfactory method. Sawing, however, produces sharp edges or burrs that may initiate defects when the stock is forged in closed dies.

Burrs and sharp edges are typically removed by a radiusing machine. State-of-the-art saws for cutting aluminum alloys are highly automated and frequently have automatic radiusing capability and control systems that permit very precise control of either stock length or stock volume and therefore stock weight.

Shearing is used less for aluminum than for steel, because aluminum alloy billets are softer and more likely to be mutilated in shearing and because the sheared ends may have unsatisfactory surfaces for forging without being conditioned. Shearing is successfully used for high-volume aluminum forgings made from wrought bar stock generally less than 50 mm (2 in.) in diameter. More information on the cutting of metal stock is available in the Section "Shearing, Slitting, and Cutting" in this Volume.

Preheating for Forging. As noted in the section "Effect of Temperature" in this article, metal temperature is a critical element in the aluminum forging process. Aluminum alloys form a very tenacious oxide coating upon heating. The formation of this coating is self-limiting; therefore, aluminum alloys do not scale to the same extent as steel does. However, most aluminum alloys are susceptible to hydrogen pickup during reheating operations such that reheating equipment and practices are also critical elements of forging process control.

Heating Equipment. Aluminum alloys are heated for forging with a wide variety of heating equipment, including electric furnaces, fully muffled or semimuffled gas furnaces, oil furnaces, induction heating units, fluidized-bed furnaces, and resistance heating units. Gas-fired semimuffled furnaces, either batch or continuous, are probably the most widely used. Heating equipment design and capabilities necessarily vary with the requirements of a given forging process. Both oil and natural gas furnaces must use low-sulfur fuel. Excessive hydrogen pickup in forged aluminum alloys manifests itself in two ways. The first is high-temperature oxidation, which is usually indicated by blisters on the surface of the forging. The second is bright flakes, or unhealed porosity, which is usually found during the high-resolution ultrasonic inspection of final forgings. Both types of hydrogen pickup are influenced by preheating furnace practices and/or furnace equipment in which water vapor as a product of combustion is the primary source of hydrogen. Fully muffled gas-fired furnaces or low relative humidity electric furnaces provide the least hydrogen pickup. Techniques are available for modifying the surface chemistry of aluminum alloys to reduce hydrogen pickup in heating equipment that has higher levels of relative humidity than desired. Protective-atmosphere furnaces are seldom used to preheat aluminum alloy forgings.

Induction heating, resistance heating, and fluidized-bed heating are frequently used in the forging of aluminum alloys in cases in which forging processes are highly automated. State-of-the-art gas-fired furnaces can also be linked with specially designed handling systems to provide full automation of the forging process.

Temperature Control. As noted in Fig. 1, 2, and 3 and in Table 1, aluminum alloys have a relatively narrow temperature range for forging. Therefore, careful control of the temperature in preheating is important. The heating equipment should have pyrometric controls that can maintain ± 5 °C (±10 °F). Continuous furnaces used to preheat aluminum typically have three zones: preheat, high heat, and discharge. Most furnaces are equipped with recording/controlling instruments and are frequently surveyed for temperature uniformity in a manner similar to that used for solution treatment and aging furnaces.

Heated aluminum alloy billets are usually temperature checked by using either contact or noncontact pyrometry based on dual-wavelength infrared systems. This latter technology, although sensitive to emissivity, has been successfully incorporated into the fully automated temperature verification systems used in automated high-volume aluminum forging processes to provide significantly enhanced temperature control and process repeatability. In the open-die forging of aluminum alloys, it is generally desirable to have billets near the high side of the forging temperature range when forging begins and to finish the forging as quickly as possible before the temperature drops excessively. Open-die forging and multiple-die closed-die forging of aluminum alloys are frequently conducted without reheating as long as critical metal temperatures can be maintained.

Heating time for aluminum alloys varies, depending on the section thickness of the stock and the furnace capabilities. However, in general, because of the increased thermal conductivity of aluminum alloys, the required preheating times are shorter than with other forged materials. Recording pyrometric instruments on furnaces can be used to provide an indication of when the metal has reached the desired forging temperature. Generally, 10 to 20 min per inch of section thickness is sufficient to ensure that the aluminum alloys have reached the desired temperature.

Time at temperature is not as critical for aluminum alloys as for some other forged materials; however, long soaking times offer no particular advantage, except for high-magnesium alloys such as 5083, and may in fact be detrimental in terms of hydrogen pickup. Generally, soaking times of 1 to 2 h are sufficient; if unavoidable delays are encountered such that soaking time may exceed 4 to 6 h, removal of the metal from the furnace is generally recommended.

Heating of Dies. As noted in the section "Effect of Die Temperature" in this article, die temperature is the second critical element in the aluminum forging process. Dies are always heated for the forging of aluminum alloys, with die temperature for closed-die forging being more critical. As noted in Table 2, the die temperature used for the closed-die forging of aluminum alloys varies with the type of forging equipment being employed and the alloy being forged. Both remote and on-press die heating systems are employed in the forging of aluminum alloys. Remote die heating systems are usually gas-fired die heaters capable of slowly heating the die blocks. These systems are used to preheat dies to the desired temperature prior to assembly into the forging equipment.

On-press die heating systems range from relatively rudimentary systems to highly engineered systems designed to maintain very tight die temperature tolerances. On-press die heating systems include gas-fired equipment, induction heating equipment, and/or resistance heating equipment. In addition, presses used for the precision forging of aluminum alloys frequently have bolsters that can be heated or cooled as necessary. State-of-the-art on-press aluminum die heating equipment can hold die temperature tolerances within ±15 °C (±25 °F) or better. Specific on-press die heating systems vary with the forging equipment used, the size of the dies, the forging process, and the type of forging produced.

Lubrication. Die lubrication is the third critical element in the aluminum forging process and is the subject of major engineering and developmental emphasis, both in terms of the lubricants themselves and the lubricant application systems.

The lubricants used in aluminum alloy forging are subject to severe service demands. They must be capable of modifying the surface of the die to achieve the desired reduction in friction, withstand the high die and metal temperatures and pressures employed, and yet leave the forging surfaces and forging geometry unaffected. Lubricant formulations are typically highly proprietary and are developed either by the lubricant manufacturers or by the forgers themselves. Lubricant composition varies with the demands of the forging process used and the forging type. The major active element in aluminum alloy forging lubricants is graphite; however, other organic and inorganic compounds are added to colloidal suspensions in order to achieve the desired results. Carriers for aluminum alloy forging lubricants vary from mineral spirits to mineral oils to water.

Lubricant application is typically achieved by spraying the lubricant onto the dies while the latter are assembled in the press; however, in some cases, lubricants are applied to forging stock prior to reheating or just prior to forging. Several pressurized-air or airless spraying systems are employed, and with high-volume highly automated aluminum forging processes, lubricant application is also automated by single- or multiple-axis robots. Lubricant can be applied with or without heating. State-of-the-art lubricant application systems have the capability of applying very precise patterns or amounts of lubricant under fully automated conditions such that the forging processes are optimized and repeatable.

Forging Process. The critical elements of the aluminum forging process, specifically strain rate, deformation mode, and type of forging process have been reviewed above, including state-of-the-art capabilities that have served to enhance control of the forging process and therefore the product it produces. In addition to the enhanced forging equipment employed in the manufacture of aluminum forging, mention was made of the organization of presses and supporting equipment into cells operating as systems; such systems are then integrated with advanced manufacturing and computer-aided manufacturing concepts. Aluminum alloy forging is thus entering an era properly termed integrated manufacturing, in which all aspects of the aluminum forging process from design to execution are heavily influenced by computer technology.

Trimming, forming, and repair of aluminum alloy forgings are intermediate processes that are necessary to achieve the desired finish shape and to control costs.

Trimming. The flash generated in most closed-die aluminum forging processes is removed by hot or cold trimming or sawing, punching, or machining, depending on the size, shape, and volume of the part being produced. Hot- or cold-trimming tools are ordinarily used to trim large quantities, especially on moderately sized forgings that are intricate and may contain several punchouts. The choice of hot or cold trimming is largely based on the complexity of the part and on cost. The trim presses employed are either mechanical or hydraulic. Trimming dies are usually constructed of 6G or 6F2 die block steel at a hardness of about 444 to 477 HB. Tools of these steels are less costly because they are often produced from pieces of worn or broken forging dies. Blades for trimming and the edges of trimming dies are frequently hardfaced to improve their abrasion resistance. In addition to these grades, O1 tool steel and/or high-alloy tool steel such as D2 hardened to 58 to 60 HRC have also been used to trim aluminum alloy forgings and may offer longer service lives. The hot trimming of aluminum alloys is usually accomplished immediately after forging without reheating.

Forming. Some aluminum alloy forging shapes combine hot forging with hot, warm, or cold forming to achieve the shape. An example is the forged and formed aluminum truck wheel shown in Fig. 9. Forming is accomplished on mechanical or hydraulic presses or on specialized forming equipment that is frequently integrated as a part of a forging cell with the forging press.

Fig. 9 Forged and formed aluminum alloy 6061-T6 truck wheels.

Repair. This is an intermediate operation that is conducted between forging stages in aluminum alloys. It is frequently necessary to repair the forgings to remove surface discontinuities created by the prior forging practice so that such discontinuities do not affect the integrity of the final forging product. The need for repair is usually a function of part complexity and the extent of the tooling manufactured to produce the part. There is typically a cost trade-off between increased tooling (or number of die sets) and requirements for intermediate repair that is unique to each forging configuration. Intermediate repair of aluminum alloys is usually accomplished by hand milling, grinding, machining, and/or chipping techniques.

Cleaning. Aluminum alloy forgings are usually cleaned as soon as possible after being forged. The following treatment is a standard cleaning process that removes lubricant residue and leaves a good surface with a natural aluminum color:

- Etch in a 4 to 8% (by weight) aqueous solution of caustic soda at 70 °C (160 °F) for 0.5 of 5 min
- Rinse immediately in hot water at 75 °C (170 °F) or higher for 0.5 to 5 min
- Desmut by immersion in a 10% (by volume) aqueous solution of nitric acid at 88 °C (190 °F) minimum
- Rinse in hot water

The immersion time in the first two steps varies, depending on the amount of soil to be removed and the forging configuration. The frequency of cleaning also depends on the forging configuration and the process used to produce it. Some forgings are not cleaned until just before final inspection. Additional information on the cleaning of aluminum alloys is available in the article "Surface Engineering of Aluminum and Aluminum Alloys" in *Surface Engineering*, Volume 5 of the *ASM Handbook.*

Heat Treatment. All aluminum alloy forgings, except 1*xxx,* 3*xxx,* and 5*xxx* series alloys, are heat treated with solution treatment, quench, and artificial aging processes in order to achieve final mechanical properties. The furnaces used to heat treat and age aluminum alloy forgings are either continuous or batch type, fully muffled gas-fired, electric, fluidized-bed, or other specially designed equipment. Because of the shape complexity of aluminum forgings, quench-racking procedures are particularly critical in obtaining the uniform and satisfactory quench necessary to achieve the required mechanical properties and to minimize distortion. Therefore, in addition to control of solution treatment and age temperature and time, racking techniques for forgings are also the subject of necessary heat treatment control processes.

Furthermore, quenching techniques for aluminum alloy forgings are also critical because of their configuration and frequently widely variant cross-sectional thicknesses within the same forging. Depending on the specific aluminum alloy being processed, quench techniques for forgings include controlled-temperature water from 20 to 100 °C (75 to 212 °F) and synthetic quenchants, such as polyalkylene glycol and others, designed to achieve the required quench rate in order to obtain the required mechanical properties without excessive distortion. State-of-the-art aluminum forging solution treatment and age furnaces have multiple control/recording systems, microprocessor furnace control and operation systems, and quench monitoring and recording equipment, including video camera systems, that provide very precise control and repeatability of the heat treatment process. These systems can be interfaced with computer-integrated manufacturing systems.

Aluminum alloy forgings are often straightened between solution treatment and aging. Straightening is typically accomplished cold using either hand (frequently, press assisted) or die straightening techniques.

Many aluminum alloy forgings in the 2*xxx* and 7*xxx* series are compressively stress relieved between solution treatment and aging in order to reduce machining distortion. Depending on the part configuration, such compressive stress relief is accomplished by cold forging with open or closed dies, achieving a permanent set of 1 to 5%. With closed-die compressive stress relief, depending on part configuration, cold forging is accomplished either in the finish-forging dies (temper designation: T*xx*54) or in a separate set of cold-work dies (temper designation: T*xx*52). Some annular and other shapes of aluminum alloy forgings are stress relieved by cold stretching (temper designation: T*xx*51). Additional information on the heat treatment of aluminum alloys, including forgings, is available in the article "Heat Treating of Aluminum Alloys" in *Heat Treating*, Volume 4 of the *ASM Handbook* and in Ref 2.

Inspection of aluminum alloy forgings takes two forms: in-process inspection and final inspection. In-process inspection, using such techniques as statistical process control and/or statistical quality control, is used to determine that the product being manufactured meets critical characteristics and that the forging processes are under control. Final inspection, including mechanical property testing, is used to verify that the completed forging product conforms with all drawing and specification criteria. Typical final inspection procedures used for aluminum alloy forgings include dimensional checks, heat treatment verification, and nondestructive evaluation.

Dimensional Inspection. All final forgings are subjected to dimensional verification. For open-die forgings, final dimensional inspection may include verification of all required dimensions on each forging or the use of statistical sampling plans for groups or lots of forgings. For closed-die forgings, conformance of the die cavities to the drawing requirements, a critical element in dimensional control, is accomplished prior to placing the dies in service by using layout inspection of plaster or plastic casts of the cavities. With the availability of CAD databases on forgings, such layout inspections can be accomplished more expediently with CAM-driven equipment, such as coordinate-measuring machines or other automated inspection techniques. With verification of die cavity dimensions prior to use, final part dimensional inspection may be limited to verifying the critical dimensions controlled by the process (such as die closure) and monitoring the changes in the die cavity. Further, with high-definition and precision aluminum forgings, CAD databases and automated inspection equipment, such as coordinate-measuring machines and 2-D fiber optics, can be used in many cases for actual part dimensional verification.

Heat Treatment Verification. Proper heat treatment of aluminum alloy forgings is verified by hardness measurements and, in the case of 7*xxx*-T7*xxx* alloys, by eddy-current inspection. In addition to these inspections, mechanical property tests are conducted on forgings to verify conformance to specifications. Mechanical property tests vary from destruction of forgings to tests of extensions and/or prolongations forged integrally with the parts. Additional information on hardness and the electrical conductivity inspection and mechanical property testing of aluminum alloys is available in the article "Heat Treating of Aluminum Alloys" in *Heat Treating*, Volume 4 of the *ASM Handbook.*

Nondestructive Evaluation. Aluminum alloy forgings are frequently subjected to nondestructive evaluation to verify surface or internal quality. The surface finish of aluminum forgings after forging and caustic cleaning is generally good. A surface finish of 125 rms or better is considered normal for forged and etched aluminum alloys; under closely controlled production conditions, surfaces smoother than 125 rms may be obtained. Selection of nondestructive evaluation requirements depends on the final application of the forging. When required, satisfactory surface quality is verified by liquid-penetrant, eddy-current, and other techniques. Aluminum alloy forgings used in aerospace applications are frequently inspected for internal quality using ultrasonic inspection techniques.

Forging of Aluminum Alloys

G.W. Kuhlman, Aluminum Company of America

Forging Advanced Aluminum Materials

The preceding discussion of aluminum alloy forging technology is based on existing, commercially available wrought alloys. However, aluminum alloy development, including ingot metallurgy (I/M) and other techniques, is providing three major groups of advanced aluminum materials designed to enhance the capabilities of aluminum in critical applications, particularly aerospace. These three groups are:

- Aluminum-lithium alloys
- Alloys produced using prealloyed powder metallurgy (P/M) based on rapid solidification or other powder-making technology, such as mechanical alloying (dispersion strengthening)
- Aluminum-base discontinuous metal-matrix composites, which can be produced by either I/M or P/M techniques

None of these three groups of advanced aluminum materials is currently used commercially, but alloy and process development, including forging, is the subject of intense efforts in order to make these materials available for future commercial applications.

Aluminum-Lithium Alloys

Reduced-density aluminum alloys with mechanical properties equivalent to those of existing high-strength alloys have been identified as an important technology for effecting major reductions in weight for aerospace applications. Lithium additions to aluminum (up to about 4%) have been shown to decrease alloy density by 7 to 10% and to increase elastic modulus. Aluminum-lithium alloy development began in the mid-1950s, but more focused efforts on this technology have been underway since 1980. Table 3 lists the composition ranges or nominal compositions of several registered I/M and developmental P/M aluminum-lithium alloys under evaluation in forgings. Listed for comparison is alloy 2020, the first registered aluminum-lithium alloy, which was withdrawn from service in the early 1970s because of inadequate fracture toughness.

Table 3 Compositions of aluminum-lithium alloys

(a) All compositions contain balance of aluminum.

(b) Maximum.

(c) Densities of wrought conventional aluminum alloys range from 2.64 g/cm^3 (0.095 lb/in.^{3}) for alloy 5056 to 2.82 g/cm^3 (0.102 lb/in.^{3}) for alloys 7178 and 2011.

Aluminum-lithium alloys have been found to be readily forgeable, with flow stresses between those of alloy 2219 and 2014 (Fig. 1). Currently, recommended forging temperatures have not been fully defined; however, for the I/M alloys 2090, 2091, and 8090 and for some P/M alloys, the required metal temperatures can be expected to be similar to those of alloys 2014, 2219, or 2618 in Table 1. For other P/M alloys, the required metal temperatures may be lower. At least one of these alloys, IN905XL, may require no heat treatment; strengthening is achieved by a combination of work hardening and dispersion strengthening.

Desired mechanical properties, specifically combinations of high strength and high fracture toughness, in several recently developed aluminum-lithium alloys are highly dependent on relatively high levels (4 to 8%) of cold reduction between solution treatment and aging. Achieving these levels of cold reduction uniformly is difficult with many closed-die forgings; therefore, most current aluminum-lithium heat-treatable alloy forgings are processed to -T6*xxx* tempers, with attendant reductions in mechanical properties. Currently, mechanical property achievements in aluminum-lithium alloy forgings are similar to those obtained with 2014-T6 or -T61 and/or 2024-T6.

Aluminum-lithium alloys are considerably more costly than the current, commercially used aluminum alloys. Therefore, it is evident that high-definition and precision, net shape forgings that significantly reduce metal input in forging manufacture and reduce subsequent machining are the most cost-effective forging methods for these alloys when they are fully commercialized.

Prealloyed P/M Alloys

Rapid solidification, mechanical alloying, and other P/M technologies have been used to develop unique compositions of high-strength, elevated-temperature, and corrosion-resistant alloys that would not be achievable with standard I/M techniques. Table 4 lists the composition ranges for several registered high-strength prealloyed P/M aluminum alloys and the nominal compositions of developmental high-strength, elevated-temperature, and/or corrosion-resistant alloys under evaluation in forgings.

Table 4 Compositions of prealloyed aluminum P/M alloys

(b) All compositions contain balance of aluminum.

High-Strength Prealloyed P/M Aluminum Alloy Forgings. The flow stresses and deformation behavior of alloys 7090, 7091, X7064, CW67, and IN9021 have been found to be similar to those of alloy 7075 (Fig. 1). These alloys have been found to be readily forgeable by all existing forging techniques and workable into all types of final forging shapes, ranging from open-die forgings to all forms of closed-die forgings. The recommended metal temperatures of these alloys for forging are the same as those for alloys 7010, 7049, 7050, and/or 7075 (Table 1), and the die temperatures are the same as those listed in Table 2.

Four of these high-strength prealloyed P/M alloys are of the 7*xxx* series, and in forgings, they are typically heat treated to -T7*xxx* tempers, with or without compressive stress relief, for optimal combinations of strength, fracture toughness, and resistance to exfoliation or stress-corrosion cracking. Prealloyed P/M aluminum alloys are far superior to I/M alloys in corrosion resistance at very high strength levels. The remaining high-strength alloy, IN9021, is typically heat treated to the -T4 temper in forgings.

Rapidly solidified or mechanically alloyed powder in these alloys is consolidated into billets ranging in size from approximately 45 kg (100 lb) to as large as 1360 kg (3000 lb) through the use of several consolidation techniques, such as vacuum hot pressing and hot isostatic pressing. In this billet form, high-strength prealloyed P/M alloys can usually be fabricated directly into forgings or, with other working techniques, such as rolling or extrusion, into bar or plate stock for forging. As with aluminum-lithium alloys, the aluminum alloys produced using prealloyed P/M techniques are considerably more expensive than the commercially used I/M 7*xxx* alloys. Therefore, high-definition and precision, net shape forgings that reduce required metal input and subsequent machining are likely to be the most cost-effective forging methods. Several of these alloys have found limited commercial application in forgings for aerospace applications that require their unique property combinations.

Corrosion-Resistant Prealloyed P/M Aluminum Alloy Forgings. Alloy IN9052 (Table 4) is an intermediate-strength prealloyed aluminum alloy with mechanical properties similar to those of I/M alloy 5083 but with superior corrosion resistance. This alloy is forged at relatively low temperatures (<370 °C, or 700 °F), and its flow stress and deformation characteristics are also similar to those of alloy 5083. As with the high-strength P/M aluminum alloys, IN9052 is consolidated into billets and then into extruded stock prior to forging. The cost of this material suggests that high-definition and/or precision forgings will be the most cost-effective forging type.

Elevated-Temperature Prealloyed P/M Aluminum Alloy Forgings. Several rapid-solidification techniques, including atomization, melt spinning, and planar casting, have been used to develop a class of prealloyed aluminum alloys with significantly improved elevated-temperature properties over those of existing wrought I/M aluminum alloys such as 2219 and 2618 and cast aluminum alloys such as A201. The nominal compositions of several of these alloys are listed in Table 4. These alloys are being developed to provide enhanced properties in forgings in the range of 205 to 345 °C (400 to 650 °F), a temperature level that exceeds the useful capability of existing aluminum alloys, and to be competitive on a density-compensated basis with some titanium alloys.

By virtue of their elevated-temperature capabilities, these alloys have been found to be difficult to fabricate into forgings, displaying flow stresses up to twice that of alloy 7075 (Fig. 1). Recommended forging temperatures for these alloys have not been completely established, but the alloys are typically forged at temperatures below 370 °C (700 °F) in order to maintain their unique microstructural features. All of these elevated-temperature aluminum alloys are not heat treatable and develop their mechanical properties through dispersion strengthening, intermetallic compounds, and/or work hardening.

The working history of these alloys has also been shown to be a critical element in their suitability for fabrication. For example, several alloys are not forgeable in the consolidated-billet form, but must be given primary working through extrusion or other techniques. However, the forging process developmental work conducted to date has demonstrated that these alloys can be successfully fabricated into sophisticated closed-die and annular forging shapes, including high-definition and precision forgings. As with all expensive advanced aluminum alloy materials, these forgings may be the most cost effective through the implementation of material and machining conservation.

Aluminum-Base Discontinuous Metal-Matrix Composites

An emerging advanced aluminum materials concept is the addition of ceramic particles, or whiskers, to aluminum-base alloys through the use of either ingot-melting or casting and/or P/M techniques, creating a new class of materials termed discontinuous metal-matrix composites. In these materials systems, the reinforcing material (for example, silicon carbide, boron carbide, or boron nitride) is not continuous, but consists of discrete particles within the aluminum alloy matrix. Unlike continuous metal-matrix composites, discontinuous metal matrix composites have been found to be workable by all existing metalworking techniques, including forging. Addition of the reinforcement to the parent aluminum alloy matrix, typically in volume percentages from 10 to 40%, modifies the properties of the alloy significantly. Typically, compared to the matrix alloy and temper, such additions significantly increase the elastic and dynamic moduli, increase strength, reduce ductility and fracture toughness, increase abrasion resistance, increase elevated-temperature properties, and do not significantly affect corrosion resistance. Table 5 lists several of the developmental discontinuous metal-matrix composite materials that are being evaluated in forgings. None of these materials yet has significant commercial application; however, alloy and forging process development continues.

Table 5 Aluminum-base discontinuous metal-matrix composite materials

Producer	**Type**	**Matrix**	**Reinforcement**[(a)]	Reinforcement loading,

		alloys		vol %
Alcoa	P/M	2*xxx*	SiC(p)	**0-30**
		7*xxx*	SiC(p)	**0-30**
Dural	I/M	2014	SiC(p)	**0-40**
		6061	SiC(p)	**0-40**
		7075	SiC(p)	**0-40**
DWA	P/M	2024	SiC(p)	**0-40**
		6061	SiC(p)	**0-40**
		7090	SiC(p)	**0-40**
		7091	SiC(p)	**0-40**

		5083	SiC(w)/SiC(p)	**0-30**
		7075	SiC(w)/SiC(p)	**0-30**
		7090	SiC(w)/SiC(p)	**0-30**
		7091	SiC(w)/SiC(p)	**0-30**
Kobe	P/M-I/M	2024	SiC(w)	**0-30**
		6061	SiC(w)	**0-30**
		7075	**SiC(w)**	**0-30**

(a) SiC(p), particulate reinforcement; SiC(w), whisker reinforcement

The forging evaluation of these materials suggest that reinforcing additions to existing aluminum alloys modify the deformation behavior and increase flow stresses. The fabrication history of such materials may also be critical to their deformation behavior in forging and final mechanical property development. Although the recommended metal temperatures in forging these materials remain to be fully defined, current efforts suggest that temperatures higher than those listed in Table 1 for matfix alloys are typically necessary. Forging evaluations have demonstrated that discontinuous metal-matrix composites based on existing wrought aluminum alloys in the 2*xxx*, 6*xxx*, and 7*xxx* series can be successfully forged into all forging types, including high-definition and precision closed-die forgings. Some evidence suggests that these materials are more abusive of closed-die tooling and that die lives in forging these materials may be shorter than is typical of the parent alloys.

Forging of Aluminum Alloys

G.W. Kuhlman, Aluminum Company of America

Aluminum Alloy Precision Forgings

Precision-forged aluminum alloys are a significant commercial forging product form that has undergone major growth in use and has been the subject of significant technological development and capital investment by the forging industry. For the purposes of this article, the term precision aluminum forgings will be used to identify a product that requires no subsequent machining by the purchaser other than, in some cases, the drilling of attachment holes. Figure 10 compares precision aluminum forging design characteristics with those of a conventional aluminum closed-die forging. Precision aluminum forgings are produced with very thin ribs and webs; sharp corner and fillet radii; undercuts, backdraft, and/or contours; and, frequently, multiple parting planes that may optimize grain flow characteristics.

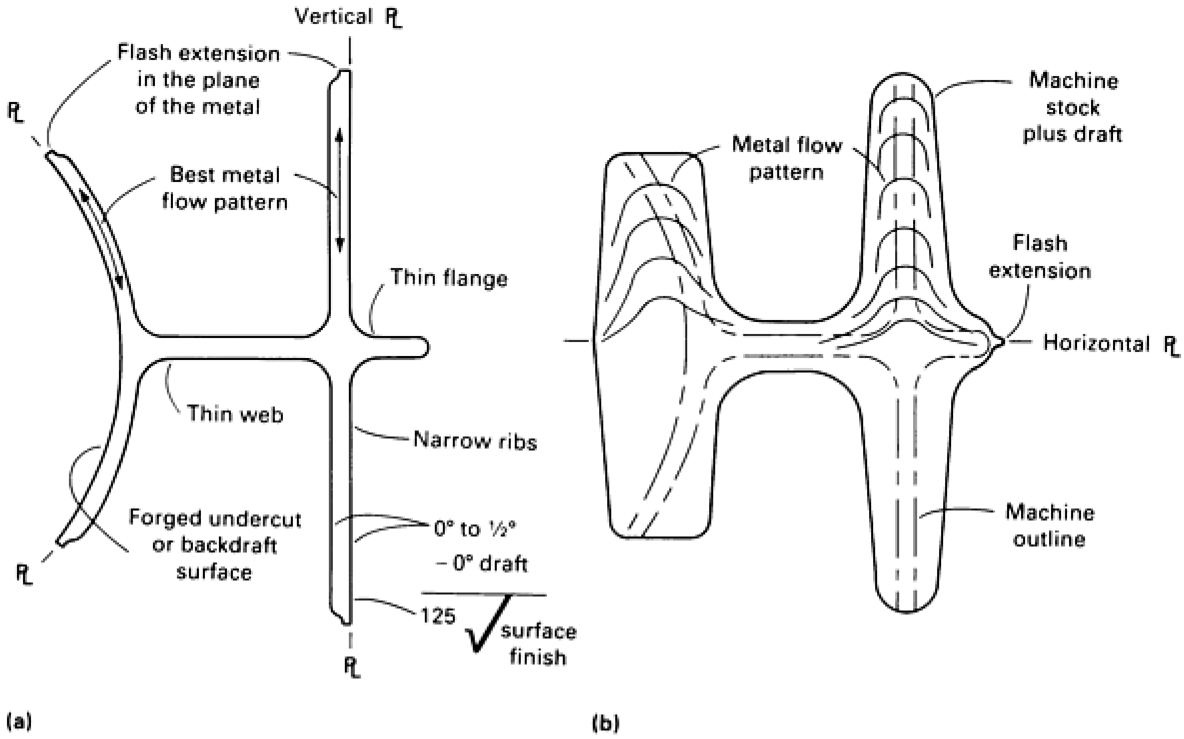

Fig. 10 Cross sections of precision (a) and conventional (b) forgings.

Design and tolerance criteria for precision aluminum forgings have been established to provide a finished product suitable for assembly or further fabrication. Precision aluminum forgings do not necessarily conform to the tolerances provided by machining of other product forms; however, as outlined in Table 6, design and tolerance criteria are highly refined in comparison to other aluminum alloy forging types and are suitable for the intended application of the product without subsequent machining by the purchaser. If the standard design and/or tolerance criteria for precision aluminum forgings are not sufficient, the forging producer frequently combines forging and machining to achieve the most cost-effective method of fabricating the necessary tolerances on the finished aluminum part.

Table 6 Design and tolerance criteria for aluminum precision forgings

Characteristic	Tolerance
Draft outside	0° +30', -0
Draft inside	1° +30', -0
Corner radii	1.5 ± 0.75 mm (0.060 ± 0.030 in.)
Fillet radii	3.3 ± 0.75 mm (0.130 ± 0.030 in.)
Contour	±0.38 mm (±0.015 in.)
Straightness	0.4 mm in 254 mm (0.016 in. in 10 in.)
Minimum web thickness[a]	2.3 mm (0.090 in.)
Minimum rib thickness	2.3 mm (0.090 in.)
Length/width tolerance	+0.5 mm, -0.25 mm (+0.020 in., -0.010 in.)
Die closure tolerance	+0.75, -0.25 mm (+0.030, -0.010 in.)
Mismatch tolerance	0.38 mm (0.015 in.)
Flash extension	0.75 mm (0.030 in.)

(a) Web thicknesses as small as 1.5 mm (0.060 in.) have been produced in certain forging designs.

Tooling and Design. Precision aluminum forging uses several tooling concepts to achieve the desired design shape; selection of the specific tooling concept is based on the design features of the precision-forged part. The three major tooling systems used are illustrated in Fig. 11. A two-piece upper and lower die system (Fig. 11a) is typically employed to precision forge shapes that can be produced with essentially horizontal parting lines. This system is very similar to the die concepts used for the fabrication of the aluminum alloy blocker, conventional, and high-definition closed-die forgings discussed above. The three-piece (or through-die) die system (Fig. 11b) consists of an upper die, a lower die (through-die), and a knockout/die insert. This system is typically employed for parts without undercuts and with vertical parting lines. The final and most complex aluminum precision-forging tooling concept is the holder (or wrap-die) system which consists of an upper die, a lower die (or holder), and multiple, movable inserts, or wraps (Fig. 11c). The multiple-insert holder/wrap-die system is used to produce the most sophisticated aluminum precision-forged shapes, including those with complex contours, undercuts, and reverse drafts.

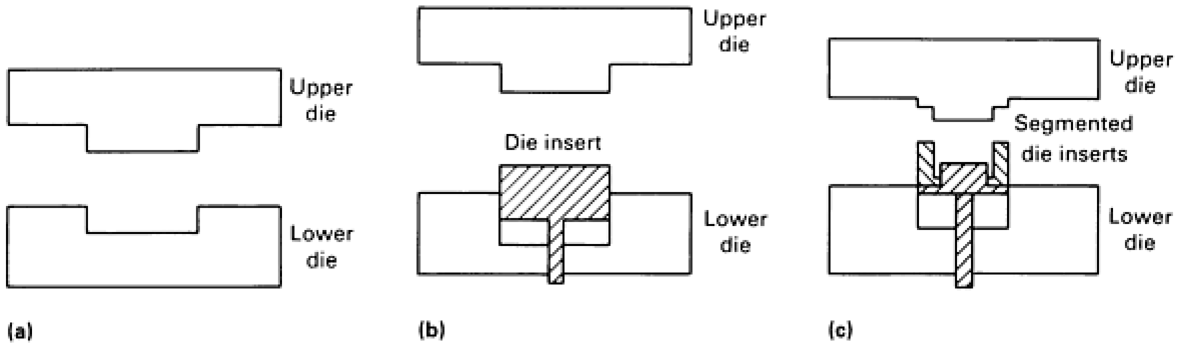

Fig. 11 Schematics of tooling concepts used in the manufacture of precision aluminum forgings. (a) Two-piece die system. (b) Three-piece die (through-die) system. (c) Multi-piece (wrap) die system. See also Fig. 12.

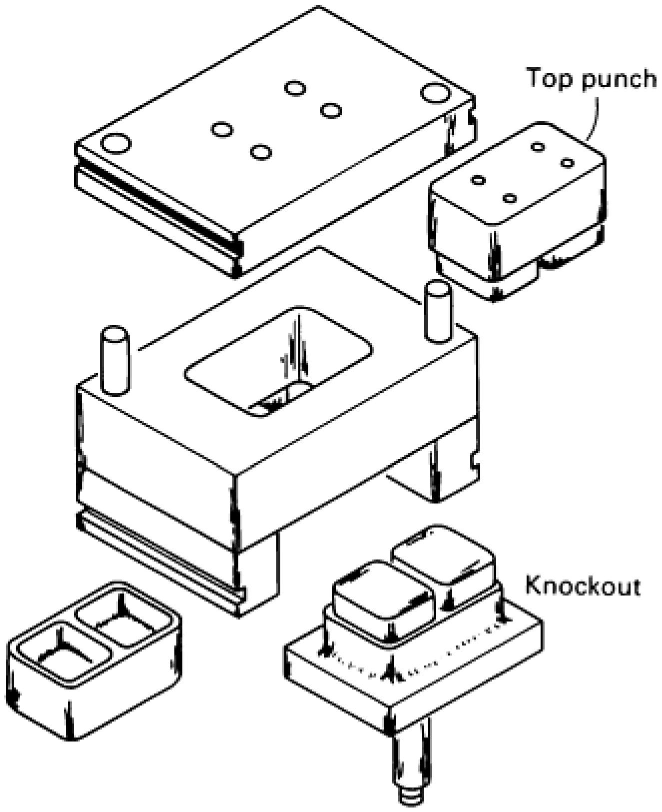
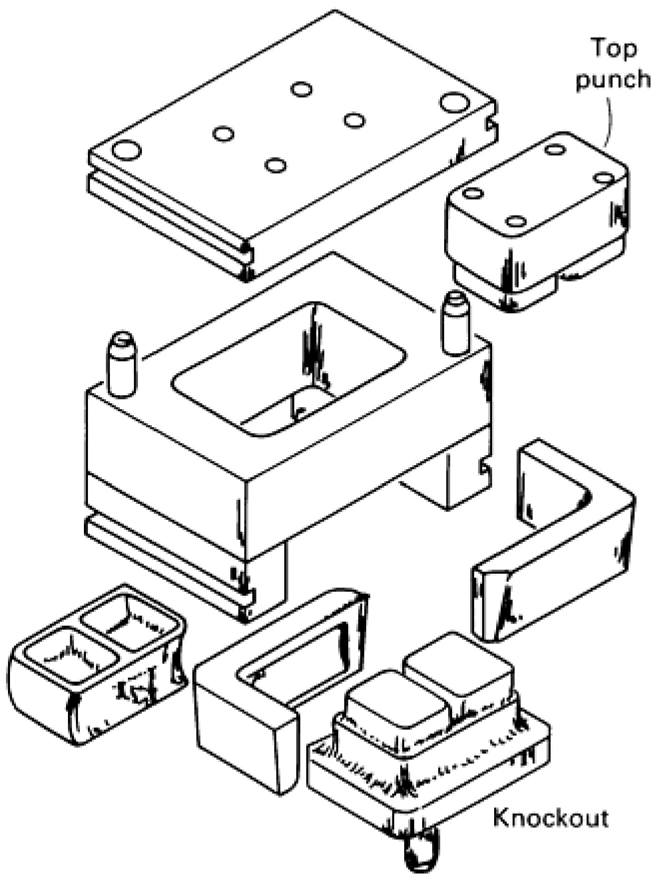
The through-die and the holder/wrap multiple-insert die systems for aluminum alloy precision forgings are critical elements in the sophistication of the precision-forging parts that can be produced. Figure 12 provides more insight into the components comprising these two die systems. These tooling concepts emerged in the early 1960s with the development of aluminum alloy precision-forging technology and have since been further refined and developed to provide increases in the size of precision part manufactured (see below).



(a)



(b)

Fig. 12 Components of a three-piece (through-die) system (a) and a multi-piece (wrap) die system (b) used for aluminum precision forgings. Source: Document D6-72713, Boeing Company, July 1985.

Because the through-die and holder/wrap-die systems are based on the commonality of significant portions of the tooling to a range of parts or to families of parts, the fabrication of dies for given precision forging is typically restricted to that necessary to produce the inserts. Thus, the cost of die manufacture for precision forgings is reduced when compared to that necessary to produce individual dies for each precision shape. However, aluminum precision-forging dies/inserts are usually two to four times more expensive than dies for other forging types for the same part.

The holder/wrap multiple-insert die concept is a highly engineered die system that can use two to six movable segments. Extraction of the part is achieved by lateral opening of the segments (wraps) once they have cleared the bottom die holder. Figure 13 illustrates the components of the wrap-die system first when the part has been forged (Fig. 13a) and then during extraction of the completed forging (Fig. 13b).

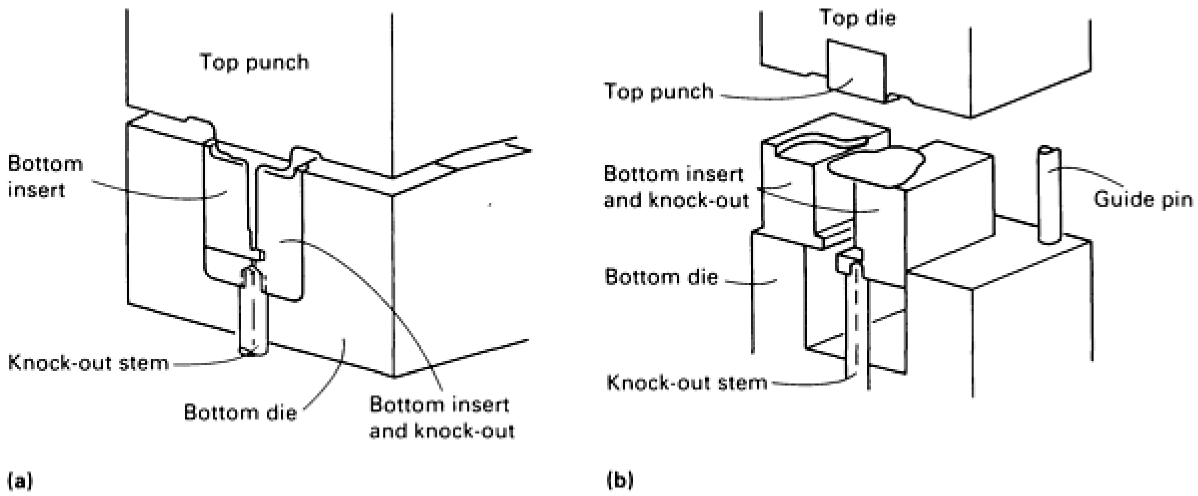


Fig. 13 Multi-piece (wrap) die system (a) during forging. (b) After forging, the die system opens to allow extraction of the completed part.

Aluminum alloy precision-forging part and tooling design are engineering-intensive activities that draw heavily on the experience of forging engineers and require interchange between producer and user to define the optimal precision-forging design for utilization, producibility, and cost control. As discussed in the section "Die Materials, Design, and Manufacture" in this article, computer-aided design, computer-aided manufacture, and computer-aided engineering (CAE) technologies have been found to be particularly effective in design and tooling manufacture activities for precision forgings to improve the design process, to assist in necessary forging process definition, and to reduce the costs of tooling manufacture.

The die materials used in dies, holders, and inserts for precision aluminum forgings are typically of the ASM 6F2 and 6G types. In some cases, inserts for high-volume precision aluminum alloy forgings are produced from hot-work grades, such as H12 and H13. Tooling for precision aluminum alloy forgings is produced by using the same techniques described above for other aluminum alloy forging types; however, CNC direct die sinking or electrical discharge machining has been found to be particularly effective for the manufacture of the close-tolerance tooling demanded by the design and tolerance criteria for precision aluminum alloy forgings.

Processing. Precision aluminum forgings can be produced from wrought stock, preformed shapes, or blocker shapes, depending on the complexity of the part, the tooling system being used, and cost considerations. Precision aluminum forgings are usually produced with multiple operations in finish dies; trimming, etching, and repair are conducted between operations.

Precision aluminum forgings are typically produced on hydraulic presses, although in some cases mechanical and/or screw presses have been effectively employed. Until recently, most precision aluminum forgings were produced on small-to-intermediate hydraulic presses with capacities in the range of 9 to 900 kN (1 to 100 tonf); however, as the size of precision parts demanded by users has increased, heavy hydraulic presses in the range of 135 to 310,000 kN (15 to 35,000 tonf) have been added or upgraded to produce this product. Forging process criteria for precision aluminum forgings are similar to those described above for other aluminum alloy forging types, although the metal and die temperatures used are usually controlled to near the upper limits of the temperature ranges outlined in Tables 1 and 2 to enhance producibility and to minimize forging pressures. The three-die systems described above are heated with state-of-the-art die heating techniques. As with other aluminum forging processes, die lubrication is a critical element in precision aluminum forging, and the die lubricants employed, although of the same genetic graphite-mineral oil formulations used for other aluminum forging processes, frequently use other organic and inorganic compounds tailored to the process demands.

Because of the design sophistication of precision aluminum forgings, this aluminum forging product is not supplied in mechanically stress-relieved tempers. However, because of the thin sections and the design complexity of this product, controlled quench rates following solution treatment, using such techniques as synthetic quenchants, are routinely employed to reduce residual stresses in the final product and/or to reduce distortion and necessary straightening to meet dimensional tolerances. In-process and final inspection for precision aluminum forgings are the same as described above for other forging products, including extensive use of automated inspection equipment, such as coordinate-measuring machines.

Precision aluminum forgings are frequently supplied as a completely finished product that is ready for assembly. In such cases, the producer may use both conventional and nonconventional machining techniques, such as chemical milling, along with forging to achieve the most cost-effective finished shape. Further, the forging producer may apply a wide variety of surface-finishing and coating processes to this product as specified by the purchaser.

Technology Development and Cost Effectiveness. Table 7 presents a summary of the history and future of the state-of-the-art in the size of aluminum precision forging producible. Within the last 5 years, the size that can be fabricated to the design and tolerance criteria listed in Table 6 has nearly doubled from 1775 cm^2 (275 in.^{2}) for H cross sections to more than 2580 cm^2 (400 in.^{2}) through enhancements of the precision aluminum forging process and equipment by forging producers. The precision forging shown in Fig. 14 illustrates the very large precision aluminum shapes being fabricated commercially. The difficult H cross-sectional forging shown in Fig. 14 has a plan view area of 2840 cm^2 (440 in.^{2}). This part incorporates some machining in its manufacture in selected regions where standard precision-forging tolerances were insufficient for assembly. Critical elements in projected changes in the state-of-the-art for aluminum precision parts are enhanced precision forging process control CAD/CAM/CAE technologies, advanced and/or integrated manufacturing technologies, and advanced die heating and die lubrication systems.

Table 7 Capabilities of the precision aluminum forging process based on part size

Forging type	Feature	Maximum size that can be processed		
		Past	Present	Future
T or U section	Plan view area	2580 cm^2 (400 in.^{2})	3870 cm^2 (600 in.^{2})	>6450 cm^2 (1000 in.^{2})
	Length	1015 mm (40 in.)	1525 mm (60 in.)	>2540 mm (100 in.)
H section	Plan view area	1775 cm^2 (275 in.^{2})	2580 cm^2 (400 in.^{2})	>3870 cm^2 (600 in.^{2})

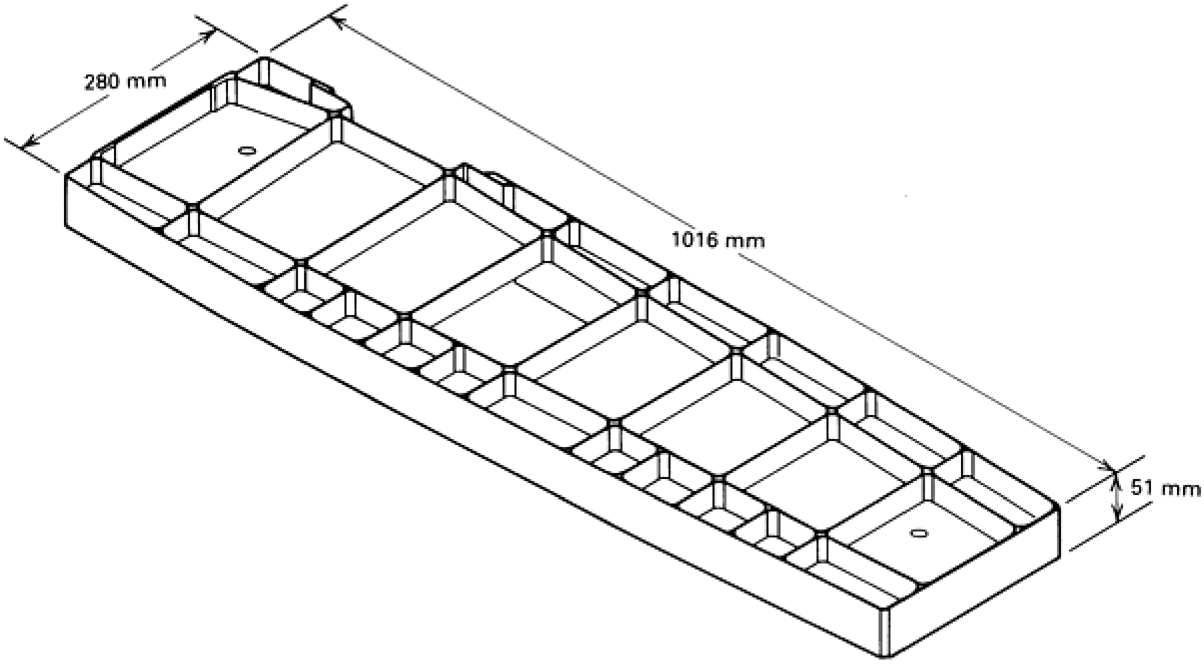

Fig. 14 Very large aluminum alloy 7075-T73 H section precision forging. Plan view area: 2840 cm^2 (440 in.^{2}); ribs 2 to 2.5 mm (0.080 to 0.100 in.) thick, 51 mm (2 in.) deep; webs typically 3 mm (0.120 in.), 2 mm (0.080 in.) in selected areas; finished weight: 5.6 kg (12.3 lb).

Selection of precision aluminum forging from the candidate methods of achieving a final aluminum alloy shape is based on value analyses for the individual shape in question. Figure 15 presents a cost comparison for a channel-type aluminum alloy part machined from plate, as machined from a conventional aluminum forging, and produced as a precision forging; costs as a function of production quantity include application of all material, tooling, setup, and fabrication costs. The breakeven point for the precision-forging method versus a conventional forging occurs with a quantity of 50 pieces, and when compared to the cost of machining the part from plate, the precision forging is always less expensive. Figure 15 also illustrates the potential cost advantages of precision aluminum alloy forgings. It has generally been found that precision aluminum forgings are highly cost effective when alternate fabrication techniques include multiple-axis machining in order to achieve the final part.

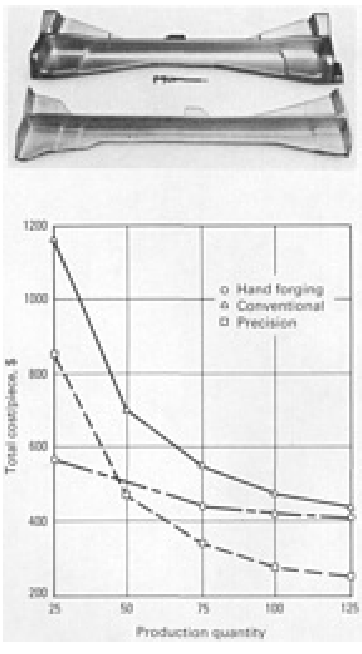

Fig. 15 Cost comparison for the manufacture of an aluminum alloy 7075-T73 component.

Recent forging industry and user evaluations have shown that precision aluminum forgings can reduce final part costs by up to 80 to 90% in comparison to machined plate and 60 to 70% in comparison to machined conventional forgings. Machining labor can be reduced by up to 90 to 95%. With such possible cost reductions in existing aluminum alloys and with the advent of more costly advanced aluminum materials, it is evident that further growth of precision aluminum forging use can be anticipated.

Forging of Aluminum Alloys

Forging of Copper and Copper Alloys

Robert A. Campbell, Mueller Brass Company

Introduction

COPPER AND COPPER ALLOY FORGINGS offer a number of advantages over parts produced by other processes, including high strength as a result of working, closer tolerances than competing processes such as sand casting, and modest overall cost. The most forgeable copper alloy, forging brass (alloy C37700), can be forged into a given shape with substantially less force than that required to forge the same shape from low-carbon steel. A less forgeable copper alloy, such as an aluminum bronze, can be forged with approximately the same force as that required for low-carbon steel.

Copper and copper alloy forgings, particularly brass forgings, are used in valves, fittings, refrigeration components, and other high-pressure liquid and gas handling applications. High-strength bronze forgings find application as mechanical parts such as gears, bearings, and hydraulic pumps.

Closed-Die Forging. Most copper alloy forgings are produced in closed dies. The sequence of operations is the same as that used for forging a similar shape from steel, that is, fullering, blocking, and finishing, as required (see the article "Closed-Die Forging in Hammers and Presses" in this Volume). However, it is estimated that 90% of the forgings produced from forging brass are forged completely in one or two blows in a finishing die. The starting slugs or blanks are usually cut from extruded bars or tubes to eliminate the blocking operation. Excessive flash is produced, but it is easily trimmed and remelted. In the forging of parts of mild to medium severity, in plants where remelting facilities are available, cutting slugs from bars or tubes is usually the least expensive approach. However, in plants that do not remelt their scrap, the flash must be sold as scrap, and it is sometimes more economical to use blocking. Figure 1 illustrates forged copper alloy parts in a variety of configurations.

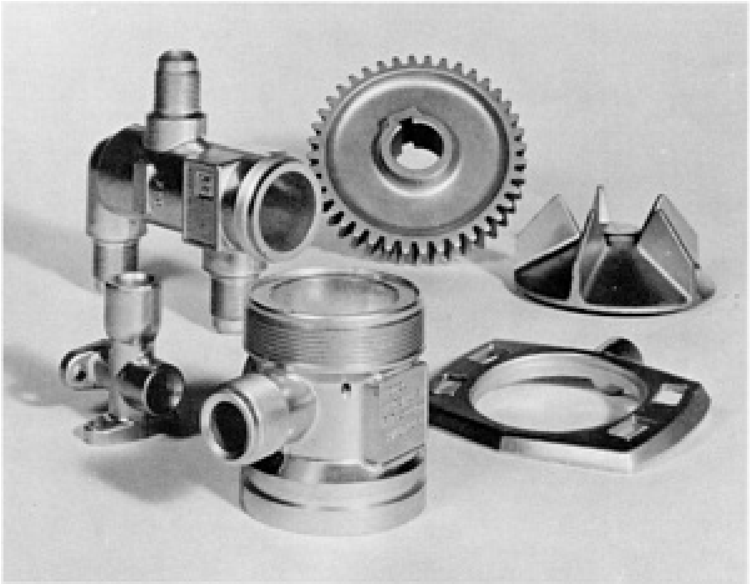

Fig. 1 Copper alloy parts made by closed-die forging. Courtesy of Mueller Brass Company

Cylindrical slugs are sometimes partially flattened before forging to promote better flow and consequently better filling of an impression. This can usually be done at room temperature between flat dies in a hammer or a press. A rectangular slug is occasionally obtained by extruding rectangular-section bar stock and sawing slugs from it.

Upset forging is used less frequently for copper alloys than for steels, primarily because copper alloys are so easily extruded. A part having a long shaftlike section and a larger-diameter head can often be made at less cost by extruding the smaller cross section from a larger one than by starting with a small cross section and upsetting to obtain the head.

In the upsetting of copper alloys, the same rule applies for maximum unsupported length as is used for steels, that is, not more than three times stock diameter. For the forging of brass, single-blow upsetting as severe as 3 to 1 (upset three times starting diameter) is considered reasonable. In practice, however, upsets of this severity are rare. The degree of allowable upset for other copper alloys is somewhat less than that for forging brass, generally in proportion to forgeability (Table 1).

Table 1 Relative forgeability ratings of commonly forged copper alloys

Ratings are in terms of the most forgeable alloy, forging brass (C37700).

Alloy	**Nominal composition**	Relative forgeability[(a)], %
C10200	99.95 min Cu	**65**
C10400	Cu-0.027 Ag	**65**
C11000	99.9 min Cu	**65**
C11300	Cu-0.027Ag + O	**65**
C14500	Cu-0.65Te-0.008P	**65**

C18200	Cu-0.10Fe-0. 90Cr-0.10 Si-0.05Pb	**80**
C37700	Cu-38Zn-2Pb	**100**
C46400	Cu-39.2Zn-0.8Sn	**90**
C48200	Cu-38Zn-0.8Sn-0.7Pb	**90**
C48500	Cu-37.5Zn-1.8Pb-0.7Sn	**90**
C62300	Cu-10Al-3Fe	**75**
C63000	Cu-10Al-5Ni-3Fe	**75**
C63200	Cu-9Al-5Ni-4Fe	**70**
C64200	Cu-7Al-1.8Si	**80**
C65500	Cu-3Si	**40**
C67500	**Cu-39Zn-1.4Fe-1Si-0.1Mn**	**80**

(a) Takes into consideration such factors as pressure, die wear, and hot plasticity

In most designs, the amount of upset can be reduced by using slugs cut from specially shaped extrusions or by using one or more blocking impressions in the forging sequence. Additional information on upset forging is available in the article "Hot Upset Forging" in this Volume.

Ring rolling is sometimes used as a means of saving material when producing ring gears or similar ringlike parts. The techniques are essentially the same as those used for steel and are described in detail in the article "Ring Rolling" in this Volume. Temperatures are the same as those for forging the same alloy in closed dies.

Cost usually governs the minimum practical size for ring rolling. Most rings up to 305 mm (12 in.) in outside diameter are more economically produced in closed dies. However, if the face width is less than about 25 mm (1 in.) it is often less expensive to produce rings no larger than 203 mm (8 in.) in outside diameter by the rolling technique. The alloy being forged is also a factor in selecting ring rolling or closed-die forging. For example, alloys such as beryllium copper that are difficult to forge are better adapted to ring rolling. For these alloys, ring rolling is sometimes used for sizes smaller than the minimum practical for the more easily forged alloys.

Robert A. Campbell, Mueller Brass Company

Forging Alloys

Copper C12200 and the copper alloys most commonly forged are listed in Table 1. They comprise at least 90% of all commercially produced copper alloy forgings. Forging brass, the least difficult alloy to forge, has been assigned an arbitrary forgeability rating of 100.

Table 2 Recommended die materials for the forging of copper alloys

Part configurations of varying severity are shown in Fig. 2.

Maximum severity	Total quantity to be forged			
	100-10,000		$\geq$10,000	
	Die material	**Hardness, HB**	**Die material**	Hardness, HB
Hammer forging				
Part 1	H11 6G, 6F2	405-433 341-375	H12	**405-448**
Part 2	6G, 6F2	341-375	6G, 6F2 H12[(a)]	**341-375** **405-448**
Part 3	6G, 6F2	269-293	6G, 6F2	**302-331**
Part 4	H11	405-433	H11	**405-433**
Part 5	6G, 6F2	302-331	6G, 6F2[(b)]	**302-331**
Press forging				
Part 1	H12 6G, 6F2	477-514 341-375	H12	**477-514**
Part 2	6G, 6F2	341-375	H12	**477-514**
Part 3	**Part normally is not press forged from copper alloys**			
Part 4	H11	405-433	6G, 6F2[(c)]	**341-375**

(a) Recommended for long runs--for example, 50,000 pieces.

(b) With either steel, use H12 insert at 405-448 HB.

(c) With either steel, use H12 insert at 429-448 HB.

Some copper alloys cannot be forged to any significant degree, because they will crack. Leaded copper-zinc alloys, such as architectural bronze, which may contain more than 2.5% Pb, are seldom recommended for hot forging. Although lead content improves metal flow, it promotes cracking in those areas of a forging, particularly deep-extruded areas, that are not completely supported by, or enclosed in, the dies. This does not mean that the lead-containing alloys cannot be forged, but rather that the design of the forging may have to be modified to avoid cracking.

The solubility of lead in β-brass at forging temperatures is about 2% maximum, but lead is insoluble in β-brass at all temperatures. Consequently, although a lead content of up to 2.5% is permissible in Cu-40Zn α-β brasses, lead in excess of 0.10% in a Cu-30Zn α-brass will contribute to catastrophic cracking.

Other copper alloys, such as the copper-nickels, can be forged only with greater difficulty and at higher cost. The copper-nickels, primarily because of their higher forging temperatures, are sometimes heated in a controlled atmosphere, thus complicating the process. The silicon bronzes, because of their high forging temperatures and their compositions, cause more rapid die deterioration than the common forging alloys.

Robert A. Campbell, Mueller Brass Company

Machines

Most copper alloy forgings are produced in crank-type mechanical presses. With these presses, the production rate is high, and less operator skill is needed and less draft is required than in forging copper alloys in hammers.

Press size is normally based on the projected (plan) area of the part, including flash. The rule of thumb is 0.5 kN of capacity per square millimeter of projected area (40 tonf/in.^{2}). Therefore, a forging with a projected area of 32.2 cm^2 (5 in.^{2}) will require a minimum of 1780 kN (200 tonf) capacity for forgings of up to medium severity. If the part is complicated (for example, with deep, thin ribs), the capacity must be increased.

Speed of the press is not critical in forging copper alloys, but minimum duration of contact between the hot forging and the die is desirable to increase die life. Detailed information on hammers and presses is available in the articles "Hammers and Presses for Forging" and "Selection of Forging Equipment" in this Volume.

Robert A. Campbell, Mueller Brass Company

Dies

Dies designed for forging copper or copper alloys usually differ from those designed for forging the same shapes from steel, as follows:

- The draft angle can be decreased for forging copper (3° max and often less than 3°)
- The die cavity is usually machined to dimensions that are 0.005 in./in. less than those for forging steels
- The die cavity is usually polished to a better surface finish for forging copper and copper alloys

Die materials and hardnesses selected for forging copper alloys depend on part configuration (forging severity) and number of parts to be produced. Figure 2 illustrates the forging severities of parts listed in Table 2.

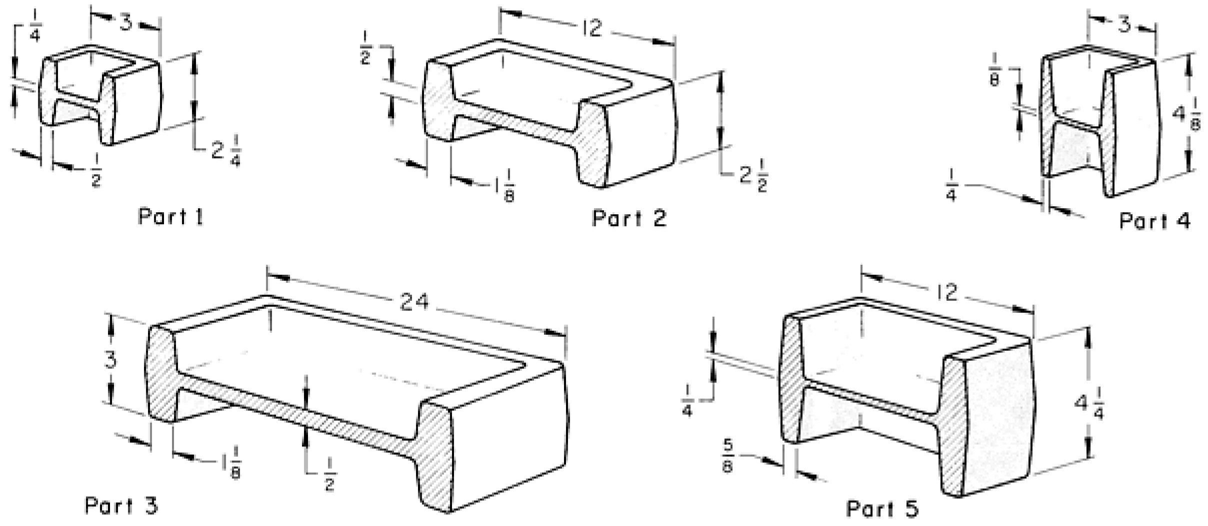

Fig. 2 Forged copper alloy parts of varying severity. See Table 2 for recommended die materials.

Whether the dies are made entirely from a hot-work steel such as H11 or H12 or whether or not inserts are used depends largely on the size of the die. Common practice is to make the inserts from a hot-work steel and to press them into rings or holders made from a low-alloy die block steel (Table 2) or L6 tool steel. Hardness of the ring or holder is seldom critical; a range of 341 to 375 HB is typical. Details on the selection of die material and data on die wear and life are available in the article "Dies and Die Materials for Hot Forging" in this Volume.

Robert A. Campbell, Mueller Brass Company

Preparation of Stock

The two methods most often used for cutting stock into slugs for forging are shearing and sawing.

Shearing is faster than other methods of cutting stock. In addition, no material is wasted in kerf. However, the ends of sheared stock are rougher than those of sawed sections. Rough or torn ends usually cannot be permitted, because forging defects are likely to nucleate from the rough ends. If shearing is used, best practice is to condition the sheared ends--for example, with a radiusing machine.

Sawing with circular saws having carbide-tipped blades is widely used as a method of preparing stock because sawed ends are usually in much better condition than sheared ends. The principal disadvantage of sawing is the loss of metal because of the kerf. In addition, if the burrs left by sawing are not removed, defects are likely to develop in the forging. Deburring of the saw sections by grinding, radiusing or barrel tumbling is always recommended.

Forging of Copper and Copper Alloys

Robert A. Campbell, Mueller Brass Company

Heating of Billets or Slugs

Optimal forging temperature ranges for ten alloys are given in Table 3. Atmosphere protection during billet heating is not required for most alloys, especially when forging temperatures are below 705 °C (1300 °F). For temperatures toward the top of the range in Table 3, a protective atmosphere is desirable and is sometimes required. An exothermic atmosphere is usually the least costly, and it is satisfactory for heating copper alloys at temperatures above 705 °C (1300 °F).

Table 3 Recommended forging temperature ranges for copper alloys

Alloy	Temperature range	
	°C	°F
C12200	730-845	**1350-1550**
C18200	650-760	**1200-1400**
C37700	650-760	**1200-1400**
C46400	595-705	**1100-1300**
C62400	705-815	**1300-1500**
C64200	730-900	**1350-1650**
C67000	595-705	**1100-1300**
C67300	595-730	**1100-1350**
C67400	595-730	**1100-1350**

Gas-fired furnaces are almost always used, and furnace design is seldom critical. Open-fired conveyor chain or belt types are those most commonly used.

Any type of pyrometric control that can maintain temperature within ±5 °C (± 10 °F) is suitable. As billets are discharged, a periodic check with a prod-type pyrometer should be made. This permits a quick comparison of billet temperature with furnace temperature.

Heating Time. The time at temperature is critical for all copper alloys, although to varying degrees among the different alloys. For forging brass (alloy C37700), the time is least critical, but for aluminum bronze, naval brass, and copper, it is most critical. Time in excess of that required to bring the billet uniformly to forging temperature is detrimental, because it causes grain growth and increases the amount of scale.

Reheating Practice. When forging in hammers, all of the impressions are usually made in one pair of dies, and reheating is rarely required. In press forging, particularly in high-production applications, blocking is often done separately, followed by trimming before the forging is completed. The operations are likely to be performed in different presses; therefore the partially completed forging is reheated to the temperature originally used.

Forging of Copper and Copper Alloys

Robert A. Campbell, Mueller Brass Company

Heating of Dies

Dies are always heated for forging copper and copper alloys, although because of the good forgeability of copper alloys, die temperature is generally less critical than for forging aluminum. Dies are seldom preheated in ovens. Heating is usually accomplished by ring burners. Optimal die temperatures vary from 150 to 315 °C (300 to 600 °F), depending on the forging temperature of the specific alloy. For alloys having low forging temperatures, a die temperature of 150 °C (300 °F) is sufficient. Die temperature is increased to as much as 315 °C (600 °F) for the alloys having the highest forging temperatures shown in Table 3.

Forging of Copper and Copper Alloys

Robert A. Campbell, Mueller Brass Company

Lubricants

Dies should be lubricated before each forging operation. A spray of colloidal graphite and water is usually adequate. Many installations include a spray that operates automatically, timed with the press stroke. However, the spray is often inadequate for deep cavities and is supplemented by swabbing with a conventional forging oil.

Forging of Copper and Copper Alloys

Robert A. Campbell, Mueller Brass Company

Trimming

Brass forgings are nearly always trimmed at room temperature. Because the forces imposed on the trimming tools are less than those for trimming steel forgings, the trimming of brass forgings seldom poses problems. Large forgings, especially in small quantities, are commonly trimmed by sawing off the flash and punching or machining the web sections. Trimming tools usually are used for trimming large quantities, especially of small forgings that are relatively intricate and require several punchouts.

Materials for trimming dies vary considerably among different plants. In some plants, it is common practice for normal trimming to make the punch from low-alloy die steel at a hardness of 46 to 50 HRC. One reason for using this steel is economy; the punches are often made from pieces of worn or broken dies. Blades for normal trimming are sometimes made by hardfacing low-carbon steels such as 1020.

In other plants both punches and blades are made from L6 steel and are heat treated to 52 to 56 HRC. Worn tools of this material can be repaired by welding with an L6 rod, remachining, and heat treating; O1 tool steel heat treated to 58 to 60 HRC has also been used for punches and blades for cold trimming. When close trimming is required, blades and punches fabricated from a high-alloy tool steel such as D2, hardened to 58 to 60 HRC, will give better results and longer life.

Hot trimming is sometimes used for one or both of the following reasons:

- For alloys such as aluminum bronzes that are brittle at room temperature
- When flash is heavy and sufficient power is not available for cold trimming

Hot trimming is usually done at 425 °C (800 °F).

Because of the lower forces involved, tools for hot trimming are simpler than those for cold trimming. Although the tool materials discussed above can also be used for hot trimming, unhardened low-carbon steel will usually suffice as a punch material. The same grade of steel with a hardfacing is commonly used as blade material.

Forging of Copper and Copper Alloys

Robert A. Campbell, Mueller Brass Company

Cleaning

Scale and excess lubricants are easily removed from copper and copper alloy forgings by chemical cleaning. Pickling in dilute sulfuric acid is the most common method for cleaning brass and most other copper alloy forgings, although hydrochloric acid can also be used. The compositions of sulfuric and hydrochloric acid solutions, the pickling procedures, and the typical uses are given in Table 4.

Table 4 Cleaning solutions and conditions for copper and copper alloy forgings

Solution	**Composition**	**Use temperature, °C (°F)**	Uses
Sulfuric acid	4-15 vol% H_2SO_4 (1.83 specific gravity); rem H_2O	Room-60 (140)	**Removal of black copper oxide scale from brass forgings; removal of oxide from copper forgings**
Hydrochloric acid	40-90 vol% HCl (35% conc); rem H_2O	Room	**Removal of scale and tarnish from brass forgings; removal of oxide from copper forgings**
"Scale" dip A	40% conc HNO_3; 30% conc H_2SO_4; 0.5% conc HCl; rem H_2O	Room	**Used with pickle and "bright" dip to give a bright, lustrous finish to copper and copper alloy forgings**
"Scale" dip B	50% conc HNO_3; rem H_2O	Room	**Used with pickle and "bright" dip to give bright, lustrous finish to copper and copper alloy forgings**
"Bright" dip	**25 vol% conc HNO_3; 60 vol% conc H_2SO_4; 0.2% conc HCl; rem H_2O**	**Room**	**Used with pickle and "scale" dip to give bright, lustrous finish to copper and copper alloy forgings**

Aluminum bronzes form a tough, adherent aluminum oxide film during forging. An effective method of cleaning aluminum bronze forgings is first to immerse them in a 10% solution (by weight) of sodium hydroxide in water at 75 °C (170 °F) for 2 to 6 min. After rinsing in water, the forgings are pickled in acid solutions in the same way as brasses.

Alloys containing substantial amounts of silicon may form oxides of silicon removable only by hydrofluoric acid or a proprietary fluorine-bearing compound. Alloys containing appreciable quantities of nickel are difficult to pickle in solutions used for brasses, because nickel oxide has a limited solubility in these solutions. For these alloys, billets should be heated in a controlled atmosphere, so that scale is kept to a minimum and can be removed by using the practice outlined above and in Table 4 for brass.

Other methods of chemical cleaning can be used, depending largely on the desired finish. Additional information is available in the article "Surface Engineering of Copper and Copper Alloys" in *Surface Engineering*, Volume 5 of the *ASM Handbook.*

Appearance. When a bright, lustrous finish is desired, the metal can be pickled in the sulfuric or hydrochloric acid pickles listed in Table 4 and then given two additional dips. Pickling removes surface oxides, and the second dip, a "scale" dip, prepares the metal for the "bright" dip that follows. "Scale" dips and "bright" dips are mixtures of sulfuric and nitric acids in proportions that vary widely from plant to plant. Generally, nitric acid accelerates the action of the dip, while sulfuric acid slows it down. These solutions are used at room temperature. Parts are first dipped in the "scale" dip, rinsed in water, dipped in the "bright" solution, rinsed in cold running water, and then rinsed in hot water and dried. Compositions of "scale" and "bright" dips are listed in Table 4.

Surface Finish. In normal practice, the surface finish of cleaned forgings is expected to be 5 μm (200 μin.) or better. By more precise control, a finish of 2.5 μm (100 μin.) or better can be obtained. Die finish is the major factor affecting the surface finish of forgings. The type of alloy forged and the amount of draft have a minor influence on surface finish.

Forging of Copper and Copper Alloys

Robert A. Campbell, Mueller Brass Company

Minimum-Draft Forgings

Zero-draft forgings can be produced from copper alloys, but are usually impractical. However, the minimum-draft concept is a practical approach for producing locating and clamping surfaces for machining operations, mating surfaces in assemblies, or other functional shapes where dimensional tolerances on such surfaces are broad enough to include normal forging tolerances but too close for normal draft angles.

Forging Design. The most obvious consideration is that any shape that has a negative draft angle would be impossible to eject without damage to the die or workpiece. With zero draft, the smallest error of form or dimension can damage the die and the workpiece. Therefore, a draft angle of $\frac{1}{8}$° should be considered the absolute minimum for production forging. This very small amount of positive draft is sufficient to eliminate the possibility of negative draft while producing forgings that have essentially zero draft.

Tolerances on closed-die forgings are normally ±0.25 mm (±0.010 in.) or better for small-to-medium forgings. It can be seen from Table 5 that a small draft angle can easily be accommodated within these tolerance limits. For example, a draft of $\frac{1}{4}$° would produce a taper of only 0.083 mm (0.00327 in.) on each side of a cavity 19 mm ($\frac{3}{4}$ in.) deep. Because the total taper of 0.166 mm (0.00654 in.) (both sides of the cavity) would be less than the usual 0.51 mm (0.020 in.) total tolerance on the cavity diameter, the part would be within tolerance for a specification of parallel sides.

Table 5 Relation of draft angle to draft for minimum-draft forgings

Draft angle, degrees	**Draft, in./in.**	Total taper on diameter, in./in.
$\frac{1}{8}$	0.00219	**0.00438**
$\frac{1}{4}$	0.00436	**0.00872**
$\frac{1}{2}$	0.00873	**0.01746**
1	**0.01745**	**0.03490**

Die Design. Conventional forging practice calls for draft angles of 2° or more on press forgings and up to 5 to 7° for hammer forgings. Draft angles of 1° or less increase cost. In general, as the draft angle is decreased, more force is required to eject the forging from the die cavity or to withdraw the punch from a hole. Conventional forgings can usually be ejected by a simple knockout pin. This method is not practical for minimum-draft forgings, because pin pressure would be sufficient to damage the part.

Ejection of minimum-draft forgings is nearly always accomplished through the use of inserted dies built on die cushions to provide a secondary action within the die. This provides a stripper action to the die so that ejection pressure is distributed over an entire surface rather than concentrated on a pin. Such double-action dies are more expensive to build and to maintain than solid dies, and their use slows the production rate.

Alloy Selection. Draft angles have no effect on the relative forgeability of copper-base alloys. Any alloy that can be forged by conventional means can be forged to minimum draft angles.

Forging of Magnesium Alloys

Introduction

The forgeability of magnesium alloys depends on three factors: the solidus temperature of the alloy, the deformation rate, and the grain size. Only forging-grade billet or bar stock should be used in order to ensure good workability. This type of product has been conditioned and inspected to eliminate surface defects that could open during forging, and it has been homogenized by the supplier to ensure good forgeability. Table 1 lists the compositions of magnesium alloys that are commonly forged, along with their forging temperatures.

Table 1 Recommended forging temperature ranges for magnesium alloys

Alloy	Recommended forging temperature[a]			
	Workpiece		Forging dies	
	°C	**°F**	**°C**	°F
Commercial alloys				
ZK21A	300-370	575-700	260-315	**500-600**
AZ61A	315-370	600-700	290-345	**550-650**
AZ31B	290-345	550-650	260-315	**500-600**
High-strength alloys				
ZK60A	290-385	550-725	205-290	**400-550**
AZ80A	290-400	550-750	205-290	**400-550**
Elevated-temperature alloys				

HM21A	400-525	750-975	370-425	**700-800**
EK31A	370-480	700-900	345-400	**650-750**
Special alloys				
ZE42A	290-370	550-700	300-345	**575-650**
ZE62	300-345	575-675	300-345	**575-675**
QE22A	**345-385**	**650-725**	**315-370**	**600-700**

(a) The strain-hardening alloys must be processed on a declining temperature scale within the given range to preclude recrystallization.

Magnesium alloys are often forged within 55 °C (100 °F) of their solidus temperature. An exception is the high-zinc alloy ZK-60, which sometimes contains small amounts of the low-melting eutectic that forms during ingot solidification. Forging of this alloy above about 315 °C (600 °F)--the melting point of the eutectic--can cause severe rupturing. This problem can be minimized by holding the cast ingot for extended periods at an elevated temperature to redissolve the eutectic and to restore a higher solidus temperature.

Machines and Dies

Machines. Hydraulic presses or slow-action mechanical presses are the most commonly used machines for the open-die and closed-die forging of magnesium alloys. In these machines, magnesium alloys can be forged with small corners and fillets and with thin web or panel sections. Corner radii of 1.6 mm ($\frac{1}{16}$ in.), fillet radii of 4.8 mm ($\frac{3}{16}$ in.), and panels or webs 3.2 mm ($\frac{1}{8}$ in.) thick are not uncommon. The draft angles required for extraction of the forgings from the dies can be held to 3° or less.

Magnesium alloys are seldom hammer forged or forged in a rapid-action press, because they will crack unless exacting procedures are used. Alloys ZK60A, AZ31B, and HM21A are more easily forged by these methods than AZ80A, which is extremely difficult to forge. Cracking can occur also in moderately severe, unsupported bending.

Magnesium alloys generally flow laterally rather than longitudinally. This characteristic must be considered in the design of tools.

Dies. Because forging temperatures for magnesium alloys are relatively low (Table 1), conventional low-alloy hot-work tool steels are satisfactory materials for forging dies. Dies are finished to a smooth, highly polished surface to prevent surface roughness, scratches, or imperfections on the forging. The high polish also promotes metal flow during forging. Wet abrasive blasting and extremely fine abrasive finishing papers are used to produce a smooth finish on die-impression surfaces.

Heating for Forging

In most cases, the mechanical properties developed in magnesium forgings depend on the strain hardening induced during forging. Strain hardening is accomplished by keeping the forging temperature as low as practical; however, if temperatures are too low, cracking will occur.

In a multiple-operation process, the forging temperature should be adjusted downward for each subsequent operation to avoid recrystallization and grain growth. In addition to controlling grain growth, the reduction in temperature allows for residual strain hardening after the final operation.

Heating can be done with fuel-fired or electrically heated furnaces. Inert or reducing atmospheres are not needed at temperatures below 480 °C (900 °F).

Because forging temperatures are well below the melting points of the various alloys, no fire hazard exists when temperatures are controlled with reasonable accuracy. However, uniformity of temperature must be maintained (at least throughout the final heating zone), and large gradients and hot spots must be avoided in the preliminary heating zones. Furnaces that are equipped with fans for recirculating the air within the furnace provide the greatest uniformity of heating.

Furnaces should be loaded so that air circulates readily throughout the work load. Close stacking or "cordwood" loading should be avoided, because it will result in low temperatures at the center of the load and possibly in overheating at the edges and exposed surfaces. Too high a temperature will cause the work metal to develop cracks from hot shortness, and too low a temperature will cause shear cracking.

Die Heating

Magnesium alloys are good conductors of heat; therefore, they are readily chilled by cold dies, causing the alloys to crack. Because die contact during forging is extensive and is maintained for a prolonged period of time, dies must be heated to temperatures not much lower than those used to heat the stock (Table 1).

Die temperature is less critical for ring-rolling tools, because the area of contact is small and the duration of contact is relatively short. Furthermore, temperature buildup during rolling compensates for heat loss. Ring-rolling tools, therefore, are heated only slightly to remove chill.

Lubrication

The lubricant used in the forging of magnesium alloys is usually a dispersion of fine graphite in a light carrier oil or kerosene. This lubricant is swabbed or sprayed onto the hot dies, so that the carrier burns off and leaves a light film of graphite. Frequently, dies are lightly relubricated after billets have been partially forged. The forging billet is sometimes dipped in the lubricant before forging. Although less convenient, lampblack may be applied directly from the sooty flame of a torch. When low die temperatures can be employed, the use of aqueous colloidal graphite contributes to cleaner working conditions.

Regardless of the lubricant selected, it is important that the coating of lubricant be thin and have complete coverage. Heavy deposits of graphite adhering to a forging can present a cleaning problem, because severe pitting or galvanic corrosion can occur if cleaning with acid is attempted. This graphite film is more readily removed by sand blasting.

Forging Practice

Forging pressures for the upsetting of magnesium alloy billets between flat dies are shown in Fig. 1. At normal press-forging speeds, the forging pressure increases and then decreases slightly with increased upset reduction, probably because work metal temperature increases during forging.

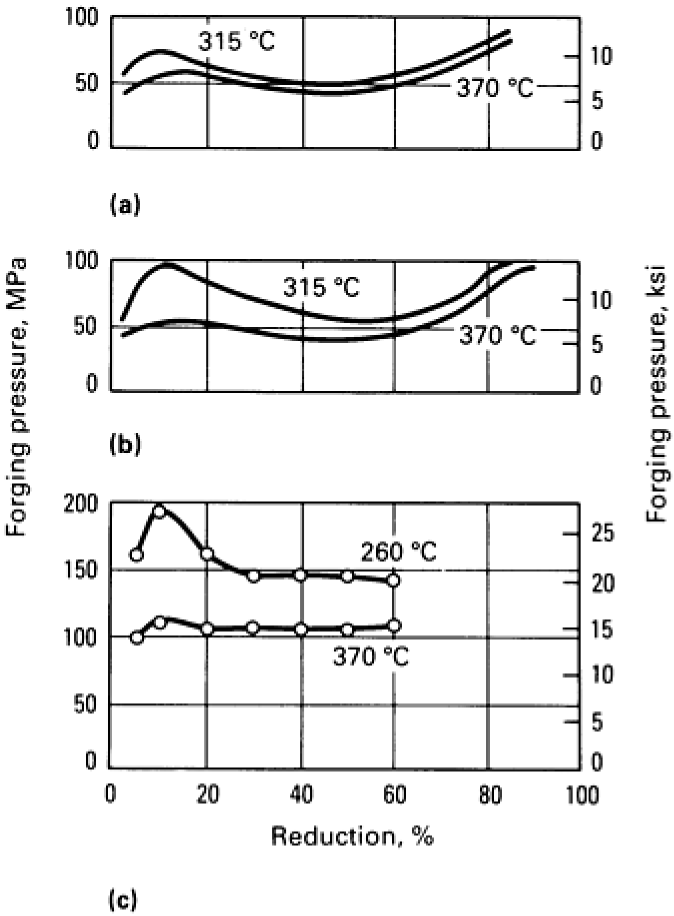

Fig. 1 Forging pressures required for the upsetting of magnesium alloy billets between flat dies. (a) Alloy AZ80A; strain rate: 0.11 s^{-1}. (b) Alloy AZ61A; strain rate: 0.11 s^{-1}. (c) Alloy AZ31B; strain rate: 0.7 s^{-1}.

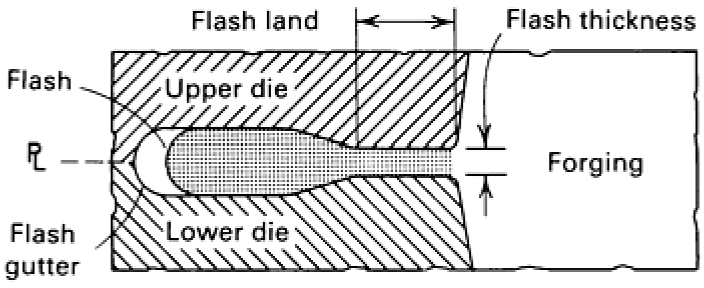
Forging load and pressure in closed-die forging vary greatly with the shape being forged. Relatively small changes in flash dimensions, for example, can result in appreciable changes in the forging load:

Flash dimensions				Forging load	
Land		**Thickness**			
mm	**in.**	**mm**	**in.**	**mn**	tonf
3.8	0.15	1.2	0.046	2.7	**300**

2.5	0.1	0.64	0.025	3.5	**385**
5.0	0.2	0.64	0.025	4.9	**550**



Forging temperature has a marked effect on forging pressure requirements. Figure 2 shows the magnitude of this effect for magnesium alloy AZ31B in comparison with aluminum alloy 6061. As Table 2 shows, at normal forging temperatures, AZ31B requires greater forging pressure than carbon steel, alloy steel, or aluminum and requires less than stainless steel. Magnesium alloys flow less readily than aluminum into deep vertical die cavities. If two dies are needed for a typical aluminum structural forging, the same part in a magnesium alloy may require three dies for successful forging.

Table 2 Approximate forging pressures required for a 10% upset reduction of various materials at normal forging temperature in flat dies

Work metal	**Forging temperature**		Forging pressure	
	°C	**°F**	**MPa**	ksi
1020 steel	1260	2300	55	**8**
4340 steel	1260	2300	55	**8**
Aluminum alloy 6061	455	850	69	**10**
Magnesium alloy AZ31B	370	700	110	**16**

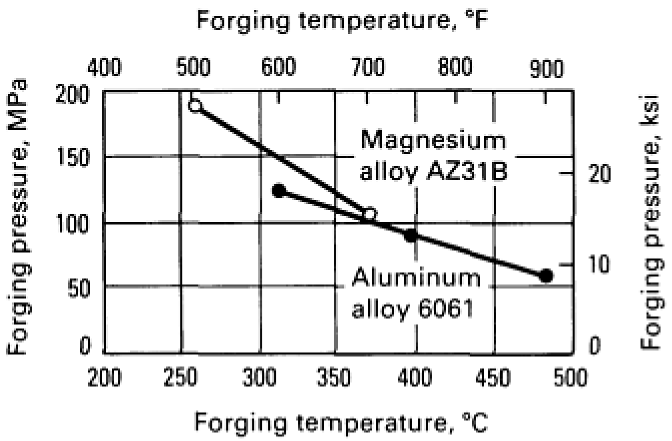


Fig. 2 Effect of forging temperature on forging pressure required for upsetting to a 10% reduction at hydraulic press speeds for a magnesium alloy and an aluminum alloy.

Grain-Size Control. An important objective in the forging of magnesium alloys is to refine the grain size. Alloys that are subject to rapid grain growth at forging temperatures (AZ31B, AZ61A, and AZ80A) are generally forged at successively lower temperatures for each operation. Common practice is to reduce the temperature about 15 to 20 °C (25 to 35 °F) after each step. For parts containing regions that receive only small reductions, all forging is often done at the lowest practical temperature to permit strain hardening. Grain growth in ZK60A and HM21A is slow at forging temperatures, and there is little risk of extensive grain growth.

Cooling Practice. Magnesium alloy forgings are water quenched directly from the forging operation to prevent further recrystallization and grain growth. With some of the age-hardening alloys, the quench retains the hardening constituents in solution so that they are available for precipitation during subsequent aging treatments.

Trimming. When only small quantities are being processed, magnesium alloy forgings are usually trimmed cold on a bandsaw. Hot trimming using a trimming press is done at 205 to 260 °C (400 to 500 °F).

Cleaning. Magnesium alloy forgings are usually cleaned in two steps. First, the workpiece is blast cleaned to remove any lubricant residue. This is followed by dipping in a solution of 8% nitric acid and 2% sulfuric acid and rinsing in warm water. The clean forgings can be dipped in a dichromate solution to inhibit corrosion if necessary.

Subsequent Heat Treatment

Forgings of some magnesium alloys, such as ZK21A, AZ31B, and AZ61A, are always used in the as-forged condition (F temper). Forgings of AZ80A, ZK60A, or HM21A can be used in either the F or T5 (artificially aged) condition. Solution treatment followed by artificial aging (T6 temper) can be used for EK31A forgings. More information on the heat treating of magnesium alloys is available in the article "Heat Treating of Magnesium Alloys" in *Heat Treating*, Volume 4 of the *ASM Handbook.*

Forging of Nickel-Base Alloys

Revised by H.H. Ruble, Inco Alloys International and S.L. Semiatin, Battelle Columbus Division

Introduction

NICKEL-BASE ALLOYS are often closed die forged into turbine blades, turbine disks, exhaust valves, chain hooks, heat exchanger headers, valve bodies, and pump bodies. Shafts and seamless rings are made by open-die forging. Seamless rings are also made by ring rolling.

Most nickel-base alloys (Table 1) are stronger and stiffer than steel. Alloy 200 (UNS N02200) and alloy 400 (UNS N04400), however, are softer than many steels. As an indication of the relative resistance to hot deformation, Table 2 lists the pressures developed in the roll gap at 20% reduction in hot rolling for five nickel-base alloys and two steels at four hot-working temperatures. Higher pressures indicate greater resistance. Sufficiently powerful equipment is of particular importance when forging alloys 800 (UNS N08800), 600 (UNS N06600), 625 (UNS N06625), and the precipitation-hardenable alloys such as 718 (UNS N07718) and X-750 (UNS N07750). These alloys were specifically developed to resist deformation at elevated temperatures.

Forging of Nickel-Base Alloys

Revised by H.H. Ruble, Inco Alloys International and S.L. Semiatin, Battelle Columbus Division

Die Materials and Lubrication

The die materials used to forge nickel-base alloys are similar to those used for stainless steel (see the articles "Forging of Stainless Steel," and "Dies and Die Materials for Hot Forging" in this Volume). The service lives of alloy steel dies used in forging nickel alloys usually range from 3000 to 10,000 pieces.

Dies can be lubricated to facilitate removal of the workpiece after forging. Sulfur-free lubricants are necessary; those made with colloidal graphite give good results.

Lubricants can be applied by swabbing or spraying. Spraying is preferred because it produces more uniform coverage.

Forging of Nickel-Base Alloys

Revised by H.H. Ruble, Inco Alloys International and S.L. Semiatin, Battelle Columbus Division

Heating for Forging

Nickel-base alloy billets can be induction heated or furnace heated before hot forging. Regardless of the heating method used, the material must be cleaned of all foreign substances. Although nickel-base alloys have greater resistance to scaling at hot-working temperatures than steels, they are more susceptible to attack by sulfur during heating. Exposure of hot metal to sulfur must be avoided. Marking paints and crayons, die lubricants, pickling liquids, and slag and cinder that accumulate on furnace hearths are all possible sources of sulfur and should be removed from the metal before heating. Metal surfaces that have been attacked by sulfur at high temperatures have a distinctly burned appearance. If the attack is severe, the material is mechanically weakened and rendered useless.

If furnace heating is used, nickel-base alloy forging preforms should be supported on metal rails or by other means in order to avoid contamination. The metal should not touch the furnace bottom or sides. Protection against spalls from the roof may also be necessary.

Fuels. Many standard fuels are suitable for the furnace heating of nickel-base alloys. An important requirement is that they be of low sulfur content.

Gaseous fuels such as natural gas, manufactured gas, butane, and propane are the best fuels and should always be used if available. They must not contain more than 2 g (30 grains) of total sulfur per 2.8 m^3 (100 ft^3) of gas and preferably not more than 1 g (15 grains) of total sulfur per 2.8 m^3 (100 ft^3) of gas.

Oil is a satisfactory fuel provided it has a low sulfur content. Oil containing more than 0.5% sulfur should not be used. Coal and coke are generally unsatisfactory, because of the difficulty in providing for proper heating conditions, inflexibility in heat control, and excessive sulfur content.

The furnace atmosphere should be sulfur free and should be continuously maintained in a slightly reducing condition, with 2% or more carbon monoxide. The atmosphere should not be permitted to alternate from reducing to oxidizing. The slightly reducing condition is obtained by reducing the air supply until there is a tendency to smoke, which indicates an excess of fuel and a reducing atmosphere. The air supply should then be increased slightly to produce a hazy atmosphere or a soft flame. Excessive amounts of carbon monoxide or free carbon are not harmful; nickel-base alloys, unlike steels, will not carburize under these conditions. However, a slight excess of fuel over air is all that is required, and the closer the atmosphere is to the neutral condition, the easier it is to maintain the required temperature. The true condition of the atmosphere is determined by analyzing gas samples taken at various points near the metal surface.

It is important that combustion take place before the mixture of fuel and air contacts the work, or the metal may be embrittled. Proper combustion is ensured by providing ample space to burn the fuel completely before the hot gases enter the furnace chamber.

General Guidelines for the Breakdown of Nickel-Base Alloys (Ref 1). Because of their high alloy content and generally narrow working temperature range, nickel-base alloys must be converted from cast ingots with care. Initial breakdown operations are generally conducted well above the γ' solvus temperature, with subsequent deformation completed below it but still high enough to avoid excessive warm working and an unrecrystallized microstructure. The original cast structure must be completely refined during breakdown, that is, before final forging, particularly when substantial levels of reduction are not imposed during closed-die forging.

Good heat retention practice during ingot breakdown is an important factor in obtaining a desirable billet microstructure. Rapid transfer of the ingot from the furnace to the forging press, as well as the use of such techniques as reheating during breakdown, is necessary to promote sufficient recrystallization during each forging pass. In addition, it has been found that diffusion of precipitation-hardening elements is associated with recrystallization during ingot conversion. Mechanical factors such as cycling speed (which affects heat losses), reduction, length of pass, die design, and press capacity all influence the degree of work penetration through the billet cross section and therefore the rate of ingot conversion.

General Guidelines for the Finish Forging of Nickel-Base Alloys. Figure 1 shows the temperature ranges for the safe forging of 12 nickel-base alloys. Use of the lower part of the temperature range may be required for the development of specific mechanical properties.

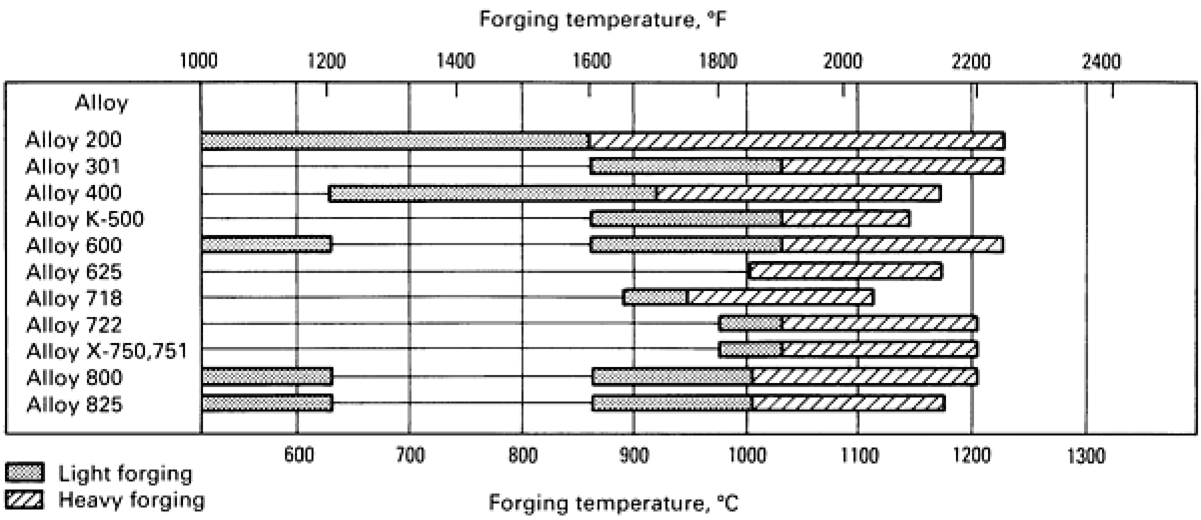

Fig. 1 Forging temperature ranges for 12 nickel-base alloys

Closed-die forging of nickel-base alloys is generally done below the γ' solvus temperature in order to avoid excessive grain growth. Approximately 80% of the reduction is scheduled in the recrystallization temperature range, with the remaining 20% done at lower temperatures to introduce a certain amount of warm work for improved mechanical properties. Preheating of all tools and dies to about 260 °C (500 °F) is recommended to avoid chilling the metal during working.

Forging Rate. A very rapid rate of forging often causes heat buildup (due to friction and deformation heating), a nonuniform recrystallized grain size, and mechanical property variations. Susceptibility to free surface ruptures also increases with forging rate (and forging temperature). Therefore, slow strain rates are typically used during the initial closed-die reductions of such alloys as Astroloy (UNS N13017) and René 95 (Ni-14Cr-8Co-3.5Mo-3.5W-3.5Nb-3.5Al-2.5Ti). With proper selection of starting stock and forging temperature, however, the forging rate is less critical. For example, some Astroloy turbine components are currently hammer forged.

Forging Reduction. A sufficient amount of recrystallization is necessary in each of a series of closed-die forging operations to achieve the desired grain size and to reduce the effects of the continuous grain-boundary or twin-boundary carbide networks that develop during heating and cooling. This condition contributes more to mechanical-property and other problems than any other single factor. Poor weldability, low-cycle fatigue, and stress rupture properties are associated with continuous grain-boundary carbide networks. Heat treatment can do very little to correct this problem without creating equally undesirable mechanical-property problems when higher solution treatment temperatures are used. All portions of a part must receive some hot work after the final heating operation in order to achieve uniform mechanical properties.

In open-die forging, a series of moderate reduction passes along the entire length of the forging is preferred. In working a square section into a round, the piece should be worked down in the square form until it approaches the final size. It should then be converted to an oversize octagon before finishing into the round. Billet corners that will be in contact with dies should be chamfered rather than left square. The work should be lifted away from the dies occasionally to permit relief of local cold areas.

Other Considerations. The precipitation-hardenable nickel alloys are subject to thermal cracking. Therefore, localized heating is not recommended. The entire part should be heated to the forging temperature.

If any ruptures appear on the surface of the metal during hot working, they must be removed at once, either by hot grinding or by cooling the work and cold overhauling. If the ruptures are not removed, they may extend into the body of the part.

For sections equal to or larger than 405 mm (16 in.) square, precautions should be taken in heating precipitation-hardenable alloys. They should be charged into a furnace at 870 °C (1600 °F) or colder and brought up to forging temperature at a controlled rate of 40 °C (100 °F) per hour.

Cooling After Forging

The rate of cooling after forging is not critical for alloys 200, 400, and 625. Alloys K-500 (UNS N05500) and 301 (UNS N03301) should be water quenched from forging temperatures to avoid the excessive hardening and cracking that could occur if they were cooled slowly through the age-hardening range and to maintain good response to subsequent aging. Alloy 825 (UNS N08825) should be cooled at a rate equal to or faster than air cooling.

Alloys 800 and 600 are subject to carbide precipitation during heating in or slow cooling through the temperature range of 540 to 760 °C (1000 to 1400 °F). If sensitization is likely to prove disadvantageous in the end use, parts made of these alloys should be water quenched or cooled rapidly in air.

The precipitation-hardenable alloys should, in general, be cooled in air after forging. Water quenching is not recommended, because of the possibility of thermal cracking, which can occur during subsequent heating for further forging or heat treating.

Forging of Nickel-Base Alloys

Revised by H.H. Ruble, Inco Alloys International and S.L. Semiatin, Battelle Columbus Division

Forging Practice for Specific Alloys

The following practices are used in the forging of nickel-base alloys. Variations from these procedures may be necessary for some specialized applications (see the sections "Thermal-Mechanical Processing" and "Isothermal Forging" in this article).

Alloy 200 should be charged to a hot furnace, withdrawn as soon as the desired temperature has been reached, and worked rapidly. The recommended range of forging temperatures is 650 to 1230 °C (1200 to 2250 °F). Because the metal stiffens rapidly when cooled to about 870 °C (1650 °F), all heavy work and hot bending should be done above that temperature. High mechanical properties can be produced by working lightly below 650 °C (1200 °F). The best range for hot bending is 870 to 1230 °C (1600 to 2250 °F).

Alloy 301. The optimum temperature range for the forging of alloy 301 is 1065 to 1230 °C (1900 to 2250 °F). Light finishing work can be done down to 870 °C (1600 °F). Finer grain size is produced in forgings by using 1175 °C (2150 °F) for the final reheat temperature and by taking at least 30% reduction of area in the last forging operation.

After hot working, the alloy should be quenched from a temperature of 790 °C (1450 °F) or above. Quenching retains the strain hardening imparted by the forging operation and produces better response to subsequent age hardening. Quenching in water containing about 2 vol% alcohol results in less surface oxidation.

Material that must be cooled prior to subsequent hot working should also be quenched. Slow cooling may cause age hardening, which sets up stresses in the workpiece that can cause cracking during subsequent reheating.

Alloy 400. The maximum heating temperature for forging alloy 400 is 1175 °C (2150 °F). Prolonged soaking at the working temperature is detrimental. If a delay occurs during processing, the furnace temperature should be reduced to 1040 °C (1900 °F) and not brought to 1175 °C (2150 °F) until operations are resumed.

The recommended metal temperature for heavy reductions is 925 to 1175 °C (1700 to 2150 °F). Light reductions may be taken at temperatures down to 650 °C (1200 °F). Working at the lower temperatures produces higher mechanical properties and smaller grain size.

A controlled forging procedure is necessary to meet the requirements of some specifications for forged hot-finished parts. Both the amount of reduction and the finishing temperature must be controlled in order to develop the desired properties.

One procedure for producing forgings to such specifications consists of taking a 30 to 35% reduction after the final reheat. This is done as follows:

- Reheat
- Forge to a section having about 5% larger area than the final shape (take at least 25% reduction)
- Cool to 705 °C (1300 °F)
- Finish to size (5% reduction)

High-tensile forgings, as described in certain military specifications, also require a minimum of 30 to 35% reduction after the last reheat. This is taken in the following manner:

- Reheat
- Forge to a section having an area about 25% larger than the final shape (take about 5% reduction)
- Cool to 705 °C (1300 °F)
- Finish to size (25% reduction)

Grain refinement is achieved by using a temperature of 1095 °C (2000 °F) for the final reheat and by increasing the amount of reduction taken after the last reheat.

Alloy K-500. The maximum recommended heating temperature for the forging of alloy K-500 is 1150 °C (2100 °F). Metal should be charged into a hot furnace and withdrawn when uniformly heated. Prolonged soaking at this temperature is harmful. If a delay occurs such that the material would be subject to prolonged soaking, the temperature should be reduced to or held at 1040 °C (1900 °F) until shortly before working is to begin, then brought to 1150 °C (2100 °F). When the piece is uniformly heated, it should be withdrawn. In the event of a long delay, the work should be removed from the furnace and water quenched.

The forging temperature range is 870 to 1150 °C (1600 to 2100 °F). Heavy work is best done between 1040 and 1150 °C (1900 and 2100 °F), and working below 870 °C (1600 °F) is not recommended. To produce finer grain in forgings, 1095 °C (2000 °F) should be used for the final reheat temperature, and at least 30% reduction of area should be taken in the last forging operation.

When forging has been completed or when it is necessary to allow alloy K-500 to cool before further hot working, it should not be allowed to cool in air, but should be quenched from a temperature of 790 °C (1450 °F) or higher. If the piece is allowed to cool slowly, it will age harden to some extent, and stress will be set up that may lead to thermal splitting or tearing during subsequent reheating. In addition, quenched material has better response to age hardening because more of the age-hardening constituent is retained in solution.

Alloy 600. The normal forging temperature range for alloy 600 is 870 to 1230 °C (1600 to 2250 °F). Heavy hot work should be done in the range from 1040 to 1230 °C (1900 to 2250 °F). Light working can be continued down to 870 °C (1600 °F). Generally, forging should not be done between 650 and 870 °C (1200 and 1600 °F) because of the low ductility of the alloy in this temperature range. Judicious working at a temperature below 650 °C (1200 °F) will develop higher tensile properties.

The rate of cooling after forging is not critical with respect to thermal cracking. However, alloy 600 is subject to carbide precipitation in the range between 540 and 760 °C (1000 and 1400 °F), and if subsequent use dictates freedom from sensitization, the part should be rapidly cooled through this temperature range.

Alloy 625 should be heated in a furnace held at 1175 °C (2150 °F) but no higher. The work should be brought as close to this temperature as conditions permit. Forging is done from this temperature down to 1010 °C (1850 °F); below 1010 °C (1850 °F) the metal is stiff and hard to move, and attempts to forge it may cause hammer splits at the colder areas. The work should be returned to the furnace and reheated to 1175 °C (2150 °F) whenever its temperature drops below 1010 °C

(1850 °F). To guard against duplex grain structure, the work should be given uniform reductions. For open-die work, final reductions of a minimum of 20% are recommended.

Alloy 718 is strong and offers considerable resistance to deformation during forging. The forces required for hot deformation are somewhat higher than those employed for alloy X-750. Alloy 718 is forged in the range from 900 to 1120 °C (1650 to 2050 °F). In the last operation, the metal should be worked uniformly with a gradually decreasing temperature, finishing with some light reduction below 955 °C (1750 °F). Figure 2 shows a forged and machined alloy 718 marine propeller blade. In heating for forging, the material should be brought up to temperature, allowed to soak a short time to ensure uniformity, and withdrawn.

Fig. 2 Forged and machined alloy 718 marine propeller blade. Courtesy of Ladish Company

Alloy 718 should be given uniform reductions in order to avoid duplex grain structure. Final reductions of 20% minimum should be used for open-die work, and 10% minimum for closed-die work. Parts should generally be air cooled from the forging temperature, rather than water quenched.

Alloy 706 (UNS N09706) is similar to alloy 718, except that alloy 706 is more readily fabricated, particularly by machining. Forging should be done using the same procedures and temperatures as those for alloy 718.

Alloy X-750. The forging range for alloy X-750 is 980 to 1205 °C (1800 to 2200 °F). Below 980 °C (1800 °F), the metal is stiff and hard to move, and attempts to work it may cause splitting. All heavy forging should be done at about 1040 °C (1900 °F), and the metal should be reheated whenever it cools to below that temperature. Forgings can be finished with some light reduction in the range between 980 and 1040 °C (1800 and 1900 °F).

As a general rule, alloy X-750 should be air cooled rather than liquid quenched from the forging temperature. Liquid quenching can cause high residual stresses that may result in cracking during subsequent heating for further hot work or for heat treatment. Parts with large cross sections and pieces with variable cross sections are especially susceptible to thermal cracking during cooling. In very large cross sections, furnace cooling may be necessary to prevent thermal cracking.

Alloy 800. Hot working of alloy 800 is started at 1205 °C (2200 °F) and heavy forging is done at temperatures down to 1010 °C (1850 °F). Light working can be accomplished down to 870 °C (1600 °F). No working should be done between 870 and 650 °C (1600 and 1200 °F). As with alloy 600, thermal cracking is not a problem, and workpieces should be cooled rapidly through the range between 540 and 760 °C (1000 and 1400 °F) to ensure freedom from sensitization.

Alloy 825. The forging range for alloy 825 is 870 to 1175 °C (1600 to 2150 °F). It is imperative that some reduction be accomplished in the range between 870 and 980 °C (1600 and 1800 °F) during final forging in order to ensure maximum corrosion resistance.

Cooling after forging should be done at a rate equal to or faster than air cooling. Heavy sections may become sensitized during cooling from the forging temperature and therefore be subject to intergranular corrosion in certain media. A stabilizing anneal of 1 h at 940 °C (1725 °F) restores resistance to corrosion. If the forged piece is to be welded and used in an environment that could cause intergranular corrosion, the piece should be given a stabilizing anneal to prevent sensitization from the heat of welding, regardless of the cooling rate after forging.

Alloy 925. The hot-working characteristics of alloy 925 (UNS N09925) are similar to those of alloy 825 at temperatures to 1095 °C (2000 °F). At higher temperatures, alloy 925 has lower ductility and higher strength. The forging range is 870 to 1175 °C (1600 to 2150 °F). For maximum corrosion resistance and highest mechanical properties after direct aging, final hot working should be done in the range of 870 to 980 °C (1600 to 1800 °F).

Alloys 722 and 751 (UNS N07722 and N07751, respectively) are forged using the same procedures and temperatures as those for alloy X-750.

Alloys 903, 907, and 909 (UNS N19903, N19907, and N19909, respectively) are best forged in three stages in order to obtain the desired properties after aging. The initial breakdown of 40% minimum reduction should be performed at a temperature of 1060 to 1120 °C (1940 to 2050 °F). For intermediate forging at a minimum of 25% reduction, these alloys should be heated between 995 to 1050 °C (1825 and 1925 °F). The final heating for alloys 907 and 909 should be 980 to 1025 °C (1800 to 1875 °F) for a minimum reduction of 20% over a falling temperature range (finishing at $\leq$925 °C, or 1700 °F). The final heating for alloy 903 should be 870 °C (1600 °F) with a final forging reduction of 40% minimum. Other nickel-base heat-resistant alloys are discussed in the article "Forging of Heat-Resistant Alloys" in this Volume.

Thermal-Mechanical Processing (TMP)

Thermal-mechanical processing refers to the control of temperature and deformation during processing to enhance specific properties. Special TMP sequences have been developed for a number of nickel-base alloys.

The design of TMP sequences relies on a knowledge of the melting and precipitation temperatures for the alloy of interest. Table 3 lists these temperatures for several nickel-base alloys. Although nickel-base (as well as iron- and cobalt-base) alloys form various carbides--for example, MC (M = titanium, niobium, etc.), M_6C (M = molybdenum and/or tungsten), or $M_{23}C_6$ (M = chromium)--the primary precipitate of concern in the processing of such materials is the γ'-strengthening precipitate. Gamma prime is an ordered face-centered cubic (fcc) compound in which aluminum and titanium combine with nickel to form Ni_3(Al, Ti). In nickel-iron alloys such as alloy 718, titanium, niobium, and to a lesser extent, aluminum combine with nickel to form ordered fcc γ' or ordered body-centered tetragonal γ". Nickel-iron base alloys are also prone to the formation of other phases, such as hexagonal close-packed Ni_3Ti (η), as in titanium-rich alloy 901, or orthorhombic Ni_3Nb (δ) in niobium-rich alloy 718.

Table 3 Critical melting and precipitation temperatures for several nickel-base alloys

Source: Ref 2

Early forging practice of nickel- and nickel-iron base alloys consisted of forging from and solution heat treating at temperatures well in excess of the γ' solvus temperature. High-temperature solution treatment dissolved all of the γ', annealed the matrix, and promoted grain growth (typical grain size ≈ASTM 3 or coarser). This was followed by one or more aging treatments that promoted controlled precipitation of γ' and carbide phases. Optimal creep and stress rupture properties above 760 °C (1400 °F) were thus achieved. Later in the development of forging practice, it was found that using preheat furnace temperatures slightly above the recrystallization temperature led to the development of finer grain sizes (ASTM 5 to 6). Coupling this with modified heat-treating practices resulted in excellent combinations of tensile, fatigue, and creep properties.

State-of-the art forging practices for nickel-base alloys rely on the following microstructural effects (Ref 3):

- Dynamic recrystallization is the most important softening mechanism during hot working
- Grain boundaries are preferred nucleation sites for recrystallization
- The rate of recrystallization decreases with the temperature and/or the extent of deformation
- Precipitation that may occur during the recrystallization can inhibit the softening process. Recrystallization cannot be completed until the precipitate coarsens to a relatively ineffective morphology

Forging temperature is carefully controlled during the thermal-mechanical processing of nickel- and nickel-iron base alloys to make use of the structure control effects of second phases such as γ'. Above the optimal forging temperature range (Table 4), the structure control phase goes into solution and loses its effect. Below this range, extensive fine precipitates are formed, and the alloy becomes too stiff to process. Several examples of specific TMP sequences are given below.

Table 4 Structure control phases and working temperature ranges for various heat-resistant alloys

Alloy	**UNS No.**	**Phases for structure control**	Working temperature range	
			°C	°F

René 95	. . .	γ' (Ni^3(Al,Ti)	1025-1135	**1875-2075**
Nickel-iron-base alloys				
901	N09901	η(Ni^3Ti)	940-995	**1725-1825**
718	N07718	δ(Ni^3Nb)	915-995	**1675-1825**
Pyromet CTX-1	**. . .**	**η(Ni^3Ti), δ(Ni^3Nb), or both**	**855-915**	**1575-1675**

Waspaloy. A typical TMP treatment of nickel-base alloys is that used for Waspaloy (UNS N07001) to obtain good tensile and creep properties. This consists of initial forging at 1120 °C (2050 °F) and finish forging below approximately 1010 °C (1850 °F) to produce a fine, equiaxed grain size of ASTM 5 to 6. Solution treatment is then done at 1010 °C (1850 °F), and aging is conducted at 845 °C (1550 °F) for 4 h, followed by air cooling plus 760 °C (1400 °F) for 16 h and then air cooling.

René 95. Initial forging of René 95 is done at a temperature between 1095 and 1140 °C (2000 and 2080 °F). Following an in-process recrystallization anneal at 1175 °C (2150 °F), finish forging (reduction ≈40 to 50%) is then imposed below the γ' solvus, typically at temperatures between 1080 and 1105 °C (1975 and 2025 °F). The large grains formed during high-temperature recrystallization are elongated and surrounded by small recrystallized grains that form during finish forging.

Alloy 901. The thermal-mechanical processing of alloy 901 is often done to produce a fine-grain structure that enhances fatigue strength (Ref 5). This is accomplished by using the η(Ni_3Ti) phase, which is introduced in a Widmanstdätten form at the beginning of processing by a heat treatment at 900 °C (1650 °F) for 8 h. Forging is then conducted at 955 °C (1750 °F), which is below the η solvus; the forging deformation is completed below the recrystallization temperature. A fine-grain structure is generated by a subsequent recrystallization treatment below the η solvus. The needle-like η phase will become spherical during forging and will restrict grain growth. Aging is then conducted according to standard procedures.

Isothermal Forging

Nickel-base alloys that are hard to work or are typically used in the cast condition can be readily forged when in a powder-consolidated form. The most common forging technique using powder preforms is isothermal forging; (see the article "Isothermal and Hot-Die Forging" in this Volume). In this process, powder is produced by inert gas atomization and is compacted into billet form by extrusion. The billets are fabricated below the γ' solvus temperature for alloys such as IN-100 in order to maintain a fine grain size and a fine distribution of precipitates. In this condition, the material exhibits superplastic properties that are characterized by large tensile elongations (during sheet forming) and good die-filling capacity (during forging). Multiples of the extruded bar are then isothermally forged into a variety of complex turbine engine and other high-temperature parts.

The key to successful isothermal forging of nickel-base alloys is the ability to develop a fine grain size before forging and to maintain it during forging. With regard to the latter, a high volume percentage of second phase is useful in preventing grain growth. Therefore, alloys such as IN-100, René 95, and Astroloy, which contain large amounts of γ', are readily capable of developing the superplastic properties necessary in isothermal forging. In contrast, Waspaloy, which contains less than 25 vol% γ' at isothermal forging temperatures, is only marginally superplastic. Nickel-iron base alloys such as alloys 718 and 901 have even lower volume fractions of precipitate and are therefore even less frequently used in isothermal forging.

As the term implies, isothermal forging consists of forging with the workpiece and the dies at the same temperature. Because this temperature is often of the order of 980 to 1095 °C (1800 to 2000 °F), the dies are usually made of molybdenum for elevated-temperature strength. The isothermal forging system must be operated in a vacuum or inert atmosphere in order to protect such die materials from oxidation.

Compared to conventional forging, isothermal forging deformation rates are slow; hydraulic press speeds of approximately 2.5 mm/min (0.1 in./min) are typical. However, the slower production rate is largely offset by the ability to forge complex shapes to closer tolerances, which leads to less machining and substantial material savings. In addition, a large amount of deformation is accomplished in one operation, pressures are low, and uniform microstructures are achieved. For example, the as-forged weight of a finish-machined 68 kg (150 lb) Astroloy disk is about 110 kg (245 lb) for a conventional forging versus 72 kg (160 lb) for the corresponding isothermal forging.

Forging of Titanium Alloys

G.W. Kuhlman, Aluminum Company of America

Introduction

TITANIUM ALLOYS are forged into a variety of shapes and types of forgings, with a broad range of final part forging design criteria based on the intended application. As a class of materials, titanium alloys are among the most difficult metal alloys to forge, ranking behind only refractory metals and nickel/cobalt-base superalloys. Therefore, titanium alloy forgings, particularly closed-die forgings, are typically produced to less highly refined final forging configurations than are typical of aluminum alloys (although precision forgings in titanium alloys are produced to the same design and tolerance criteria as aluminum alloys; see the section "Titanium Alloy Precision Forgings" in this article) and to equivalent or more refined forging design sophistication than carbon or low-alloy steel forgings, because of reduced oxidation or scaling tendencies in heating. Because of the high cost of titanium alloys in comparison to other commonly forged materials, such as aluminum and alloy steels, final forging design criteria in titanium closed-die forgings are typically balanced between producibility demands and cost considerations (particularly machining costs and overall metal recovery).

In addition, the working history and forging parameters used in titanium alloy forging have a significant impact on the final microstructure (and therefore the resultant mechanical properties) of the forged alloy--perhaps to a greater extent than in any other commonly forged material. Therefore, the forging process in titanium alloys is used not only to create cost-effective forging shapes but also, in combination with thermal treatments, to create unique and/or tailored microstructures to achieve the desired final mechanical properties through thermomechanical processing (TMP) techniques. For a given titanium alloy forging shape, the pressure requirements in forging vary over a large range, depending primarily on the chemical composition of the alloy, the forging process being used, the forging strain rate, the type of forging being manufactured, lubrication conditions, and die temperature. The chemical compositions, characteristics, and typical mechanical properties of all wrought titanium alloys referred to in this article are reviewed in the article "Wrought Titanium and Titanium Alloys" in *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials*, Volume 2 of the *ASM Handbook.*

Forging of Titanium Alloys

G.W. Kuhlman, Aluminum Company of America

Titanium Alloy Classes

Because of the strong relationship among the required forging process parameters, deformation behavior, and mechanical properties of the various titanium alloys, it is necessary to review the classes of titanium alloys that are forged and their typical thermomechanical processing requirements, which exert a strong influence on forging part design and forging process selection. Titanium and its alloys exist in two allotropic forms:

- The hexagonal close-packed (hcp) α phase
- The body-centered cubic (bcc) β phase

The more difficult to deform α phase is usually present at low temperatures, while the more easily deformed β phase is present at high temperatures. However, the addition of various alloying elements (including other metals and such gases as oxygen, nitrogen, and hydrogen) stabilizes either the α or β phase. The temperature at which a given titanium alloy transforms completely from α to β is termed the beta transus, β_t, and is a critical temperature in titanium alloy forging process criteria.

Titanium alloys are divided into three major classes, based on the predominant allotropic form(s) present at room temperature:

- α/near-α alloys
- α-β alloys
- β/metastable β alloys

Each of these types of titanium alloys has unique forging process criteria and deformation behavior. Further, the forging process parameters, often in combination with subsequent thermal treatments, are manipulated for each alloy type to achieve the desired final forging microstructure and mechanical properties (heat treatment serves a different purpose in titanium alloys from that in aluminum alloys or alloy steels, as discussed below). Table 1 lists most of the commonly forged titanium alloys by alloy class, along with the major alloying elements constituting each alloy.

Table 1 Recommended forging temperature ranges for commonly forged titanium alloys

Alloy	**β_t**		**Process**[a]	Forging temperature[b]

(a) C, conventional forging processes in which most or all of the forging work is accomplished below the β_t of the alloy for the purposes of desired mechanical property development. This forging method is also referred to as α-β forging. B, βforging processes in which some or all of the forging is conducted above the β_t of the alloy to improve hot workability or to obtain desired mechanical property combinations. C/B, either forging methodology (conventional or β) is employed in the fabrication of forgings or for alloys, such as β alloys, that are predominately forged above their β_t but may be finish forged at subtransus temperatures.

(b) These are recommended metal temperature ranges for conventional α-β, or β forging processes for alloys for which the latter techniques are reported to have been employed. The lower limit of the forging temperature range is established for open-die forging operations in which reheating is recommended.

(c) Alloys for which there are several compositional variations (primarily oxygen or other interstitial element contents) that may affect both β_t and forging temperature ranges.

(d) This alloy is forged and used both with and without the silicon addition; however, the β_t and recommended forging temperatures are essentially the same.

(e) Alloys designed to be predominately β forged.

(f) Ti-17 has been classified as an α-β and as a near-β titanium alloy. For purposes of this article, it is classified as an α-β alloy.

Alpha/Near-Alpha Alloys. Alpha titanium alloys contain elements that stabilize the hcp α phase at higher temperatures. These alloys (with the exception of commercially pure titanium, which is also an α alloy) are among the most difficult titanium alloys to forge. Typically, α/near-α titanium alloys have modest strength but excellent elevated-temperature properties. Forging and TMP processes for αalloys are typically designed to develop optimal elevated-temperature properties, such as strength and creep resistance. The β_t of α/near-α alloys typically ranges from 900 to 1065 °C (1650 to 1950 °F).

Alpha-Beta Alloys. Alpha-beta titanium alloys represent the most widely used class of titanium alloys (with Ti-6Al-4V being the most widely used of all titanium alloys) and contain sufficient β stabilizers to stabilize some of the β phase at room temperature. Alpha-beta titanium alloys are generally more readily forged than α alloys and are more difficult to forge than some β alloys. Typically, α-β alloys have intermediate-to-high strength with excellent fracture toughness and other fracture-related properties. Forging and TMP processes for α-β alloys are designed to develop optimal combinations of strength, fracture toughness, and fatigue characteristics. The β_t of α-β alloys typically ranges from 870 to 1010 °C (1600 to 1850 °F).

Beta/Metastable Beta Alloys. Beta alloys are those alloys with sufficient β stabilizers that the bcc β phase is the predominant allotropic form present at room temperature. Beta titanium alloys are usually easier to fabricate than other classes of titanium alloys, although β alloys may be equivalent to, or more difficult to forge than α-β alloys under certain forging conditions. Beta titanium alloys are characterized by very high strength with good fracture toughness and excellent fatigue characteristics; therefore, forging and TMP processes are designed to optimize these property combinations. The β_t of β titanium alloys ranges from 650 to 870 °C (1200 to 1600 °F).

Forging of Titanium Alloys

G.W. Kuhlman, Aluminum Company of America

Forgeability

Titanium alloys are considerably more difficult to forge than aluminum alloys and alloy steels, particularly with conventional forging techniques, which use nonisothermal die temperatures of 535 °C (1000 °F) or less and moderate strain rates (hot-die and isothermal forging of titanium alloys are discussed in depth in the article "Isothermal and Hot-Die Forging" in this Volume). Figure 1 compares the flow stresses of several commonly forged titanium alloys at strain rate of 10/s with the flow stress of 4340 alloy steel at a strain rate of 27/s. In Fig. 1, commercially pure titanium and Ti-8Al-1Mo-1V are α alloys, Ti-6Al-4V and Ti-6Al-6V-2Sn are α-β alloys, and Ti-13V-11Cr-3Al and Ti-10V-2Fe-3Al are β alloys.

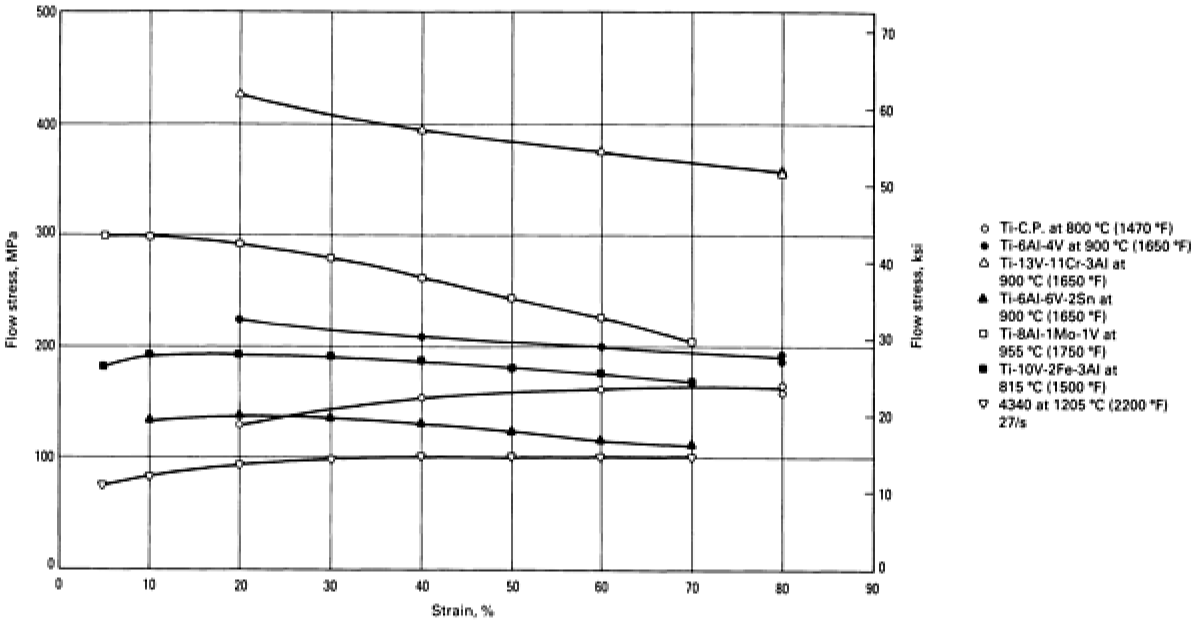

Fig. 1 Flow stress of commonly forged titanium alloys at 10/s strain rate compared to 4340 alloy steel at 27/s strain rate.

At this rapid strain rate (representative of a strain rate typical of a mechanical press or other rapid strain rate forging equipment), the β alloy Ti-13V-11Cr-3Al has the highest flow stress even at a temperature well above the β_t of the alloy; at rapid strain rates, very highly alloyed titanium alloys retard dislocation glide and other mechanisms that hasten deformation behavior. The α alloy Ti-8Al-1Mo-1V has the next highest flow stress and is typical of this class of titanium alloys. The α-β alloys Ti-6Al-4V and Ti-6Al-6V-2Sn have intermediate flow stresses at temperatures below their β_t, with the more highly βstabilized Ti-6Al-6V-2Sn having lower flow stresses than Ti-6Al-4V. Commercially pure titanium flow stress for the noted strain rate and sub-β_t temperature is similar to that for the α-β alloys. Finally, at a temperature slightly above its β_t, the metastable β alloy Ti-10V-2Fe-3Al has flow stresses lower than those of the α-β alloy Ti-6Al-4V. The flow stresses of all of the noted titanium alloys exceed that of the alloy steel 4340--in some cases by four to five times.

Effect of Temperature. The deformation characteristics of all classes of titanium alloys are very sensitive to metal temperature during deformation processes such as forging. This effect is illustrated in Fig. 2 for three alloys, each representative of one class of titanium alloy. For each of these alloys, forging pressure increases dramatically with relatively small changes in metal temperatures. For example, the forging pressure for the α alloy Ti-8Al-1Mo-1V increases nearly three times as the metal temperature decreases by approximately 95 °C (200 °F). Therefore, it is important in forging titanium alloys to minimize metal temperature losses in the transfer of heated pieces from furnace to the forging equipment and to minimize contact with the much cooler dies during conventional forging processes.

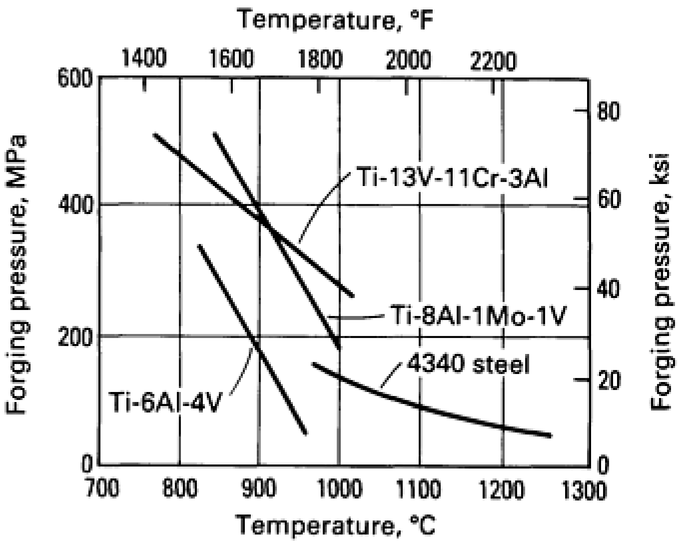

Fig. 2 Effect of forging temperature on forging pressure for three titanium alloys and 4340 alloy steel. Source: Ref 1.

The effect of temperature variations on the flow stresses of common titanium alloys does vary with alloy class. These effects are illustrated in Fig. 3(a), 3(b), and 3(c) for representative α, α-β, and β alloys, respectively. In comparing Fig. 3(a) to (c), it is evident that the more difficult-to-forge α alloys such as Ti-8Al-1Mo-1V (Fig. 3a) display the greatest sensitivity to metal temperature. For example, the flow stress at 10/s and 900 °C (1650 °F) is two to three times that of the alloy at 1010 °C (1850 °F) (the latter temperature is below the β_t of the alloy). In Fig. 3(b), the α-β alloy Ti-6Al-4V also displays sensitivity to metal temperature, but to a lesser extent than the α alloy Ti-8Al-1Mo-1V, especially at higher levels of total strain. In Fig. 3(b), at 1000 °C (1830 °F), Ti-6Al-4V is being deformed at or above the nominal β_t of the alloy, in which the structure is entirely bcc and considerably easier to deform. Finally, for the βalloy Ti-10V-2Fe-3Al less metal temperature sensitivity is displayed, also at higher levels of total strain. At 815 °C (1500 °F), Ti-10V-2Fe-3Al is being deformed above the β_t of the alloy, with an attendant reduction in flow stresses in comparison to sub β_t deformation at 760 °C (1400 °F). However, at this high strain rate, the flow stress reduction achieved by deforming βalloys above their β_t is less than the flow stress reduction achieved by deforming α-β alloys above their β_t.

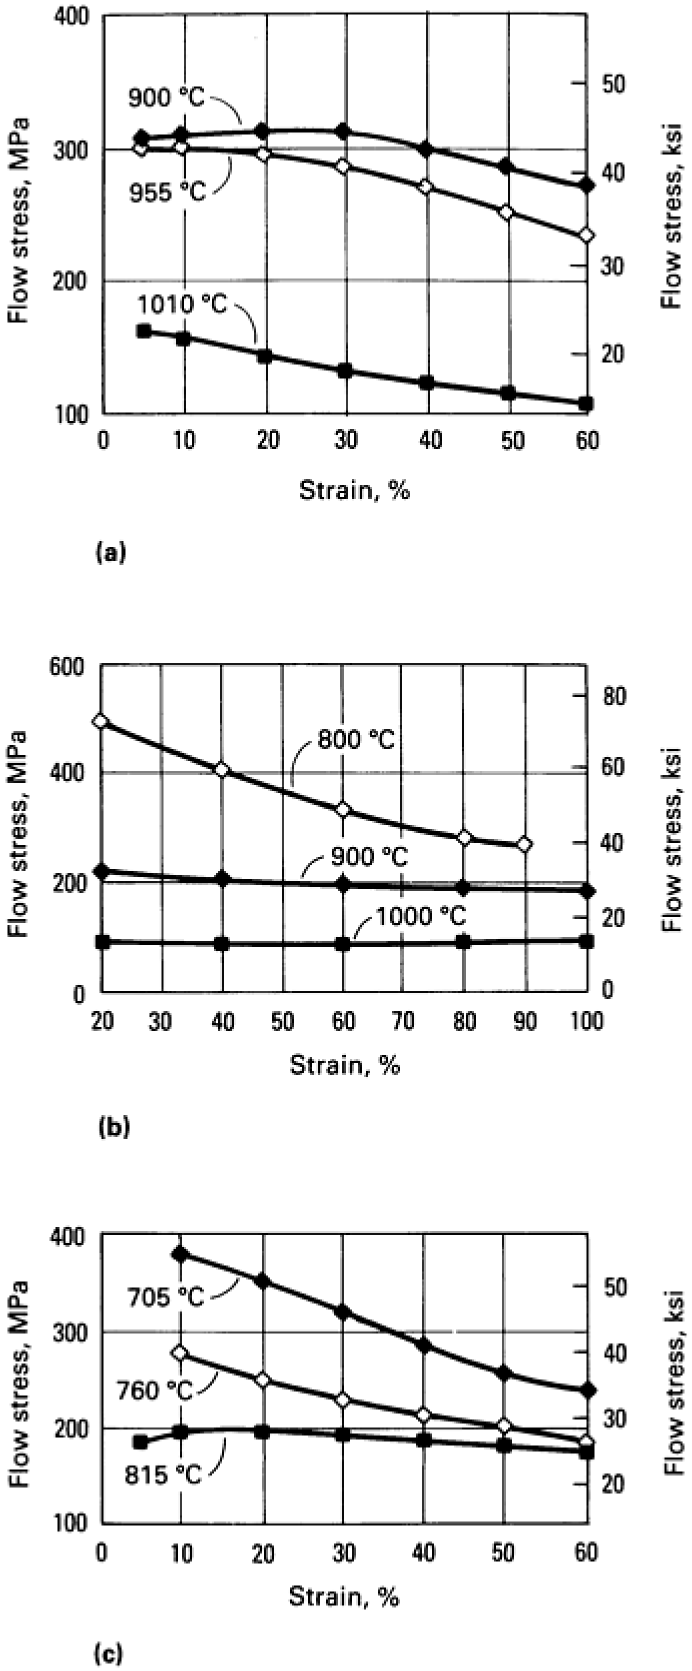

Fig. 3 Effect of forging temperature on flow stress of titanium alloys at 10/s strain rate. (a) α **alloy Ti-8Al-1Mo-1V. (b)** α-β **alloy Ti-6Al-4V. (c) Metastable** β**alloy Ti-10V-2Fe-3Al.**

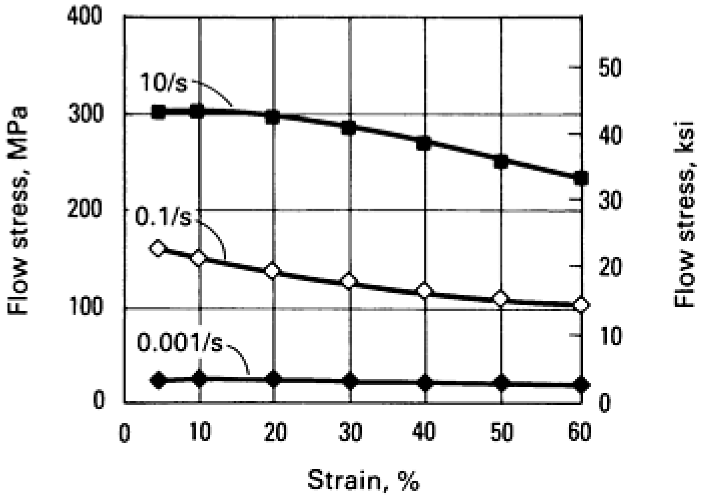
As with other forged materials, many titanium alloys display a strain-softening behavior at the strain rates typically used in conventional forging techniques. As shown in Fig. 3(a) to (c), strain softening is typically observed when such alloys are forged below their β_t and is observed to a much lesser extent when these alloys are deformed above their β_t (for example, Fig. 3b and c for Ti-6Al-4V and Ti-10V-2Fe-3Al). The differences in strain-softening behavior are a function of the differences in microstructure present during the deformation above or below the β_t of the alloy. The equiaxed α in a β matrix structure, typical of subtransus forging, has been found to redistribute strain and to promote dislocation movement more effectively than acicular α in a transformed β structure, leading to increased strain softening in the former.

Flow stresses describe the lower limit of the deformation resistance of titanium alloys as represented by ideal deformation conditions and are therefore rarely present during actual forging processes. However, flow stress information, as a function of such forging process variables as temperature and strain rate, is useful in designing titanium alloy forging processes. Because of other forging process variables, such as die temperature, lubrication, prior working history, and total strain, actual forging pressures or unit pressure requirements may significantly exceed the pure flow stress of any given alloy under similar deformation conditions.

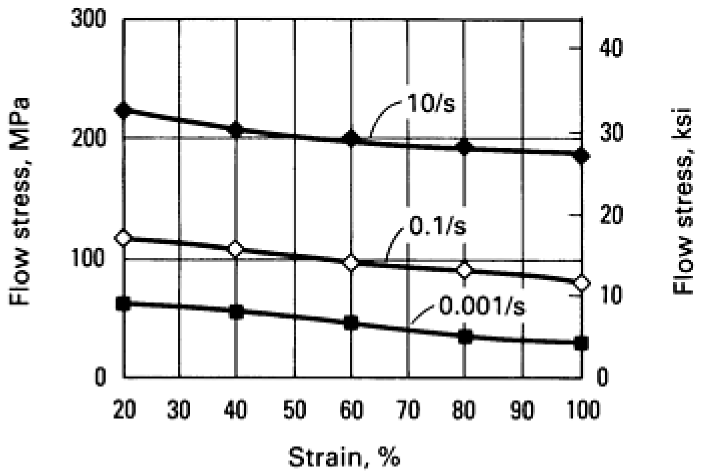
Table 1 lists recommended metal temperatures for 27 commonly forged α, α-β, and βtitanium alloys. With some exceptions, these alloys can be forged to the same degree of severity; however, the power and/or pressure requirements needed to achieve a given forging shape may vary with each individual alloy and particularly with alloy class. As a general guide, metal temperatures of β_t - 28 °C (50 °F) for α/β forging and β_t + 42 °C (75 °F) for β forging, are recommended.

Table 1 lists the recommended range of forging temperatures, with the upper limit based on prudent proximity (from furnace temperature variations and minor composition variations) to the nominal β_t of the alloy in the case of conventional, sub-β_t forging (see below) and without undue metallurgical risks in the case of super-β_t forging (see below). The lower limit of the specified ranges is the temperature at which forging should be discontinued in the case of open-die forging to avoid excessive cracking and/or other surface quality problems.

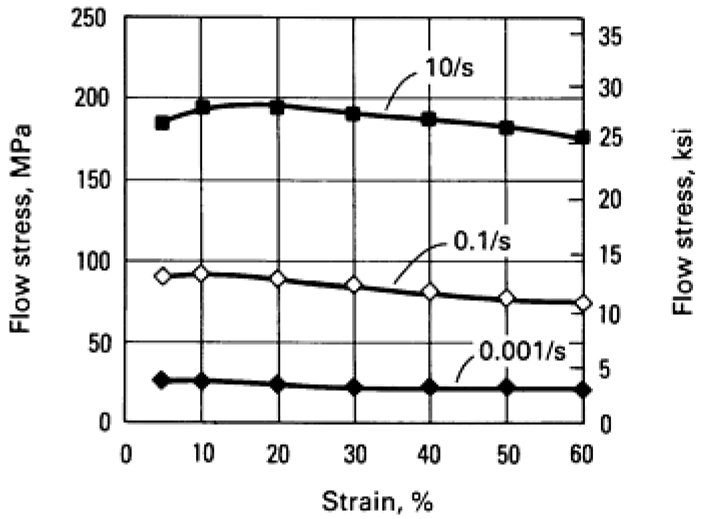
Effect of Deformation Rate. Titanium alloys are highly strain rate sensitive in deformation processes such as forging--considerably more so than aluminum alloys or alloy steels. The strain rate sensitivity for representative alloys from each of the three classes is illustrated in Fig. 4(a) for the αalloy Ti-8Al-1Mo-1V, in Fig. 4(b) for the α-β alloy Ti-6Al-4V, and in Fig. 4(c) for the β alloy Ti-10V-2Fe-3Al. For each of these alloys, as the deformation rate is reduced from 10/s to 0.001/s, the flow stress can be reduced by up to ten times. For example, the flow stress for Ti-6Al-4V at 900 °C (1650 °F), 50% strain, and 10/s is 205 MPa (30 ksi); at 0.001/s, the flow stress is 50 MPa (7 ksi), a fourfold reduction.



(a)



(b)



(c)

Fig. 4 Effect of three strain rates (0.001, 0.1, and 10/s) on flow stress of three titanium alloys forged at different temperatures. (a) α alloy Ti-8Al-1Mo-1V at 955 °C (1750 °F). (b) α-β alloy Ti-6Al-4V at 900 °C (1650

°F). (c) Metastable β alloy Ti-10V-2Fe-3Al at 815 °C (1500 °F).

From the known strain rate sensitivity of titanium alloys, it appears to be advantageous to deform these alloys at relatively slow strain rates in order to reduce the resistance to deformation in forging; however, under the nonisothermal conditions present in the conventional forging of titanium alloys, the temperature losses encountered by such techniques far outweigh the benefits of forging at slow strain rates. Therefore, in the conventional forging of titanium alloys with relatively cool dies, intermediate strain rates are typically employed as a compromise between strain rate sensitivity and metal temperature losses in order to obtain the optimal deformation possible with a given alloy. As discussed in the article "Isothermal and Hot-Die Forging" in this Volume, major reduction in resistance to deformation of titanium alloys can be achieved by slow strain rate forging techniques under conditions where metal temperature losses are minimized through dies heated to temperatures at or close to the metal temperature.

With rapid deformation rate forging techniques, such as the use of hammers and/or mechanical presses, deformation heating during the forging process becomes important. Because titanium alloys have relatively poor coefficients of thermal conductivity, temperature nonuniformity may result, giving rise to nonuniform deformation behavior and/or excursions to temperatures that are undesirable for the alloy and/or final forging mechanical properties. As a result, in the rapid strain rate forging of titanium alloys, metal temperatures are often adjusted to account for in-process heat-up, or the forging process (sequence of blows, and so on) is controlled to minimize undesirable temperature increases, or both. Therefore, within the forging temperature ranges out-lined in Table 1, metal temperatures for optimal titanium alloy forging conditions are based on the type of forging equipment to be used, the strain rate to be employed, and the design of the forging part.

Effect of Die Temperature. The dies used in the conventional forging of titanium alloys, unlike some other materials, are heated to facilitate the forging process and to reduce metal temperature losses during the forging process--particularly surface chilling, which may lead to inadequate die filling and/or excessive cracking. Table 2 lists the recommended die temperatures used for several titanium alloy forging processes employing conventional die temperatures. Dies are usually preheated to these temperature ranges using the die heating techniques discussed below. In addition, because the metal temperature of titanium alloys exceeds that of the dies, heat transfer to the dies occurs during conventional forging, frequently requiring that the dies be cooled to avoid die damage. Cooling techniques include wet steam, air blasts, and, in some cases, water.

Table 2 Die temperature ranges for the conventional forging of titanium alloys

Forging process/equipment	Die temperature	
	°C	°F
Open-die forging		
Ring rolling	150-260	300-500
	95-260	200-500
Closed-die forging		
Hammers	95-260	200-500
Upsetters	150-260	300-500
Mechanical presses	150-315	300-600

Screw presses	150-315	**300-600**
Orbital forging	150-315	**300-600**
Spin forging	95-315	**200-600**
Roll forging	95-260	**200-500**
Hydraulic presses	**315-480**	**600-900**

Forging of Titanium Alloys

G.W. Kuhlman, Aluminum Company of America

Forging Methods

Titanium alloy forgings are produced by all of the forging methods currently available, including open-die (or hand) forging, closed-die forging, upsetting, roll forging, orbital forging, spin forging, mandrel forging, ring rolling, and forward and backward extrusion. Selection of the optimal forging method for a given forging shape is based on the desired forging shape, the sophistication of the design of the forged shape, the cost, and the desired mechanical properties and microstructure. In many cases, two or more forging methods are combined to achieve the desired forging shape, to obtain the desired final part microstructure, and/or to minimize cost. For example, open-die forging frequently precedes closed-die forging to preshape or preform the metal to conform to the subsequent closed dies, to conserve the expensive input metal, and/or to assist in overall microstructural development.

The hot deformation processes conducted during the forging of all three classes of titanium alloys form an integral part of the overall thermomechanical processing of these alloys to achieve the desired microstructure and therefore the first- and second-tier mechanical properties. By the design of the working process history from ingot to billet to forging, and particularly the selection of metal temperatures and deformation conditions during the forging process, significant changes in the morphology of the allotropic phases of titanium alloys are achieved that in turn dictate the final mechanical properties and characteristics of the alloy. Fundamentally, there are two principal metallurgical approaches to the forging of titanium alloys:

- Forging the alloy predominantly below the β_t
- Forging the alloy predominantly above the β_t

However, within these fundamental approaches, there are several possible variations that blend these two techniques into processes that are used commercially to achieve controlled microstructures that tailor the final properties of the forging to specification requirements and/or intended service applications. The following sections in this article describe the two basic forging techniques used for titanium alloys, particularly the α/near-α, α-β, and metastable β alloys. In fully β stabilized alloys, manipulation of the α phase through forging process techniques is less prevalent; therefore, fully β stabilized alloys are typically forged above the β_t of the alloy.

Conventional (α-β) forging of titanium alloys, in addition to implying the use of die temperatures of 540 °C (1000 °F) or less, is the term used to describe a forging process in which most or all of the forging deformation is conducted at temperatures below the β_t of the alloy. For α, α-β, and metastable β alloys, this forging technique involves working the material at temperatures where both α and βphases are present, with the relative amounts of each phase being dictated by the composition of the alloy and the actual temperature used. With this forging technique, the resultant as-forged microstructure is characterized by deformed or equiaxed primary αin a transformed β matrix; the volume fraction of primary α is dictated by the alloy composition and the actual working history and temperature (Fig. 5a). Alpha-Beta forging is typically used to develop optimal strength/ductility combinations and optimal high/low-cycle fatigue properties. With conventional α-β forging, the effects of working on microstructure, particularly αmorphology changes, are cumulative; therefore, each successive α/β working operation adds to the structural changes achieved in earlier operations.

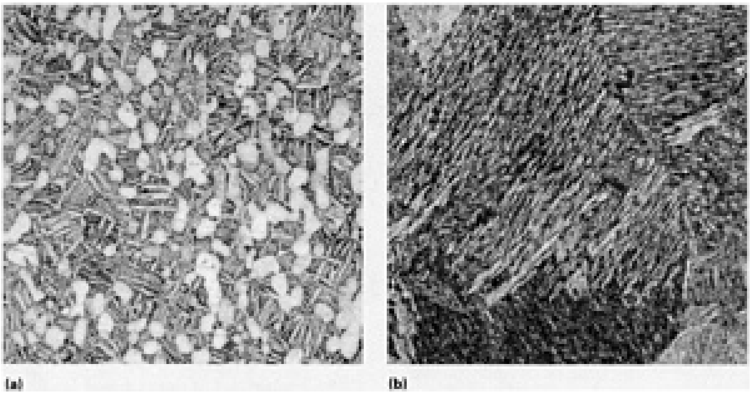

Fig. 5 Typical microstructure of forged titanium alloys. (a) α -β forging/heat treatment of alloy Ti-6Al-4V. Equiaxed primary αin transformed β. 200×. (b) β forging of alloy Ti-6Al-4V. Widmanstätten or acicular primary αin transformed β. 200×.

Example 1: Conventional α-β Forging of a Compressor Disk in Three Operations.

A 660 mm (26 in.) diam compressor disk, with a rim 44.5 mm (1.75 in.) thick and a web 19 mm (0.75 in.) thick was α-β forged from Ti-6Al-4V in three operations, as follows:

- Upset forged in a 160 kN (35,000 lbf) hammer, using a starting stock temperature of 980 °C (1800 °F) to reduce the stock height from 250 to 75 mm (10 to 3 in.)
- Blocked in a 160 kN (35,000 lbf) hammer to a rough contour, using a starting temperature of 955 °C (1750 °F), reducing rim thickness to 50 mm (2 in.) and web thickness to 25 mm (1 in.)
- Finish forged in a 160 kN (35,000 lbf) hammer to the final outline, starting at 955 °C (1750 °F), reducing rim thickness to 44.5 mm (1.75 in.) and web thickness to 19 mm (0.75 in.)

Beta forging, as the term implies, is a forging technique for α, α-β, and metastable β alloys in which most or all of the forging work is done at temperatures above the β_t of the alloy. In commercial practice, β forging techniques typically involve supertransus forging in the early and/or intermediate stages with controlled amounts of final deformation below the β_t of the alloy. Actual final subtransus working criteria are dependent on the alloy, the forging design, and the mechanical property combinations sought.

In β forging, the working influences on microstructure are not fully cumulative; with each working-cooling-reheating sequence above the β_t, the effects of the prior working operations are at least partially lost because of recrystallization from the transformation upon heating above the β_t of the alloy. Beta forging techniques are used to develop microstructures characterized by Widmanstätten or acicular primary α morphology in a transformed β matrix (Fig. 5b). This forging process is typically used to enhance fracture-related properties, such as fracture toughness and fatigue crack propagation resistance, and to enhance the creep resistance of α and α-β alloys. In fact, several recently developed α alloys (such as IMI 829 and 834) are designed to be β forged to develop the desired final mechanical properties. There is often a loss in strength and ductility with β forging as compared to α-β forging. Beta forging, particularly of α and α-β alloys, has the advantages of significant reduction in forging unit pressures and reduced cracking tendency, but it must be done under carefully controlled forging process conditions to avoid nonuniform working, excessive grain growth, and/or poorly worked structures, all of which can result in final forgings with unacceptable or widely variant mechanical properties within a given forging or from lot to lot of the same forging.

Example 2: Comparison of α-β and βForging of a Wing Spar Airframe Component in Ti-6Al-4V.

The wing spar forging shown in Fig. 6 is an example of a large titanium alloy component forged in a heavy hydraulic press. This forging weighs 262 kg (578 lb) and is produced using three press operations on a 310 or 450 MN (35,000 or 50,000 tonf) press with three sets of dies: first block, second block, and finish. For conventional α-β forging, all forging operations are conducted below the β_t of the alloy, using metal temperatures of 940 to 970 °C (1725 to 1775 °F).

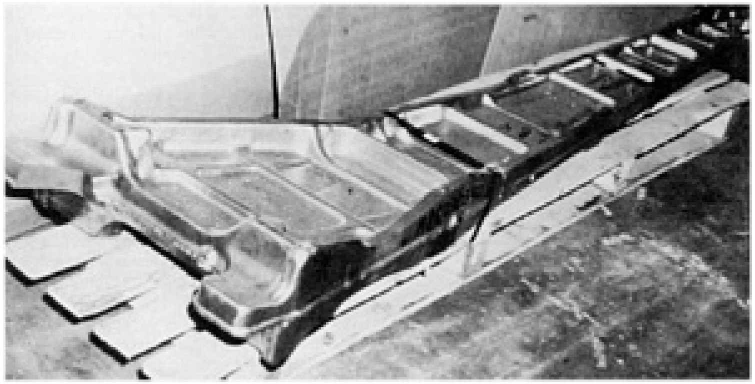

Fig. 6 Titanium alloy wing spar forged in a closed-die using α-β and β forging techniques. The part is 2.8 m (110 in.) long and weighs 262 kg (578 lb).

For β forging, two forging methods were investigated:

- Beta 1: first block only above the β_t of the alloy with second block and finish below the transus of the alloy
- Beta 2: first and second block above the transus of the alloy and finish forging only below the transus of the alloy

The metal temperature used for the β forging processes was 1040 to 1065 °C (1900 to 1950 °F). Table 3 lists the typical mechanical properties achieved in this wing spar forging with all three forging processes where the final heat treatment was an anneal at 705 to 730 °C (1300 to 1350 °F). Therefore, when β forging processes are used to produce this wing spar forging in annealed Ti-6Al-4V, the resulting yield and tensile strengths and ductilities (elongation and reduction in area) are reduced, but fracture toughness is improved over conventional α-β forging.

(a) L, longitudinal; T, transverse

Open-die forging is used to produce small quantities of titanium alloy forgings for which closed-dies may not be justified (see the article "Open-Die Forging" in this Volume). The quantity of forgings that warrants the use of closed dies varies considerably, depending largely on the size and shape of the forging. The open-die forging of titanium is also used to produce prototypes or small quantities of parts that might be machined from a solid billet or plate. However, because of the high cost of titanium alloys, considerable metal and machining costs can often be saved by using open-die forgings rather than machining from a solid shape. Finally, open-die forging is frequently used to make preform shapes, ranging from pancakes or biscuits to highly contoured shapes, for subsequent closed-die forgings. As with other materials, the complexity of open-die forged shapes can be consistently reproduced with state-of-the-art flat die forging equipment (see the article "Forging of Aluminum Alloys" in this Volume).

Closed-Die Forging. By far the greatest tonnage of conventionally forged titanium alloys is produced in closed dies. Closed-die titanium alloy forgings can be classified similarly to other materials, such as aluminum, as blocker-type (achieved with single set of dies or block/finish dies), conventional (achieved with two or more sets of dies), high-definition (also requiring two or more sets of dies), and precision forgings (frequently employing hot-die or isothermal forging techniques). Precision titanium alloy forgings are discussed below. Blocker-type titanium alloy forgings are typically produced in relatively less expensive dies, with design and tolerance criteria between those of open-die and conventional forgings. Conventional closed-die titanium forgings cost more than blocker-type, but the increase in cost is usually justified because of reduced machining costs. Finally, high-definition titanium alloy forgings are also more costly than conventional forging, but may also be justified by reduced machining. Preforming using open-die, upsetting, and/or roll forging frequently precedes all types of titanium alloy closed-die forging processes (see the article "Closed-Die Forging in Hammers and Presses" in this Volume).

In comparison with aluminum alloy closed-die forgings, all types of closed-die forgings in titanium alloys are typically produced to more generous design and/or tolerance criteria, reflecting the increased difficulty in forging these alloys. Figure 7 shows a large main landing gear beam forging produced in the α-β alloy Ti-6Al-4V. This relatively high volume main landing gear beam has been fabricated with a progression of closed-die forging designs in an effort to reduce the overall cost of the final machined part. Figures 8(a), 8(b), and 8(c) illustrate one cross section from this forging and the three types of closed-die forging approaches used to manufacture this part.

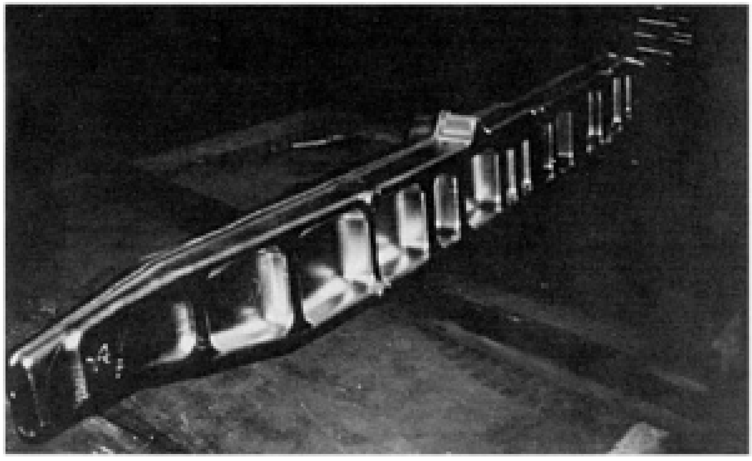

Fig. 7 Boeing 757 main landing gear beam forged of alloy Ti-6Al-4V using three available closed-die forging methods (blocker type, conventional, and high definition); see Fig. 8. The part weighs 1400 kg (3000 lb) and has 1.71 m^2 (2650 $in.^2$) plan view area (PVA); it is 498.3 mm (19.62 in.) high, 4467.1 mm (175.87 in.) long, and 339.3 mm (13.36 in.) deep.

Fig. 8 Cross sections of Boeing 757 part shown in Fig. 7 illustrating design and tolerance criteria for the 272 kg (600 lb) machined weight forging obtained from three closed-die forging methods, along with their respective forging weights. (a) Blocker type, 1364 kg (3007 lb). (b) Conventional, 1087 kg (2397 lb). (c) High definition, 879 kg (1937 lb).

Figure 8(a) shows the original blocker-type configuration (designed prior to finalization of the machined part) produced in two sets of dies. As a blocker-type part, the forging weighed 1364 kg (3007 lb) versus a machined part weight of 272 kg (600 lb) for an overall recovery from the raw forging of 20% (or a buy-to-fly ratio of 5 to 1). When the final machine part geometry had been better defined, the part was redesigned to a conventional forging (Fig. 8b) weighing 1087 kg (2397 lb), increasing the recovery from the raw forging of 25% (buy-to-fly of 4 to 1). Sufficient machining and metal cost savings were realized through this redesign to justify the costs of construction of a new set of dies. Finally, after some additional final machined part refinements, the part was redesigned to a high-definition shape (Fig. 8c), reducing the as-forged weight to 879 kg (1937 lb) and increasing the overall recovery of 31% (buy-to-fly of 3.3 to 1). Again, a cost savings was realized that justified the construction of new dies. Therefore, from blocker-type to close tolerance, the as-forged weight was reduced by nearly 500 kg (1100 lb), and the forged part/machined part recovery was increased by 11%--a significant cost savings.

Upset forging is sometimes the sole method used for forging a specific shape, such as turbine engine disks, from titanium alloys. More often, however, upsetting is used as a method of preforming to reduce the number of forging operations or to save material input, as is true for other materials (see the article "Hot Upset Forging" in this Volume). Upsetting in titanium alloys is often preferred to extrusion for creating large-headed sections adjacent to smaller cross sections. In the upset forging of titanium alloys, the unsupported length of a round section to be upset should not exceed 2.5 times the diameter; for a rectangular or square cross section, 2.5 times the diagonal. The maximum amount of upset achievable in titanium alloys without reheating depends on the alloy, but for the more readily deformable alloys, it is usually 2.5 times the diameter (or diagonal). Without several heating and upsetting operations, it is impossible to produce an upset in titanium alloys as thin or having as sharp corners as are typically produced in alloy steels.

Roll forging can be the sole forging operation used in the production of certain types of products in titanium alloys, as with other materials (see the article "Roll Forging" in this Volume); however, the roll forging of titanium alloys is much more widely used to make preform shapes, to save input material, or to reduce the number of closed-die forging operations. The roll forging of titanium alloys is frequently used for stock gathering and distribution of parts, such as blades, which have major differences in metal volume demands.

Rotary (orbital) forging is a variation of closed-die forging that is successfully used on titanium alloys for the manufacture of parts characterized by surfaces of revolution, such as turbine disks and other components with axial symmetry (see the article "Rotary Forging" in this Volume). The rotary forging of titanium alloys, because of the incremental nature of the deformation in this process, can provide enhanced final forging design sophistication and tolerances over that possible in other closed-die forging equipment, such as hammers, mechanical/screw presses, and hydraulic presses.

Spin forging can also be used in titanium alloy forging fabrication, as with aluminum and other materials. This technique combines closed-die forging and computer numerically controlled (CNC) spin forgers and achieves very close tolerance, axisymmetric, hollow shapes (see the article "Forging of Aluminum Alloys" in this Volume). Similar shape capability is possible in titanium alloys with attendant final component cost reductions from reduced material input and reduced final machining. As with aluminum, spin-forged shapes in titanium alloys can be produced to much tighter out-of-round and concentricity tolerances than competing techniques, such as forward or backward extrusion.

Ring rolling has been successfully used for producing a wide variety of rectangular and contoured annular shapes in titanium alloys and other materials. The methods used in ring rolling titanium alloys are essentially the same as those used for alloy steels (see the article "Ring Rolling" in this Volume). In addition to ring rolling, other forging methods, such as upset forging and punching, mandrel forging, and forward/backward extrusion, are sometimes used on titanium alloys to produce small or prototype quantities of annular shapes with predominant grain orientations in directions other than circumferential, as is typically achieved with ring rolling. Ring rolling is effective for a variety of titanium alloys of all types to reduce the cost of the final part through the fabrication of a near-net shape; a primary application is rotating and nonrotating turbine engine components.

Forward or backward extrusion is a variation of the closed-die forging of titanium alloys and other materials that can be used to produce hollow, axisymmetric shapes with both ends open or one end closed. Titanium alloys are among the most difficult materials to extrude because of their high resistance to deformation, temperature sensitivity, and abrasive nature. However, with properly designed and constructed tooling (usually from hot-work die steels; see the section "Die Specifications" in this article) and extrusion processes, the forward or backward extrusion of a variety of titanium alloys can be accomplished (additional information on extrusion is available in the article "Conventional Hot Extrusion" in this Volume). The extrusion of titanium alloys is usually accomplished from above the β_t of the alloy; therefore, the forward/backward extrusion applications of titanium alloys must be tolerant of the transformed microstructure and resultant properties. Forward or backward extrusion is also used to produce annular shape preforms for ring rolling or other closed-die forging operations, in which the subsequent fabrication processes may successfully modify the as-extruded microstructure. Selection of forward or backward extrusion is usually based on part geometry and press opening restrictions. Some state-of-the-art presses are equipped with openings in the upper cross-head to accommodate the fabrication of very long backward extrusions, either solid or hollow.

Forging of Titanium Alloys

Forging Equipment

Conventional titanium alloy forgings are produced on the full spectrum of forging equipment, from hammers and presses to specialized forging machines. Selection of forging equipment for a given titanium alloy shape is based on the capabilities of the equipment, forging design sophistication, desired forging process, and cost. The types of forging equipment used are discussed in the articles "Hammers and Presses for Forging" and "Selection of Forging Equipment" in this Volume).

Hammers. Gravity and power-assisted drop hammers are extensively used for the open-die and closed-die conventional forging of titanium alloys because of the relatively low fabrication costs associated with such equipment, their ability to impart progressive deformation to these difficult-to-work alloys, and the relatively short time the workpiece is in contact with the much cooler dies. Although the power requirements for the hammer forging of titanium alloys exceed those for aluminum alloys or alloy steels, hammers have been found to be effective in the manufacture of titanium alloy forgings of almost any size, but hammers are more often used for medium-to-large forgings, including axisymmetric shapes such as turbine disks and relatively generously designed airframe components. Because hammers deform the metal with high deformation speeds, the impact/strain rate of a hammer in forging titanium alloys may cause localized temperature variations, which may adversely affect the final forging microstructure. However, with proper control of hammer-forging processes, the temperature increase can be effectively exploited to facilitate the completion of the desired forging process and to increase the total deformation time before the titanium alloy cools below the recommended forging temperature range.

Mechanical presses are extensively used for the fabrication of small-to-medium titanium alloy forgings, with forging shape sophistication ranging from relatively simple shapes to precision forgings. A prime example of a conventionally forged, precision titanium alloy part manufactured on a mechanical press is turbine engine compressor and fan blades. The relatively rapid deformation rates available in mechanical presses are effectively exploited to produce the complex contours and tight tolerances associated with such airfoil shapes. As with hammers, the rapid deformation rate typical of mechanical presses may introduce temperature variations; however, with control of input material distribution, metal temperature, and the deformation conditions, uniform final forging microstructures are readily achievable. Mechanical presses are typically used for producing titanium alloy forgings weighing less than 9.1 kg (20 lb) and are seldom used for forgings weighing over 45 kg (100 lb). Figure 9 illustrates the forging processes used to manufacture a large turbine engine fan blade. The processes used in addition to block and finish forging on a large mechanical press include upsetting and gathering in order to distribute material properly before die forging.

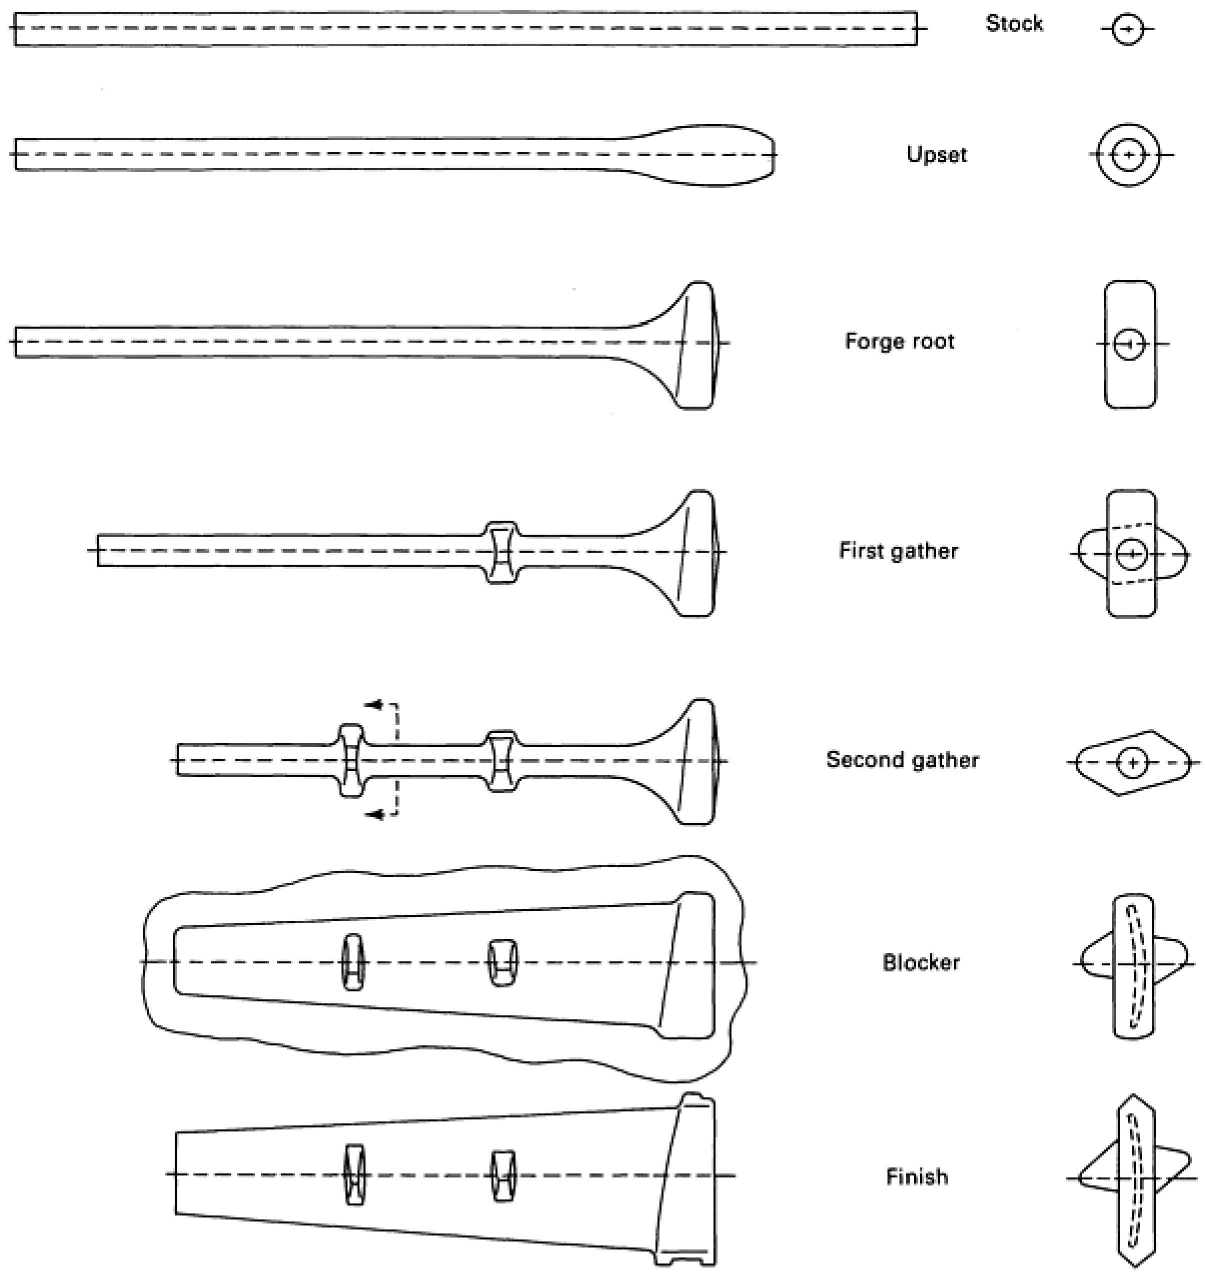

Fig. 9 Fabrication stages in the manufacture of a large alloy Ti-6Al-4V turbine engine fan blade.

Screw presses are also effective in the manufacture of titanium alloy forgings, including both simple shapes and precision forgings such as turbine engine blades and prosthetic devices. The more controlled deformation rate possible in a screw press has been exploited with titanium alloys in the manufacture of highly configured (twisted) titanium alloy blades and double-platform blades, such as those illustrated in Fig. 10.

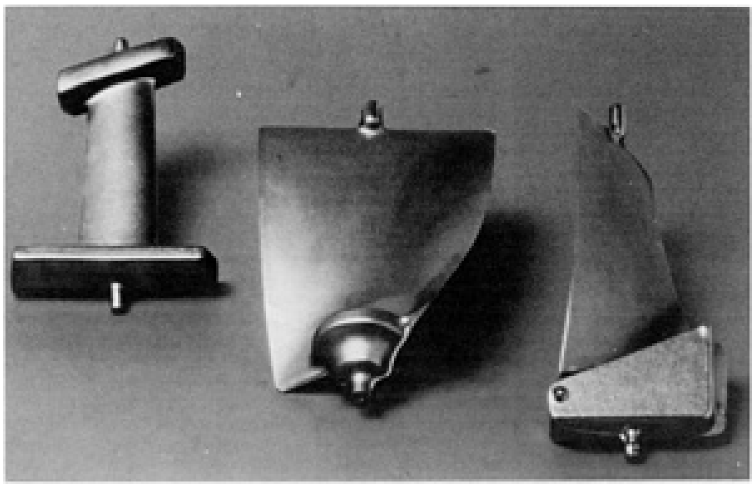

Fig. 10 Highly configured (twisted) alloy Ti-6Al-4V and alloy Ti-8Al-1Mo-1V turbine engine fan and compressor blades that were forged in screw presses.

Hydraulic presses are seldom used to manufacture small titanium alloy forgings (except for precision forgings), but are extensively used to manufacture large forgings weighing 1400 kg (3000 lb) and more. Hydraulic presses are also used to manufacture hand forgings and preforms for subsequent closed-die forging. Because the deformation achieved in a hydraulic press occurs at slower strain rates, metal temperature is usually more uniform in the forging than with rapid strain rate equipment. However, in the conventional hydraulic press forging of titanium alloys, metal temperature losses are encountered because of the time associated with the deformation and the contact with the cooler dies. Therefore, in the hydraulic press forging of titanium alloys, the metal temperatures employed are typically near the upper limits of the recommended ranges in Table 1, and insulative materials such as fiberglass are often used between the workpiece and the dies to retard heat transfer from the metal to the dies.

Figure 11 illustrates the largest closed-die titanium alloy forging ever manufactured. A 450 MN (50,000 tonf) hydraulic press was used. This is one of four main landing gear beam forgings used in the Boeing 747. This Ti-6Al-4V forging is over 6.22 in (245 in.) long and weighs over 1400 kg (3000 lb). It is manufactured using incremental forging techniques in two sets of dies in order to obtain sufficient unit pressure from the 450 MN (50,000 tonf) press.

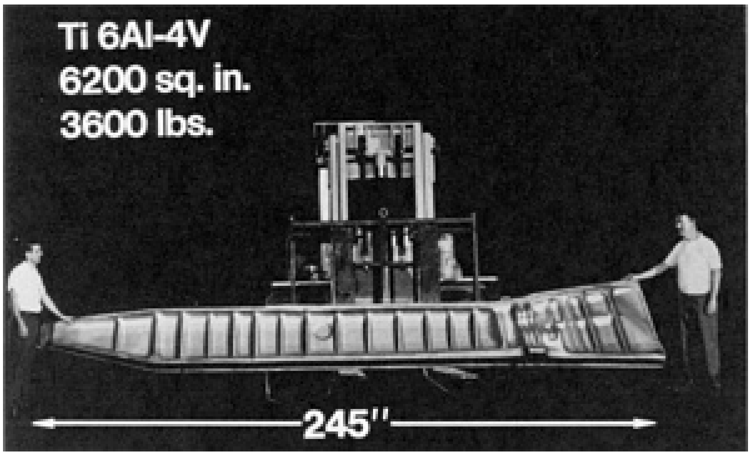

Fig. 11 Largest closed-die titanium alloy forging ever manufactured, a Boeing 747 main landing gear beam. Part was produced on a 450 MN (50,000 tonf) hydraulic press. Dimensions given in inches.

Figure 12 illustrates two other very large, highly configured Ti-6Al-4V titanium alloy airframe forgings that were also produced on a 450 MN (50,000 tonf) press--the upper and lower bulkheads for the F-15 aircraft. The smaller, upper bulkhead weighs 305 kg (670 lb), and the larger lower bulkhead weighs 725 kg (1600 lb). These three forgings (Fig. 11 and 12) illustrate not only the size of the titanium alloy forgings produced on hydraulic presses but also in conjunction with the 757 main landing gear beam shown in Fig. 7, illustrate the highly sophisticated forging design capability possible in the conventional forging of these difficult-to-fabricate alloys in the relatively slow strain rate conditions present in hydraulic presses. Such design sophistication is achieved through the optimization of forging die design and the hydraulic press forging processes used for titanium alloys.

Fig. 12 Alloy Ti-6Al-4V forgings for upper and lower bulkheads used on the F-15 that were produced on a 450 MN (50,000 tonf) hydraulic press using conventional forging methods.

Forging of Titanium Alloys

G.W. Kuhlman, Aluminum Company of America

Die Specifications

The critical elements of the closed-die forging of titanium alloys are die materials selection, die design, and die manufacture. The dies are a major part of the total cost of such forgings; however, as a percentage of total cost, the die cost for titanium alloys may be less than that for such materials as aluminum or alloy steels because of the much higher materials costs associated with titanium alloys. Further, forging process parameters and forging design capabilities are affected by die design, and the dimensional integrity of the finished titanium is in large part controlled by the die cavity. Therefore, the closed-die forging of titanium alloys requires the use of dies that are specifically designed for titanium for the following reasons:

- The shrinkage allowance in die sinking for titanium alloys is typically 0.004 mm/mm (0.004 in./in.) versus 0.006 mm/mm (0.006 in./in.) for aluminum alloys and 0.011 mm/mm (0.011 in./in.) for alloy steels
- Titanium alloys fill die contours less readily than alloy steel, stainless steel, or aluminum alloys; therefore, the die impressions for forging titanium alloys usually must have larger radii and fillets. For intricate or high-definition titanium forgings, more forging steps and therefore more die sets are typically required for titanium than for other materials, such as alloy steels or aluminum
- Dies for forging titanium alloys must be stronger than those for steel or aluminum alloys because greater unit pressures are usually needed to forge these alloys. Dies for titanium alloys may be up to 50% thicker, in terms of sidewalls and depth below the cavity, for the same depth and severity of die

impression than those used for alloy steels or aluminum. Without this increase in sidewall and/or below-cavity thickness, the risk of catastrophic die failure or excessive die distortion is significantly higher, and the number of die resinks that can be made without risk of die failure will be fewer.

- The surface finish requirements for titanium alloy dies are more stringent than those for alloy steels because of the generally poorer flow characteristics of titanium alloys

Die Materials. For the conventional forging of titanium alloys, the die materials used in closed-die forging are identical to the materials employed for aluminum alloys or alloy steels. Because of the higher temperatures associated with titanium alloy forgings, hot-work die steels such as H12 and H13 can be used more frequently with titanium alloys, especially as inserts or in small dies, than with aluminum alloys. The main body of the dies for titanium alloys is usually constructed of 6G or 6F2 die steels (see the article "Dies and Die Materials for Hot Forging" in this Volume), and/or the many proprietary grades within these composition limits offered by a number of die steel producers, at a hardness of 341 to 375 HB. A hot-work die steel at a higher hardness can then be inserted into the die cavities.

Die hardness for titanium alloys, as with other materials, depends on the severity and depth of the cavity and on the forging equipment that will be used to manufacture the forging. For hydraulic press forging, hot-work die steels are usually heat treated to 47 to 55 HRC. For dies with more severe impressions, the lower side of this range (47 to 49 HRC) is used; for dies with minimum severity, the upper side of the range (53 to 55 HRC) is used. For hammer and/or mechanical press forging, die hardness can be reduced by at least three points in order to increase toughness. Generally, the forger balances the desire for high die hardness to minimize wear with lower die hardness to increase toughness. For especially demanding or very high volume titanium forging processes (such as forward or backward extrusion, mechanical/screw press closed-die forging, and some open-die forging), hot-work die steels (H12 and H13) are used for the main body of the dies, and in some cases wrought/cast nickel-base alloys such as Alloy 718 (UNS N07718) have been successfully used where the increased cost associated with these materials is justified by improved die service life.

Even though the forging temperatures for titanium alloys are lower than those for alloy steels, die wear is generally greater in the conventional forging of titanium alloys because of the increased resistance of these alloys to deformation and the very abrasive nature of the oxide/scale coating present on these alloys during forging. Therefore, in addition to using inserts from higher-hardness hot-work die steels, other steps are frequently taken to improve the wear resistance of dies for titanium alloy forgings and to maintain the integrity of the die cavity. These steps include surface treatments/modification and modification of critical forging design parameters (with customer input) to minimize wear. Surface treatments that have been successfully used include a variety of state-of-the-art processes, such as special welding techniques, carburizing, nitriding, and surface alloying.

Example 3: Increase in the Size of Fillets That Reduced Die Wear.

The assembly rib shown in Fig. 13 was originally produced from alloy Ti-6Al-4V as a conventional closed-die forging with 4.8 mm (0.19 in.) radii at the flash land near the parting line around the forging. This fillet is shown as "Original design" in Fig. 13. Excessive die wear occurred at the fillet. The die design was revised by enlarging this fillet from 4.8 to 9.7 mm (0.19 to 0.38 in.) ("Improved design," Fig. 13). The alteration solved the problem by reducing die wear in this area to a normal level.

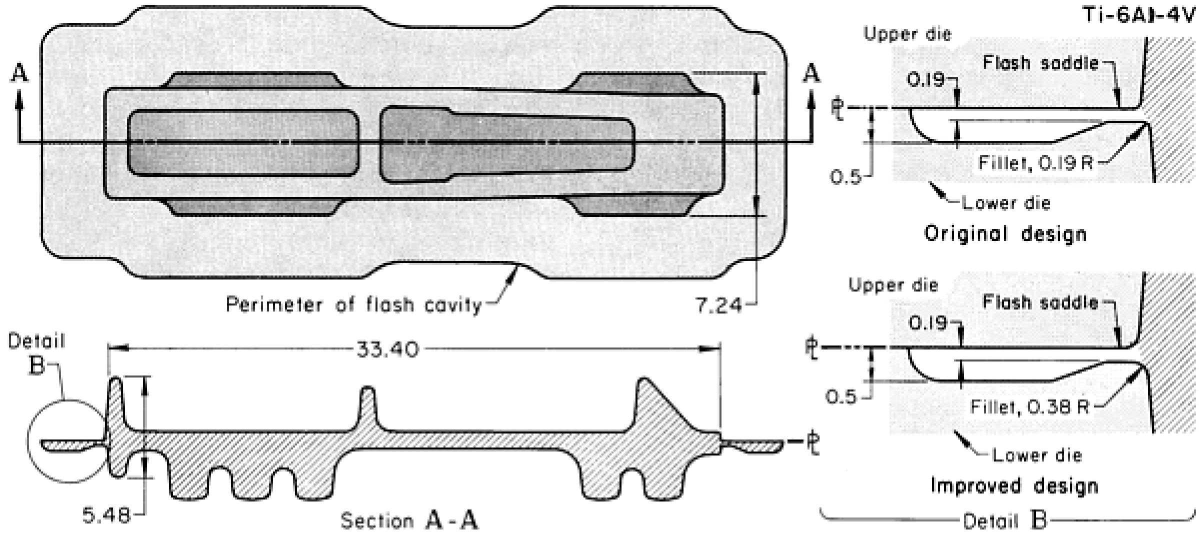

Fig. 13 Assembly rib for which forging die was redesigned to enlarge radius of fillets at flash saddle in order to increase die life. Dimensions given in inches.

Die Design. As with other materials, a key element in the cost control of dies for titanium forging and in the successful fabrication of titanium alloy forgings is die design and die system engineering. Dies for conventional closed-die titanium forgings are most frequently manufactured as stand-alone die blocks; however, in some cases, conventional closed-die, and particularly precision, titanium alloy forgings can be made from inserts in die holder systems. Die holder systems may be universal, covering a wide range of potential die sizes, or may be constructed to handle families of parts having similar overall geometries or sizes. The design of titanium alloy forging dies is highly intensive in engineering skills and is based on extensive empirical knowledge and experience. A compendium of titanium forging design principles and practices is provided in Ref 2.

As with aluminum alloys, forging design for titanium alloys is engineering intensive, and the advent of computer-aided design (CAD) hardware and software has had a significant impact on titanium alloy die design. The use of CAD technology in forging design is discussed in the article "Forging Process Design" in this Volume. As discussed in the article "Forging of Aluminum Alloys" in this Volume, CAD forging part design for titanium alloys is also institutionalized and widely used for titanium alloys. Computer-aided design databases are then used with computer-aided manufacturing (CAM) to produce dies, to direct the forging process, and to assist in final part verification and quality control. Heuristic, artificial intelligence, and deformation modeling techniques are also being applied to a variety of titanium alloys to enhance the forging design process. Further, because of the critical structural changes achieved in the forging of titanium alloys, these expert systems and finite-element models will be used to predict final part microstructures in advance of actually committing to the production forging process. Because of the flow characteristics of titanium alloys, special design features are often incorporated into the dies to restrict or to enhance metal flow in certain locations of a forging, as discussed in the following example.

Example 4: Use of Corrugations in Flash Land to Reduce Outward Flow of Flash.

A rectangular box forging (Fig. 14) was used experimentally to determine the effect of corrugations in restricting metal flow. The flash land surrounding the box was originally designed without corrugations. Because of the variation in wall thickness of the part, metal flowed more readily to the heavier walls, thus starving the sidewalls and resulting in inadequate fill. To restrain the flow of metal at the end walls, corrugations were added to the flash land at both ends (Detail A, Fig. 14). The flash land along the sidewalls was not corrugated (Detail B, Fig. 14). The restraint to flow provided by the corrugations was sufficient to fill the sidewalls completely. The corrugations also made possible a savings in the amount of metal required to complete the forging.

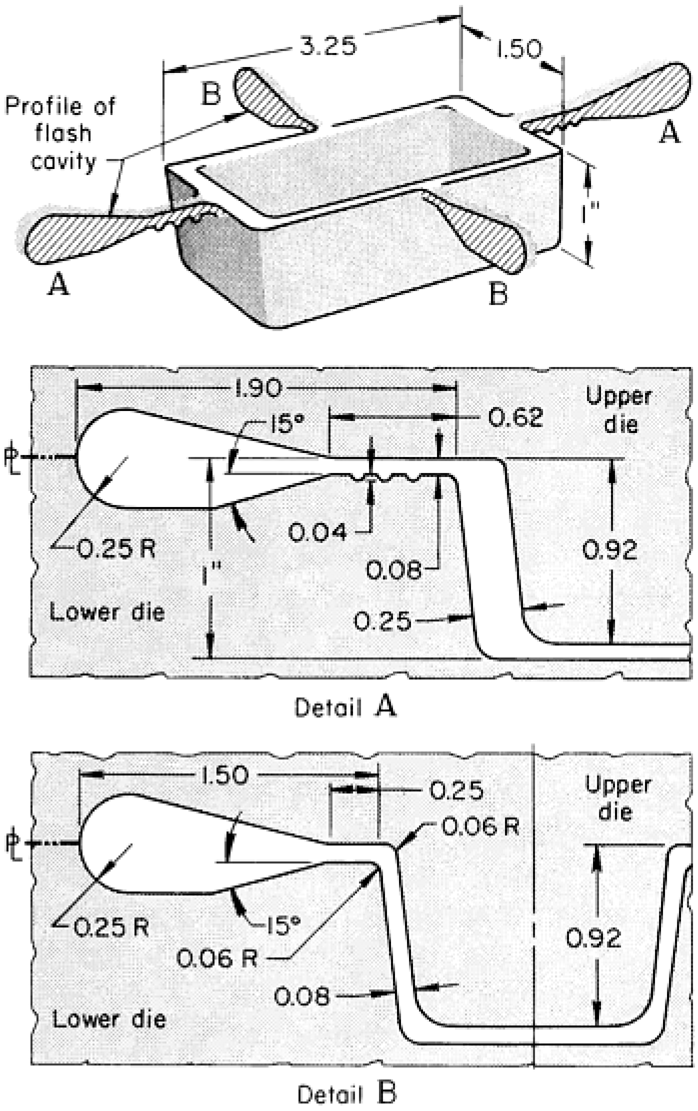

Fig. 14 Corrugations in the flash saddle at the end of a box forging that improved metal flow to the side walls. Dimensions given in inches.

Die Manufacture. Titanium alloy forging dies, which are similar to the aluminum alloy dies discussed in the article "Forging of Aluminum Alloys" in this Volume, are produced by a number of techniques, including hand sinking, copy milling from a model, electrodischarge machining (EDM), and CNC direct sinking. With CAD databases now available, CAM-driven CNC sinking of titanium alloy dies can provide the same benefits as those described for aluminum alloys.

Titanium Alloy Forging Processing

The common elements in the manufacture of any conventional titanium alloy forging include preparation of the forging stock, preheating of the stock, die heating, lubrication, the forging process, trimming and repair, cleaning, heat treatment, and inspection. The critical aspects of each of these elements for titanium alloys are reviewed below.

Forging Stock. In the manufacture of titanium alloy forgings, the predominant forms of forging stock used are billet (round, octagonal, rectangular, or square) and bar that has been fabricated by primary hot-working processes from titanium alloy ingot. The conversion of titanium alloy ingot to forging stock is a critical part of the overall titanium alloy forging process because it affects the overall cost of the starting material used for forging and because ingot conversion plays an important role in the overall macro- and microstructural development of the final titanium alloy forgings. Only rarely is titanium alloy ingot directly forged into finished titanium alloy forging components, and even then early forging stages are used to refine the ingot structure.

Titanium alloy ingot is primarily hot worked using forging techniques; however, hot rolling can be used for bar stock. A series of working operations is carried out on titanium ingot that typically involves multiple upsetting and drawing procedures to impart primary work to the alloy, to refine the relatively coarse as-cast grain size, and to achieve the desired starting macrostructure and microstructure for forging.

Titanium ingot conversion can be accomplished by the forger or by the primary titanium metal producer. Ingot conversion working procedures, forging stock macrostructural (grain size) or microstructural requirements, nondestructive testing of the forging stock, and mechanical property testing of the forging stock for a given alloy/size/type of forging stock are usually based on the specific forging involved, the forging equipment that will be used to manufacture it, cost considerations, and final forging structural and mechanical property requirements. Requirements for the forging stock are usually the subject of specifications by the forger or are negotiated between the forger and the metal supplier. In addition, the ultimate forging customer and/or federal, military, or other governmental specifications, such as AMS 2380 (Ref 3), may impose specific requirements on the manufacture of titanium alloy ingot (for example, required melting practices and melting controls), the forging stock fabricated from such ingot, macro- and microstructural requirements for forging stock, and necessary tests and nondestructive inspections for the qualification of titanium alloy forging stock.

Surface preparation of titanium alloy billet or bar forging stock is important not only for the satisfactory performance of the stock in subsequent forging but also because detailed, stringent ultrasonic inspection is frequently performed on the forging stock (as required by customer or other specifications) as a critical part of the overall quality assurance functions on titanium alloy forgings. Ultrasonic inspection (USI) of the billet is often preferred to USI of the final forged shape because of the more regular geometric shape. Furthermore, billet conversion involves a mode of deformation that tends to enlarge critical defects making them more readily detectable. Such ultrasonic inspection is typically conducted by multiple scan and/or automated techniques on properly prepared rounds, rectangles, or squares. Therefore, titanium alloy billet or bar stock is typically ground or machined to remove all defects and to prepare the surface for the type of ultrasonic inspection that will be performed.

Preparation of Forging Stock. Properly fabricated and qualified titanium alloy forging stock is then prepared for forging using several cutting methods, including shearing, sawing, and flame cutting. As a class of materials, titanium alloys are considerably more difficult to cut than most other forged metals, except for superalloys and refractory metals. Shearing is used only on relatively small sizes of titanium alloy forging stock, typically 50 mm (2 in.) and less in diameter. Sawing techniques include cold sawing, machine hacksawing (for small-to-intermediate sizes and low volumes), machine band sawing (also for small-to-intermediate sizes and low volumes), and abrasive sawing (for intermediate-to-large rounds and squares). In all sawing operations, but particularly the abrasive sawing of titanium alloys, it is necessary to control the sawing operation through coolants, speeds, and feeds to prevent overheating during cutting; such overheating may result in cracking during subsequent forging. Flame cutting, using oxy-gas and plasma techniques, is used to cut rectangular and square forging billet in thicknesses to approximately 250 mm (10 in.). Because flame cutting leaves residual disturbed surfaces and heat-affected zones, typically $\sim$1.5 mm ($\sim$0.060 in.), it may be necessary to grind flame-cut surfaces to remove the slag and heat-affected material that may be conducive to surface cracking under severe deformation.

Preheating for Forging. Prior to preheating for forging, most titanium forging stock is coated with ceramic coatings to retard oxidation. Precoating and other titanium alloy forging lubrication issues are discussed below. The heating of titanium alloys for forging is a crucial part of the forging process, both in terms of preventing excessive contamination during heating by oxygen, nitrogen, and hydrogen and controlling the metal temperature within the narrow temperature limits necessary for the successful forging of titanium alloys.

Heating Equipment. Titanium alloys are heated for forging with various types of heating equipment, including electric furnaces, open or semimuffled gas furnaces, oil furnaces, induction heating, fluidized-bed heating, and resistance heating. Open-fired gas and electric furnaces, either continuous (for example, rotary) or batch, are the most widely used. Heating equipment design and capabilities necessarily vary with the requirements of a given forging process. Titanium alloys have an extreme affinity for all gaseous elements present during exposure to the atmospheric conditions prevalent in most heating techniques, except vacuum.

Above about 595 °C (1100 °F), titanium alloys react with both oxygen and nitrogen to form scale. Underlying the scale is an oxygen/nitrogen enriched zone called α case; both oxygen and nitrogen stabilize the α phase. This α case zone may be hard and brittle, and if deep enough, it can cause cracking and/or increased tooling wear. Therefore, titanium alloys are precoated, and heating practices and/or furnace operating conditions are controlled to minimize the development of α case. With most titanium alloys, the formation of scale and α case is a diffusion-controlled process that may be limited by precoating and/or by the furnace operating parameters. Alpha and α-β titanium alloys tend to form more scale and α case than β alloys when heated under similar temperature and furnace conditions.

In addition, titanium alloys have an extreme affinity for hydrogen. Although reducing atmospheres, as used with some ferrous alloy forging, may retard the formation of scale and α case in titanium alloys, hydrogen atmospheres dramatically increase the risk of hydrogen pickup. Therefore, in addition to precoats, which also assist in the retardation of hydrogen pickup, most titanium alloy heating systems are designed to provide oxidizing conditions (through the use of excess air in gas-fired furnaces) in order to minimize the presence of hydrogen.

Induction heating, resistance heating, and fluidized-bed heating are frequently used in forging titanium alloys where forging processes are automated. State-of-the-art gas and electric furnaces for titanium alloys also often have fully automated handling systems.

Temperature Control. As noted in Fig. 1, 2, 3, 4 and Table 1, titanium alloys have a relatively narrow temperature range for conventional forging. Further, metal temperature is critical to the microstructure of titanium alloy forgings. Therefore, temperature control in preheating for forging titanium alloys is highly critical and is usually obtained through the capabilities and control of the heating equipment. Titanium alloy heating equipment should be equipped with pyrometric controls that can maintain ±14 °C (±25 °F) or better. Titanium alloy stock heating equipment is often temperature uniformity surveyed in much the same manner as with heat-treating furnaces. Continuous rotary furnaces used for titanium alloys typically have three zones: preheat, high heat, and discharge. Most furnaces are equipped with recording/controlling instruments, and in some batch furnace operations separate load thermocouples are used to monitor furnace temperature during preheating operations.

In addition to highly controlled heating equipment and heating practices, the temperature of heated titanium alloy billets can be verified with contact pyrometry or non-contact optical pyrometers. The latter equipment must be used with care because it is emissivity sensitive and may provide different temperature indications when the metal is observed inside the hot furnace versus when the metal has been removed from the furnace. In most closed-die and open-die forging operations, it is desirable to have titanium alloy metal temperatures near the upper limit of the recommended temperature ranges. In open-die forging, the lower limit of the recommended ranges is usually the point at which forging must be discontinued to prevent excessive surface cracking.

Heating Time. It is good practice to limit the exposure of titanium alloys in preheating to times just adequate to ensure that the center of the forging stock has reached the desired temperature in order to prevent excessive formation of scale and α case. Actual heating times will vary with the section thickness of the metal being heated and with furnace capabilities. Because of the relatively low thermal conductivity of titanium alloys, necessary heating times are extended in comparison to aluminum and alloy steels of equivalent thickness. Generally, 1.2 min/mm (30 min/in.) of ruling section is sufficient to ensure that titanium alloys have reached the desired temperature.

Heating time at a specific temperature is critical in titanium alloys for the reasons outlined above. Long soaking times are not necessary and introduce the probability of excessive scale or α case. Generally, soaking times should be restricted to 1 to 2 h, and if unavoidable delays are encountered, where soaking time may exceed 2 to 4 h, removal of the metal from the furnace is recommended.

Heating of Dies. Dies are always preheated in the closed-die conventional forging of titanium alloys, as noted in Table 2, with die temperature varying with the type of forging equipment used. Dies for titanium alloy forging are usually preheated in remote die heating systems, although on-press equipment is sometimes used. Remote die heating systems are usually gas-fired die heaters, which can slowly heat the die blocks to the desired temperature range before assembly into the forging equipment.

With some conventional forging processes, particularly the hydraulic press forging of titanium alloys, the temperature of the dies may increase during forging. Die damage may occur without appropriate cooling. Therefore, titanium alloy dies are often cooled during forging using wet steam, air, or occasionally water.

For those conventional forging processes in which die temperatures tend to decrease, on-press heating systems ranging from rudimentary to highly sophisticated are used. The techniques used include gas-fired equipment, induction heating equipment, resistance heating equipment, or combinations of these methods.

Lubrication is also a critical element in the conventional forging of titanium alloys and is the subject of engineering and process development emphasis in terms of the lubricants used and the methods of application. With titanium alloy conventional forging, a lubrication system is used that includes ceramic precoats of forging stock and forgings, die lubrication, and, for certain forging processes, insulation.

Ceramic Glass Precoats. Most titanium alloy forging stock and forgings are precoated with ceramic precoats prior to heating for forging. These ceramic precoats, which are formulated from metallic and transition element oxides and other additives, provide several functions, such as:

- Protection of the reactive titanium metal from excessive contact with gaseous elements present during heating
- Insulation or retardation of heat losses during transfer from heating to forging equipment
- Lubrication during the forging process

The formulation of the ceramic precoat is varied with the demands of the forging process being used, the alloy, and the forging type. Modification of the ceramic precoat formulation usually affects the melting or softening temperature, which ranges from 595 to 980 °C (1100 to 1800 °F) for most commercially available precoats for titanium alloys. Experience has shown that ceramic precoats with a viscosity of 20 to 100 Pa · s (200 to 1000 poise) at operating temperature provide optimal lubricity and desired continuous film characteristics for protecting the metal during heating and for preventing galling and metal pickup during forging. The actual formulations of ceramic precoats are often proprietary to the forger or the precoat manufacturer. Ceramic precoats are usually colloidal suspensions of the ceramics in mineral spirits or water, with the latter being the most common. Finally, most conventional titanium forging die design techniques include allowances for ceramic precoat thickness in sinking the die cavity to ensure the dimensional integrity of the final forging.

Ceramic precoats are applied using painting, dipping, or spraying techniques; state-of-the-art dipping and/or spraying processes are fully automated. Necessary ceramic precoat thicknesses vary with the precoat and the specific forging process, but generally fall in the range of 0.01 to 0.1 mm (0.0005 to 0.005 in.). Most ceramic precoats require a curing process following application to provide sufficient green strength for handling. Curing procedures range from drying at room temperature to automated furnace curing at temperatures to approximately 150 °C (300 °F).

Die lubricants are also used in the conventional closed-die forging of titanium alloys. Such die lubricants are subject to severe demands and are formulated to modify the surface of the dies to achieve the desired reduction in friction under conditions of very high metal temperatures and die pressures and yet leave the forging surfaces and forging geometry unaffected. Die lubricant formulations for titanium alloys are usually proprietary, developed either by the forger or the lubricant manufacturer. Die lubricant composition is varied with the demands of the specific forging process; however, the major active element in titanium alloy die lubricants is graphite. In addition, other organic and inorganic compounds are added to achieve the desired results because of the very high temperatures present. Carriers for titanium alloy die lubricants vary from mineral spirits to mineral oils to water.

Titanium alloy die lubricants are typically applied by spraying the lubricant onto the dies. Several pressurized air or airless systems are employed, and with high-volume, highly automated titanium alloy forging processes, die lubricant application is also automated by single or multiaxis robots. Some state-of-the-art application systems can apply very precise patterns or amounts of lubricant under fully automated conditions.

Insulation. In the conventional forging of titanium alloys in relatively slow strain rate processes such as hydraulic press forging, insulative materials in the form of blankets are often used to reduce metal temperature losses to the much cooler dies during the initial deformation stages. The insulative blankets are usually fabricated from fiberglass that is formulated to provide the necessary insulative properties. Blanket thickness varies with specific materials of fabrication and desired insulative properties, but generally ranges from 0.25 to 1.3 mm (0.010 to 0.050 in.). If insulative blankets are used, allowance is made in die sinking tolerances for modification of die cavity dimensions to ensure the dimensional integrity of the finished forging. Insulative blankets are usually applied to the dies immediately before insertion of the hot metal for forging.

Forging Process. The critical elements of the titanium conventional forging process (including metal/die temperature, strain rate, deformation mode, and the various forging processes and state-of-the-art forging capabilities reviewed above) must be controlled to achieve the desired final forging shape. Titanium alloy forgings are produced in enhanced forging and supporting equipment organized into cells that operate as advanced manufacturing systems and are then integrated with CAM concepts and other techniques. As with other materials, titanium alloy conventional forging is entering an era that is properly termed integrated manufacturing, in which all aspects of the titanium alloy forging process from design to execution are heavily influenced by computer technology.

Trimming is an intermediate operation that is necessary for the successful fabrication of conventional titanium alloy forgings. The flash generated in most closed-die titanium alloy forging processes is removed by hot trimming, sawing, flame cutting, or machining, depending on the size, complexity, and production volume of the part being produced. Hot trimming is generally the least expensive method and is used on relatively high volume small-to-intermediate size titanium alloy forgings. Most hot trimming punches are made from 6G or 6F2 die block material with hardnesses from 388 to 429 HB. Hot trimming blades are usually made from high-alloy steel, such as AISI D2, hardened to 58 to 60 HRC. Blades can be made from other materials that are usually hardfaced with cobalt-base alloy materials offered by several suppliers. Typically, the desired minimum flash temperature for the hot trimming of titanium alloys is 540 °C (1000 °F), although fewer trimming problems will occur if the flash temperature is as high as possible. Hot trimming is best accomplished in conjunction with the hot-forging process, rather than in separate heating and trimming operations. Cold trimming is rarely used for titanium alloys because the flash is very hard and may be brittle under such conditions, leading to unsatisfactory trimming or safety hazards.

Hot trimming is sometimes facilitated by the incorporation of certain design features into the die, the forging, or both. Figure 15 shows a flap hinge forging for which flash was distributed between upper and lower dies (Details A and B, Fig. 15). The dies were designed so that the flash would always be at a point where the draft was nearly vertical; therefore, the flash could be trimmed with minimal interference with the profile of the forging.

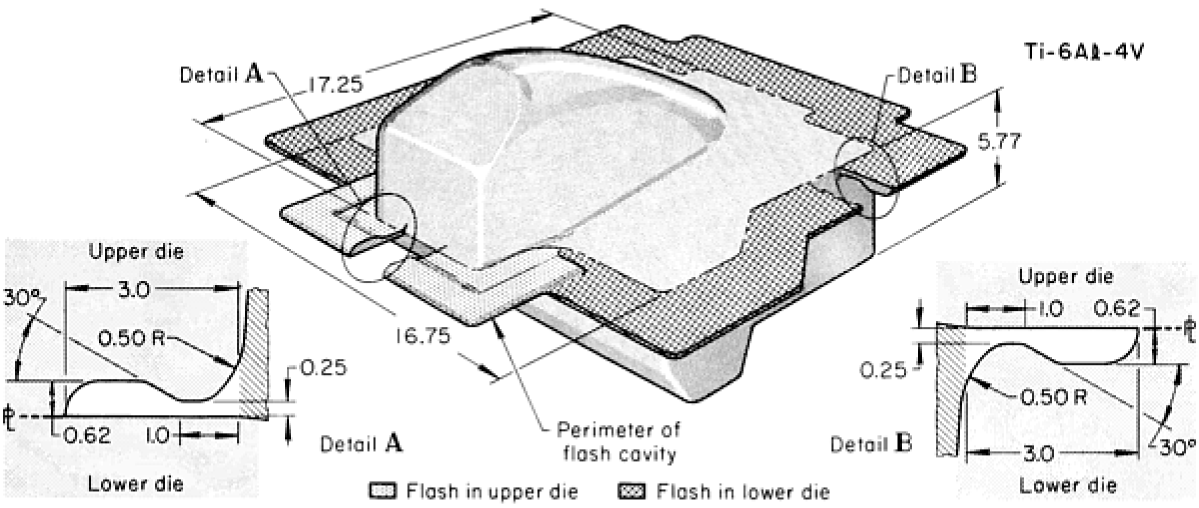

Fig. 15 Flap hinge forged in dies designed to provide uniform flash around the forging and to shift flash impression from upper to lower die. Dimensions given in inches.

The hot trimming of titanium alloy flash can be dangerous because the flash may shatter rather than trim or bend if the metal is allowed to cool below the above recommended temperature. Occasionally, a forging may jump in the impression during hammer forging and may be slightly out of position before the next blow can be stopped; unless protection is provided, flash may extrude between the dies and fly through the shop. Therefore, a flash trap should be used in the hammer forging of titanium alloys. This is usually accomplished by attaching a skirt to the top forging die. This skirt shields the striking face of the bottom die while the dies are separated. If flash breaks off, the skirt will intercept the pieces.

Machining and trimming operations are usually accomplished cold. Machine band sawing, with specially designed abrasive blades, has been shown to be an effective method of removing relatively thin titanium alloy flash where part volumes are low. Flame cutting is effective with large forgings and/or with thick flash where hot trimming is not feasible, because of either the size of the part or low part volume. Using oxy-gas, plasma, or other techniques, flash 50 mm (2 in.) or more in thickness can be successfully and economically removed. State-of-the-art flame cutting equipment used to trim titanium alloy forgings incorporates fixtures and automated systems that exploit CAD databases on titanium alloy forgings and CAM procedures. Depending on customer specifications and subsequent processing, the flame-cut flash may be repaired or left as cut. Flame cutting of flash should be accomplished prior to heat treatment so that the heat-affected zone (HAZ) is rendered machinable.

Machining, such as profile milling, can be employed on relatively low volume or intricate forgings, such as certain precision forgings, where other flash removal techniques may jeopardize the dimensional integrity of the forging.

Repair. As an intermediate operation between forging stages in most conventionally forged titanium alloys, repair of the forging is often necessary to remove surface discontinuities created by prior forging processes so that such defects do not affect the integrity of the final forging product. The necessity for intermediate repair is usually a function of the part complexity, the alloy, the forging processes, and other factors in the forging operation. For example, intermediate repair is generally required on structural shapes, but is often unnecessary on disk shapes. Compared to some other forged metals, titanium alloys are difficult to repair, requiring abrasive grinding techniques that are typically labor intensive.

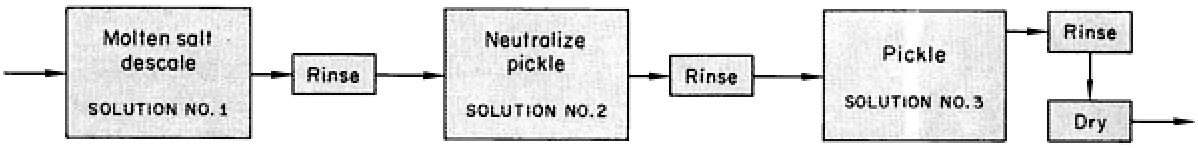
To facilitate the surface repair, titanium alloy forgings should be cleaned (discussed below) to remove the hard α case, which can cause excessive grinding tool wear. With some alloys, such as α alloys, surface repair is best accomplished after preheating the metal to about 260 to 370 °C (500 to 700 °F). Localized temperature increases may occur during abrasive grinding and, because of the poor thermal conductivity of titanium alloys, may create high thermal stresses. From the notch effect of the crack, these stresses in grinding may be high enough to propagate cracks during the repair process. Increasing the metal temperature on sensitive alloys reduces the stresses and decreases the probability of further cracking in repair. Soft silicon carbide rather than alumina grinding wheels should be used to minimize heat generation. Dye penetrant or liquid penetrant inspection techniques can be used on repaired titanium alloy forgings to ensure the removal of all surface discontinuities.

Cleaning. The oxide scale and underlying α case layers that form on all titanium alloys during heating for forging or in heat treatments are brittle and can promote cracking in subsequent forging or, in the case of finished forgings, can cause excessive machine tool wear during machining. Consequently, it may be desirable to remove the oxide and α case layers between successive forging operations, and it is mandatory to remove these layers from the finished forging before shipment to customers.

Cleaning techniques for titanium alloy forgings involve two processes--one for removing the oxide scale and the other for removing the α case layer. Scale removal can be accomplished by mechanical methods, such as gritblasting, or chemical methods, such as molten-salt descaling. Selection of the descaling method is based on part size, part complexity, and/or costs.

Gritblasting has been found to be effective in removing the scale layer, which can vary in thickness from 0.13 to 0.76 mm (0.005 to 0.030 in.). The media used in gritblasting can range from zircon sand to steel grit (typically 100 to 150 mesh) under air pressure (or equivalent) of up to 275 Pa (40 psi). Gritblasting is most frequently used on intermediate-to-large titanium alloy forgings, although it can be used for any size forging. Gritblasting equipment varies considerably, ranging from large horizontal table units to relatively small tumbling units. Gritblasting is followed by acid pickling (see below) to remove the α case.

Molten-salt descaling is another effective method of removing oxide scale and is also followed by acid pickling to remove the α case. Figure 16 shows a typical flow chart for a molten-salt descaling system followed by acid pickling. Molten-salt descaling must be closely controlled to prevent the work metal from becoming embrittled. The racks used in molten-salt descaling are usually wood, titanium, or stainless steel in order to prevent the generation of an electrical potential between the workpiece and the racks, which may result in preferential attack of the workpiece and arcing. Molten-salt descaling is most frequently used on small-to-intermediate size titanium alloy forgings, and in the case of high-volume forging parts, such systems are fully automated.



Solution No.	Type of solution	Composition of solution	Operating temperature		Cycle time, min
			°C	°F	
1	Descale	60-90% NaOH, rem $NaNO_3$ and Na_2CO_3	425-510	(800-950)	**20-50**
2	Neutralize	5-15% HNO_3 in H_2O	Room	Room	**2-5**

Fig. 16 Flow chart of operations for molten-salt descaling, neutralizing pickling, and final pickling of titanium alloys.

Acid pickling (sometimes referred to as chemical milling) is used to remove the underlying αcase, after the oxide scale has been removed, by the following procedure:

- Clean thoroughly with gritblasting or alkaline salt cleaning
- Rinse thoroughly in clean running water if alkaline cleaning has been used
- Pickle for 5 to 15 min in an aqueous nitric-hydrofluoric acid solution containing 15 to 40% HNO_3 and 1 to 5% HF and operated at 25 to 60 °C (75 to 140 °F). Usually, acid content of the pickling solution (particularly for α-β and βalloys) is near the middle of the above ranges (for example, from 30 to 35% HNO_3 and 2 to 3% HF, or an HNO_3 to HF ratio ranging 10:1 to 15:1). Alternatively, chemical solutions with approximately 2:1 ratio of HNO_3:HF have been found to remove 0.025 mm/min. (0.001 in./min) and to minimize hydrogen pickup.

The preferred bath operating temperature is 30 to 60 °C (90 to 140 °F). As the acid mixture is used, the titanium content in the bath increases and reduces the effectiveness of the bath. Titanium contents in excess of 12 g/L are usually considered to be maximum before the solution must be discarded. However, systems are available for reducing the contained titanium, including solution treatment/filtering and/or other organic chemical additions that can extend the life of pickling baths.

- Rinse parts thoroughly in clean water
- Rinse in hot water to hasten drying; allow to dry

The required metal removal and the pickling times achieved in acid pickling are dictated by several factors, including depth of α case to be removed, pickle tank operating conditions, process specification requirements, and potential for hydrogen pickup by the workpiece. Acid pickling presents the potential for excessive hydrogen pickup in titanium alloys; therefore, this process must be carefully controlled. Metal removal rates in acid pickling are usually 0.03 mm/min (0.001 in./min) or more, although the metal removal rate is heavily influenced by such factors as the alloy, acid concentrations, bath temperature, and contained titanium. Metal removal levels of 0.25 to 0.38 mm (0.010 to 0.015 in.) per surface are usually sufficient to remove the αcase; however, greater or lesser amounts of metal removal may be necessary, depending on the alloy and the specific conditions present for the forging in question.

Metal removal is monitored by witness pads on the forging (using an appropriate maskant), by test panels processed with the forgings, by actual forging measurement, or by other process control techniques. In addition, some process and/or materials specifications for titanium alloy forgings require verification of α case removal on the final forgings. The techniques used on representative samples of the lot of forgings include metallographic examination and/or microhardness measurements.

As a guide only, hydrogen pickup in acid pickling may be up to 10 ppm of hydrogen for each 0.03 mm (0.001 in.) of surface metal removal, depending upon specific pickling solution and concentration and temperature conditions. In acid pickling, αalloys tend to absorb less hydrogen than α-β alloys, which in turn tend to pick up less hydrogen than β alloys. Current process and/or material specifications for titanium alloy forgings always require measurement of final hydrogen content on each lot of forgings using either vacuum fusion or vacuum extraction techniques (typical specifications require maximum hydrogen contents in forgings of 125 to 150 ppm). Therefore, acid pickling parameters must be controlled--often to individual forging shapes and/or specific alloys--to avoid final hydrogen contents in excess of specification requirements, which can be corrected only by vacuum annealing. The potential for hydrogen pickup in acid pickling is significantly increased by decreased rates of metal removal (due to increased titanium content of the solution), higher bath temperatures (for example, bath temperatures higher than 60 °C, or 140 °F), and higher surface-area-to-volume relationships in the workpieces. Generally, the speed of metal removal through solution concentration and temperature must exceed the rate of hydrogen diffusion. With appropriate controls, acid pickling is used to remove precise amounts of material in order to remove αcase and/or to assist in obtaining the required forging dimensions (for example, in titanium precision forgings) without an undue increase in hydrogen content. Additional information on the cleaning of titanium alloys is available in the article "Surface Engineering of Titanium and Titanium Alloys" in *Surface Engineering*, Volume 5 of the *ASM Handbook.*

Heat Treatment. Most titanium alloy forgings are thermally treated after forging, with heat treatment processes ranging from simple stress-relief annealing to multiple-step processes of solution treating, quenching, aging, and/or annealing designed to modify the microstructure of the alloy to meet specific mechanical property criteria. Selection of the heat treatment for titanium alloy forgings is based on the alloy, forging configuration, and mechanical property objectives. The furnaces used to thermally treat titanium alloy forgings are either continuous or batch gas-fired, electric, fluidized-bed, vacuum, or other specially designed equipment. Titanium alloy forgings that are heat treated in other than vacuum furnaces can be processed with or without ceramic precoats for protection from reaction during the thermal processes, depending on such factors as the alloy, the specific heat-treating equipment, the forging type (that is, conventional versus precision), and process/material specification requirements. The thermal treatments used for titanium alloys in forgings and other product forms are also discussed in Ref 4 and in the article "Heat Treating of Titanium and Titanium Alloys" in *Heat Treating*, Volume 4 of the *ASM Handbook.*

Annealing is used on forgings of most types of titanium alloys in order to remove the deformation and/or thermal stresses imparted as a result of forging hot-working processes and/or postforging cooling rates. Annealing is generally done in the temperature range of 595 to 925 °C (1100 to 1700 °F), depending on the specific alloy. It does not cause significant microstructural modification and is applied to conventional titanium alloy forgings primarily to facilitate the subsequent fabrication of the forgings, including machining.

Multiple-Step Heat Treatments. To modify the microstructure and resultant mechanical properties (such as strength, ductility, fatigue, creep, and fracture toughness) of many forged titanium alloys, multiple-step heat treatments (such as solution treatment plus aging/annealing, recrystallization annealing, duplex annealing, and so on) are often used. The terminology for these treatments is frequently borrowed from aluminum alloys; however, the metallurgical effects obtained are actually changes in allotropic phase relationships or phase morphology. As with the solution treatment of aluminum alloy forgings, if such multiple-step thermal treatment processes are applied to titanium alloy forgings, then racking procedures, quench rates, quench media, and so on, are the subject of forged titanium alloy heat treatment process specification and process control. Furthermore, as previously discussed, when preheating for forging, precoats, furnace atmosphere and/or furnace operating conditions in heat treatment of titanium alloy forging must be controlled to prevent excessive hydrogen pickup.

Straightening of titanium alloy forgings is often necessary in order to meet dimensional requirements. Unlike aluminum alloys, titanium alloys are not easily straightened when cold, because the high yield strength and modulus of elasticity of these alloys result in significant springback. Therefore, titanium alloy forgings are straightened primarily by creep straightening and/or hot straightening (hand or die), with the former being considerably more prevalent. Creep straightening of most alloys may be readily accomplished during annealing and/or aging processes with the temperatures prevalent during these processes; however, if the annealing/aging temperature is below about 540 to 650 °C (1000 to 1200 °F), depending on the alloy, the times needed to accomplish the desired creep straightening can be extended. Creep straightening is accomplished with rudimentary or sophisticated fixtures and loading systems, depending on part complexity and the degree of straightening required. In hot hand or die straightening, which are used most frequently on small-to-intermediate size forgings, the forgings are heated to the annealing or aging temperature, hot straightened, and then stress relieved at a temperature below that used during hot straightening.

Inspection of titanium alloy forgings takes two forms: in-process inspection and final inspection. In-process inspection techniques, such as statistical process control and/or statistical quality control, are used to determine that the product being manufactured meets critical characteristics and that the forging processes are under control. Final inspection, including mechanical property testing, is used to verify that the completed forging product conforms to all drawing and specification criteria. The final inspection procedures used on titanium alloy forgings are discussed below.

Dimensional Inspection. All final titanium alloy forgings are subjected to dimensional verification. For open-die forgings, final dimensional inspection may include verification of all required dimensions on each forging or, by using statistical sampling plans, on groups or lots of forgings. For closed-die forgings, conformance of the die cavities to drawing requirements, a critical element in dimensional control, is accomplished before placing the dies in service by using layout inspection of plaster or plastic casts of the cavities. With the availability of CAD databases on forgings, such layout inspections can be accomplished more expediently with CAM-driven coordinate-measuring machines or other automated inspection techniques. With verification of die cavity dimensions prior to use, final titanium part dimensional inspection can be limited to verification of critical dimensions controlled by the process, such as die closure, and to the monitoring of changes in the die cavity. Given the abrasive nature of titanium alloys during forging, die wear is a potential problem that can be detected by appropriate final inspection. Further, with high-definition and precision titanium forgings, CAD databases and automated inspection equipment (such as coordinate-measuring machines and 2-D fiber optics) can often be used for actual part dimensional verification.

Heat Treatment Verification. Hardness is not a good measure of the adequacy of the thermomechanical processes accomplished during the forging and heat treatment of titanium alloys, unlike most aluminum alloys and many heat-treatable ferrous alloys. Therefore, hardness measurements are not used to verify the processing of titanium alloys. Instead, mechanical property tests (for example, tensile tests and fracture toughness) and metallographic/microstructural evaluation are used to verify the thermomechanical processing of titanium alloy forgings. Mechanical property and microstructural evaluations vary, ranging from the destruction of forgings to the testing of extensions and/or prolongations forged integrally with the parts. Further discussion on testing and metallographic methodologies for titanium alloy forgings is available in *Mechanical Testing*, Volume 8, and *Metallography and Microstructures*, Volume 9 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

Nondestructive Evaluation. Titanium alloy forgings are often submitted to nondestructive evaluation to verify internal and surface quality. The surface of conventional titanium alloy forgings after forging and cleaning is relatively good--inferior to aluminum alloy forgings but generally superior to low-alloy steel forgings. A surface finish of 250 rms or better is considered normal for conventionally forged and acid pickled titanium alloy forgings, although precision forged surfaces may be smoother than 250 rms under closely controlled forging conditions and in certain types of titanium forgings.

The selection of nondestructive evaluation requirements depends on the final application of the forging. In addition to the detailed high-resolution ultrasonic inspection frequently performed on critical titanium alloy forging stock before forging (as noted above), the final titanium alloy forgings can also be submitted to ultrasonic inspection. With conventional open-die or closed-die forgings that will be machined on all surfaces, visual inspection after a good etch or chemical mill is adequate for detection of surface defects. Surface inspection techniques, such as penetrant inspection, can be performed, but are not recommended; because of the surface roughness typical of conventional titanium alloy forgings, spurious indications are frequently encountered that result in excessive inspection/repair costs for nonvalid indications. However, for precision titanium forgings, whose surfaces are typically superior to those of open-die or other closed-die titanium alloy forgings, liquid penetrant, eddy current, and other surface inspection techniques are used. Additional information on surface and internal inspection techniques and inspection criteria is available in *Failure Analysis and Prevention*, Volume 11 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

Selection of Forging Method

Selection of the optimal titanium forging method (that is, open-die versus closed-die, and within closed die: blocker, conventional, high-definition, or precision forging) involves the application of value analysis techniques. Although titanium alloys are considerably more expensive than other materials, such as aluminum and ferrous alloys, specific economic results are highly part dependent. Except when mechanical properties, required grain flow, and/or specific program objectives dictate the use of a specific forging method, there are several fabrication options that are competitive candidates for the manufacture of titanium alloy shapes. The relative cost relationships between the options for titanium alloys are similar to those described for aluminum alloys in the article "Forging of Aluminum Alloys" in this Volume.

However, with titanium alloys, forging processes and methods that increase overall recovery from forged shape to finished part and reduce machining costs may have a more significant impact on total final part costs than with other materials because of the very high material costs and higher machining costs for titanium alloys as compared to ferrous or aluminum-base materials. The high material and machining costs associated with titanium alloys often result in lower break-even points (that is, lower quantities) for more expensive forging processes such as conventional, high-definition, and precision forging than for less expensive but more metal-intensive processes such as plate hog-outs, open-die forgings, or blocker-type forgings. The potential reduction in expensive material losses and machining costs through the redesign of a representative titanium alloy conventional forging is illustrated in Fig. 7 and 8(a) through (c) for a large main landing gear beam.

Selection of the most economical forging method for a given shape in titanium alloys is a process that must include consideration of all the intrinsic and extrinsic costs of manufacture, both on the part of the forger and the user. Further, as the size of the titanium alloy forging sought increases to very large parts, such as the large landing gear beams illustrated in Fig. 7 and 11, the range of possible forging methods and forging design sophistication may be restricted because of the forging process requirements for, and the difficulty in forging, titanium alloys versus the available capacity of the forging equipment.

Forging of Titanium Alloys

Forging Advanced Titanium Materials

The above review of titanium alloy conventional forging technology is based on existing commercially available wrought titanium alloys. However, titanium alloy/materials development, using ingot metallurgy and other techniques, is providing advanced titanium materials that may present additional challenges in the manufacture of conventional forgings. Three of the major classes of titanium-base materials currently under development are:

- A new class of alloys based on intermetallic compounds
- Titanium powder metallurgy materials
- Titanium-base metal-matrix composites

Currently, none of these titanium materials developments has matured sufficiently for specific alloy formulations to be discussed; however, it is appropriate to review some of the critical demands these new materials approaches will place on forging as a cost-effective method of making advanced titanium alloy shapes.

Titanium Aluminides. A new class of elevated-temperature titanium alloys is emerging that is based on intermetallic compounds with aluminum, along with additions of other alloying elements to make these alloys workable and to achieve the desired mechanical property combinations. Titanium aluminide alloys are based on two compounds: Ti_3Al or α-2, and TiAl or γ. Titanium aluminide alloys have been found to offer elevated-temperature characteristics that are competitive with those of super-alloys at a significantly reduced density. Initial α-2 alloys have been found to be workable by forging, while initial α alloys may not be workable by deformation processes such as forging.

Preliminary α-2 titanium aluminide alloys have been found to display very high β_t values--higher than existing α titanium alloys (for example, 1040 to 1150 °C, or 1900 to 2100 °F). Further, these preliminary alloys have deformation characteristics that are considerably more difficult than those of existing α titanium alloys and similar to those of nickel/cobalt-base superalloys. However, under properly defined metal deformation conditions, some titanium aluminide α-2 alloys have been made to behave superplastically. It appears that the necessary forging processes will be similar to those used for some difficult-to-fabricate α titanium alloys and that carefully controlled conventional, hot-die, and/or isothermal forging techniques will be necessary for successful forging fabrication.

Titanium Powder Metallurgy (P/M) Materials. Several rapid-solidification, chemical reduction, and/or blending technologies are being used to produce titanium alloy P/M materials, either on a limited commercial scale or on a research scale. Most current efforts are directed toward alternate fabrication of components through powder metallurgy for existing alloys (Table 1). In many cases, the forging process has been found to contribute to the successful fabrication of final components from P/M-base titanium alloys through enhanced thermomechanical processing, microstructural modification, and/or improved component quality as a result of the deformation achieved in forging. Although most current titanium alloy P/M producing methods, particularly rapid solidification, are expensive, some evidence suggests that overall fabrication costs and the recovery of certain components can be significantly improved by combining P/M and forging processes. Future titanium alloy P/M development is expected to include alloys that are specifically formulated for P/M technology, and as with other materials (such as the nickel/cobalt-base superalloys), titanium forging can be combined with P/M consolidation (through vacuum hot pressing, hot isostatic pressing, and so on) to achieve cost-effective shapes with the desired and/or unique properties.

Titanium Metal-Matrix Composites. Using P/M-base titanium alloys and other techniques, titanium-base discontinuous metal-matrix composites are also being explored for the development of enhanced titanium materials with unique mechanical property capabilities. As discussed in the previous section, the controlled deformation typical of forging has often been successfully employed in the fabrication of experimental components from such composite titanium materials. The matrix titanium alloys used include existing and developmental alloys with a variety of ceramic whisker/particulate materials. The reactivity of titanium with many candidate ceramic compounds is of concern for the successful development of this technology. Currently, titanium-base metal-matrix alloy/materials development is an embryonic technology; however, the forging process can be expected to play a significant role in the fabrication technology for these materials.

Titanium Alloy Precision Forgings

As with aluminum alloys (see the article "Forging of Aluminum Alloys" in this Volume), titanium alloy precision forgings can be identified by a variety of terminologies; however, in each case, this product form requires significantly reduced and/or no final machining on the part of the user (detailed information on precision forging is available in the article so titled in this volume). Precision forged titanium alloys are a significant commercial forging product that is undergoing major growth in usage and has been the subject of major forging process technology development and capital investment by the forging industry. For the purpose of this article, the term net precision titanium forging will be defined as a product that requires no subsequent machining by the user, and the term near-net precision titanium forging will be defined as a product requiring some metal removal (typically accomplished in a single machining operation) by the user. Fabrication of net or near-net titanium alloy precision forgings is determined by the alloy being forged and by value analysis for fabrication of the most cost-effective precision forged product.

The first precision forged titanium alloy products commercially produced were turbine engine compressor and fan blades (see Fig. 17); conventional forging process techniques were used. With hot-die/isothermal forging techniques (see the article "Isothermal and Hot-Die Forging" in this Volume), very complex cross-section, precision forged airframe components such as the splice angle shown in Fig. 18 are being manufactured. Titanium alloy precision forgings are produced with very thin webs and ribs; sharp corner and fillet radii; undercuts, backdraft, and/or contours; and, frequently, multiple parting planes (which may optimize grain flow characteristics) in the same manner as aluminum alloy precision forgings.

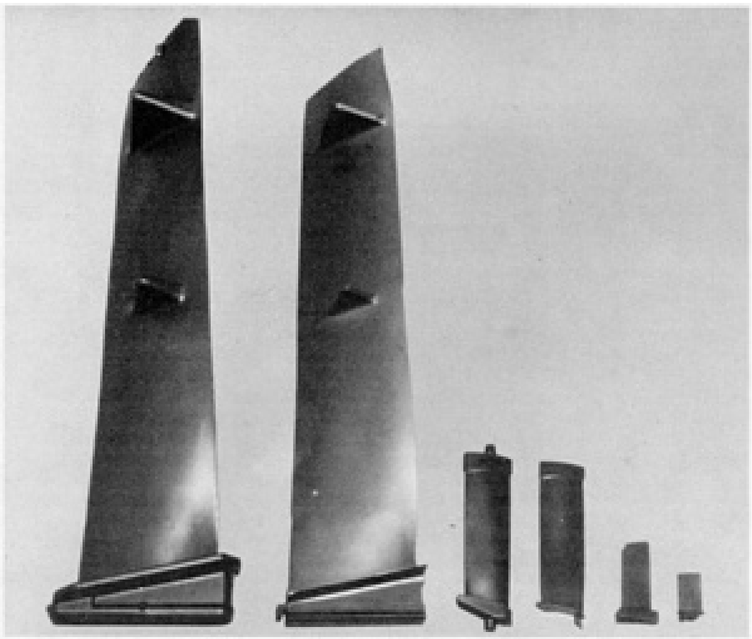

Fig. 17 Three pairs of precision forged Ti-6Al-4V airfoils. Left member of each pair is as-forged; right member, as finish machined. The largest of the three pairs of airfoils measures approximately 152 mm (6 in.) wide at base and 610 mm (24 in.) long.

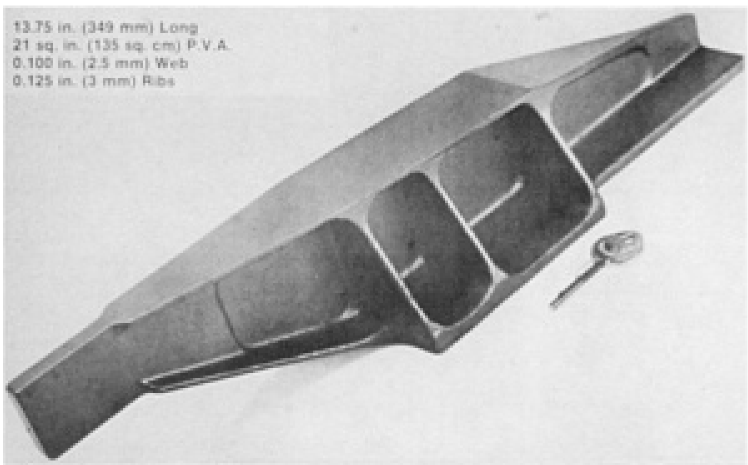

Fig. 18 Precision forged alloy Ti-6Al-6V-2Sn and alloy Ti-10V-2Fe-3Al splice fitting produced using hot-die/isothermal forging techniques to illustrate shape complexity capabilities of the process.

Design Criteria. The design and tolerance criteria for precision titanium forgings are similar to those for aluminum alloy precision forgings and have been established to provide a finished product suitable for assembly or subsequent fabrication by the user. Precision titanium alloy forgings, with the exception of airfoils, do not necessarily conform to the same tolerances provided by machining of other product forms; however, as indicated in Table 4, design and tolerance criteria for titanium precision forgings are highly refined in comparison to other titanium alloy forging types and are suitable for the intended application of the product. If the standard precision forging design and tolerance criteria are not sufficient for the final component, then the forging producer frequently combines conventional and/or hot-die/isothermal forging with machining to achieve the most cost-effective method of fabrication to the required tolerances on the finished part.

Table 4 Net titanium alloy precision forging design/tolerance criteria for selected parts and processes for metastable β and α-β alloys

Feature	**Current**	Goal
PVA, m^2 ($in.^2$)	Up to 0.193 (300)	**0.290 (450)**
Length, mm (in.)	Up to 1015 (40)	**1525 (60)**
Length/thickness tolerance, mm (in.)	+0.5, -0.25 (+0.020, -0.010)	**+0.75, -0.25 (+0.030, -0.010)**
Contour tolerance, mm (in.)	±0.38 (±0.015)	**±0.63 (±0.025)**
Draft		
Outside	0°; +30, -0°	**Same**
Inside	1°; +30, -1°	**Same**
Corner radii, mm (in.)	1.5; +0.75, -1.5 (0.060; +0.030, -0.060)	**Same**
Fillet radii, mm (in.)	3.3; +0.75, -1.5 (0.130; +0.030, -0.060)	**Same**
Straight within, mm (in.)	0.25 each 254 mm (0.010 each 10 in.)	**Same**
Minimum web thickness, mm (in.)	2.3 (0.090)[a]	**2.5 (0.100)**
Minimum rib thickness, mm (in.)	**2.3 (0.090)[a]**	**2.5 (0.100)**

(a) In some designs and under some processing conditions, minimum web thickness can be as thin as 1.5 mm (0.060 in.) and minimum rib thickness can be as thin as 2.0 mm (0.080 in.).

The titanium precision forging design and tolerance criteria achievable may vary with the alloy type because all titanium alloys are not necessarily equivalent in workability using either conventional forging techniques or hot-die/isothermal forging technology. Generally, the net titanium precision forging design parameters given in Table 4 apply to more readily workable β and metastable β alloys (such as Ti-10V-2Fe-3Al) and selected designs and forging processes for α-β alloys (such as Ti-6Al-4V and Ti-6Al-6V-2Sn). However, with more difficult-to-fabricate α titanium alloys and certain forging designs and/or forging processes for α-β alloys, the more cost-effective forging technique may be near-net titanium precision forgings with modified design criteria (for example, typically 1.5 to 2.3 mm, or 0.060 to 0.090 in., machining allowance per surface), and modified rib/web thickness, fillet radii, corner radii, and so on) but with the same dimensional tolerances outlined in Table 4. Table 4 also indicates that as the size of the net titanium precision forging is increased to 0.290 m^2 (450 in.^{2}), some modification in design and tolerance criteria is appropriate.

Tooling and Design. Precision titanium forging uses several tooling concepts to achieve the desired design shape, with the specific tooling concept based on the design features of the precision forging and the forging process used. Similar tooling design concepts outlined for aluminum alloys (see Fig. 11(a) to (c) in the article "Forging of Aluminum Alloys" in this Volume) are also used with titanium alloys. For conventional forging processes for titanium precision forgings, of which turbine airfoils are the primary example, the two-piece upper and lower die concept is the predominant approach. The other tooling concepts shown in Fig. 11(b) and in the article "Forging of Aluminum Alloys" are used in the hot-die or isothermal forging of titanium precision forgings.

For conventional titanium precision forgings, the die materials employed in tooling are either 6F2 or 6G types or hot-work die materials such as H12 and H13. Tooling for conventional titanium precision forgings is designed and produced using the same techniques as those described above for other forging types; however, CNC direct die sinking and/or EDM electrode manufacture from CAD forging and tooling databases has been found to be particularly effective for the manufacture of the close-tolerance tooling demanded by precision titanium forgings.

The die materials used for the hot-die/isothermal forging of titanium alloys are reviewed in the article "Isothermal and Hot-Die Forging" in this Volume. Selection of the die material is based on the alloy to be forged, necessary forging process conditions (for example, metal/die temperatures, die stresses, strain rate, and total deformation), forging part design, and cost considerations. Cast, wrought, and/or consolidated powder techniques are used to fabricate die blocks/inserts from superalloy materials, including Alloy 718, Waspaloy, Udimet 700, Astroloy, Alloy 713LC (Ni-12Cr-6Al-4.5Mo-2Nb-0.6Ti-0.1Zr-0.05C-0.01B), and Alloy 100 (Ni - 15.0Co - 10.0Cr - 5.5Al - 4.7Ti-3.0Mo - 1.0V - 0.6Fe - 0.15C - 0.06Zr-0.015B), with these materials listed in order of increasing temperature capability from 650 to 980 °C (1200 to 1800 °F). Most of these die materials require more expensive nonconventional machining techniques for die sinking, with electrode discharge machining being the most prevalent technique. Computer-aided design part and tooling databases have also been effectively combined with CAM-driven CNC EDM electrode manufacturing techniques to reduce the cost of die manufacture. Typically, the manufacture of a set of dies for titanium precision forging with hot-die/isothermal forging costs up to seven times that required for the dies for the manufacture of the same part in aluminum. Heated holder and insert techniques can reduce the cost factor for titanium hot-die/isothermal precision forging dies to three times the cost of the same dies for an aluminum alloy.

Forging Processing. Conventional and hot-die/isothermal forging processes for precision titanium forgings use the same steps as those outlined above for other forging types. Precision titanium forgings can be produced from wrought stock, preformed shapes, or blocker shapes, depending on the complexity of the part, the tooling system being employed, and cost considerations. For example, for the conventional forging of airfoil shapes such as blades, multiple forging processes are used (because of the high cost of raw materials) to prepare the preshape necessary for the successful fabrication of the precision part in order to conserve input material and to facilitate the precision forging process. Precision titanium forging stock fabrication and inspection criteria are similar to those described above for other titanium alloy forging types.

Unlike aluminum alloy precision forging shapes, conventionally forged titanium alloy precision forgings are usually not produced in multiple operations in finish dies, but rather by a progression of processes in multiple die sets. However, with hot-die/isothermal forging processes for precision titanium parts, multiple operations in a given die set are used. Conventionally forged titanium precision forgings are usually produced on mechanical and/or screw presses, although hammers or hydraulic presses are occasionally used for certain designs. For hot-die/isothermally fabricated precision titanium forgings, hydraulic presses are used exclusively to obtain the desired slow strain rates and controlled deformation conditions. The mechanical and/or screw presses currently used for the fabrication of conventional titanium precision forgings range up to 150 MN (17,000 tonf) (maximum press capability of up to 280 MN, or 31,000 tonf, for the largest screw press), and hydraulic presses for the hot-die/isothermal precision forging processing of titanium alloys range up to 90 MN (10,000 tonf). Other large hydraulic presses, up to 310 MN (35,000 tonf), with necessary forging process capabilities are available for the hot-die/isothermal forging of titanium (as well as aluminum alloy precision forging) as this titanium alloy forging technology is scaled-up in size.

Conventional and hot-die/isothermal forging process criteria for the precision forging of titanium alloys are similar to those described above for other titanium alloy forging types. With conventional forging, the metal and die temperatures used are usually controlled to be near the upper limits of the temperature ranges outlined in Tables 1 and 2 to enhance producibility and to minimize unit pressures. The hot-die and isothermal forging parameters employed in the precision forging of titanium alloys (see the article "Isothermal and Hot-Die Forging" in this Volume) use the metal temperatures listed in Table 1. Die temperature selection in hot-die/isothermal forging is based on the alloy, die material/die heating system, specific forging process demands (for example, the viability of near-isothermal/hot die versus isothermal conditions), sophistication of the forging design, and thermomechanical processing criteria.

Because of the stringent dimensional tolerances associated with conventionally and hot-die/isothermally forged titanium precision forgings, dies are typically heated using state-of-the-art on-press heating systems, such as resistance and/or induction heating. These heating systems maintain uniform die temperatures, typically ±14 °C (± 25 °F) or better, in order to reduce dimensional variations. As with other forging types, precoating and die lubrication are critical elements in the conventional forging of titanium precision forgings, and the precoats and die lubricants used are similar to those for other forging types, although lubricant materials are often specially formulated for an individual forging design and forging process. Insulative blankets are generally not used for the conventional forging of precision titanium forgings, because such materials may adversely affect the dimensional integrity of the forged parts.

Die heating and lubrication techniques for the hot-die/isothermal forging of titanium alloys are described in the article "Isothermal and Hot-Die Forging" in this Volume. Gas-fired, infrared, resistance, and/or induction heating systems are selected based on the die temperature to be achieved, die temperature uniformity criteria, tooling system employed, and cost considerations. These systems must heat the die stack to the required temperature and maintain the heated dies at consistent temperatures--typically ±14 to 28 °C (±25 to 50 °F). The precoats used in the hot-die/isothermal forging of titanium alloys are selected or formulated for specific metal/die temperature conditions. Under some conditions, parting agents such as boron nitride are used on the dies to facilitate part removal with minimum distortion.

Straightening is often a critical process in the manufacture of conventionally or hot-die/isothermally forged titanium precision forgings. The straightening techniques used, with airfoils as a critical example, are predominantly die straightening procedures with the metal and dies at elevated temperatures. In this process, time-temperature-pressure parameters are controlled, usually with small-to-intermediate size hydraulic presses, to achieve the desired deformation conditions and therefore the dimensional conformance. Hot-die or isothermal forming techniques (with dies at temperatures from 705 to 925 °C, or 1300 to 1700 °F) are often used to straighten conventionally or hot-die/isothermally forged titanium alloy precision forgings, particularly large airfoil shapes.

Forging stock preparation; thermal treatments; in-process cleaning, trimming, and repair; and in-process and final inspection and thermal treatment verification processes, with the exception of nondestructive evaluation, are the same as those described above for other titanium alloy forging types. Because of the highly configured nature and thin sections typical of precision titanium parts, ultrasonic inspection cannot be used on finished parts; the exception is turbine engine disks, which are usually inspected using highly sophisticated, automated ultrasonic inspection equipment. Frequently, for airframe precision titanium forgings, airfoils, and other precision titanium shapes, the detailed ultrasonic inspection performed on the forging stock before fabrication is sufficient to ensure satisfactory internal quality in the final part. Unlike other titanium alloy forging types, precision titanium forgings, which are used in service with most (if not all) of the as-forged surfaces intact, are frequently inspected by sensitive liquid penetrant inspection techniques to ensure adequate surface quality.

Precision titanium forgings are frequently supplied as a completely finished product that is ready for assembly by the user. In such cases, the forging producer can use both conventional milling and unconventional machining techniques, such as chemical milling and electrode discharge machining, along with forging, to achieve the most cost-effective finished titanium shape. Further, the forging producer can apply a wide variety of surface finish and/or coating processes to this product as specified by the purchaser. More information on surface finish and coating processes for titanium alloys is available in the article "Surface Engineering of Titanium and Titanium Alloys" in *Surface Engineering*, Volume 5 of the *ASM Handbook.*

Technology Development Effectiveness. Figure 19 presents a summary of the history and future of the state-of-the-art in the size of titanium alloy precision forging that can be produced. Figure 19 differentiates between net and near-net precision titanium alloy forging technology development because not all titanium alloys are equally producible under either conventional or hot-die/isothermal forging approaches, and in order to ensure the fabrication of the most cost-effective final product, as described above, both net and near-net titanium precision forgings are used commercially.

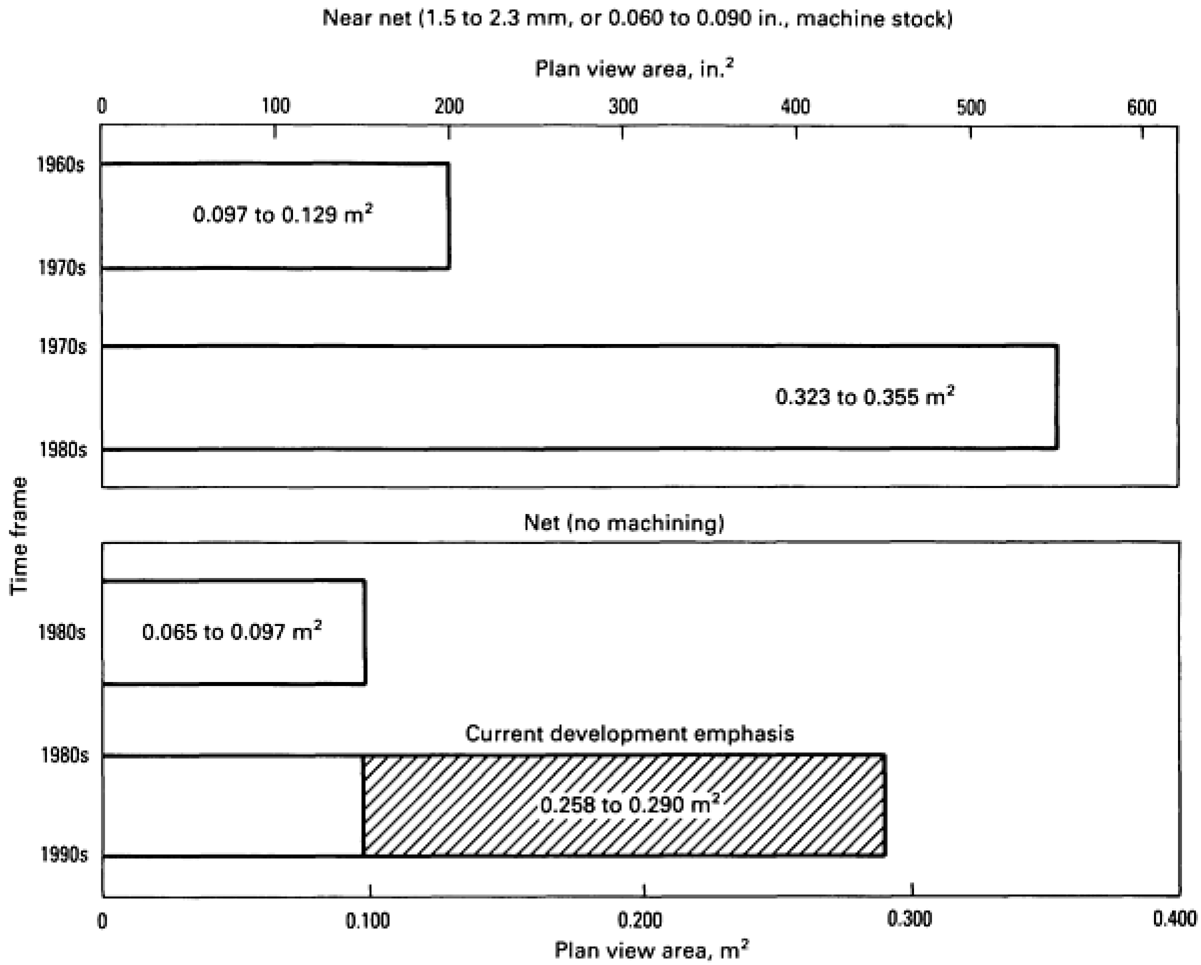

Fig. 19 Past and future near-net and net titanium alloy precision forging capabilities gaged in terms of plan view area.

As a result of both conventional and hot-die/isothermal forging technology developmental efforts, the size of the net titanium precision forging that can be fabricated to the design and tolerance criteria given in Table 4 has tripled--from 0.081 m^2 (125 in.^{2}) to over 0.194 m^2 (300 in.^{2}) PVA. The critical elements in projected changes in the state-of-the-art for titanium precision forgings, both in terms of size and cost effectiveness, are enhanced precision forging process control, CAD/CAM/CAE technologies, advanced and/or integrated manufacturing technologies, enhanced die heating systems, improved lubrication systems, and the availability of large superalloy die blocks necessary for the hot-die/isothermal forging of these alloys.

The selection of precision titanium forging from the various methods available for achieving a final titanium shape is based on the value analyses conducted for each individual shape in question. Figure 20 shows a cost comparison for an engine mount part (Fig. 20a) manufactured by machining from Ti-6Al-4V plate, by machining from a Ti-6Al-4V conventional forging, and produced as a precision forging in Ti-10V-2Fe-3Al using hot-die/isothermal forging. In the analysis shown in Fig. 20(b), the precision forging is always less costly than the machined conventional forging, and the break-even point between the precision forging and the machined plate hog-out occurs in as few as 40 pieces. The costs used in this analysis included all material, tooling, setup, and fabrication costs for each method of manufacture. Analyses of other parts have also shown that titanium precision forged shapes are highly cost effective in comparison with other fabrication approaches, particularly when the other methods require multiple-axis machining techniques to achieve the final part geometry.

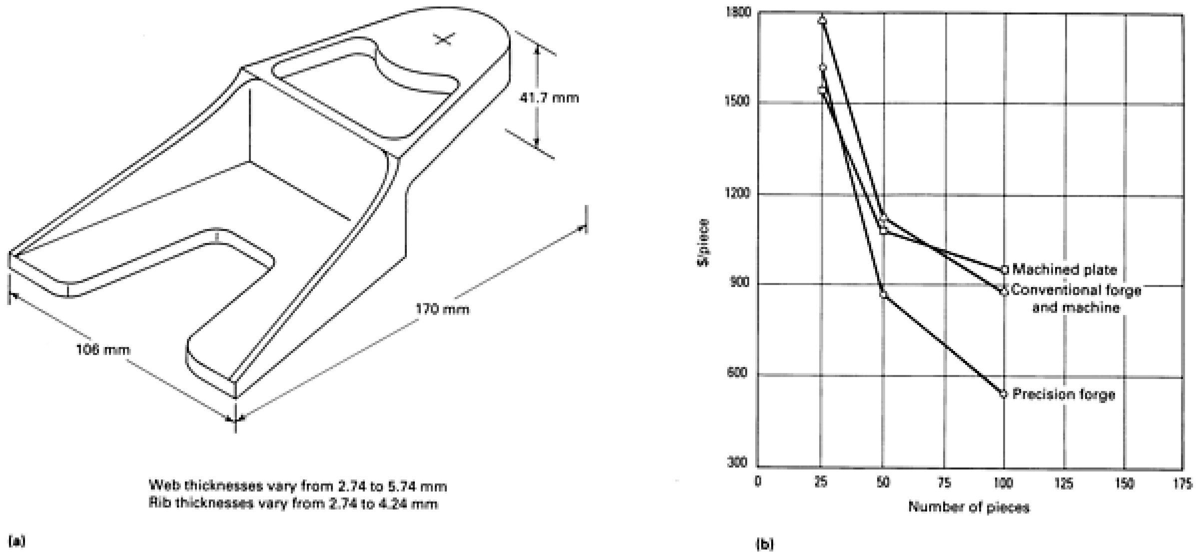

Fig. 20 Cost comparison for an engine mount part. (a) Net-shape precision forged Ti-10V-2Fe-3Al engine mount produced by hot-die/isothermal forging. (b) Cost compression of the engine mount shown to illustrate the cost-effectiveness of precision forging.

As outlined in the article "Forging of Aluminum Alloys" in this Volume, forging industry and user evaluations of precision titanium alloy forgings have indicated that final part costs can be reduced by 80 to 90% or more in comparison to machined plate, and by 60 to 70% or more in comparison to machined conventional forgings. With potential cost reductions such as these, it is evident that further growth in precision titanium forging usage can be anticipated.

Introduction

COLD HEADING is a cold-forging process in which the force developed by one or more strokes (blows) of a heading tool is used to upset (displace) the metal in a portion of a wire or rod blank in order to form a section of different contour or, more commonly, of larger cross section than the original. The process is widely used to produce a variety of small- and medium-sized hardware items, such as bolts and rivets. Cold heading, however, is not limited to the cold deformation of the ends of a workpiece nor to conventional upsetting; metal displacement may be imposed at any point, or at several points, along the length of the workpiece and may incorporate extrusion in addition to upsetting. In cold heading, the cross-sectional area of the initial material is increased as the height of the workpiece is decreased. Advantages of the process over machining of the same parts from suitable bar stock include:

- Almost no waste material
- Increased tensile strength from cold working
- Controlled grain flow

Although cold heading is principally used for the production of heads on rivets or on blanks for threaded fasteners, a variety of other shapes can also be successfully and economically formed by the process. Figure 1 illustrates the cold heading of an unsupported bar or wire on a horizontal machine.

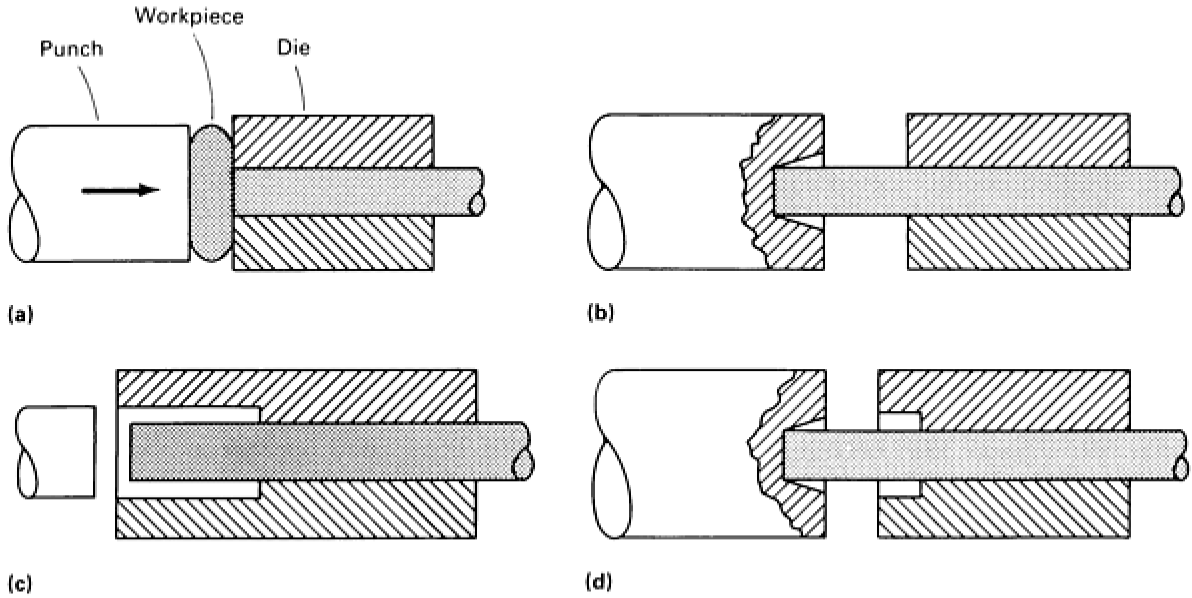

Fig. 1 Schematics of the cold heading on an unsupported bar in a horizontal machine. (a) Head formed between punch and die. (b) Head formed in punch. (c) Head formed in die. (d) Head formed in punch and die.

Materials for Cold Heading

Cold heading is most commonly performed on low-carbon steels having hardnesses of 75 to 87 HRB. Copper, aluminum, stainless steels, and some nickel alloys can also be cold headed. Other nonferrous metals and alloys, such as titanium, beryllium, magnesium, and the refractory metals and alloys, are less formable at room temperature and may crack when cold headed. These metals and alloys are sometimes warm headed (see the section "Warm Heading" in this article).

Carbon and Alloy Steels. Steels containing up to about 0.20% C are the easiest materials to cold head. Medium-carbon steels containing up to 0.40 to 0.45% C are fairly easy to cold work, but formability decreases with increasing carbon and manganese content. Alloy steels with more than 0.45% C, as well as some grades of stainless steel, are very difficult to cold head and result in shorter tool life than that obtained when heading low-carbon steels.

Microstructure also influences the upsettability of steels. The work material can sometimes be cold worked during the wire-drawing process, resulting in an increase in tensile strength and difficulty in cold heading. Large deformations or difficult-to-work materials often require process or spheroidization annealing before cold heading.

Stainless Steels. Some stainless steels, such as the austenitic types 302, 304, 305, 316, and 321 and the ferritic and martensitic types 410, 430, and 431, can be cold headed. These materials work harden more rapidly than carbon steels and are therefore more difficult to cold head. More power is required, and cracking of the upset portion of the work metal is more likely than with carbon or low-alloy steels. These problems can be alleviated by preheating the work metal (see the section "Warm Heading" in this article).

Rating Formability. Metals and alloys are rated for cold heading on the basis of the length of stock, in terms of diameter, that can be successfully upset. Equipped with flat-end punches, most cold-heading machines can upset to approximately two diameters of low-carbon steel wire per stroke. If the unsupported length is increased beyond about two diameters, the stock is likely to fold onto itself, as shown in Fig. 2. For more formable metals, such as copper and some copper alloys, the length of upset per stroke may be up to four diameters (Ref 1). Punches and dies can, however, be designed to increase the headable length of any work metal. For example, with a coning punch (Fig. 3) or a bulbing punch, it is possible to head as much as 6 diameters of low-carbon steel stock in two strokes.

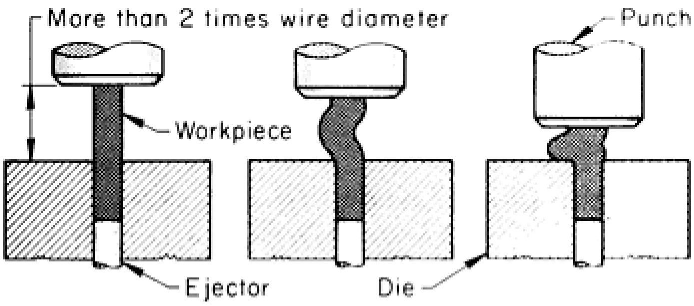

Fig. 2 Typical folding effect obtained with a flat-end punch when heading low-carbon steel having an unsupported length of more than about 2 diameters.

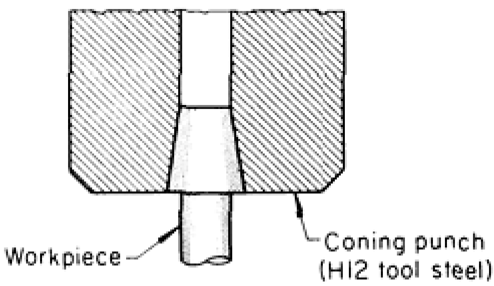

Fig. 3 Use of a coning punch in the first blow of a two-blow heading operation to enable upsetting of up to 6 diameters in two strokes.

Headability is sometimes expressed as the heading limit, which is the ratio of the diameter of the largest possible headed portion to the diameter of the stock. There is usually a direct relationship between reduction of area in a tensile test and heading limit as defined above.

Cold Heading

Equipment

Standard cold headers are classified according to two characteristics:

- Whether the dies open and close to admit the work metal or are solid
- The number of strokes (blows) the machine imparts to the workpiece during each cycle

The die in a single-stroke machine has one mating punch; in a double-stroke machine, the die has two punches. The two punches usually reciprocate so that each contacts the workpiece during a machine cycle.

Single-stroke solid-die headers are made in sizes of $\frac{1}{8}$, $\frac{3}{16}$, $\frac{1}{4}$, $\frac{5}{16}$, $\frac{3}{8}$, $\frac{1}{2}$, $\frac{5}{8}$, $\frac{3}{4}$, and 1 in. These sizes refer to the approximate diameter of stock that can be headed. Because they are single-stroke machines, product design is limited to less than two diameters of stock to form the head. Single-stroke extruding can also be done in this type of machine. These machines are used to make rivets, rollers and balls for bearings, single-extruded studs, and clevis pins.

Double-stroke solid-die headers are available in the same sizes as single-stroke solid-die headers. These machines can make short-to-medium length products (usually 8 to 16 diameters long), and they can make heads that are as large as three times the stock diameter. These machines can be equipped for relief heading, which is a process for filling out sharp corners on the shoulder of a workpiece, or a square under the head.

Some extruding can also be done in these machines. Because of their versatility over single stroke cold headers, double-stroke solid-die headers are extensively used in the production of fasteners.

Single-stroke open-die headers are made for smaller-diameter parts of medium and long lengths and are limited to heading 2 diameters of stock because of their single stroke. Extruding cannot be done in this type of machine, but small fins or a point can be produced by pinching in the die, if desired. Similar machines are used to produce nails.

Double-stroke open-die headers are made in a wider range of sizes than single-stroke open-die headers and can produce heads as large as three times stock diameter. They cannot be used for extrusion, but they can pinch fins on the workpiece, when required. They will generally pinch fins or small lines under the head of the workpiece when these are not required; if these fins or lines are objectionable, they must be removed by another operation.

Three-blow headers utilize two solid dies along with three punches and are classified as special machines. Having the same basic design as double-stroke headers, these machines provide the additional advantage of extruding or upsetting in the first die before double-blow heading or heading or trimming in the second die. Three-blow headers combine the process of trapped extrusion and upsetting in one single machine to produce special fasteners having small shanks but large heads. These headers are also ideal for making parts with stepped diameters in which the transfer of the workpiece would be accomplished with great difficulty.

Transfer and progressive headers are solid-die machines with two or more separate stations for various steps in the forming operation. The workpiece is automatically transferred from one station to the next. These machines can perform one or more extrusions, can upset and extrude in one operation, or can upset and extrude in separate operations. Maximum lengths of stock of various diameters headed in these machines range from 152 mm (6 in.) with 3.8 in. diameter to 255 mm (10 in.) with $\frac{3}{4}$ in. diameter. These machines can produce heads of five times stock diameter or more.

Boltmaking machines are solid-die headers similar to transfer and progressive headers, but they can trim, point, and roll threads. Boltmaking machines usually have a cut-off station, two heading stations, and one trimming station served by the transfer mechanism. An ejector pin drives the blank through the hollow trimming die to the pointing station. The trimming station can be used as a third heading station, or for extruding. Boltmaking machines are made for bolt diameters $\frac{3}{16}$, $\frac{1}{4}$, $\frac{5}{16}$, $\frac{3}{8}$, $\frac{1}{2}$, $\frac{5}{8}$, $\frac{3}{4}$, 1, and $1\frac{1}{4}$ in.

Rod headers are open-die headers having either single or double stroke. They are used for extremely long work (8 to 160 times stock diameter). The workpiece is cut to length in a separate operation in another machine and fed manually or automatically into the rod header.

Reheaders are used when the workpiece must be annealed before heading is completed--for example, when the amount of cold working needed would cause the work metal to fracture before heading was complete. Reheaders are made as either open-die or solid-die machines, single or double stroke, and can be fed by hand or hopper. Punch presses are also used for reheading.

Nut formers generally have four or five forming dies and a transfer mechanism that rotates the blank 180° between one or two dies or all the dies. Therefore, both ends of the blank are worked, producing workpieces with close dimensions, a fine surface finish, and improved mechanical characteristics. A small slug of metal is pierced from the center of the nut, which amounts to 5 to 15% waste, depending on the design of the nut.

Operation. Most cold-heading machines used in high production are fed by coiled wire stock. The stock is fed into the machine by feed rolls and passes through a stationary cutoff quill. In front of the quill is a shear-and-transfer mechanism. When the wire passes through the quill, the end butts against a wire stop or stock gage to determine the length of the blank to be headed. The shear actuates to cut the blank. The blank is then pushed out of the shear into the transfer, which positions the blank in front of the heading die. The heading punch moves forward and pushes the slug into the die; at the same time, the transfer mechanism releases the slug and moves back into position for another slug.

In the die, the slug is stopped by the ejector pin, which acts as a backstop and positions the slug with the correct amount protruding for heading. In a single- or double-stroke header, the heading operation is completed in this die, and the ejector pin advances to eject the finished piece. In a progressive header or a boltmaking machine, the transfer mechanism has fingers in front of each of several dies. After each stroke, the ejector pin pushes the workpiece out of the die. The transfer mechanism grips it and advances it to the next station. In boltmaking machines, the last station in the heading area is a trimming station. The trimming die (which is on the punch side) is hollow, and the die ejector pin drives the trimmed workpiece completely through the die and, by an air jet or other means, through a tube to the pointing station.

Pointers are of two types. Some have cutters that operate much like a pencil sharpener in putting a point on the workpiece (thus producing some scrap); others have a swaging or extruding device that forms the point by cold flow of the metal.

The pointed workpiece is placed in a thread roller. A boltmaking machine has a thread roller incorporated into it. The rolling dies are flat pieces of too] steel with a conjugate thread form on their faces. As the workpiece rolls between them, the thread form is impressed on its shank, and it drops out of the dies at the end, often as a finished bolt.

Tools

The tools used in cold heading consist principally of punches and dies. The dies can be made as one piece (solid dies) or as two pieces (open dies), as shown in Fig. 4.

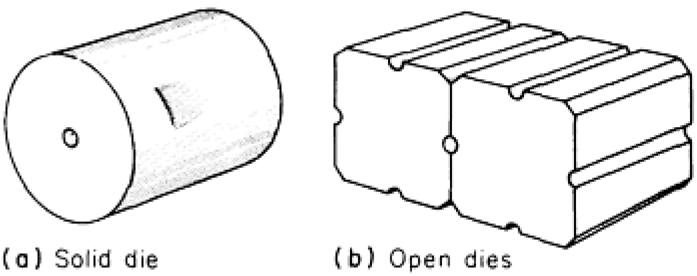

Fig. 4 Solid (one-piece) and open (two-piece) cold-heading dies.

Solid dies (also known as closed dies) consist of a cylinder of metal with a hole through the center (Fig. 4a). They are usually preferred for the heading of complex shapes. Solid dies can be made entirely from one material, or can be made with the center portion surrounding the hole as an insert of a different material. The choice of construction depends largely on the length of the production run and/or complexity of the part. For extremely long runs, it is sometimes desirable to use carbide inserts, but it may be more economical to use hardened tool steel inserts in a holder of less expensive and softer steel.

When a solid die is made in one piece, common practice is to drill and ream the hole to within 0.076 to 0.13 mm (0.003 to 0.005 in.) of finish size before heat treatment. After heat treatment, the die is ground or honed to the desired size.

Solid dies are usually quenched from the hardening temperature by forcing the quenching medium through the hole, making no particular attempt to quench the remainder of the die. By this means, maximum hardness is attained inside the hole; the outer portion of the die is softer and therefore more shock resistant.

Because the work metal is not gripped in a solid die, the stock is cut to length in one station of the header, and the cut-to-length slug is then transferred by mechanical fingers to the heading die. In the heading die, the slug butts against a backstop as it is headed. Ordinarily, the backstop also serves as an ejector.

Open Dies (also called two-piece dies) consist of two blocks with matching grooves in their faces (Fig. 4b). When the grooves in the blocks are put together, they match to form a die hole as in a solid die. The die blocks have as many as eight grooves on various faces so that as one wears, the block can be turned to make use of a new groove. Because the grooves are on the outer surface of the blocks, open-die blocks are quenched by immersion to give maximum hardness to the grooved surfaces. Open dies are usually made from solid blocks of tool steel, because of the difficulty involved in attempting to make the groove in an insert set in a holder. Open dies are made by machining the grooves before heat treating, then correcting for any distortion by grinding or lapping the grooves after heat treating.

In open-die heading, the dies can be permitted to grip the workpiece, like the gripper dies in an upsetting machine. When this is done, the backstop required in solid-die heading is not necessary. However, some provision for ejection is frequently incorporated into open-die heading.

Design. The shape of the head to be formed in the workpiece can be sunk in a cavity in either the die or the punch or sometimes partly in each. The decision on where to locate the cavity often depends on possible locations of the parting line on the head. It must be possible to extract the workpiece from both the punch and the die. It is generally useful, but not entirely necessary, to design some draft in the workpiece head for ease of ejection.

An important consideration in the design of cold-heading tools is that the part should stay in the die and not stick in the punch. Therefore, it is particularly difficult to design tooling for midshaft upsets. Where possible, the longest part of the shank is left in the die. There is less of a problem with open dies that use a special die-closing mechanism. Some punches are equipped with a special synchronized ejector mechanism to ensure that the workpiece comes free.

At best, cold heading imposes severe impact stress on both punches and dies. Minor changes in tool design often register large differences in tool life, as described in the following example.

Example 1: Improvements in Heading Tool Design That Eliminated Tool Failure.

The recessed-head screw shown in Fig. 5(a) was originally headed by the heading tool shown in Fig. 5(b). After producing only 500 pieces, the tool broke at the nib portion ("Point of failure," Fig. 5b).

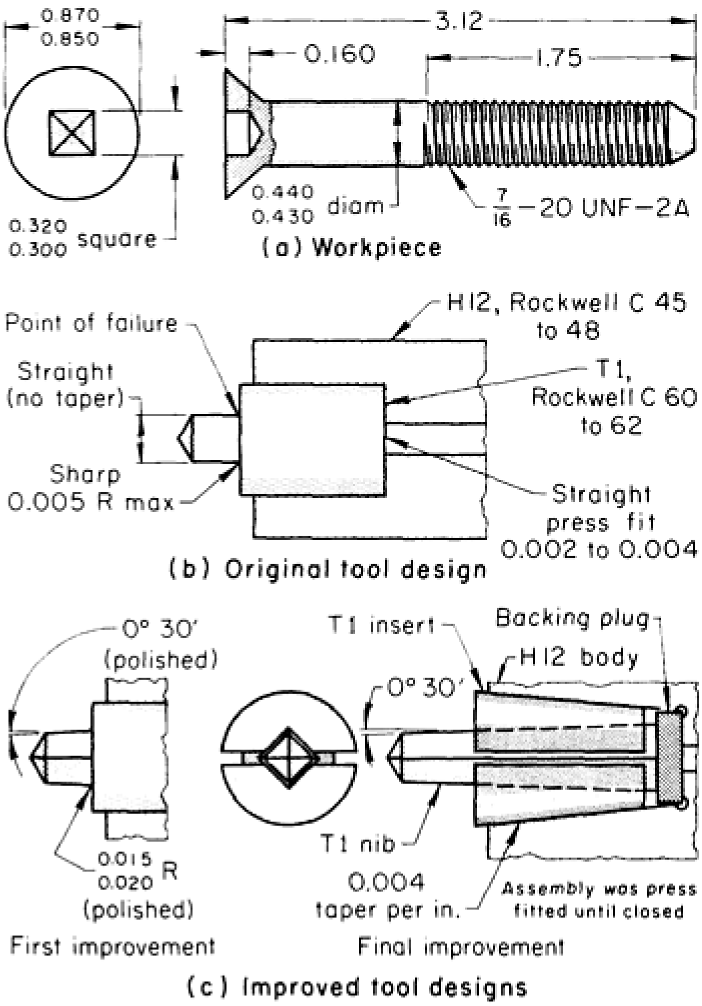

Fig. 5 Improvements in heading tool design to eliminate tool failure in the production of recessed-head screws. Dimensions given in inches.

The design of the heading tool was improved by adding a radius and a slight draft to the nib (Fig. 5c). The entire nib was then highly polished. The redesigned tools produced 12,000 to 27,000 pieces before breakage occurred, but this tool life was still unacceptable.

A final design improvement is shown at the right in Fig. 5(c). The nib was made to fit a split holder, using a slight taper to prevent the nib insert from being pulled from the split holder as the header withdrew from the workpiece. Tools of this design did not break and produced runs of more than 100,000 pieces before the nib was replaced because of wear.

Tool Materials

The shock loads imposed on cold-heading tools must be considered in the selection of tool materials. For optimal tool life, it is essential that both punches and dies have hard surfaces (preferably 60 HRC or higher). However, except for the heading of hard materials, the interior portions of the tools must be softer (40 to 50 HRC, and sometimes as low as 35 HRC for larger tools), or breakage is likely.

To meet these conditions, shallow-hardening tool steel such as W1 or W2 is extensively used for punches and open dies and for solid dies made without inserts. Inserts are commonly made from higher-alloy tool steels, such as D2 or M2, or from tungsten carbide having a relatively high percentage of cobalt (13 to 25%).

Shock-resistant tool steel such as S1 is also used for the cold heading of tools, especially for the heading of intricate shapes when a tool steel such as W1 has failed by cracking. The shock-resistant steels are generally lower in hardness than preferred for maximum resistance to wear, but it is often necessary to sacrifice some wear resistance to gain resistance to cracking.

Producing bolts that have square portions under the heads or dished heads or both can result in tool failure. Under these conditions, a change in grade of steel for the tools is sometimes mandatory.

Preparation of Work Metal

The operations required for preparing stock for cold heading may include heat treating, drawing to size, machining, descaling, cutting to length, and lubricating.

Heat Treating. The cold-heading properties of most steels are improved by process annealing, spheroidizing, or stress relieving. In general, process annealing is done at the steel mill on steels with low-to-medium carbon content. Additional heat treatment is not used unless required, for at least two reasons:

- The process could cost more than any savings realized in cold heading
- Cold-headed products often depend for their final strength on work hardening before and during the heading process, and if reannealed before cold heading, they may lose much of their potential strength

Carbon steels (1000 series) with up to about 0.25% C are usually cold headed in the mill-annealed condition as received from the steel supplier. If the heading is severe, they can be reannealed at some stage in the heading operations, but they are rarely given a full anneal before cold heading. Carbon steels (1000 series) with 0.25 to 0.44% are also mill annealed. However, because higher carbon content decreases workability, they are sometimes normalized or annealed above the upper transformation temperature; more frequently, a spheroidizing treatment is used. Carbon steels that contain more than 0.44% C, most modified carbon steels (1500 series), and all alloy steels are fully spheroidized. Heat-treating methods for steels and nonferrous metals are described in *Heat Treating*, Volume 4 of the *ASM Handbook.* In practice, experience often indicates the need for annealing or spheroidizing to prevent cracking of the work metal or to obtain acceptable tool life or both.

Drawing to size produces stock of uniform cross section that will perform as predicted in dies that have been carefully sized to fill out corners without flash or die breakage. Drawing to size also improves strength and hardness when these properties are to be developed by cold work and not by subsequent heat treatment.

Turning and Grinding. Drawn wire can have defects that carry over into the finished workpiece, exaggerated in the form of breaks and folds. Seams in the raw material that cause these defects may not be deep enough to be objectionable in the shank or body of a bolt, but can cause cracks in the head during cold heading or subsequent heat treatment. Surface seams and laps can be removed by turning, grinding, or shaving at the wire mill or by machining the headed product.

Descaling. Work metal that has been heat treated usually needs to be descaled before cold heading. Scale can cause lack of definition, defects on critical surfaces, and dimensional inaccuracy of the workpiece.

Methods of descaling include abrasive blasting, water jet blasting, pickling, wire brushing, and scraping. Selection of method depends largely on the amount of scale present and on the required quality of the surfaces on the headed workpieces. Acid pickling is usually the least expensive method for complete removal of heavy scale (see the articles on surface engineering of specific metals in *Surface Engineering*, Volume 5 of the *ASM Handbook*).

Cutting to Length. In a header that has a shear-type cutoff device as an integral part of the machine, cutting to length by shearing is a part of the sequence. In applications in which cutting to length is done separately, shearing is the method most commonly used for bars up to about 50 mm (2 in.) in diameter (see the article "Shearing of Bars and Bar Sections" in this Volume). For larger diameters, sawing is generally used. Gas cutting and abrasive-wheel cutting are used less often than shearing and sawing.

Lubrication. Although some of the more ductile metals can be successfully cold headed to moderate severity without a lubricant, most metals to be cold headed are lubricated to prevent galling of the dies, sticking in the dies, and excessive die wear. Lubricants used include lime coating, phosphate coating, stearates and oils, and plating with softer metals such as copper, tin, or cadmium.

The ultimate in lubrication for steel to be cold headed is a coating of zinc phosphate with stearate soap--the same as used for the cold extrusion of steel (see the article "Cold Extrusion" in this Volume). A similar treatment is often used for aluminum. However, for workpieces produced entirely by cold heading, this treatment is seldom necessary, except for extremely severe heading.

In the cold heading of carbon and alloy steel wire, common practice is to coat the work metal with a dry lubricant during the last draw. The lubricants most often used are calcium stearate or aluminum stearate. First, the wire is pickled to remove scale, dirt, and any previous coatings. It is then coated with lime, phosphate, or borax, which acts as a base coating. Calcium or aluminum stearate is added as a dry lubricant. The lubricant sticks to the base coating and is fused by the heat developed when the wire passes through the drawing die. For severe heading, extrusion oils are sometimes used (often in addition to the treatments given above) in the header/former, particularly when experience has proved that oil will improve results.

Stainless steel is usually electroplated with copper and then lubricated with oil or molybdenum disulfide. Oxalates are sometimes used instead of the copper plating.

In the cold heading of nonferrous metals, the need for lubrication varies from metal to metal. Nickel-base alloys, especially the high-strength alloys, require very good lubrication. These metals are usually copper plated and then given a stearate coating. The coatings are later removed with nitric acid.

The more formable nickel-base alloys are usually also copper plated. If the heading is not severe, however, they can be headed with a stearate coating only, which can be removed with hot water. Nitric acid cannot be used on Monel, because the acid will attack the base metal.

Copper-base alloys have the least need for lubrication. For normal heading operations, oil or drawing compound is added at the header. For severe heading, a stearate coating can be added during the last draw of the wire. Sulfurized oil should not be used for cold heading of copper-base alloys unless some staining can be tolerated.

Aluminum header wire is generally coated with stearate. Aluminum needs more lubrication for cold heading than copper, but much less than nickel.

In all cold heading, best practice is to use the simplest and the least lubricant that will provide acceptable results, for two reasons:

- Excessive amounts of lubricant may build up in the dies, resulting in scrapped workpieces or damaged dies
- Removal of lubricant is costly (the cost of removing lubricant usually increases in proportion to the effectiveness of the lubricant)

Complex Workpieces

Cold-headed products that have more than one upset portion need not be formed in two heading operations; many can be made in one operation of a double-stroke header. The length of stock that may be partly upset is generally limited to five times the diameter of the wire. The only other limitation is that the header must be able to accommodate the diameter and length of wire required for the workpiece.

Three pieces, each with two end upsets, that were made completely in one operation in a double-stroke open-die header are shown in Fig. 6(a). These parts were made at a rate of 80 pieces per minute. Production rate is limited only by the speed of the machine used, not by the item being produced.

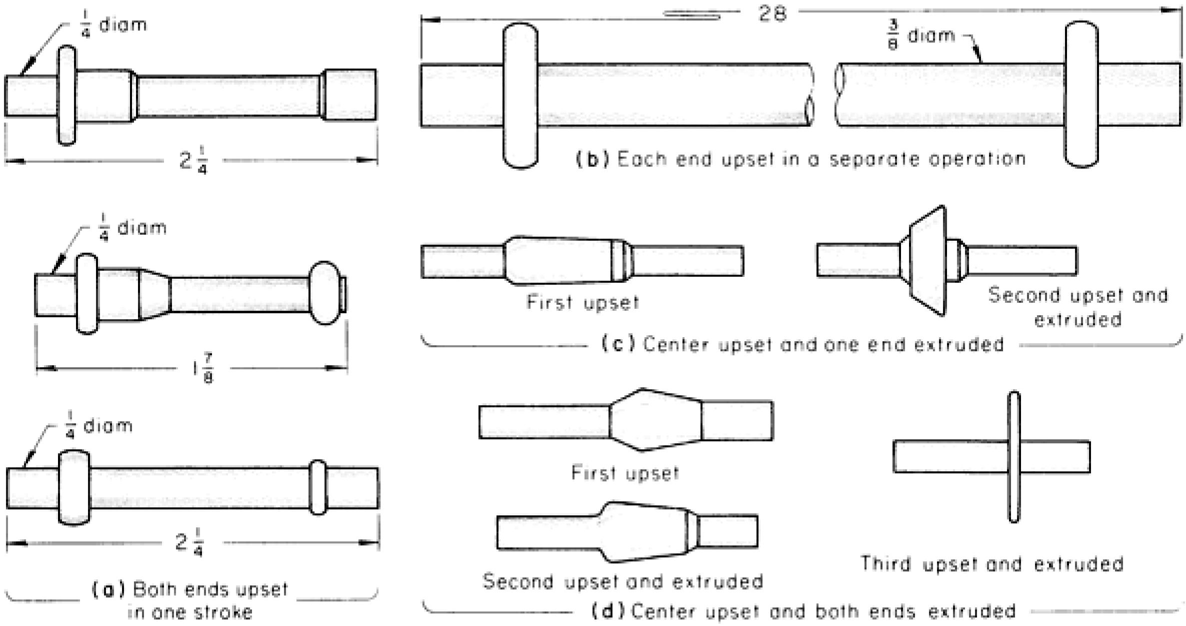

Fig. 6 Typical parts with center upsets or upsets at both ends. Dimensions given in inches.

The product becomes more expensive when the upsetting operation has to be performed twice, as in production of the 710 mm (28 in.) long axle bolt shown in Fig. 6(b). This part required two upsetting operations because the die in a standard double-stroke cold header was not long enough to form both upsets in the machine at the same time. One or more additional operations may be needed for workpieces that require pointing as well as a complex upset.

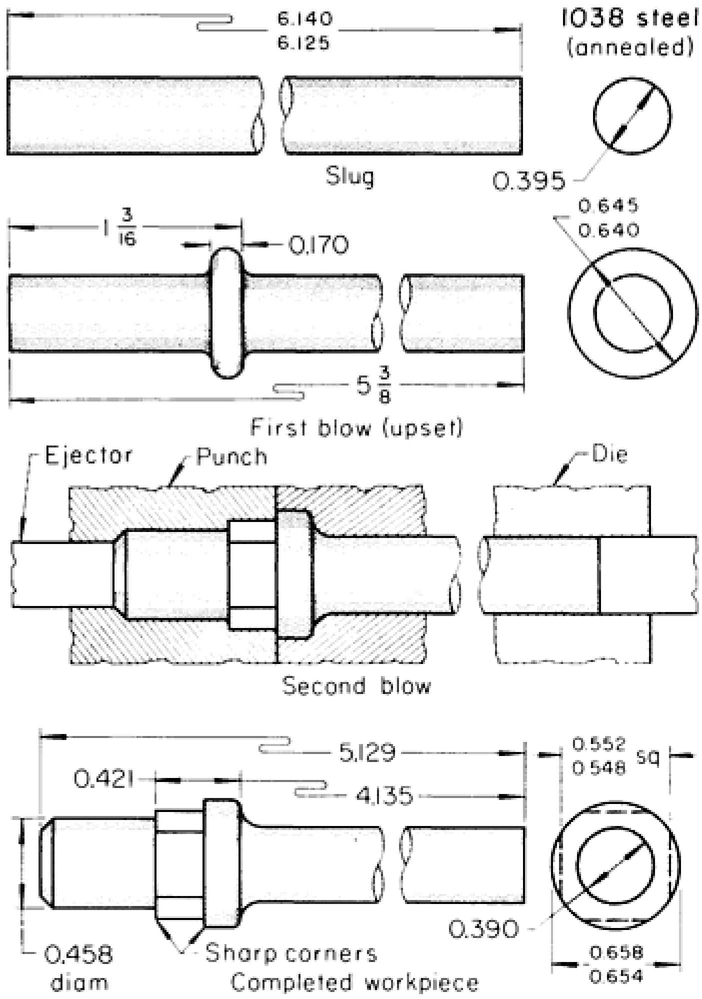
Center Upsetting. Most cold heading involves forming an upset at the end of a section of rod or wire. However, the forming of upsets at some distance from the end is common practice.

The trailer-hitch-ball stud shown in Fig. 6(c) is representative of an upset performed midway between the ends of the wire blank. This stud was upset and extruded in two strokes in a $\frac{3}{4}$ in. solid-die machine. The diameter of one end section is smaller than that of the original wire, and the round center collar is flared out to more than $2\frac{1}{2}$ times the wire diameter. The center-collar stud shown in Fig. 6(d) is another example of a center upset. Both ends of the stud were extruded below wire size, while the center collar was expanded to more than three times the original wire diameter. This stud was formed in three strokes in a progressive header.

Control of the volume of work metal to prevent formation of flash and to prevent excessive loads on the tools is important in most cold-heading operations. In center upsetting, control of metal volume is usually even more important, not only to prevent flash and tool overload but also to prevent folds. A technique used successfully in one application of center upsetting is described in the following example.

Example 2: Production of a Complex Center Upset in Two Blows.

A blank for a bicycle-pedal bolt (Fig. 7) required sharp corners on the edges and corners of the square portion and a complete absence of burrs or fins in the collar area. In heading, any excess pressure applied on the collar portion to fill the corners and edges of the square resulted in flash or overfill on the collar portion. It was necessary to upset the collar portion in one blow and to form the square in a second blow in order to fabricate this part successfully (Fig. 7). The folds generally produced by this technique were avoided by careful control of size. By forming the collar completely during the first blow and almost completely confining it during the second blow, the remainder of the metal was controlled so that it could be directed into filling the square. Therefore, the pressure needed to form and fill the square was confined to this area and not allowed to cause further upsetting in any other portion. Accurate control of the headed volume depended on the accuracy of the cut blank and of the collar formed in the first blow.



Machine	$\frac{1}{2}$ in. boltmaking machine
Tool material	M2 inserts, 62-64 HRC
Lubricant	Stearate on stock
Production rate	4200 pieces per hour[(a)]
Tool life	10,000-15,000 pieces

(a) At 100% efficiency

Economy in Cold Heading

Cold heading is an economical process because of high production rates, low labor costs, and material savings. Production rates range from about 2000 to 50,000 pieces per hour, depending on part size. Fewer machines are needed to meet production requirements than with other processes, resulting in reduced costs for equipment, maintenance, and floor space. Labor costs are minimal because most operations are performed automatically, requiring labor only for setup, supervision, and parts handling.

Material savings results from the elimination or reduction in chips produced. When cold heading is combined with other operations, such as extrusion, trimming, and thread rolling, the savings is considerable (see the section "Combined Heading and Extrusion" in this article). Subsequent machining or finishing of the cold-headed parts is usually not necessary. This can be especially beneficial when relatively expensive work materials are used. The following example describes the replacement of machining by cold heading to reduce production costs of a copper alloy nozzle component.

Example 3: Machining Replaced by Cold Heading to Save Material.

A blank for a threaded copper alloy C10200 (oxygen-free copper) nozzle component (Fig. 8) was originally produced by machining from bar stock. A material savings of more than 50% was effected by producing the component by cold heading rather than machining. The same shape and dimensional accuracy were produced by both methods. In both cases, threads were rolled in a separate operation.

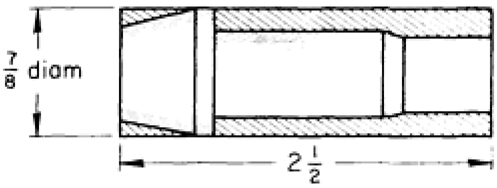

Fig. 8 Copper alloy C10200 nozzle component blank that was originally machined but was switched to cold heading to save the work metal indicated by the shaded regions. Dimensions given in inches.

Dimensional Accuracy

Work can be produced to much closer tolerances in cold headers than in hot headers. Tolerances on parts produced by single-stroke headers need to be wider than on parts given two or more blows. Rivets, often formed in single-stroke machines, have tolerances of ±0.38 mm (±0.015 in.) except where otherwise specified. Shanks for rolled threads are allowed only ±0.038 mm (±0.0015 in.). Small parts can usually have closer tolerances than large parts. Tolerances can often be maintained as close as 0.025 mm (±0.001 in.), although maintenance of a tolerance this close increases product cost; requires careful control of machines, tools, and work metal; and is unusual in practice.

The following example demonstrates tolerance capabilities and shows dimensional variations obtained in production runs of specific cold-headed products.

Example 4: Variation in Dimensions of a Valve-Spring Retainer Produced in a Nut Former.

The valve-spring retainer shown in Fig. 9 was produced from fine-grain aluminum-killed 1010 steel (No. 2 bright annealed, cold-heading quality) in a five-station progressive nut former. To determine the capabilities of the machine and tools for long-run production, several thousand pieces were made from three separate coils. Distribution charts were prepared for two critical dimensions on randomly selected parts made from each coil. Results are plotted in Fig. 9. Lots 1, 2, and 3 include parts made from the three different coils. As a further test of machine and tool capabilities, the tooling was set to a mean taper dimension for lot 1, high side for lot 2, and low side for lot 3.

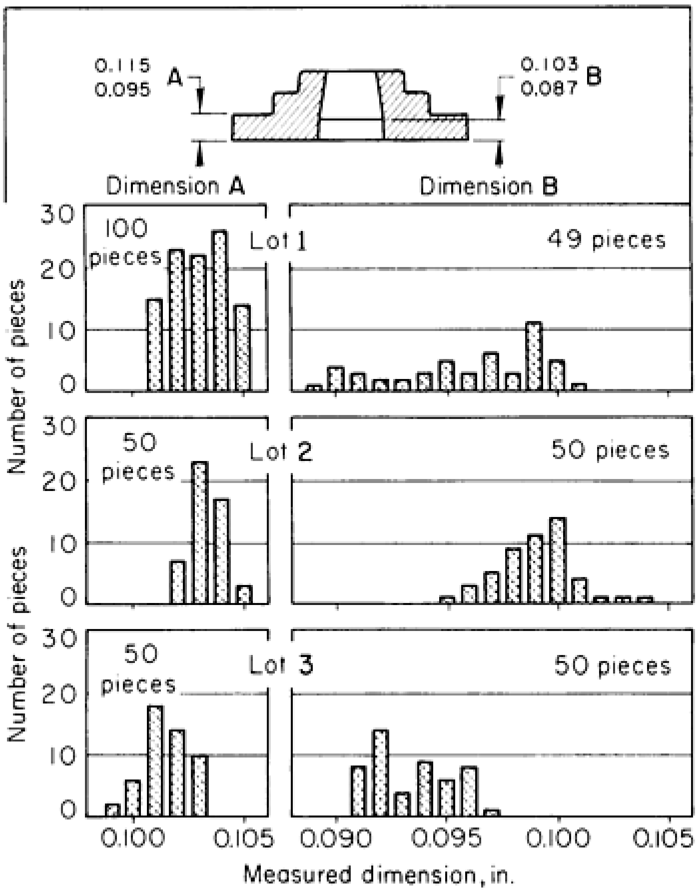

Fig. 9 Variations in dimensions of 1010 steel valve spring retainers randomly selected from three lots. Parts were produced in a five-station nut former. Dimensions given in inches.

The accuracy that could be maintained on thickness of a flat surface is demonstrated in Fig. 9. Although specifications permitted a total variation of 0.51 mm (0.020 in.) on seat thickness, actual spread did not exceed 0.13 mm (0.005 in.) for parts made from the three coils. A greater total variation was experienced for the taper-depth dimension. When the tools were set for mean, the total variation was 0.33 mm (0.013 in.) which was still within the 0.41 mm (0.016 in.) allowable (lot 1). With tools set for high side, total variation was only 0.25 mm (0.010 in.), although one part was 0.025 mm (0.001 in.) out of the allowable range (lot 2). Optimal results were obtained on the taper dimension when tools were set for the low side (lot 3); total spread was only 0.18 mm (0.007 in.).

Surface Finish

Surfaces produced by cold heading are generally smooth and seldom need secondary operations for improving the finish. Surface roughness, however, can vary considerably among different workpieces or among different areas of the same workpiece, depending on:

- Surface of the wire or bar before heading
- Amount of cold working in the particular area
- Lubricant used

- Condition of the tools

Cold drawing of the wire before cold heading will improve the final surface finish. The best finish on any given workpiece is usually where direct contact has been made with the tools, such as on the top of a bolt head or on an extruded shank portion where cold working is severe.

The lubricant is likely to have a greater effect on the appearance of a headed surface than on surface roughness as measured by instruments. For example, heavily limed or stearate-coated wire produces a dull finish, but the use of grease or oil results in a high-luster finish.

The condition of the tools is most important in controlling the workpiece finish. Rough surfaces on punches or dies are registered on the workpiece. Therefore, the best surface finish is produced only from tools that are kept polished.

The ranges of finish shown on the square-necked bolt in Fig. 10 are typical for such a part when headed from cold-drawn steel, using ground and polished tools. The best finish is on the top of the head and on the extruded shank, while the poorest finish is on the outer periphery of the round head.

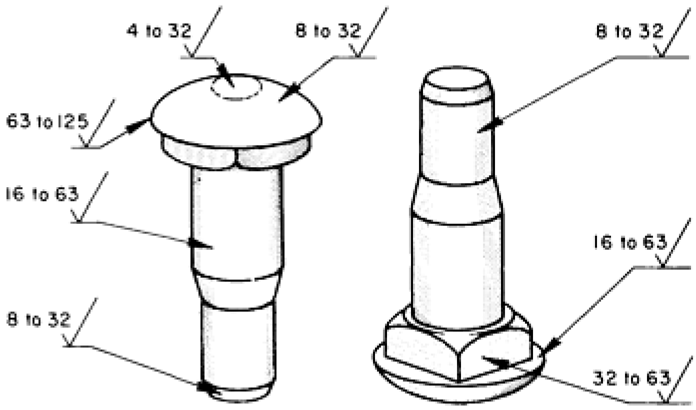

Fig. 10 Typical variations in surface roughness at various locations on a square-necked bolt headed from cold-drawn steel with ground and polished tools. Roughness given in microinches.

Combined Heading and Extrusion

It is common practice to combine cold heading with cold extrusion, and this often permits the selection of a work metal size that greatly lessens forming severity and prolongs tool life. Two parts shown in Fig. 6, a trailer-hitch-ball stud (Fig. 6c) and a center-collar stud (Fig. 6d), reflect the flexibility in design obtained by combining center upsetting and extrusion. In addition to increased tool life, other advantages can sometimes be obtained by combining cold heading and cold extrusion, as shown in the following two examples.

Example 5: Combined Heading and Extrusion That Eliminated Machining.

As shown in Fig. 11, lawnmower wheel bolts were originally produced by heading the slug and simultaneously extruding the opposite end to 13.34 mm (0.525 in.) in diameter, by coining and trimming the round head to a hexagonal shape, and by turning the bolt blank to 8.4 mm (0.331 in.) in diameter in a secondary operation prior to thread rolling.

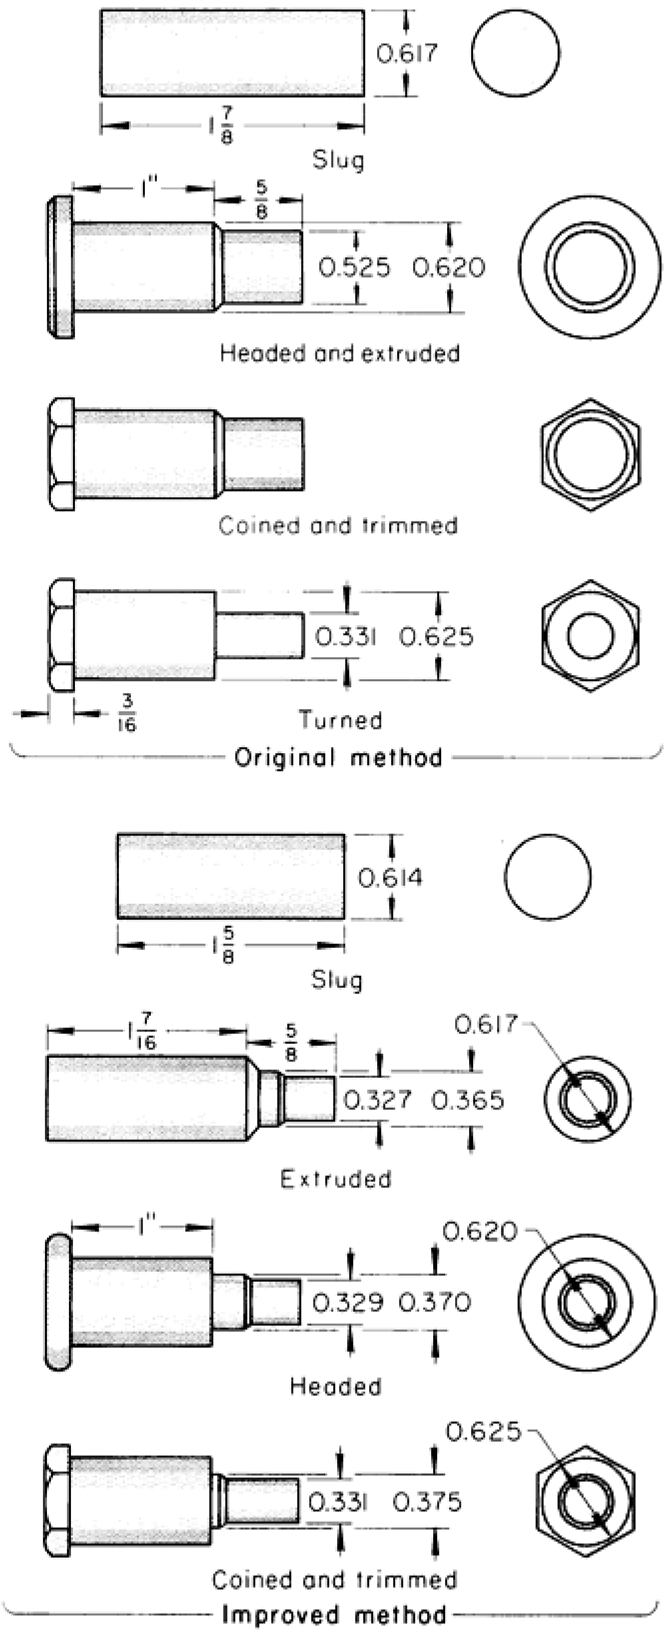

Fig. 11 Combined extrusion and cold heading used to reduce production costs for a 1018 steel lawnmower wheel. A turning operation was eliminated by cold extruding the diameter to be roll threaded. Dimensions given in inches.

By an improved method (Fig. 11), the slug was extruded to form two diameters on the shank end, then headed, coined, and trimmed. By this procedure, the minor extruded diameter was ready for thread rolling; no turning was required. The improved method not only reduced costs by eliminating the secondary turning operation but also produced a stronger part, because flow lines were not interrupted at the shoulder.

Because of the turning operation, production by the original method was only 300 pieces per hour. With the improved method, 3000 pieces could be produced per hour.

Example 6: Combining Extrusion With Heading to Decrease Heading Severity.

A socket-head cap screw was originally produced by heading 23.2 mm (0.915 in.) diam wire in four blows, using four dies. By an improved method (Fig. 12), the screw was produced by starting with a larger wire (25.1 mm, or 0.990 in., in diameter) and then combining forward extrusion with a heading operation in a first blow and completing the head by backward extrusion in a second blow. Thus, one die and two punches replaced four dies and four punches for a reduction in tool cost of about 50%. The improved method also permitted the part to be processed in a $\frac{3}{4}$ × 8 in. double-stroke header.

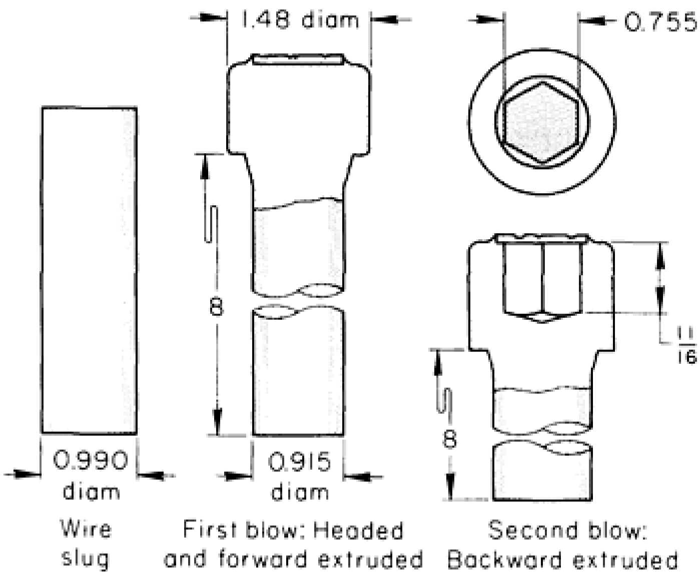

Fig. 12 Production of a large 4037 steel cap screw by extruding and heading in two blows. Dimensions given in inches.

The 25.1 mm (0.990 in.) starting diameter was cold drawn at the header from hot-rolled lime-coated 4037 steel with soap applied for a drawing lubricant. Molybdenum disulfide paste was applied as a lubricant when the cold-drawn stock entered the machine for shearing to length.

Warm Heading

In warm heading (a variation of the cold-heading process), the work metal is heated to a temperature high enough to increase its ductility. A rise in work metal temperature usually results in a marked reduction in the energy required for heading the material. Temperatures for warm heading range from 175 to 540 °C (350 to 1000 °F), depending on the characteristics of the work metal.

Applications. Warm heading is occasionally used to produce an upset that would have required a larger machine if the upsetting were done cold, but by far the most extensive use of warm heading is for the processing of difficult-to-head metals, such as austenitic stainless steels. Because they work harden rapidly, austenitic stainless steels are best headed at slow ram speeds.

The data shown in Fig. 13 suggest that the speed of the heading punch greatly affects the headability of these stainless steels. According to investigations, 80% of the loss in ductility caused by heading speed can be recovered if the metal is heated to between 175 and 290 °C (350 and 550 °F). The increase in headability with increasing temperature is indicated in Fig. 14.

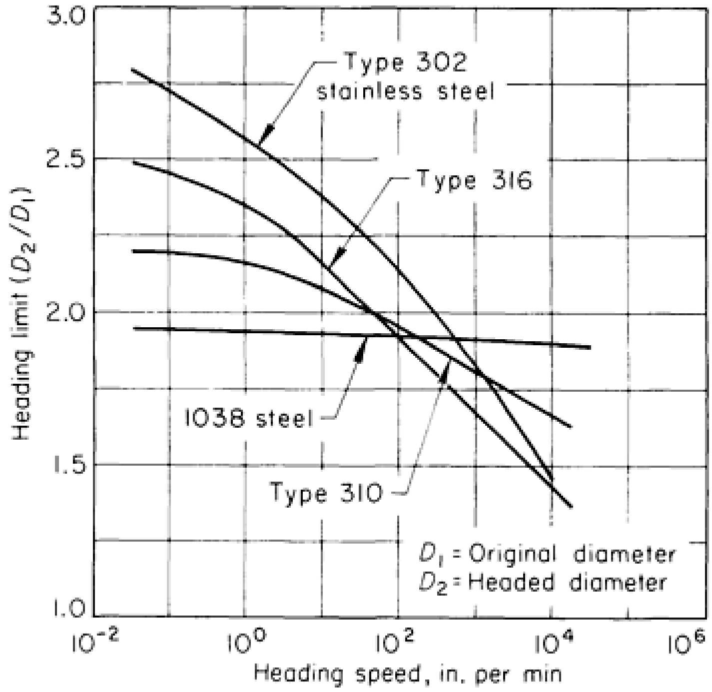

Fig. 13 Effect of heading speed on heading limits for three austenitic stainless steels and for 1038 steel.

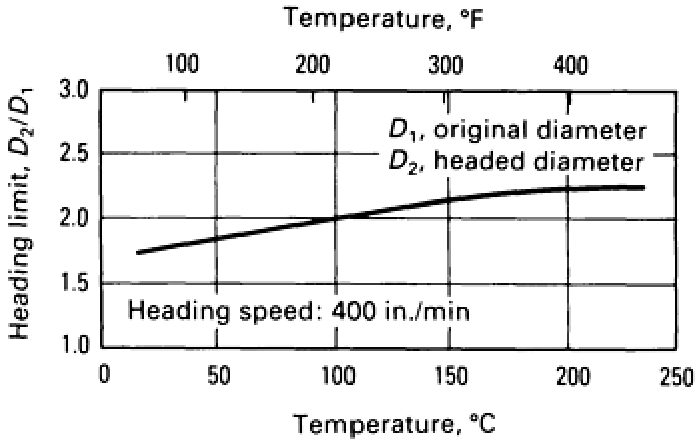

Fig. 14 Effect of work metal temperature on heading limit of austenitic stainless steel.

Machines and Heating Devices. Warm-heading machines are essentially the same as cold-heading machines except that warm-heading machines are designed to withstand the elevated temperature of the work metal. Induction heating coils or resistance heating elements can be used as auxiliary heating equipment.

Induction heating is the method most commonly used to heat work material for warm heading, although direct resistance heating is also used in some applications. The main disadvantage of induction heating is the high initial cost of the power supply. Therefore, its use is generally restricted to continuous high production.

Direct resistance heating, on the other hand, has the advantages of simplicity of equipment, accuracy of control, safety (because voltage is low), and adaptability to heating of a continuous length of work metal. The usual setup for resistance heating employs a second feeder-roll stand similar to that already on the header. The second stand is positioned about 1.5 m (5 ft) behind the first, and the wire stock (work metal) is fed through both sets of rolls. Leads from the electrical equipment are attached to the two sets of rolls, and the circuit is completed by the portion of the wire that passes between them. The wire (work metal) then becomes the resistance heater in the circuit.

Tools. Whether or not the same tools can be used for warm heading as for cold heading depends entirely on the temperature of the tools during operation. Although the tools usually operate at a temperature considerably lower than that of the work metal, it is important that the tool temperature be known. Tool temperature can be checked with sufficient accuracy by means of temperature-sensitive crayons. Under no circumstances should the tool be allowed to exceed the temperature at which it was tempered after hardening. This tempering temperature is usually 150 °C (300 °F) for carbon tool steel such as W1 or W2. Tools made from a high-alloy tool steel, such as D2, ordinarily should not be permitted to operate above 260 °C (500 °F).

When tool temperatures exceed those discussed above, the use of tools made from a hot-work tool steel, such as H12, is appropriate. However, the lower maximum hardness of such a steel somewhat limits its resistance to wear. A high-speed tool steel such as M2 will provide the high hardness and the resistance to tempering needed for long tool life.

Other Advantages of Warm Heading. As the heading temperature of a work-hardenable material increases, the resulting hardness decreases, as shown in Fig. 15. Therefore, if a material is warm headed, the hardness will remain low enough to permit such secondary operations as thread rolling, trimming, drilling, and slotting.

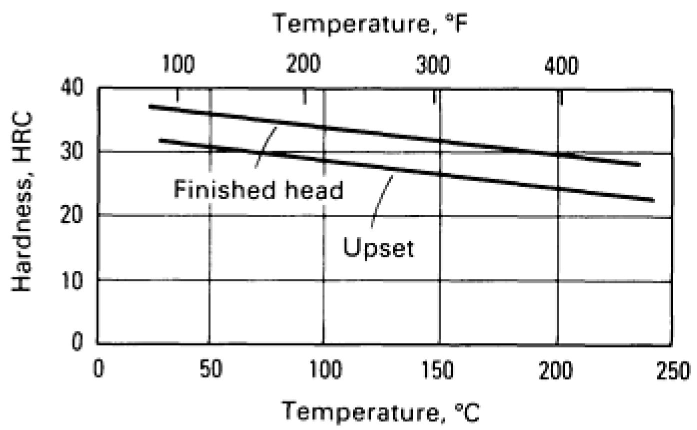

Fig. 15 Effect of heading temperature on the hardness of the upset portion and finished head of type 305 stainless steel flat-head machine screws.

In cold heading, the upset head of a work-hardening metal is very hard, a rolled thread is moderately hard, and the undeformed shoulder is relatively soft. These variations can be minimized by warm heading.

Cold Heading

Introduction

COLD EXTRUSION is so called because the slug or preform enters the extrusion die at room temperature. Any subsequent increase in temperature, which may amount to several hundred degrees, is caused by the conversion of deformation work into heat. Cold extrusion involves backward (indirect), forward (direct), or combined backward and forward (indirect-direct) displacement of metal by plastic flow under steady, though not uniform, pressure. Backward displacement from a closed die is in the direction opposite to punch travel. Workpieces are often cup-shaped and have wall thicknesses equal to the clearance between the punch and die. In forward extrusion, the work metal is forced in the direction of the punch travel. These two basic methods of extrusion are sometimes combined so that some of the work metal flows backward and some forward. All three of these types of cold extrusion are shown in Fig. 1.

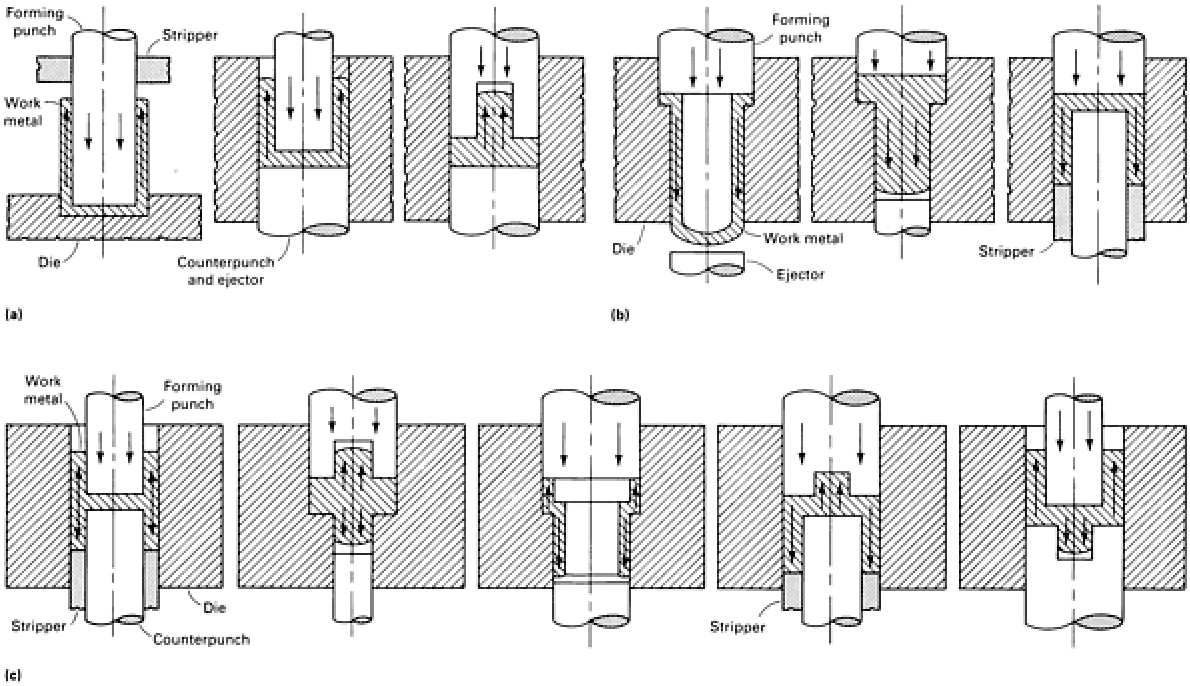

Fig. 1 Displacement of metal in cold extrusion. (a) Backward extrusion. (b) Forward extrusion. (c) Combined backward and forward extrusion

In cold extrusion, a punch applies pressure to the slug or preform, causing the work metal to flow in the required direction. The relative motion between punch and die is obtained by attaching either one (almost always the die) to the stationary bed and the other to the reciprocating ram. The axis of the machine can be vertical or horizontal. The pressure can be applied rapidly as a sharp blow, as in a crank press or header (impact extrusion), or more slowly by a squeezing action, as in a hydraulic press. The pressure exerted by the punch can be as low as 34.5 MPa (5 ksi) for soft metals or as high as 3100 MPa (450 ksi) for extrusion of alloy steel.

Work Hardening of Metals. Metals are work hardened when they are deformed at temperatures below their recrystallization temperatures. This can be an advantage if the service requirements of a part allow its use in the as-formed condition. (Under some conditions, heat treatment is not needed.) Work hardening, however, raises the ratio of yield strength to tensile strength and lowers ductility. Therefore, when several severe cold extrusion operations follow one another, ductility must be restored between operations by annealing. Any scale formed during annealing must be removed by blasting or pickling before subsequent extrusion. The effect of cold extrusion on the hardness across a section of extruded steel is described in the section "Extrusion Ratio" in this article.

In spite of the high pressure applied to it, the metal being extruded is not compressed to any measurable amount. Except for scale losses in annealing or the inadvertent formation of flash, constancy of volume throughout a sequence of operations is ensured. For all practical purposes, volumetric calculations can be based on the assumption that there is no loss of metal.

Cold-Extruded Metals. Aluminum and aluminum alloys, copper and copper alloys, low-carbon and medium-carbon steels, modified carbon steels, low-alloy steels, and stainless steels are the metals that are most commonly cold extruded. The above listing is in the order of decreasing extrudability. The equipment and tooling are basically the same regardless of the metal being extruded (see the sections "Equipment," "Tooling," and "Tool Materials" in this article).

Cold Extrusion Versus Alternative Processes. Cold extrusion competes with such alternative metal-forming processes as cold heading, hot forging, hot extrusion, machining, and sometimes casting. Cold extrusion is used when the process is economically attractive because of:

- Savings in material
- Reduction or elimination of machining and grinding operations, because of the good surface finish and dimensional accuracy of cold-extruded parts
- Elimination of heat-treating operations, because of the increase in the mechanical properties of cold-extruded parts

Cold extrusion is sometimes used to produce only a few parts of a certain type, but it is more commonly used for mass production because of the high cost of tools and equipment.

Revised by P.S. Raghupathi, Battelle Columbus Division; W.C. Setzer, Consultant; and M. Baxi, Ullrich Copper, Inc.

Extrusion Ratio

Extrusion ratio *R* is determined by dividing the original area undergoing deformation by the final deformed area of the workpiece:

$$R = \frac{A_0}{A_f}$$

Because volume remains constant during extrusion, the extrusion ratio can also be estimated by increase in length. An extrusion ratio of 4 to 1 indicates that the length has increased by approximately a factor of four.

The metal being extruded has a large effect on the maximum ratio that is practical. Some typical approximate maximum extrusion ratios are 40 for aluminum alloy 1100, 5 for 1018 steel and 3.5 for type 305 stainless steel and similar austenitic grades.

Extrusion pressure increases with extrusion ratio. Figure 2 shows that extrusion ratio has a larger effect on ram pressure in the forward extrusion of carbon steel than either carbon content or type of annealing treatment. Figure 3 illustrates the effect of tensile strength on extrudability in terms of ram pressure for both the backward and forward extrusion of low-carbon and medium-carbon steels of the 1000, 1100, and 1500 series at different extrusion ratios.

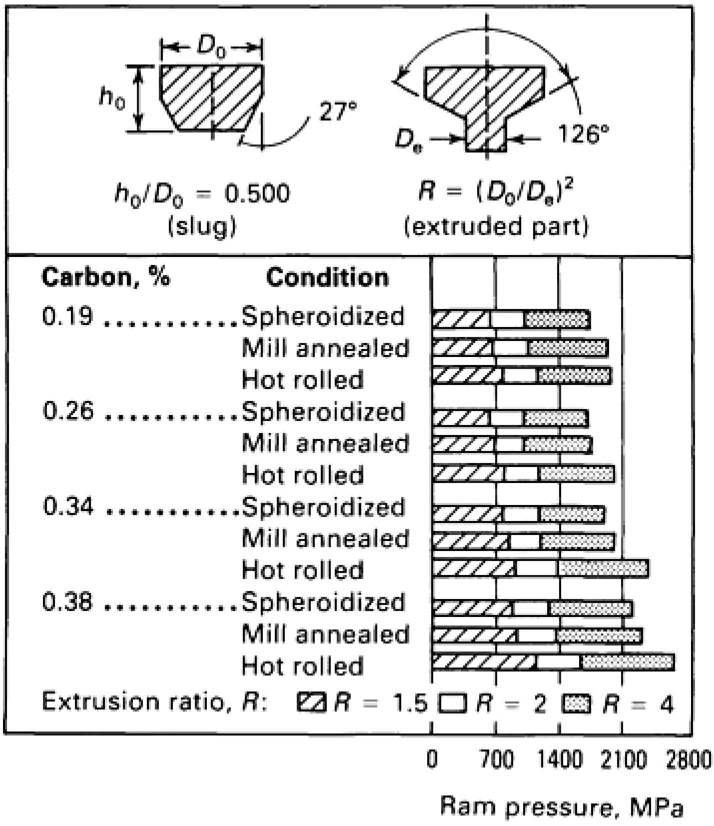

Fig. 2 Effect of carbon content, annealing treatment, and extrusion ratio on maximum ram pressure in the forward extrusion of the carbon steel part from the preformed slug

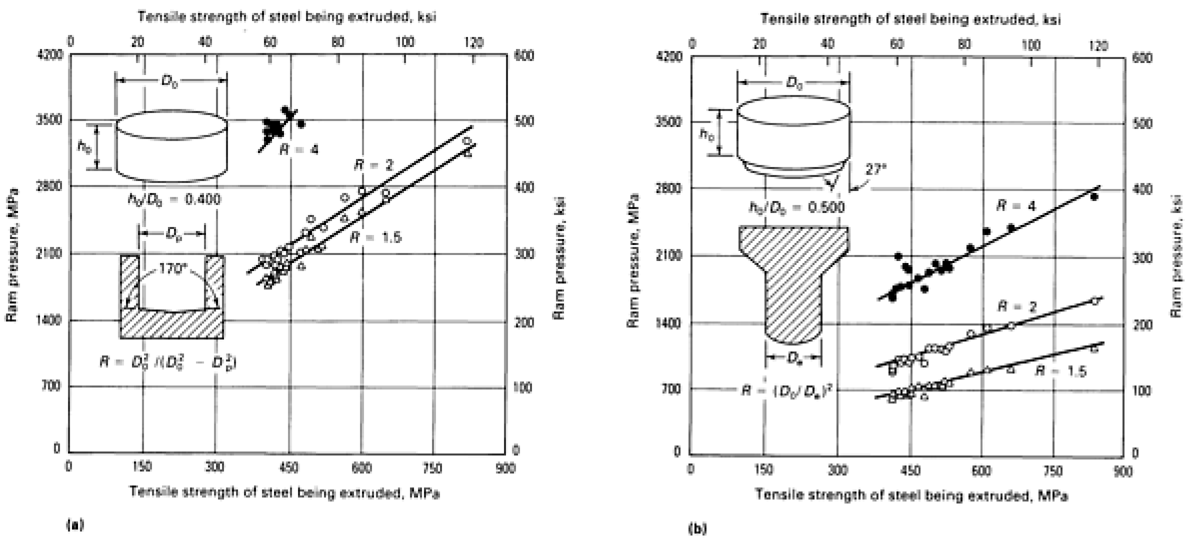

Fig. 3 Effect of tensile strength on ram pressure required for backward (a) and forward (b) extrusion of low- and medium-carbon steels at different extrusion ratios. Data are for AISI 1000, 1100, and 1500 series steels containing 0.13 to 0.44% C.

Extrusion Ratio Versus Work Hardening. Because an increase in extrusion ratio results in a corresponding increase in the amount of cold deformation, the effects of work hardening will normally vary directly with extrusion ratio. Data on the changes in tensile properties of the work metal during cold extrusion are given in Example 3.

Revised by P.S. Raghupathi, Battelle Columbus Division; W.C. Setzer, Consultant; and M. Baxi, Ullrich Copper, Inc.

Extrusion Ratio

Extrusion ratio *R* is determined by dividing the original area undergoing deformation by the final deformed area of the workpiece:

$$R = \frac{A_0}{A_f}$$

Because volume remains constant during extrusion, the extrusion ratio can also be estimated by increase in length. An extrusion ratio of 4 to 1 indicates that the length has increased by approximately a factor of four.

The metal being extruded has a large effect on the maximum ratio that is practical. Some typical approximate maximum extrusion ratios are 40 for aluminum alloy 1100, 5 for 1018 steel and 3.5 for type 305 stainless steel and similar austenitic grades.

Extrusion pressure increases with extrusion ratio. Figure 2 shows that extrusion ratio has a larger effect on ram pressure in the forward extrusion of carbon steel than either carbon content or type of annealing treatment. Figure 3 illustrates the effect of tensile strength on extrudability in terms of ram pressure for both the backward and forward extrusion of low-carbon and medium-carbon steels of the 1000, 1100, and 1500 series at different extrusion ratios.

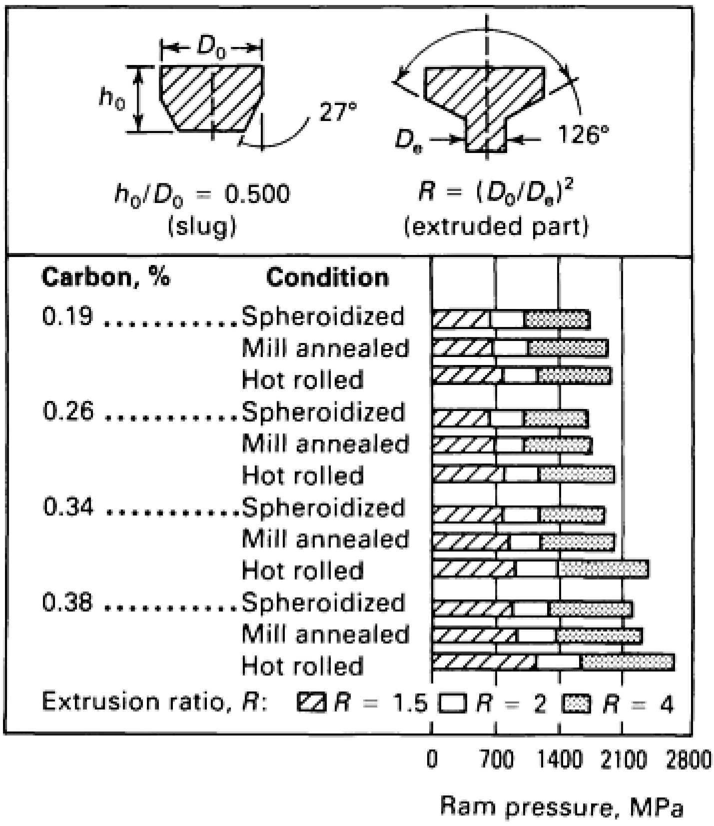

Fig. 2 Effect of carbon content, annealing treatment, and extrusion ratio on maximum ram pressure in the forward extrusion of the carbon steel part from the preformed slug

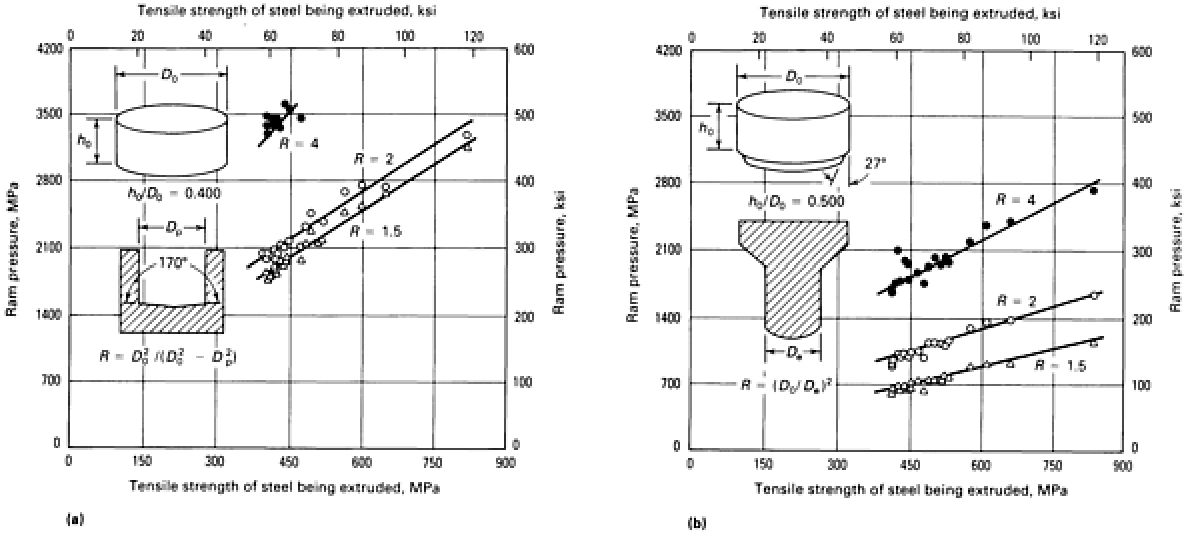

Fig. 3 Effect of tensile strength on ram pressure required for backward (a) and forward (b) extrusion of low- and medium-carbon steels at different extrusion ratios. Data are for AISI 1000, 1100, and 1500 series steels containing 0.13 to 0.44% C.

Extrusion Ratio Versus Work Hardening. Because an increase in extrusion ratio results in a corresponding increase in the amount of cold deformation, the effects of work hardening will normally vary directly with extrusion ratio. Data on the changes in tensile properties of the work metal during cold extrusion are given in Example 3.

Cold Extrusion

Effect of Composition and Condition on Extrudability of Steel

The extrudability of steel decreases with increasing carbon or alloy content. Extrudability is also adversely affected by greater hardness. Free-machining additives, such as sulfur or lead, are likely to impair extrudability. Nonmetallic inclusions, particularly the silicate type, are also detrimental to extrudability.

Carbon Content. The cold extrusion of steels containing up to 0.45% C is common practice, and steels with even higher carbon contents have been successfully extruded. However, it is advisable to use steels of the lowest carbon content that will meet service requirements. Most carbon and alloy steels that are extruded contain 0.10 to 0.25% C. However, in some applications, steels with more than 0.45% (especially alloy steels) are cold extruded.

Figure 2 shows the results of an investigation conducted in one plant to determine the effects of carbon content, type of annealed structure, and extrusion ratio on the ram pressure required to forward extrude a specific shape from carbon steels. These data show that ram pressures are essentially the same for steels containing 0.19 and 0.26% C, regardless of the other variables, but that ram pressure is markedly increased as carbon content reaches 0.34 and 0.38%. The steel slugs (Fig. 2) were coated with zinc stearate over zinc phosphate and were extruded under laboratory conditions at a rate of 635 mm/min (25 in./min).

Alloy Content. For a given carbon content, most alloy steels are harder than plain carbon steels and are therefore more difficult to extrude. Most alloy steels also work harden more rapidly than their carbon steel counterparts; therefore, they sometimes require intermediate annealing.

Hardness. The softer a steel, the easier it is to extrude. Steels that have been spheroidize annealed are in their softest condition and are therefore preferred for extrusion. Figure 2 shows that spheroidized steels were extruded at lower ram pressures than hot-rolled or mill-annealed steels, regardless of other variables. The data in Fig. 3 show that ram pressure must be increased as tensile strength increases for steels of low-to-medium carbon content at three extrusion ratios. However, operations that precede or follow extrusion may make it impractical to have the steel in its softest condition. Extremely soft steels of low-to-medium carbon content have poor shear-ability and machinability; therefore, some extrudability is occasionally sacrificed. Annealing techniques that produce a partly pearlitic structure are ideal for many extrusion applications in which shearability or machinability is important.

Free-machining steels, containing such additives as lead and sulfur, are not preferred for cold extrusion. Extrusions from these steels are more susceptible to defects than extrusions from their nonfree-machining counterparts. In addition, because parts produced by cold extrusion generally require only minimal machining (this is often the primary reason for using cold extrusion), there is much less need for free-machining additives than when parts are produced entirely by machining.

The successful extrusion of free-machining steels depends on the amount of upset, the flow of metal during extrusion, and the quality requirements of the extruded part. Free-machining steels can generally withstand only the mildest upset without developing defects. If it is under compression at all times during flow, a free-machining steel will probably extrude without defects. However, rupture is likely if compressive force is suddenly changed to tensile force.

Nonmetallic Inclusions. The fewer the inclusions, the more desirable the steel is for cold extrusion. Silicate inclusions have been found to be the most harmful. Therefore, some steels have been deoxidized with aluminum rather than silicon in an attempt to keep the number of silicate inclusions at a minimum. The aluminum-killed steels have better extrudability in severe applications.

Extrusion Quality

Carbon steel bars are available at additional cost in two classes of extrusion quality: cold extrusion quality A and cold extrusion quality B. The mill preparation for cold extrusion quality A is the same as that used for special-quality bars; cold extrusion quality B is a still higher quality.

Higher quality refers primarily to fewer external and internal defects. Hot scarfing and more rigorous inspection of the billets are additional operations that are performed at the mill to prepare cold extrusion quality B material.

Alloy steel without a quality extra is used in applications similar to those of cold extrusion quality A for carbon steel. Alloy steels are also available as cold-heading quality, which parallels cold extrusion quality B for carbon steel. Boron-modified steels for heading and extrusion are also available.

The advisability of paying the additional cost for cold extrusion quality B or cold-heading quality steel depends on the severity of extrusion, the quality requirements of the extruded part, and the cost of rejected parts in comparison with the extra cost for these steels.

Severity of extrusion refers mainly to the extrusion ratio. If the ratio is low and the work metal is kept under compression during flow, it is unlikely that cold extrusion quality B steel will be beneficial. On the other hand, if the ratio is high or if the work metal is in tension at times during metal flow, cold extrusion quality B steel should be considered.

The cold extrusion of many parts involves both extrusion and upsetting. Upsetting is the more critical of the two operations, and the severity of the upset should determine the quality of steel required.

The overall quality requirements of the finished part must be considered. Minor defects are sometimes acceptable in the finished part, or they may be removable in normal machining.

More information on the workability of metals is available in the Section "Evaluation of Workability" in this Volume.

Equipment

Hydraulic presses, mechanical presses, special knuckle-joint presses for cold extrusion, special cold-forging machines, and cold-heading machines are used in cold extrusion. Most cold extrusion operations are performed on mechanical presses or cold-heading machines. Of the two, mechanical presses are used more often, because of their adaptability to other types of operations. Mechanical presses are generally more costly and are capable of higher speeds than hydraulic presses of similar capacity. A disadvantage of a mechanical press is its limited length of stroke.

A cold-heading machine combines the essential features of a mechanical press with mechanisms that feed in bar stock, shear slugs, and transfer the slugs to the die and then to other dies if required.

Hydraulic presses represent only a small fraction of the total number of presses used for cold extrusion. However, hydraulic presses are especially well suited to the production of parts requiring long working strokes.

Proper selection of the press is important for successful cold extrusion and for the prevention of excessive maintenance charges. Mechanical presses must have:

- Sufficient flywheel energy (insufficient energy results in overloading and heating of the motor, as well as parts that are incompletely formed)
- Sufficient torque capacity in the drive mechanism to deliver the necessary force at the required point above the bottom of the stroke
- Rigid structural members to prevent excessive deflection under concentrated loading

Power Requirements. Because of work metal and tool variables, data resulting from laboratory studies of power requirements for cold extrusion are generally not applicable to shop practice. The following rules can be used as guidelines in estimating pressure, force, and horsepower requirements:

- Determine the effective contact area of the forming tool. In backward extrusion, this area is the cross-sectional area of the punch tip. For forward extrusion, the effective contact area is the annular area of the die shoulder
- Determine the extrusion ratio and ascertain that the ratio is within practical limits (see the section "Extrusion Ratio" in this article)
- Consider the tool materials used. Properly supported punches and dies made of tool steel can be operated at peak pressures as high as 2415 MPa (350 ksi). Carbide punches can be operated at peak pressures to 2760 MPa (400 ksi), and carbide dies at 3100 MPa (450 ksi)
- Peak extrusion forces can be safety estimated as the product of effective contact area (as determined in the first item in this list) and peak allowable stress (as indicated in the third item in this list). The condition of the press equipment, tools, and work material, the design of the tools, and the lubricant used, all affect the maximum extrusion ratio obtainable in a particular operation
- The energy required is calculated as the product of extrusion force and distance over which it must act to form the part. The horsepower required can be calculated from this energy and the frequency at which the energy is to be delivered
- At operating speed, flywheel energy must be four to ten times that required per stroke for extrusion; the exact multiple depends on cycle time and type of motor

Power requirements can be estimated on the basis of extrusion ratio. Other methods for determining power requirements, generally more complex, consider the influence of several interrelated variables, including the properties of the metal to be extruded, the size and shape of the part, the thickness of the wall to be produced (or reduction of area), the temperature, the effect of lubrication, the blank shape and thickness, and the grain size and orientation.

Cold Extrusion

Tooling

Knowledge of the forces acting on tool components is not always a matter of certainty, and the design of tools is more often dictated by the dimensions of the part to be formed than by considerations of metal flow, lubrication, and other processing variables. Although many engineering components are, or can be, designed to last indefinitely, this is seldom true in the design of highly stressed, consumable tools for cold extrusion in which a tool life of 100,000 pieces is likely to be considered above average. On the other hand, conventional design criteria are applicable to the less highly stressed, nonconsumable tools for extrusion. Accordingly, it is convenient to distinguish between consumable tooling components, such as punches and dies, and nonconsumable ones, such as shrink rings and pressure pads.

Estimation of Load. Knowledge of the forces or pressures required for forward or backward extrusion is essential in design for determining tool stresses and for selecting suitable press equipment. Methods for estimating these requirements, including a method based on extrusion ratio, are discussed in the section "Power Requirements" in this article. The pressure to be applied is a function of the deformation resistance and degree of deformation. Deformation resistance, in turn, is affected by the composition, mechanical properties, and condition of the work material; the external frictional forces applied; and the size and shape of both the initial slug and the finished workpiece. Practical experience has shown that for the tool steels and carbides currently in use, the specific forming pressure at the punch should not exceed about 2370 MPa (344 ksi) and the die internal pressure should not exceed about 1895 MPa (275 ksi). If the estimated pressures exceed these limits, either the degree of deformation must be reduced or a considerably shorter tool life must be accepted.

The consumable tools (punch, die, and ejector) make direct contact with the metal to be extruded. These tools are exposed to a specific load and to wear. Their design should incorporate features that will conform to the design requirements of the workpiece while minimizing specific load and wear. It is usually possible to design tools that will satisfy both objectives by facilitating the flow of metal and reducing losses due to internal and external friction.

Tool Assembly Components. The components of a typical tool assembly used for the backward extrusion of steel parts are identified in Fig. 4. There is considerable variation in the tooling practice and design details of tool assembly components. Some of the principal factors affecting the design of punches and dies for backward and forward extrusion are discussed below and in the Selected References in this article.

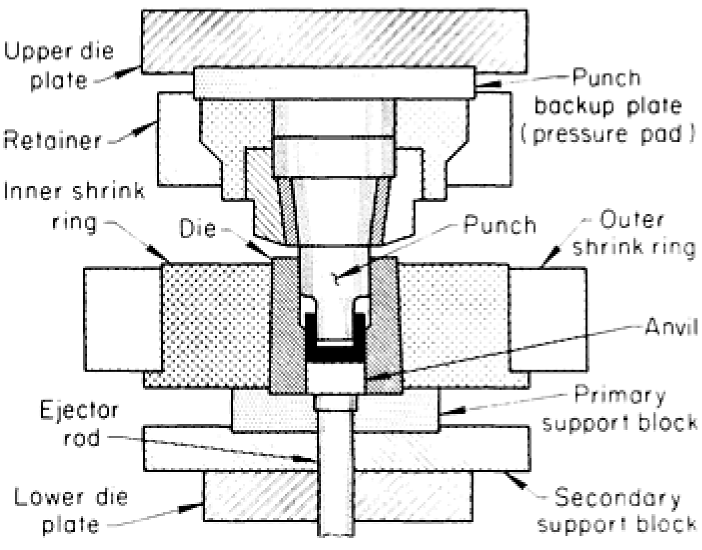

Fig. 4 Tools constituting a typical setup for the backward extrusion of steel parts

Punch Design. A major problem in punch design consists of assessing the nature and magnitude of the stresses to which the punch is subjected in service. Because the stresses are dynamic, fatigue effects will arise, and these fatigue effects, in conjunction with the inherently brittle nature of hardened tool steels, necessitate care in avoiding design features likely to produce stress concentrations. The stability problems that may arise when slender punches are used will be affected by the accuracy of alignment provided by the tool set or the press itself, or by factors in the extrusion operation, such as punch wander, initial centering, and use of distorted slugs. The ratio of punch length to punch diameter also affects stability; a ratio of about 3 to 1 is probably the maximum for cold extrusion of steel using tool steel punches.

The design of the punch nose has a significant effect on extrusion pressures and tool life. In backward extrusion acceptable results are obtained with a nose profile consisting of a truncated cone having an included angle of 170 to 180°, with an edge radius of 0.51 to 2.54 mm (0.020 to 0.100 in.), and a land length of 1.27 to 1.9 mm (0.050 to 0.075 in.) with the shank relieved 0.1 to 0.2 mm (0.004 to 0.008 in.) on the diameter. Although they reduce initial punch stresses, small cone angles or large radii are undesirable, because of rapid lubricant depletion and the risk of metal-to-metal contact. Design of the punch nose to distribute the lubricant properly during extrusion is essential for minimizing the pressures developed.

The area ratio between punch shank and head is also an important design factor. A large ratio will have the effect of spreading the punch load over a large area of pressure pad. On the other hand, it will require a wider block of metal for its fabrication with a resultant cost increase. Because pressure pads are less expensive than punches, it is generally advisable to favor the smaller ratios. The pressure pad, which transmits the load from the back of the punch to the die set, should be designed for economy, ease of replacement, and efficiency in reducing the number of punch failures.

Die Design. In forward extrusion, the die is under maximum pressure, and this pressure is not distributed uniformly. Therefore, the tool designer must calculate the hoop (tensile) stresses on the inner die wall and provide adequate reinforcement. Ordinarily, pressures of less than about half the yield strength of the die do not require reinforcement, while those in excess of this value do require reinforcement.

Extrusion dies are usually inserted in one or more shrink rings to provide reinforcement. These rings prestress the die in compression by providing interference fits between rings and die. This results in lower working stress and therefore longer fatigue life of extrusion tools. A similar technique is used to shrink radially segmented die inserts together to prevent the segments from separating under load. Permanent shrink-fit assemblies are sometimes made by heating the outer ring to facilitate assembly. Interchangeable die inserts are usually force fitted mechanically, using a tapered press fit and molybdenum disulfide as a lubricant. Of the two methods, shrinking-on by heating is generally preferred, because a cylindrical hole and shaft are easier to fabricate than a tapered hole and shaft. However, a taper fit has several advantages, such as:

- The hardness and yield strength of the various die components are not lowered (as they would be by heating) and can be measured with dependable accuracy
- The prestress value is ensured by strict control of the input measurements
- Release and exchange of the inner die bushings is quick, easy, and inexpensive
- Die parts can be standardized
- Hot-working die steels are not required

The most commonly used taper angle is $\frac{1}{2}$ to 1°. The conditions for obtaining the specified advantages of the taper force fit are careful preparation of the taper shell surfaces and exact agreement between taper angles of corresponding contact faces. If the shell surfaces do not provide uniform support over the entire die length, the prestresses will be unequal, and the reinforcement will not be fully effective.

In some setups, the first reinforcement is applied by taper force fit and the second (outer) reinforcement by shrinking-on. It is advisable to standardize on the size of reinforcing elements. In general, no further advantage is gained by making the outside diameter of a reinforcement more than four to five times the die diameter.

In forward extrusion, die angles are determined by the shape of the workpiece and by the operating sequence. In general, an angle of 2α = 24 to 70° (Fig. 5) is selected for the forward extrusion of solids, and an angle of 2α = 60 to 126° is preferred for extruding hollow parts, the angle varying inversely with wall thickness. Ejection pressure on the work increases with decreasing die angle, because greater friction must be overcome. This pressure also increases with an increase in the length of the part. Extrusion pressure causes elastic expansion of the die, which shrinks when the pressure is discontinued. Accordingly, very high wall pressures are developed, and these require correspondingly high ejection pressures.

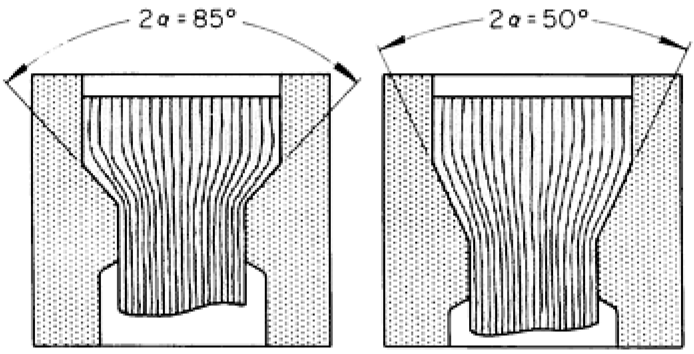

Fig. 5 Measurement of die angle in dies for forward extrusion

Tooling Setups. Metals can be cold extruded by different tooling setups, depending mainly on the size and shape of the workpiece, the composition of the work metal, and the quantity requirements. The principal types of tooling employed and examples of products formed by each type are discussed below.

Single-station tooling forms the part in one stroke of the press. Additional operations may be required for finishing. Closed-end containers, such as toothpaste tubes, are formed in this manner.

Multiple-station tooling involves a series of separate dies arranged so that the rough blank is made into a preform, which then proceeds through successive operations until the required form is produced.

Multiple-station tooling is often used for semicontinuous operations because of the need for annealing, pickling, and lubrication between operations, although it is also adaptable to continuous operations that use a transfer mechanism. This procedure has also been used in the cold forming of 75 and 155 mm shell bodies involving backward and forward extrusion.

Transfer presses are similar in concept to multiple-station tooling, that is, they can perform several operations in succession. For example, a transfer press may shear, preform, extrude, and finish draw the part in consecutive operations. Mechanical fingers transfer the workpiece from one operation to the next. Pole pieces for alternator rotors have been produced in transfer presses.

Upsetters or headers are used for continuous operation, frequently incorporating both backward and forward extrusion and cold heading. Fasteners such as hexagonal socket-head cap screws are typical examples of parts produced in upsetters.

Rotating dial or indexing can be applied for manual or automatic production. In operation, the table of the press holding the dies indexes, and the head containing the punches remains stationary except for vertical movement. Slugs can be fed automatically, and one or more parts can be formed with each stroke of the press. Instrumentation stops the operation immediately in the event of misalignment, punch breakage, or a wrong-size slug. Gear extrusions are representative examples of parts produced in this type of tooling, at the rate of two extrusions for each press stroke.

Cold Extrusion

Tool Materials

Recommended materials for extrusion punches include M2 and M4 high-speed tool steels and tungsten carbide. Tool steel punches should be heat treated to a hardness of 62 to 66 HRC, and they must have a high compressive yield strength. Die inserts are usually fabricated from such alloy tool steels as D2, M2, and M4, and are heat treated to 58 to 64 HRC, depending on the steel.

Tungsten carbide is extensively used because it provides good die life, high production rates, and good dimensional control. Tungsten carbide often finds application as a punch material in backward extrusion. Retainer rings or housings used for tungsten carbide dies should have sufficient strength and toughness to prevent splitting and failure of the working tools. Shrink rings should be fabricated from hot-work die steels such as H11 or H13 heat treated to 46 to 48 HRC. Outer housings are often made from H13 die steel or from 4340 alloy steel. More information on die materials is available in the article "Dies and Die Materials for Hot Forging" in this Volume.

Cold Extrusion

Preparation of Slugs

The preparation of slugs often represents a substantial fraction of the cost of producing cold-extruded parts.

Producing the Slug Shape. Despite the loss of metal, sawing and cutting off in a machine, such as an automatic bar machine, are widely used methods of producing slugs. The advantages of these methods include dimensional accuracy, freedom from distortion, and minimal work hardening. Shearing is an economical means of producing slugs. Variation in the sizes of the slugs is a major disadvantage of shearing. If slugs are allowed to vary in size, die design must allow for the escape of excess metal in the form of flash. An alternative to die adjustment in some applications is to compensate for the distortion and other discrepancies in sheared slugs by coining the slugs to desired dimensions.

Hot-rolled bar is usually the least costly form of steel for making slugs, but hot-rolled bars are likely to have deeper surface seams and greater depth of decarburized layers than cold finished bars. In addition, the variation in the outside diameter of hot-rolled bars will cause considerable variation in weight or volume of the slug, despite close control in cutting to length. Whether or not the surface seams and decarburization can be tolerated depends largely on the severity of extrusion and the quality requirements of the extruded part. In many applications, acceptable extrusions can be produced with slugs cut from hot-rolled bars.

Cold-finished bars are more expensive than hot-rolled bars. The size variation in cold-finished bars is considerably less than that in hot-finished bars. However, some seams and decarburization will also be present in cold-finished bar stock unless removed by grinding, turning, or other means. Some plants gain the advantage of cold-drawn bars by passing hot-rolled bars or rods through a cold-drawing attachment directly ahead of the slug-cutting operation.

Machined or ground bars are more costly than cold-drawn bars, but eliminate the difficulties caused by decarburization, seams, and variation in outside diameter. For some extrusions, especially those subjected to surface treatments that cannot tolerate a decarburized layer, requirements are such that previously machined bars or machined slugs must be used.

Surface Preparation of Steel Slugs. Phosphate coating for cold extrusion is almost universal practice. The primary purposes of this coating are, first, to form a nonmetallic separating layer between the tools and workpiece and, second, by reaction with or absorption of the lubricant, to prevent its migration from bearing surfaces under high unit pressures. During extrusion, the coating flows with the metal as a tightly adherent layer.

The recommended preparation of steel slugs for extrusion consist of alkaline cleaning, water rinsing, acid pickling, cold and hot water rinsing, phosphate coating, and rinsing. These are discussed below.

Alkaline cleaning is done to remove oil, grease, and soil from previous operations so that subsequent pickling will be effective. Alkaline cleaning can be accomplished by spraying the slugs with a heated (65 to 70 °C, or 150 to 160 °F) solution for 1 to 2 min or by immersing them in solution at 90 to 100 °C (190 to 212 °F) for 5 to 10 min.

Water rinsing is done to remove residual alkali and to prevent neutralization of the acid pickling solution. Slugs are usually rinsed by immersion in overflowing hot water, but they may also be sprayed with hot water.

Acid Pickling. Most commercial installations use a sulfuric acid solution (10% by volume) at 60 to 90 °C (140 to 190 °F). Pickling can be accomplished by spraying for 2 to 15 min or by immersion for 5 to 30 min, depending on surface conditions (generally, the amount of scale). Three times are usually sufficient to remove all scale and to permit a good phosphate coating. Bright annealing or mechanical scale removal, such as shot blasting, as a substitute for pickling has proved unsatisfactory for severe extrusion. However, the use of a mechanical scale-removing method prior to pickling can reduce pickling time, and for producing extrusions of mild severity, the mechanical (or bright annealing) methods have often been used without subsequent pickling.

Cold and hot water rinsing can be carried out by immersion or spraying for $\frac{1}{2}$ to 1 min for each rinse. Two rinses are used to ensure complete removal of residual pickling acid and iron salts. Cold water rinsing is usually of short duration, with heavy overflow of water to remove most of the residual acid. Hot water at about 70 °C (160 °F) increases the temperature of the workpiece and ensures complete rinsing.

Phosphate coating is performed by immersion in zinc phosphate at 70 to 80 °C (160 to 180 °F) for 3 to 5 min. Additional information is available in the article "Phosphate Coatings" in *Surface Engineering*, Volume 5 of the *ASM Handbook.*

Rinsing with cold water, applied by spraying for $\frac{1}{2}$ min or by immersion for 1 min, removes the major portion of residual acids and acid salts left over from the phosphating solution. This rinse is followed by a neutralizing rinse applied by spraying or immersion for $\frac{1}{2}$ to 1 min using a well-buffered solution (such as sodium carbonate), which must be compatible with the lubricant. In the second rinse, the remaining residual acid and acid salts in the porous phosphate coating are neutralized so that absorption of, or reaction with, the lubricant is complete.

Stainless steels are not amenable to conventional phosphate coating (which is why stainless steels are more difficult to extrude than carbon steels); copper plating of stainless steel slugs is preferred. Lime coating is sometimes substituted successfully for copper plating. In extreme cases, the stainless steel can be zinc plated and then coated with zinc phosphate and a suitable soap lubricant. Methods of surface preparation for nonferrous metals are discussed in the sections "Cold Extrusion of Copper and Copper Alloy Parts" and "Cold Extrusion of Aluminum Alloy Parts" in this article.

Revised by P.S. Raghupathi, Battelle Columbus Division; W.C. Setzer, Consultant; and M. Baxi, Ullrich Copper, Inc.

Lubricants for Steel

A soap lubricant provides the best results for the extrusion of steel. Slugs are immersed in a dilute (45 to 125 mL/L, or 6 to 16 oz/gal.) soap solution at 65 to 90 °C (145 to 190 °F) for 3 to 5 min. Some soaps are formulated to react chemically with the zinc phosphate coating, resulting in a layer of water-insoluble metal soap (zinc stearate) on the surfaces of the slugs. This coating has a high degree of lubricity and maintains a film between the work metal and tools at the high pressures and temperatures developed during extrusion.

Other soap lubricants, with or without filler additives, can be used effectively for the mild extrusion of steel. This type of lubricant does not react with the phosphate coating, but is absorbed by it.

Although the lubricant obtained by the reaction between soap and zinc phosphate is optimal for extruding steel, its use demands precautions. If soap accumulates in the dies, the workpieces will not completely fill out. Best practice is to vent all dies so that the soap can escape and to keep a coating of mineral seal oil (applied as an air-oil mist) on the dies to prevent adherence of the soap.

When steel extrusions are produced directly from coiled wire (similar to cold heading), the usual practice is to coat the coils with zinc phosphate, using the procedure outlined in the section "Preparation of Slugs" in this article. This practice however, has one deficiency; because only the outside diameter of the work metal is coated, the sheared ends are uncoated at the time of extrusion. This deficiency is partly compensated for by constantly flooding the work with sulfochlorinated oil. Because the major axis of a heading machine is usually horizontal, there is less danger of entrapping lubricant than when extruding in a vertical press.

Cleaning the extruded parts can be a significant item in the cost of cold extrusion. In general, the more effective the lubricant, the more difficult it is to remove. The methods used for removing pigmented drawing compounds are usually effective for removing the lubricants used for cold extrusion.

Cold Extrusion

Revised by P.S. Raghupathi, Battelle Columbus Division; W.C. Setzer, Consultant; and M. Baxi, Ullrich Copper, Inc.

Selection of Procedure

The shape of the part is usually the primary factor that determines the procedure used for extrusion. For example, many cuplike parts are produced by backward extrusion, while shaftlike parts and hollow shapes can usually be produced more easily by forward extrusion. For many shapes, both forward and backward extrusion are used. Other factors that influence procedure are the composition and condition of the steel, the required dimensional accuracy, quantity, and cost.

The procedures used to extrude a given shape from highly extrudable steels are simpler than those used for more difficult-to-extrude steels. For difficult steels, it may be necessary to incorporate more passes and one or more annealing operations into the process. Some shapes may not be completely extrudable from a difficult-to-extrude steel; one or more machining operations may be required.

Normal extrusion procedures are associated with certain ranges of dimensional accuracy (see the section "Dimensional Accuracy" in this article). Special procedures and controls can provide greater-than-normal accuracy at higher cost.

Cold extrusion is ordinarily not considered unless a large quantity of identical parts must be produced. The process is seldom used for fewer than 100 parts, and more often it is used for hundreds of thousands of parts or continuous high production. Quantity requirements determine the degree of automation that can be justified and often determine whether the part will be completed by cold extrusion (assuming it can be if tooling is sufficiently elaborate) or whether, for low quantities, a combination of extruding and machining will be more economical.

Cost per part extruded usually determines:

- The degree of automation that can be justified
- Whether a combination of extruding and machining should be used for low-quantity production
- Whether it is more economical to extrude parts for which better-than-normal dimensional accuracy is specified or to attain the required accuracy with secondary operations

It is sometimes possible to extrude a given shape by two or more different procedures. Under these conditions, cost is usually the deciding factor. Several procedures for extruding specific steel parts, categorized mainly by part shape, are discussed in the following sections.

Cuplike Parts

The basic shape of a simple cup is often produced by backward extrusion, although one or more operations such as piercing or coining are frequently included in the operations sequence. For cuplike parts that are more complex in shape, a combination of backward and forward extrusion is more often used. The following example describes combined backward extrusion and coining for the fabrication of 5120 steel valve tappets.

Example 1: Backward Extrusion and Coining for Producing Valve Tappets.

The valve tappet shown in Fig. 6 was made from fine-grain, cold-heading quality 5120 steel. Slugs were prepared by sawing to a length of 25.9 to 26.0 mm (1.020 to 1.025 in.) from bar stock 22.0 to 22.1 mm (0.867 to 0.871 in.) in diameter. Slugs were tumbled to round the edges, then phosphated and lubricated with soap.

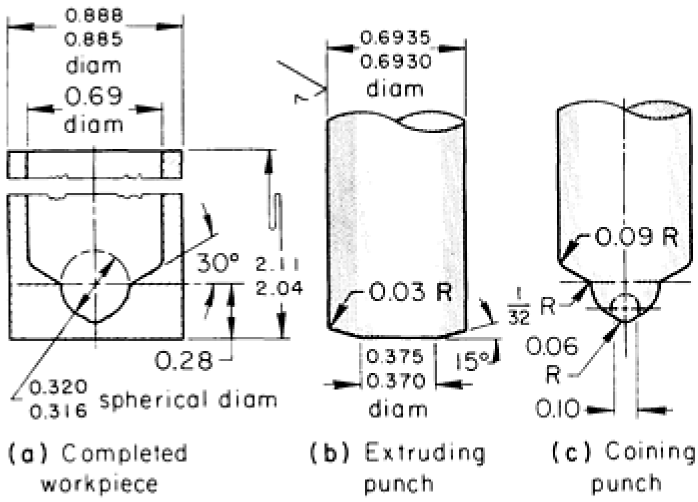

Fig. 6 5120 steel valve tappet (maximum hardness: 143 HB) produced by extrusion and coining with punches shown. Dimensions given in inches

The slugs were fed automatically into the two loading stations of the eight-station dial, then extruded, coined, and ejected. One part was produced in each set of four stations (two parts per stroke). This technique helped to keep the ram balanced, thus avoiding tilting of the press ram, prolonging punch life, and reducing eccentricity between the outside and inside diameters of the extruded part. An eccentricity of less than 0.25 mm (0.010 in.) total indicator reading (TIR) was required. The cup could not be extruded to the finished shape in one hit, because a punch of conelike shape would pierce rather than meter-out the phosphate coating. Therefore, two hits were used--the first to extrude and the second to coin. Punches are shown in Fig. 6(b) and 6(c). Axial pressure on the punch was about 2205 MPa (320 ksi).

Tubular Parts

Backward and forward extrusion, drawing, piercing, and sometimes upsetting are often combined in a sequence of operations to produce various tubular parts. The following example describes a procedure for extruding a part having a long tubular section.

Example 2: Producing Axle-Housing Spindles in Five Operations.

An axle-housing spindle was produced from a slug by backward extruding, piercing, and three forward extruding operations, as shown in Fig. 7. The 10 kg (22.5 lb) slug was prepared by sawing and then annealing in a protective atmosphere at 675 to 730 °C (1250 to 1350 °F) for 2 h, followed by air cooling. The slug was then cleaned, phosphate treated, and coated with soap. After backward extruding and piercing, and again after the first forward extruding operation, the work-piece was reannealed and recoated.

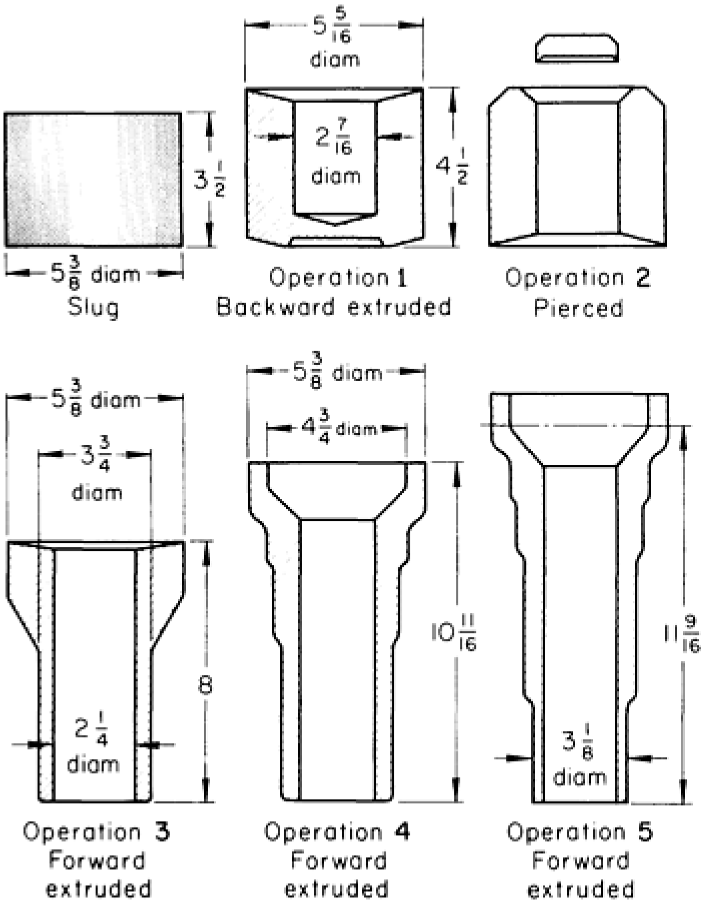

Fig. 7 1030 steel (hardness: 75 to 80 HRB) axle-housing spindle produced by extruding and piercing in five operations. Dimensions given in inches

A 49 MN (5500 tonf) crank press operated at 14 strokes per minute was used. The punches were made of D2 tool steel, and the die inserts of A2 tool steel.

Stepped Shafts

Three methods are commonly used to cold form stepped shafts. If the head of the shaft is relatively short (length little or no greater than the headed diameter), it can be produced by upsetting (heading). For a head more than about $2\frac{1}{2}$ diameters long, however, upsetting in a single operation is not advisable; buckling will result because of the excessive length-to-diameter ratio of the unsupported portion of the slug. Under these conditions, forward extrusion or multiple-operation upsetting should be considered.

Forward extrusion can be done in a closed die or an open die (Fig. 8). In a closed die, the slug is completely supported, and the cross-sectional area can be reduced by as much as 70%. Closed-die extrusion gives better dimensional accuracy and surface finish than the open-die technique. However, if the length-to-diameter ratio of the slug is more than about 4 to 1, friction along the walls of the die is so high that the closed-die method is not feasible, and an open die must be used. In an open die, reduction must be limited to about 30%, or the unsupported portion of the slug will buckle. Stepped shafts can, however, be extruded in open dies using several consecutive operations, as described in the following example.

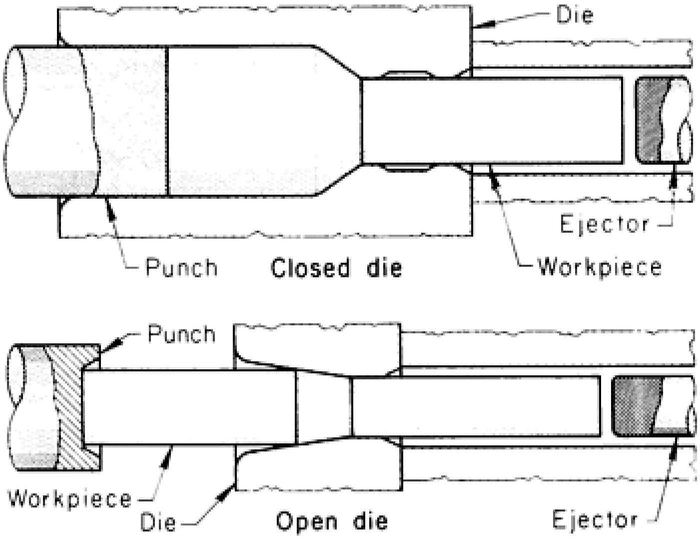

Fig. 8 End of stroke in the forward extrusion of a stepped shaft in a closed die and an open die

Example 3: Transmission Output Shaft Forward Extruded in Four Passes in an Open Die.

A transmission output shaft was forward extruded from a sheared slug in four passes through a four-station open die, as shown in Fig. 9. Extrusion took place in two directions simultaneously. Transfer from station to station was accomplished by a walking-beam mechanism.

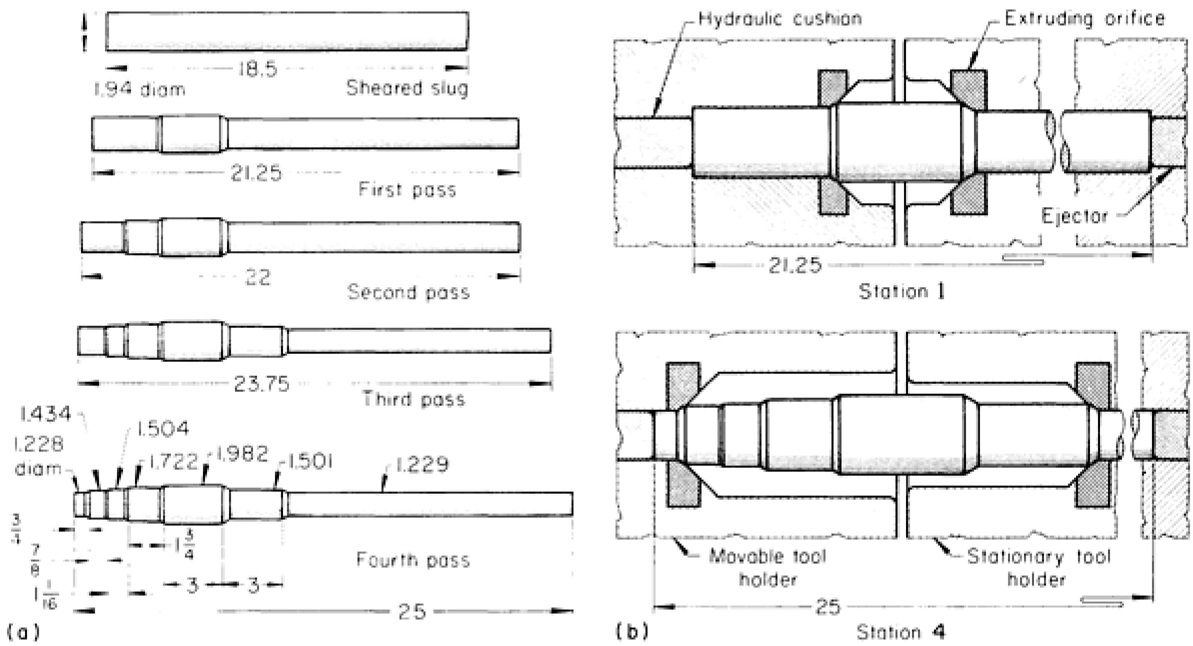

Fig. 9 4028 steel transmission shaft produced by four-pass forward extrusion in a four-station open die. (a) Shapes produced in extrusion. (b) Two of the die stations. Dimensions given in inches

Air-actuated V-blocks (not shown in Fig. 9) were used to clamp the large diameter of the shaft to prevent buckling. A hydraulic cushion (Fig. 9) contacted the slug at the start of the stroke and remained in contact with the workpiece throughout the cycle. Therefore, extrusion into the stationary tool holder took place first, ensuring that variation in finished length, caused by variation in stock diameter, was always in the movable tool holder. Each station of the die was occupied by a workpiece at all times; a finished piece was obtained with each stroke of the press. The amount of area reduction was about the same for each pass and totaled 65% for the four passes.

The cold working caused a marked change in the mechanical properties of the workpiece. Tensile strength increased from 585 to 945 MPa (85 to 137 ksi), yield strength increased from 365 to 860 MPa (53 to 125 ksi), elongation decreased from 26 to 7%, and reduction of area decreased from 57 to 25%.

Extrusion Combined with Cold Heading

The combination of cold extrusion and cold heading is often the most economical means of producing hardware items and machinery parts that require two or more diameters that are widely different (see also the article "Cold Heading" in this Volume). Such parts are commonly made in two or more passes in some type of heading machine, although presses are sometimes used for relatively small parts. Presses are required for the heading and extruding of larger parts.

Parts that have a large difference in cross-sectional area and weight distribution cannot be formed economically from material equivalent in size to the smallest or largest diameter of the completed part. The most economical procedure consists of selecting material of an intermediate size, achieving a practical amount of reduction of area during forward extrusion, and forming the large sections of the part by heading. This practice is demonstrated in the following examples.

Example 4: Adjusting Screw Blank Produced by Forward Extrusion and Severe Heading in Three Operations.

The blank for a knurled-head adjusting screw, shown in Fig. 10, was made from annealed and cold-drawn rod that was coated with lime and a soap lubricant at the mill. In this condition, the rod was fed to a heading machine, in which it was first cut to slug lengths. The slugs were then lubricated with an oil or a water-soluble lubricant containing extreme-pressure additives. As shown in Fig. 10, the slug was extruded in one die, and the workpiece was then transferred to a second die, in which it was cold headed in two operations--the first for stock-gathering, and the second for completing the head (which represents severe cold heading). Except for the extrusion die, which was made from carbide, all dies and punches were made from M2 and D2 steels hardened to 60 to 62 HRC. Tool life for the carbide components was 1 million pieces; for the tool steel components, 250,000 pieces. Production rate was 6000 pieces per hour.

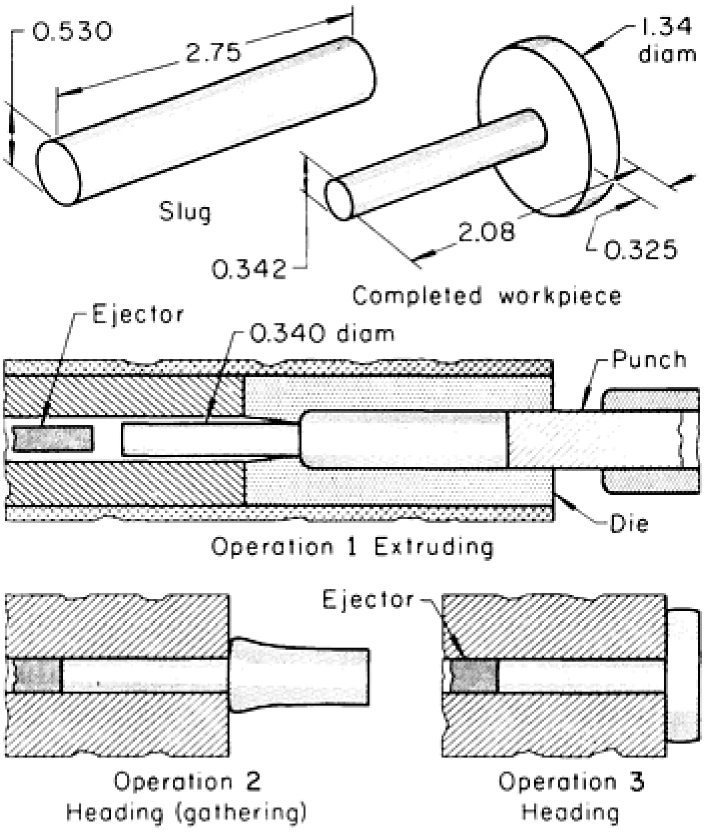

Fig. 10 1018 steel adjusting-screw blank formed by forward extruding and severe cold heading. Dimensions given in inches

Extrusion of Hot Upset Preforms

Although the use of symmetrical slugs as the starting material for extrusion is common practice, other shapes are often used as the starting slugs or blanks. One or more machining operations sometimes precede extrusion in order to produce a shape that can be more easily extruded. The use of hot upset forgings as the starting material is also common practice. Hot upsetting followed by cold extrusion is often more economical than alternative procedures for producing a specific shape. Axle shafts for cars and trucks are regularly produced by this practice; the advantages include improved grain flow as well as low cost. A typical application is described in the following example.

Example 5: Hot Forging and Cold Extrusion of Rear-Axle Drive Shafts.

The fabrication of rear-axle drive shafts (Fig. 11) for passenger cars and trucks by three-operation cold extrusion improved surfaces (and consequently fatigue resistance), maintained more uniform diameters and closer dimensional tolerances, increased strength and hardness, and simplified production. The drive shafts were hot upset forged to form the flange and to preform the shaft, and they were cold extruded to lengthen the shaft. The flange could have been upset as a final operation after the shaft had been cold extruded to length, but this would have required more passes in the extrusion press than space allowed. Hot upsetting and cold extrusion replaced a hammer forging and machining sequence after which the flange, a separate piece, had been attached.

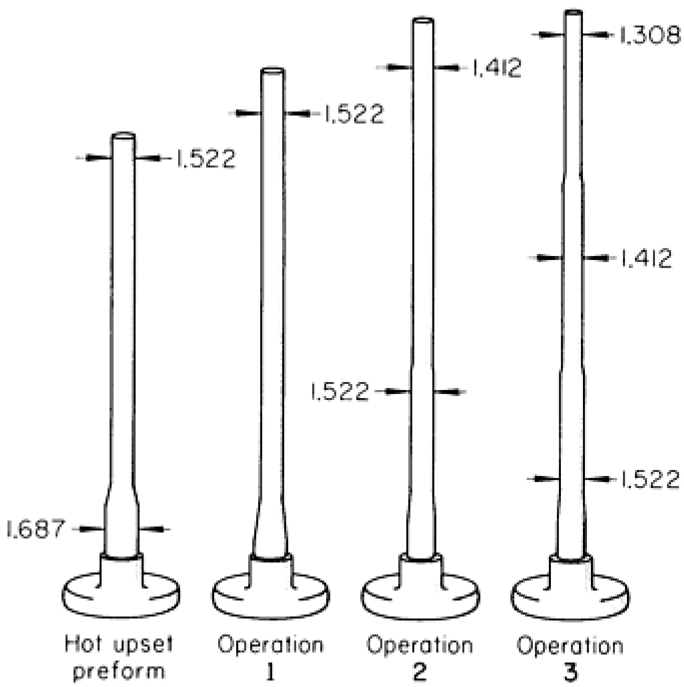

Fig. 11 1039 steel rear-axle drive shaft produced by cold extruding an upset forging in three operations. Billet weight: 36 kg (79.5 lb). Dimensions given in inches

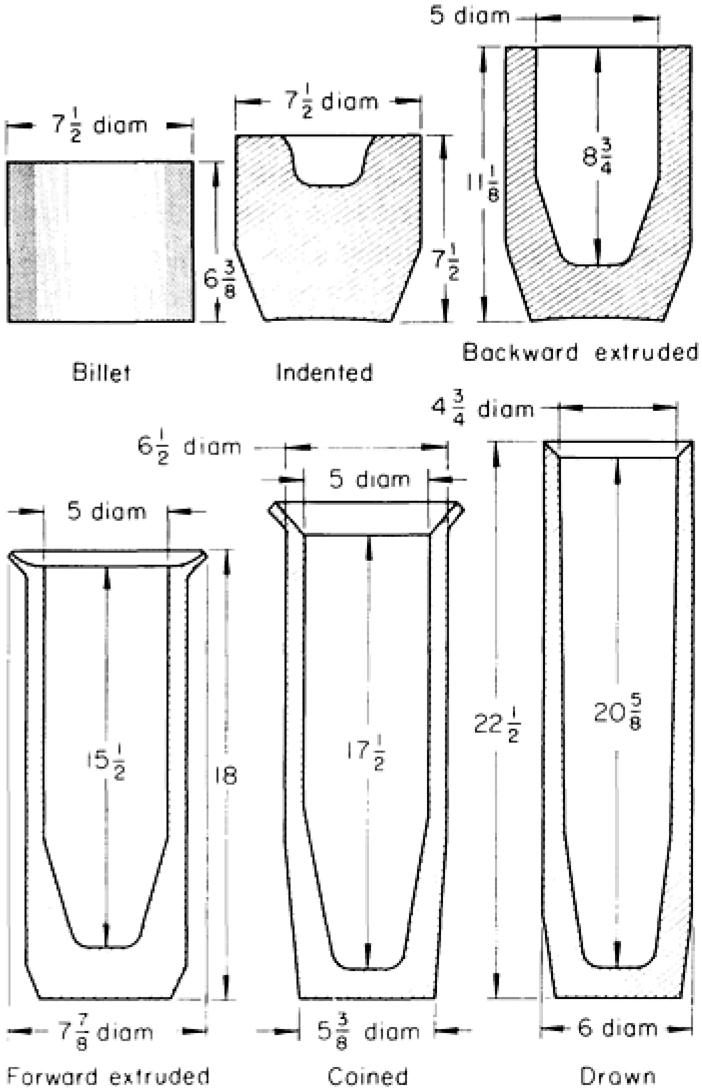
Steel was extrusion-quality 1039 in 42.9 mm ($1\frac{11}{16}$ in.) diam bars. The bars were sheared to lengths of 757 to 929 mm ($29\frac{13}{16}$ to $36\frac{9}{16}$ in.), then hot forged and shot blasted. A continuous conveyor took the hot upset preforms through a hot alkaline spray cleaner, a hot spray rinse, a zinc phosphating bath (75 °C, or 165 °F, for 5 min), a cold spray rinse, a hot spray rinse, and finally a soap tank (90 °C, or 190 °F, for 5 min). As shown in Fig. 11, cold extrusion was a three-operation process that increased the length of the shaft and reduced the smallest diameter to 33.2 mm (1.308 in.).

Extrusion of Large Parts

Although most cold extrusion of steel is confined to relatively small parts (starting slugs seldom weigh more than 11.3 kg, or 25 lb), much larger parts have been successfully cold extruded. For press operations, the practical extremes of part size are governed by the availability of machinery and tool materials, the plasticity of the work material, and economical production quantities. Bodies for large-caliber ordnance shells have been successfully produced by both hot and cold extrusion processes. The procedure used in the production of these large parts by cold extrusion is described in the following example.

Example 6: Use of Extrusion in Multiple-Method Production of Shell Bodies.

Figure 12 shows the progression of shapes resulting from extrusion, coining, and drawing in a multiple-method procedure for producing bodies for 155 mm shells from descaled 1012 steel billets 190 mm ($7\frac{1}{2}$ in.) in diameter that weighed 36 kg (79.5 lb) each. The sequence of operations is listed with Fig. 12. Production of these shell bodies was designed for semicontinuous operation that included annealing, cleaning, and application of lubricant between press operations.



Sequence of operations

Cold saw the billet.
Chamfer sawed edges.
Apply lubricant as follows:

Degrease in boiling caustic; rinse.
Pickle in sulfuric acid; rinse.

Apply zinc phosphate.
Apply zinc stearate.

Cold size indent (see illustration above).
Induction normalize (925 to 980 °C, or 1700 to 1800 °F).
Apply lubricant as in step 3.
Backward extrude (see illustration).
Induction normalize (see step 5).
Apply lubricant as in step 3.
Forward extrude in two stages to shape in illustration.
Anneal lip by localized induction heating (815 to 830 °C, or 1500 to 1525 °F).
Apply lubricant as in step 3.
Coin base and form boat tail to finish dimension and coin bottom (see illustration).
Final draw (see illustration).
Turn and recess lip.
Induction anneal nose (790 to 815 °C, or 1450 to 1500 °F).
Apply lubricant as in step 3.
Expand bourrelet in No. 6 press.
Form nose.
Anneal for relief of residual stress.

Fig. 12 1012 steel 155 mm (6 in.) shell body produced by a multiple-step procedure that included cold extrusion. Dimensions given in inches

Dimensional Accuracy

In cold extrusion, the shape and size of the workpiece are determined by rigid tools that change dimensionally only from wear. Because tool wear is generally low, successive parts made by cold extrusion are nearly identical. The accuracy that can be achieved in cold extrusion depends largely on the size and shape of the given section.

Tolerances for cold extrusion are commonly denoted as close, medium, loose, and open. Definitions of these tolerances, as well as applicability to specific types of extrusions, are discussed below.

Close tolerance is generally considered to be ±0.025 mm (±0.001 in.) or less. Close tolerances are usually restricted to small (<25 mm, or 1 in.) extruded diameters.

Medium tolerance denotes ±0.13 mm (±0.005 in.). Extruded diameters of larger parts (up to 102 mm, or 4 in.), headed diameters of small parts, and concentricity of outside and inside diameters in backward extruded parts are typical of dimensions on which it is practical to maintain medium tolerance.

Loose tolerance denotes ±0.38 mm (±0.015 in.). This tolerance generally applies to short lengths of extruded parts less than about 89 mm ($3\frac{1}{2}$ in.) long.

Open tolerance is generally considered to be greater than ±0.38 mm (±0.015 in.). This tolerance applies to length dimensions of large, slender parts (up to 508 mm, or 20 in., and sometimes longer).

Variation. With reasonable maintenance of tools and equipment, the amount of variation of a given dimension is usually small for a production run. Some drift can be expected as the tools wear and work metal properties vary from lot to lot.

Cold Extrusion

Revised by P.S. Raghupathi, Battelle Columbus Division; W.C. Setzer, Consultant; and M. Baxi, Ullrich Copper, Inc.

Causes of Problems

The problems most commonly encountered in cold extrusion are:

- Tool breakage
- Galling or scoring of tools
- Workpieces sticking to dies
- Workpieces splitting on outside diameter or cupping in inside diameter
- Excessive buildup of lubricant in dies

Table 1 lists the most likely causes of these problems.

Table 1 Problems in cold extrusion and some potential causes

Problem	Potential cause
Tool breakage	**Slug not properly located in die** **Slug material not completely annealed** **Slug not symmetrical or not properly shaped** **Improper selection or improper heat treatment of tool material** **Misalignment and/or excessive deflection of tools and equipment** **Incorrect preloading of dies** **Damage caused by double slugging or overweight slugs**
Galling or scoring of tools	**Improper lubrication of slugs** **Improper surface finish of tools** **Improper selection or improper heat treatment of tool material** **Improper edge or blend radii on punch or extrusion die**
Workpieces sticking to dies	**No back relief on punch or die** **Incorrect nose angle on punch and incorrect extrusion angle of die** **Galled or scored tools**
Workpieces splitting on outside diameter or forming chevrons on inside diameter	**Slug material not completely annealed** **Reduction of area either too great or too small** **Excessive surface seams or internal defects in work material** **Incorrect die angles**
Excessive buildup of lubricant on dies	**Inadequate vent holes in die** **Excessive amount of lubricant used** **Lack of a means of removal of lubricant, or failure to prevent lubricant buildup by spraying the die with an air-oil mist**

Cold Extrusion of Aluminum Alloy Parts

Aluminum alloys are well adapted to cold (impact) extrusion. The lower-strength, more ductile alloys, such as 1100 and 3003, are the easiest to extrude. When higher mechanical properties are required in the final product, heat-treatable grades are used.

The cold extrusion process should be considered for aluminum parts for the following reasons. High production rates--up to 4000 pieces per hour--can be achieved. However, even when parts are large or of complex shape, lower production rates may still be economical. The impact-extruded part itself has a desirable structure. It is fully wrought, achieving maximum strength and toughness. It is a near-net shape. There is no parting line, and all that may be required is a trim to tubular sections. Surface finish is good. Impacts have zero draft angles, and tolerances are tight. Once impacted, sections can be treated in the same manner as any other piece of wrought aluminum.

From a design standpoint, aluminum impacts should be considered in the following situations:

- For hollow parts with one end partially or totally closed
- When multiple-part assemblies can be replaced with a one-piece design
- When a pressure-tight container is required
- When bottoms must be thicker than the walls or the bottom design includes bosses, tubular extensions, projections, or recesses
- When a bottom flange is required
- When bottoms, sidewalls, or heads have changes in section thickness

Aluminum provides the characteristics of good strength-to-weight ratio, machinability, corrosion resistance, attractive appearance, and high thermal and electrical conductivity. It is also nonmagnetic, nonsparking, and nontoxic.

Although nearly all aluminum alloys can be cold extruded, the five alloys listed in Table 2 are most commonly used. The alloys in Table 2 are listed in the order of decreasing extrudability based on pressure requirements. The easiest alloy to extrude (1100) has been assigned an arbitrary value of 1.0 in this comparison.

Table 2 Relative pressure requirements for the cold extrusion of annealed slugs of five aluminum alloys (alloy 1100 = 1.0)

Alloy	Relative extrusion pressure
1100	**1.0**
3003	**1.2**
6061	**1.6**
2014	**1.8**

7075	**2.3**

Temper of Work Metal

The softer an alloy is, the more easily it extrudes. Many extrusions are produced directly from slugs purchased in the O (annealed, recrystallized) temper. In other applications, especially when slugs are machined from bars, the slugs are annealed after machining and before surface preparation. The raw material is often purchased in the F (as-fabricated) temper to improve machinability, and the cut or punched slugs are then annealed before extrusion.

When extruding alloys that will be heat treated, such as 6061, common practice is to extrude the slug in the O temper, solution treat the preform to the T4 temper, and then size or finish extrude. This procedure has two advantages. First, after solution treatment, the metal is reasonably soft and will permit sizing or additional working, and, second, the distortion caused by solution treatment can be corrected in final sizing. After sizing, the part can be aged to the T6 temper, if required.

Size of Extrusions

Equipment is readily available that can produce backward and forward extrusions up to 406 mm (16 in.) in diameter. Backward extrusions can be up to 1.5 in (60 in.) long. The length of forward extrusions is limited only by the cross section of the part and the capacity of the press. Irrigation tubing with a 152 mm (6 in.) outside diameter and a 1.47 mm (0.058 in.) wall thickness has been produced in lengths up to 12.2 m (40 ft). Small-outside-diameter tubing (<25 mm, or 1 in.) has been produced by cold extrusion in 4.3 in (14 ft) lengths.

Hydraulic extrusion and forging presses, suitably modified, are used for making very large extrusions. Parts up to 840 mm (33 in.) in diameter have been produced by backward extrusion from high-strength aluminum alloys in a 125 MN (14,000 tonf) extrusion press. Similar extrusions up to 1 m (40 in.) in diameter have been produced in large forging presses.

Presses

Both mechanical and hydraulic presses are used in the extrusion of aluminum. Presses for extruding aluminum alloys are not necessarily different from those used for steel. There are, however, two considerations that enter into the selection of a press for aluminum. First, because aluminum extrudes easily, the process is often applied to the forming of deep cuplike or tubular parts, and for this application, the press should have a long stroke. Again, because aluminum extrudes easily, the process is often used for mass production, which requires that the press be capable of high speeds.

The press must have a stroke that is long enough to permit removal of the longest part to be produced. Long shells are sometimes cold extruded in short-stroke knuckle-type presses, in which the punch is tilted forward or backward for removal of the workpiece.

Because of their high speeds, mechanical crank presses are generally preferred for producing parts requiring up to about 11 MN (1200 tonf) of force. Production of as many as 70 extrusions per minute (4200 per hour) is not unusual, and higher production rates are often obtained. Therefore, auxiliary press equipment is usually designed for a high degree of automation when aluminum is to be extruded.

Cold-heading machines are also used for the cold extrusion of aluminum parts. Hollow aluminum rivets are formed and extruded in cold headers in mass-production quantities. In general, the extruded parts are small and usually require an upsetting operation that can be done economically in a cold header.

Tooling

Tools designed especially for extruding aluminum may be different from those used for steel, because aluminum extrudes more easily. For example, a punch used for the backward extrusion of steel should not have a length-to-diameter ratio greater than about 3 to 1, however, this ratio, under favorable conditions, can be as high as 17 to 1 for aluminum (although a 10 to 1 ratio is usually the practical maximum).

Dies. Three basic types of dies for extruding aluminum are shown in Fig. 13. Solid dies are usually the most economical to make. Generally, a cavity is provided in each end so that the die can be reversed when one end becomes cracked or worn.

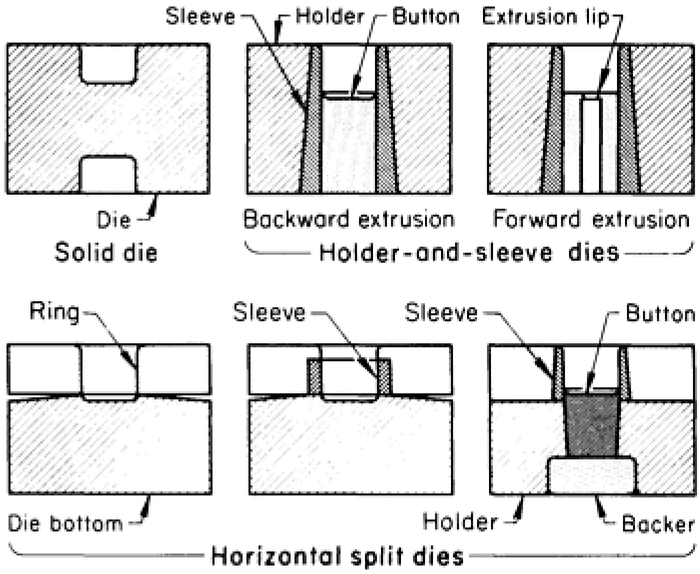

Fig. 13 Three types of dies used in the cold extrusion of aluminum alloy parts

Holder-and-sleeve dies are used when extrusion pressures are extremely high. This type of die consists of a shrink ring or rings (the holder), a sleeve, and an insert (button). The die sleeve is prestressed in compression in the shrink ring to match the tension stress expected during extrusion.

Horizontal split dies are composed of as many as four parts: a shrink ring, a sleeve (insert), and a one-piece or two-piece base. Figure 13 identifies the one-piece base as a die bottom, and the components of the two-piece base as a holder and a backer.

Compared to the die cavities used in the backward extrusion of steel, the die cavities for aluminum shown in Fig. 14 are notably shallow, reflecting a major difference in the extrusion characteristics of the two metals. Steel is more difficult to extrude, requiring higher pressures and continuous die support of the workpiece throughout the extrusion cycle. In contrast, aluminum extrudes readily, and when the punch strikes the slug in backward extrusion, the metal squirts up the sides of the punch, following the punch contours without the external restraint or support afforded by a surrounding die cavity.

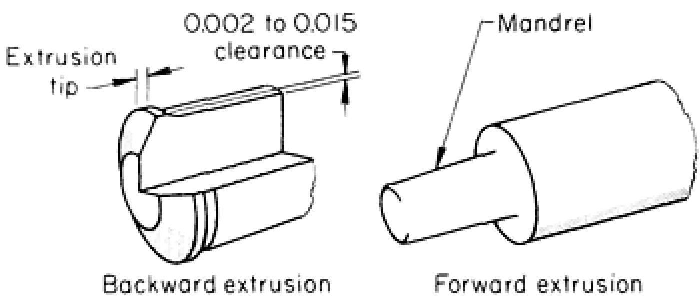

Fig. 14 Typical punches for backward and forward extrusion of aluminum alloy parts. Clearance given in inches

Punches. Typical punches for forward and backward extrusion are shown in Fig. 14. In the backward extrusion of deep cuplike parts, specially designed punches must be used to facilitate stripping.

Tool Materials. Typical tool materials and their working hardnesses for the extrusion of aluminum are given in Table 3. Additional information on tool materials is available in the section "Tool Materials" in this article.

Table 3 Typical tool steels used in extruding aluminum

Tool	**AISI steel**	Hardness, HRC
Die, solid	W1	**65-67**
Die sleeve[(a)]	D2	**60-62**
	L6	**56-62**
	H13	**48-52**
Die button[(b)]	H11	**48-50**
	H13	**48-50**
	L6	**50-52**

	H13	**42-48**
	4130	**36-44**
	4140	**36-44**

(a) Cemented carbide is sometimes used for die sleeves.

(b) Maraging steel is sometimes used for die buttons.

Stock for Slugs

Slugs for extrusions are obtained by blanking from plate; by sawing, shearing, or machining from bars; or by casting. In general, the methods for preparing aluminum slugs are similar to those for preparing slugs from other metals and are therefore subject to the same advantages and limitations (see the section "Preparation of Slugs" in this article).

Rolled aluminum alloy plate is widely used as a source of cold extrusion stock. The high speed at which slugs can be prepared is the major advantage of blanking from rolled plate. When slug thickness is greater than about 50 mm (2 in.) or when the thickness-to-diameter ratio is greater than about 1 to 1, blanking from plate is uneconomical, if not impossible. Blanking is also excessively wasteful of metal, which negates a principal advantage of the cold extrusion process.

Sawing from bars is widely used as a method of obtaining slugs. More accurate slugs are produced by sawing than by blanking; however, as in blanking, a considerable amount of metal is lost.

When "doughnut" slugs are required, they can be sawed from tubing, or they can be punched, drilled, or extruded. Machined slugs (such as those produced in an automatic bar machine) are generally more accurate but cost more than those produced by other methods.

Cast slugs can also be used; the selection of a cast slug is made on the basis of adequate quality at lower fabricating cost. Compositions that are not readily available in plate or bar stock can sometimes be successfully cast and extruded. There is often a savings in metal when a preform can be cast to shape.

Tolerance on slug volume may vary from ±2% to ±10%, depending on design and economic considerations. When extrusions are trimmed, as most are, slug tolerance in the upper part of the above range can be tolerated. When extrusions are not trimmed and dimensions are critical, the volume tolerance of the slugs must be held close to the bottom of the range. In the high-quantity production of parts such as thin-wall containers, the degree to which slug volume must be controlled is often dictated by metal cost.

Surface Preparation

Slugs of the more extrudable aluminum alloys, such as 1100 and 3003, are often given no surface preparation before a lubricant is applied prior to extrusion. For slugs of the less extrudable aluminum alloys or for maximum extrusion severity or both, surface preparation may be necessary for retention of lubricant. One method is to etch the slugs in a heated caustic solution, followed by water rinsing, nitric acid desmutting, and a final rinse in water. For the most severe extrusion, slug surfaces are given a phosphate coating before the lubricant is applied. Additional information on the alkaline etching, acid desmutting, and phosphate coating of aluminum alloys is available in the article "Surface Engineering of Aluminum and Aluminum Alloys" in *Surface Engineering*, Volume 5 of the *ASM Handbook.*

Lubricants. Aluminum and aluminum alloys can be successfully extruded with such lubricants as high-viscosity oil, grease, wax, tallow, and sodium-tallow soap. Zinc stearate, applied by dry tumbling, is an excellent lubricant for extruding aluminum. In applications in which it is desirable to remove the lubricant, water-soluble lubricants are used to reduce the wash cycle.

The lubricant should be applied to metal surfaces that are free from foreign oil, grease, and dirt. Preliminary etching of the surfaces (see above) increases the effectiveness of the lubricant.

For the most difficult aluminum extrusions (less extrudable alloys or greater severity or both), the slugs should be given a phosphate treatment, followed by application of a soap that reacts with the surface to form a lubricating layer similar to that formed when extruding steel.

Impact Parts

Impact parts range from simple cuplike parts such as compressed air filter bowls, switch housings, and brake pistons to such complex parts as aerosol cylinders and ribbed cans, electrical fittings, motor housings, and home appliance parts. Numerous examples and design criteria are given in "Aluminum Impacts Design Manual and Application Guide" (see the Selected References at the end of this article).

Shallow cuplike parts can be easily extruded from most of the wrought aluminum alloys. If the wall thickness is uniform and the bottom is nearly flat, shallow cups can be produced in one hit (blow) at high production rates; if the shape is more complex, two or more hits may be needed. In the following example two hits were used to produce a part with an internal boss.

Example 7: Use of a Preform for Producing a Complex Bottom.

The aluminum alloy 1100-O housing shown in Fig. 15 required two extrusion operations on a hydraulic 3 MN (350 tonf) press because of the internal boss, which was formed by backward extrusion in a second operation, as shown in Fig. 15. The blended angle in the preform functioned as a support for the finishing punch during extrusion of the internal boss. This counteracted the side pressure that was created as the metal flowed into the cavity of the finishing punch.

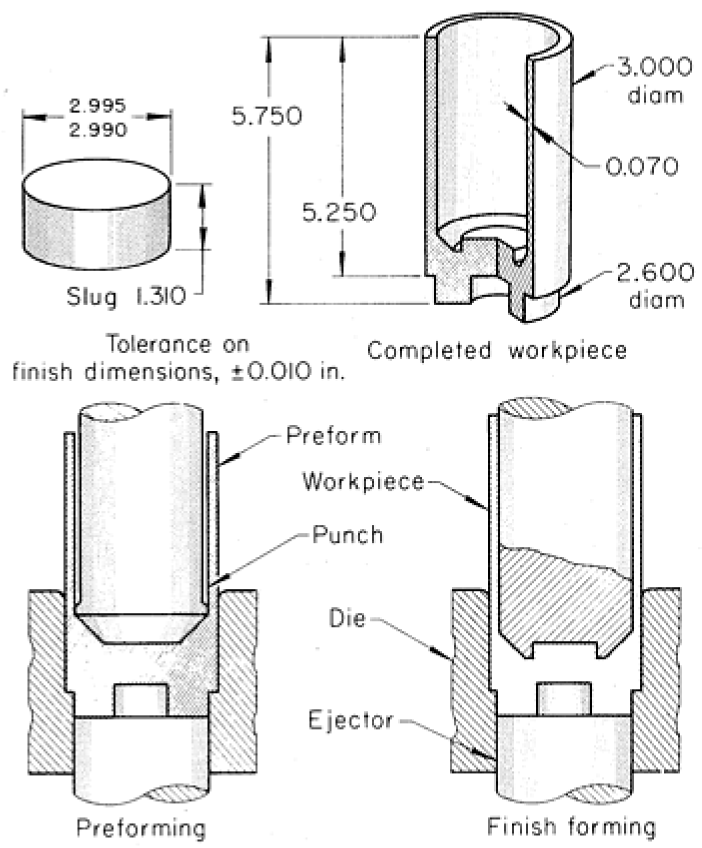

Fig. 15 Aluminum alloy 1100-O housing that was extruded in two operations because of an internal boss.

Dimensions given in inches

The slug was sawed from bar and annealed; zinc stearate lubricant was used. The production rate was 350 pieces per hour for the preforming operation and 250 pieces per hour for finish forming. Minimum tool life was 100,000 pieces.

Deep Cuplike Parts. Although cups having a length as great as 17 times the diameter have been produced, this extreme condition is seldom found in practice, because a punch this slender is likely to deflect and cause nonuniform wall thickness in the backward-extruded product. The length of the cup and the number of operations (use of preform) are not necessarily related. Whether or not a preform is required depends mainly on the finished shape, particularly of the closed end. When forming deep cups from heat-treatable alloys such as 6061, if the amount of reduction is 25% or more in the preform, the workpiece should be reannealed and relubricated between reforming and finish extruding.

Parts with Complex Shapes. Producing extrusions from aluminum and aluminum alloys in a single hit is not necessarily confined to simple shapes. The extrusion described in Example 9 was produced in a single hit despite its relatively complex shape. For extrusions with longitudinal flutes, stems, or grooves, the use of one of the most extrudable alloys, such as 1100, is helpful in minimizing difficulties. Sometimes, however, a less extrudable alloy can be used to form a complex shape in one hit.

The successful extrusion of complex shapes, especially in a single hit, depends greatly on tool design and slug design. Some developmental work is usually required for each new job before it can be put into production.

Example 8: Maximum Extrudability for a Complex Shape.

The hydraulic cylinder body shown in Fig. 16 was extruded from a solid slug in one hit. Aluminum alloy 1100, which has maximum extrudability, was required for this part because of the abrupt changes in section of the cylinder body. Surface cracks and laps resulted when more difficult-to-extrude alloys were used. The different wall thicknesses and steps in this design represent near-maximum severity for extruding in one hit, even with the most extrudable alloy. During the development of this part, it was necessary to change the face angles, shorten the steps, and blend the outside ribs more gradually to ensure complete fillout. The part was produced on a 7 MN (800 tonf) mechanical press set at 4.4 MN (500 tonf). The slug was sawed from bar, annealed, and lubricated with zinc stearate. Production rate in a single-station die was 300 pieces per hour, and minimum tool life was 70,000 pieces.

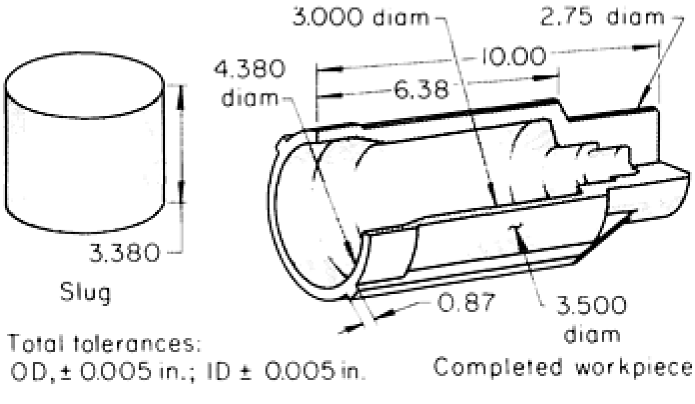

Fig. 16 Aluminum alloy 1100-O hydraulic cylinder body extruded in one hit. The complexity of this part is close to the maximum producible for one-hit extrusion of alloy 1100-O. Dimensions given in inches

Dimensional Accuracy

In general, aluminum extrusions are manufactured to close tolerances. The closeness depends on size, shape, alloy, wall thickness, type and quality of tooling, and press equipment. Lubrication and slug fit in the die are also important.

Wall thickness tolerances range from ±0.025 to ±0.13 mm (±0.001 to ±0.005 in.) for relatively thin-wall cylindrical shapes of moderate size extruded from low-strength alloys, but may be as great as ±0.25 to ±0.38 mm (±0.010 to ±0.015 in.) for large parts of high-strength alloys. Wall-thickness tolerances for rectangular shells range from ±0.13 to ±0.38 mm

(±0.005 to ±0.015 in.), depending on size, alloy, and nominal wall thickness. Diameter tolerances typically range from ±0.025 mm (±0.001 in.) for small parts to ±0.25 to ±0.38 mm (±0.010 to ±0.015 in.) for large high-strength alloy parts. Closer control of diameter can be achieved on small heavy-wall parts by centerless grinding of the extrusions (provided the alloy is one that can be ground satisfactorily). Dimensional tolerances in the forged portion of the impact are influenced by the same variables as those listed above, but a range of ±0.13 to ±0.38 mm (±0.005 to ±0.015 in.) is typical. Variations in extruded length usually necessitate a separate trimming operation.

Surface finish typically ranges from 0.5 to 1.8 μm (20 to 70 μin.). Smoother surfaces can sometimes be obtained by using extreme care in surface preparation and lubrication of the work metal and by paying close attention to the surface condition of the tools.

Cold Extrusion

Revised by P.S. Raghupathi, Battelle Columbus Division; W.C. Setzer, Consultant; and M. Baxi, Ullrich Copper, Inc.

Cold Extrusion of Copper and Copper Alloy Parts

Oxygen-free copper (Copper Development Association alloy C10200) is the most extrudable of the coppers and copper-base alloys. Other grades of copper and most of the copper-base alloys can be cold extruded, although there are wide differences in extrudability among the different compositions. For example, the harder copper alloys, such as aluminum-silicon bronze and nickel silver, are far more difficult to extrude than the softer, more ductile alloys, such as cartridge brass (alloy C26000), which can satisfactorily withstand cold reduction of up to 90% between anneals.

Alloys containing as much as 1.25% Pb can be successfully extruded if the amount of upset is mild and the workpiece is in compression at all times during metal flow. Copper alloys containing more than 1.25% Pb are likely to fracture when cold extruded.

The pressure required for extruding a given area for one of the more extrudable coppers or copper alloys (such as C10200 or C26000) is less than that required for extruding low-carbon steel. However, the pressure required for extruding copper alloys is generally two to three times that required for extruding aluminum alloys (depending on the copper or aluminum alloy being compared).

The length of a backward-extruded section is limited by the length-to-diameter ratio of the punch and varies with unit pressure. This ratio should be a maximum of 5 to 1 for copper. A ratio of 10 to 1 is common for the extrusion of aluminum, and ratios as high as 17 to 1 have been used. The total reduction of area for copper or copper alloys, under the best conditions, should not exceed 93%.

Equipment and Tooling

Copper and copper alloys can be extruded in hydraulic or mechanical presses or in cold-heading machines. Tooling procedures and tool materials for the extrusion of copper alloys are essentially the same as those for extruding steel (see the section "Tool Materials" in this article).

Preparation of Slugs

Sawing, shearing, and machining are the methods used to prepare copper and copper-alloy slugs. Each method has advantages and limitations. Sawing or shearing is generally used to produce solid slugs. Machining (as in a lathe) or cold forming in auxiliary equipment is seldom used unless a hole in the slug, or some other modification, is required.

Surface Preparation. In applications involving minimum-to-moderate severity, copper slugs are often extruded with no special surface preparation before the lubricant is applied. However, for the extrusion of harder alloys (aluminum bronze, for example) or for maximum severity or both, best practice includes the following surface preparation before the lubricant is applied:

- Cleaning in an alkaline cleaner to remove oil, grease, and soil

- Rinsing in water
- Pickling in 10 vol% sulfuric acid at 20 to 65 °C (70 to 150 °F) to remove metal oxides
- Rinsing in cold water
- Rinsing in a well-buffered solution, such as carbonate or borate, to neutralize residual acid or acid salts

Lubrication. Zinc stearate is an excellent lubricant for extruding copper alloys. Common practice is to etch the slugs as described above and then to coat them by dry tumbling in zinc stearate.

Examples of Practice

The following examples describe typical production practice for extruding parts from copper and brass. The part described in Example 10 could have been made by forging, casting, or machining; however, cold extrusion produced more accurate dimensions than forging or casting, consumed less material than machining, and was the lowest-cost method.

Example 9: Shearing, Heading, Piercing, Extruding and Upsetting in a Header.

The plumbing fitting shown in Fig. 17 was made of electrolytic tough pitch copper (alloy C11000) rod cold drawn (about 15% reduction of area) to a diameter of 26.9 mm (1.06 in.). The pipe-taper diameter and the 22.2 mm (0.875 in.) diameter of the tube socket were critical, being specified within 0.064 mm 0.0025 in.).

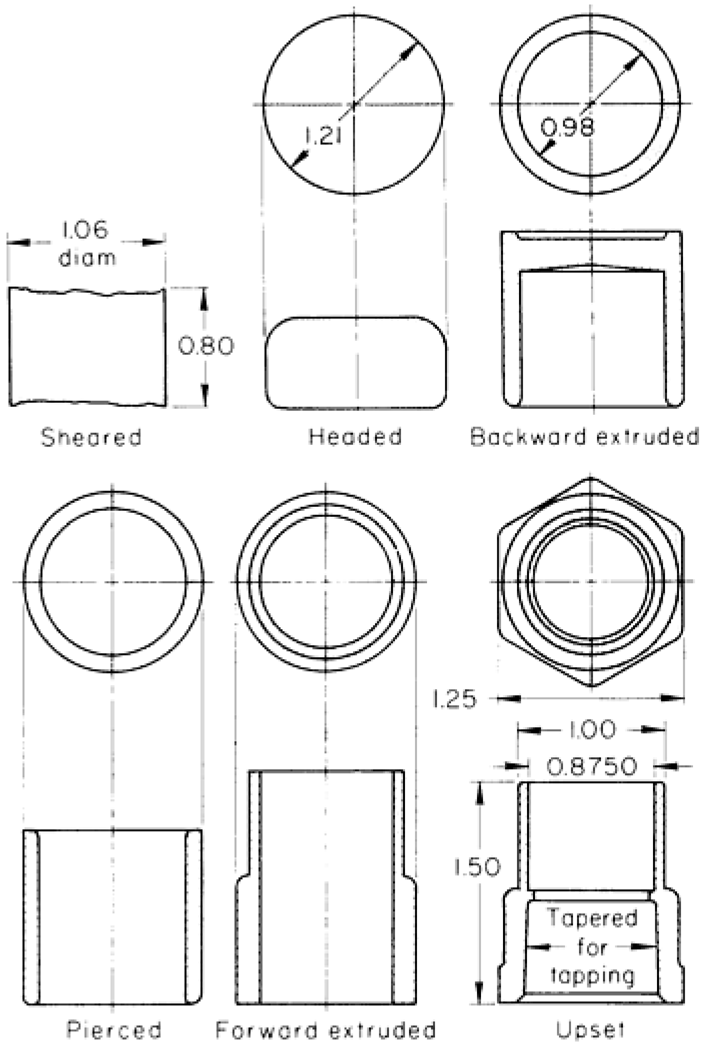

Fig. 17 Copper alloy C11000 plumbing fitting produced by the operations shown, including cold forward extrusion. Dimensions given in inches

Manufacture of the fitting consisted of feeding the rod stock into the cold-heading machine, which cut the stock into slugs 20.3 mm (0.80 in.) long and transferred the slugs progressively to dies for heading, backward extruding, piercing, forward extruding, and upsetting (Fig. 17). Only trimming on each end and tapping were required for completion. The extrusion equipment consisted of a five-die cold-heading machine.

The final cross-sectional area of the thin end after extrusion was 16.4% of the 30.7 mm (1.21 in.) diam headed preform from which the fitting was made. A reduction of this magnitude could have been made in one operation if a cylindrical rod were being extruded from the preform. The shape, however, was not suitable for production in one operation. Therefore, the fitting was made by backward and forward extrusion and mild upsetting. Production rate at 100% efficiency was 3600 pieces per hour, and minimum life of the D2 tool steel dies was 200,000 pieces.

Difficult Extrusions. The part described in the following example represents a difficult extrusion for two reasons. First, the metal (tellurium copper, alloy C14500) is one of the more difficult-to-extrude copper alloys, and second, the configuration (12 internal flutes and 12 external ribs) is difficult to extrude regardless of the metal used.

Example 10: Extrusion Versus Brazed Assembly for Lower Cost.

The rotor shown in Fig. 18 was originally produced by brazing a machined section into a drawn ribbed and fluted tubular section. By an improved method, this rotor was extruded from a sawed, annealed slug in one hit in a 1.7 MN (190 tonf) mechanical press. A lanolin-zinc stearate-trichloroethylene lubricant was used to produce 1800 pieces per hour. The extruded rotor was produced at less cost and had better dimensional accuracy than the brazed assembly, and there were fewer rejects. Minimum tool life was 50,000 pieces.

Impact Extrusion of Magnesium Alloys

Impact extrusion is used to produce symmetrical tubular magnesium alloy workpieces, especially those with thin walls or irregular profiles for which other methods are not practical. As applied to magnesium alloys, the extrusion process cannot be referred to as cold because both blanks and tooling must be preheated to not less than 175 °C (350 °F); workpiece temperatures of 260 °C (500 °F) are common.

Length-to-diameter ratios for magnesium extrusions may be as high as 15 to 1. There is no lower limit, but parts with ratios of less than about 2 to 1 can usually be press drawn at lower cost. A typical ratio is 8 to 1, and parts with higher length-to-diameter ratios are more amenable to forward extrusion than to backward extrusion. At all ratios, the mechanical properties of magnesium extrusions normally exceed those of the blanks from which they are made, because of the beneficial effects of mechanical working.

Equipment and Tooling

Mechanical presses are faster than hydraulic presses and are therefore used more often for impact extrusion, except when long strokes are needed. Presses with a capacity of 900 kN (100 tonf) and a stroke of 152 mm (6 in.) are adequate for most extrusion applications. Up to 100 extrusions per minute have been produced. Extrusion rate is limited only by press speed.

Dies for the impact extrusion of magnesium alloys differ from those used for other metals, because magnesium alloys are extruded at elevated temperature (usually 260 °C, or 500 °F). Common practice is to heat the die with tubular electric heaters. The die is insulated from the press, and an insulating shroud is built around the die. The top of the die is also covered, except for punch entry and the feeding and ejection devices. The punch is not heated, but it becomes hot during continuous operation; therefore, the punch should be insulated from the ram.

Punches and dies are usually made of a hot-work tool steel, such as H12 or H13, heat treated to 48 to 52 HRC. In one application, tools made of heat-treated H13 produced 200,000 extrusions. Carbide dies can be used and can extrude up to 10 million pieces.

The sidewalls of the die cavity should have a draft of approximately 0.002 mm per mm (0.002 in. per in.) of depth, which prevents the extrusion from sticking in the cavity. In normal operation, the part stays on the punch and is stripped from it on the upward stroke.

Procedure

Preparation of Slugs. Magnesium alloy slugs are prepared by the same methods as other metals--sawing from bar stock or blanking from plate, if rough edges can be tolerated. Slugs can also be made by casting. Slugs must be uniform in size and shape for centering in the die in order to ensure uniform wall thickness on the extrusion, which in turn depends on the clearance between die and punch. Slugs are lubricated by tumbling in a graphite suspension for 10 min until a dry coat develops.

For automatic impact extrusion of magnesium parts, the lubricated slugs are loaded into a hopper feed. The slugs are heated by an electric heater as they pass along the track between the hopper and the die.

Extrusion Practice. The heated slug is loaded onto the heated die, and the press is activated to produce the extrusion. Operating temperatures for the extrusion of magnesium alloys range from 175 to 370 °C (350 to 700 °F), depending on composition and operating speed. The operating temperature should be held constant in order to maintain tolerances.

In practice, slugs and dies are usually heated to 260 °C (500 °F) for feeding by tongs, because the rate of operation is slow. In automatic feeding, the slug and die temperature can be as low as 175 °C (350 °F), because speed is greater; dies absorb heat during operation and can increase in temperature by as much as 65 °C (150 °F). When a decrease in properties is not important, operating temperatures can be higher.

Extrusion Pressures

Pressures for the impact extrusion of magnesium alloys are about half those required for aluminum and depend mainly on alloy composition, amount of reduction, and operating temperature. Table 4 shows the pressures required to extrude several magnesium alloys to a reduction of area of 85% at temperatures ranging from 230 to 400 °C (450 to 750 °F).

Table 4 Pressures required for the impact extrusion of four magnesium alloys at various temperatures

Test pieces were extruded to a reduction in area of 85%.

AZ80A	496	72	483	70	441	68	455	66	441	64	428	62	414	**60**

Thermal Expansion

Magnesium has a relatively high coefficient of thermal expansion compared to steel. Therefore, in order to ensure that the magnesium extrusion, when cooled to room temperature, will be within dimensional tolerance, it is necessary to multiply the room-temperature dimensions of steel tools by a compensatory factor for the temperature at which the magnesium alloy is to be extruded.

Tolerances

The tolerances for magnesium alloy extrusions are influenced by the size and shape of the part, the length-to-diameter ratio, and the press alignment. Table 5 gives typical tolerances for a magnesium part with a length-to-diameter ratio of 6 to 1.

Table 5 Typical tolerances for a magnesium alloy extrusion with a length-to-diameter ratio of 6 to 1

Dimension	Tolerance, mm (in.)
Diameter	**±0.05 (±0.002)**[(a)]
Bottom thickness	**±0.13 (±0.005)**[(b)]

Introduction

HOT EXTRUSION is the process of forcing a heated billet to flow through a shaped die opening. The temperature at which extrusion is performed depends on the material being extruded (Table 1). Hot extrusion is used to produce long, straight metal products of constant cross section, such as bars, solid and hollow sections, tubes, wires, and strips, from materials that cannot be formed by cold extrusion (see the article "Cold Extrusion" in this Volume). The three basic types of hot extrusion are nonlubricated, lubricated, and hydrostatic (Fig. 1). This article will discuss only nonlubricated and lubricated hot extrusion; hydrostatic extrusion is covered in the article "Hydrostatic Extrusion" in this Volume.

Table 1 Typical billet temperatures for hot extrusion

Material	Billet temperature	
	°C	°F
Lead alloys	90-260	200-500
Magnesium alloys	340-430	650-800
Aluminum alloys	340-510	650-950
Copper alloys	650-1100	1200-2000
Titanium alloys	870-1040	1600-1900
Nickel alloys	1100-1260	2000-2300

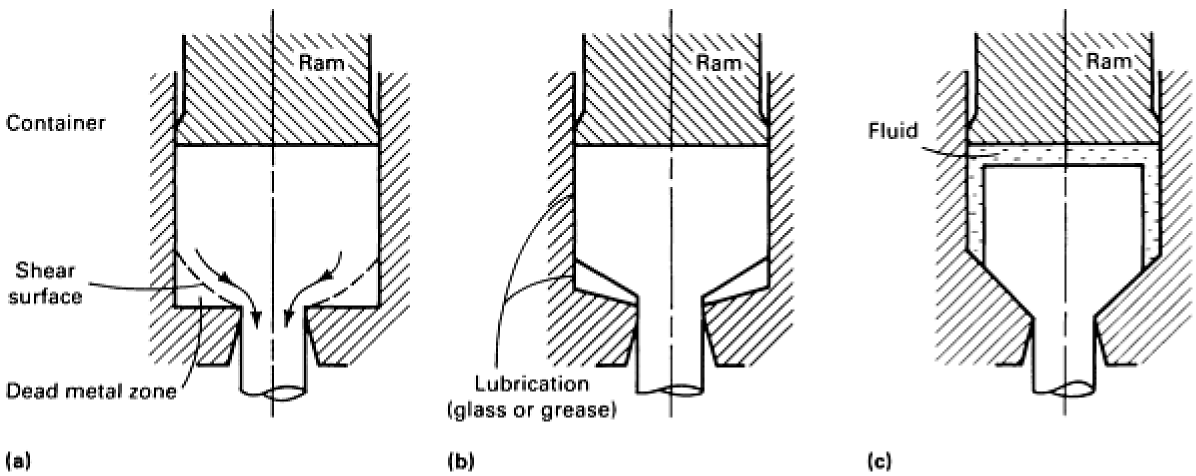

Fig. 1 Schematics of the nonlubricated (a), lubricated (b), and hydrostatic (c) extrusion processes.

In nonlubricated hot extrusion, the material flows by internal shear, and a dead-metal zone is formed in front of the extrusion die (Fig. 1a). Lubricated extrusion, as the name implies, uses a suitable lubricant (usually glass or grease) between the extruded billet and the die (Fig. 1b). In hydrostatic extrusion, a fluid film present between the billet and the die exerts pressure on the deforming billet (Fig. 1c). The hydrostatic extrusion process is primarily used when conventional lubrication is inadequate--for example, in the extrusion of special alloys, composites, or clad materials. For all practical purposes, hydrostatic extrusion can be considered an extension of the lubricated hot extrusion process.

Nonlubricated Hot Extrusion

Nonlubricated hot extrusion is a relatively straightforward process once the conditions have been defined. However, a large number of metallurgical and processing factors interact and affect the mechanical properties, surface finish, and corrosion resistance of the final extruded shape. This extrusion method uses no lubrication on the billet, container, and die, and it can produce very complex sections, with mirror surface finishes and close dimensional tolerances, that are considered to be net extrusions. A flat-face (shear-face) die is often used in nonlubricated hot extrusion.

There are basically two methods of hot extruding materials without lubrication:

- Forward, or direct, extrusion
- Backward, or indirect, extrusion

In forward extrusion (Fig. 2a), the ram travels in the same direction as the extruded section, and there is relative movement between the billet and the container (Ref 1). In backward extrusion (Fig. 2b), the billet does not move relative to the container, and a die or punch is pushed against the billet to produce solid parts.

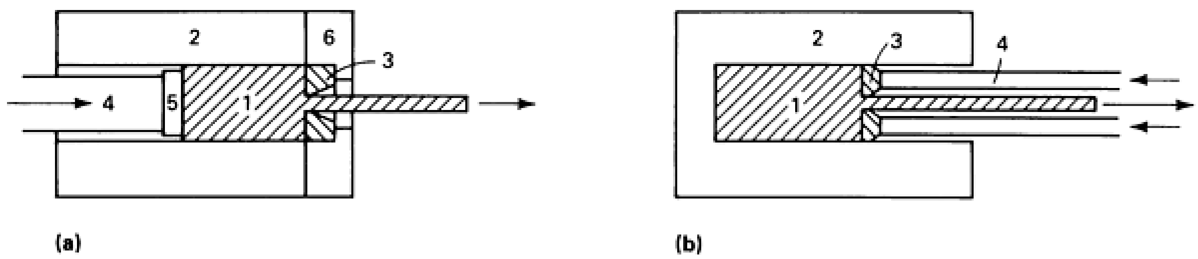

Fig. 2 Basic methods of extrusion. (a) Forward (direct). (b) Backward (indirect). 1, billet; 2, container; 3, die; 4, stem; 5, dummy block; 6, die backer.

Forward Extrusion

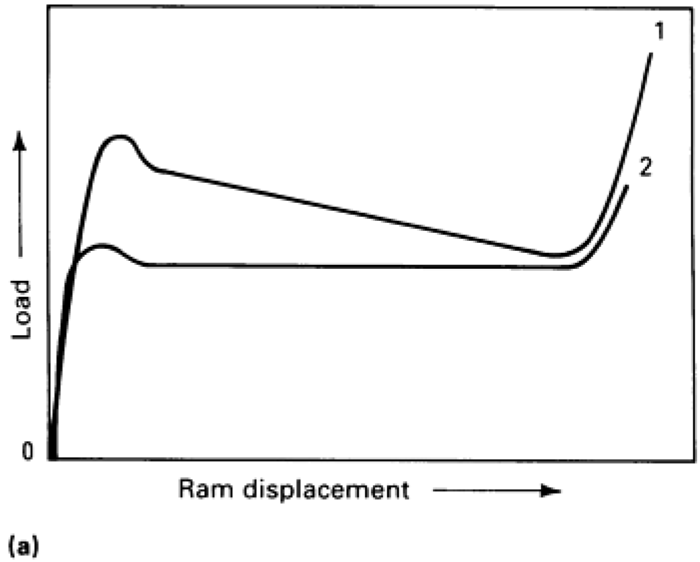
A typical sequence of operations for the forward extrusion of a solid section is as follows (Ref 1):

- The heated billet and the dummy block are loaded into the container
- The billet is extruded by the force of the ram being pushed against it. This upsets the billet, then forces

the metal to flow through the die. During extrusion, a thin shell of material may be left on the container walls. Extrusion is halted in order to leave a thin disk of material (butt) in the container

- The container is separated from the die, the extruded section with the butt, and the dummy block
- The discard (butt) is sheared off
- The shear die, the container, and the ram are returned to their initial (loading) positions

Typical load versus ram displacement curves for forward and backward extrusion are illustrated in Fig. 3, which shows that the load in forward extrusion initially increases very rapidly as the billet upsets to fill the container. This is followed by a further increase in pressure, and extrusion begins. A somewhat cone-shaped deformation zone then develops in front of the die aperture. After the maximum load has been reached, the extrusion pressure falls as the billet length decreases until a minimum is reached, then rapidly increases again. This last pressure increase occurs because only a disk of the billet remains and the metal must flow radially toward the die aperture. Resistance to deformation increases considerably with decreasing thickness.



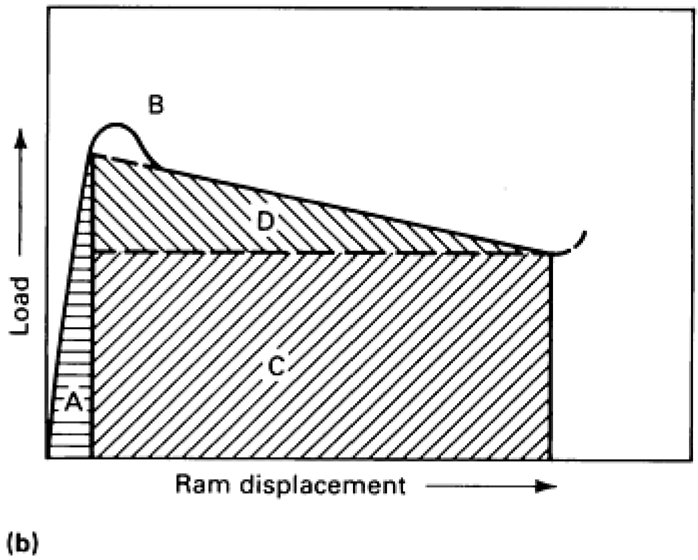


Fig. 3 Typical load versus ram displacement curves for nonlubricated extrusion processes. (a) Load versus ram displacement curves for forward (Curve 1) and backward (Curve 2) extrusion. (b) Division of the work of deformation. A, work of upsetting; B, work needed to initiate deformation; C, work of deformation; D, work

needed to overcome friction and shearing in direct extrusion

Backward Extrusion

In backward extrusion of a solid workpiece, the die is pushed by the hollow stem and moves relative to the container, but there is no relative displacement between the billet and the container (Ref 1). As a result, there is no frictional stress at the billet/container interface; therefore, the extrusion load and the temperature generated by deformation and friction are reduced, as shown in Fig. 3. The sequence of operations for the backward extrusion of a solid section is as follows:

- The die is inserted into the press
- The billet is loaded into the container
- The billet is extruded, leaving a butt
- The die and the butt are separated from the section

Backward extrusion offers a number of advantages, as follows:

- A 25 to 30% reduction in maximum load relative to direct extrusion
- Extrusion pressure is not a function of billet length, because there is no relative displacement between the billet and the container. Therefore, billet length is not limited by the load required for this displacement but only by the length and stability of the hollow stem needed for a given container length
- No heat is produced by friction between the billet and the container; consequently, no temperature increase occurs at the billet surface toward the end of extrusion, as is typical in the direct extrusion of aluminum alloys. Therefore, in backward extrusion, there is a lesser tendency toward cracking of the surfaces and edges, and extrusion speeds can be significantly higher
- The service life of the tooling is increased, especially that of the inner liner, because of reduced friction and temperatures

The disadvantage of backward extrusion is that impurities or defects on the billet surface affect the surface of the extrusion and are not automatically retained as a shell or discard in the container. As a result, machined billets are used in many cases. In addition, the cross-sectional area of the extrusion is limited by the size of the hollow stem.

Lubricated Hot Extrusion

Generally, aluminum alloys are extruded without lubrication, but copper alloys, titanium alloys, alloy steels, stainless steels, and tool steels are extruded with a variety of graphite and glass-base lubricants. Commercial grease mixtures containing solid-film lubricants, such as graphite, often provide little or no thermal protection to the die. For this reason, die wear is significant in the conventional hot extrusion of steels and titanium alloys.

The Sejournet process is the most commonly used for the extrusion of steels and titanium alloys (Ref 2). In this process, the heated billet is rolled over a bed of ground glass or is sprinkled with glass powder to provide a layer of low-melting glass on the billet surface. Before the billet is inserted into the hot extrusion container, a suitable lubricating system is positioned immediately ahead of the die. This lubricating system can be a compacted glass pad, glass wool, or both. The prelubricated billet is quickly inserted into the container, along with the appropriate followers or a dummy block. The extrusion cycle is then started.

As a lubricant, glass exhibits unique characteristics, such as its ability to soften selectively during contact with the hot billet and, simultaneously, to insulate the hot billet material from the tooling. The tooling is usually maintained at a temperature that is considerably lower than that of the billet. In the extrusion of titanium and steel, the billet temperature is usually 1000 to 1250 °C (1830 to 2280 °F), but the maximum temperature the tooling can withstand is 500 to 550 °C (930 to 1020 °F). Therefore, compatibility can be attained only by using the appropriate lubricants, insulative die coating, and ceramic die inserts and by designing dies to minimize tool wear. Glass lubricants have performed satisfactorily on a production basis in extruding long lengths.

The choice between grease and glass lubricants is based mainly on the extrusion temperature. At low temperatures, lubrication is used only to reduce friction. At moderate temperatures, there is also some insulation between the hot billet and the tooling from the use of partially molten lubricants and vapor formation in addition to the lubrication effect. At temperatures above 1000 °C (1830 °F), the thermal insulation of the tooling from overheating is of equal importance to the lubricating effect, particularly with difficult-to-extrude alloys. The lubrication film can also impede oxidation. Lubricants can be classified into two groups, according to temperature:

- *Below 1000 °C (1830 °F):* Grease lubrication, such as grease, graphite, molybdenum disulfide, mica, talc, soap, bentonite, asphalt, and plastics (for example, high-temperature polyimides)
- *Above 1000 °C (1830 °F):* Glass lubrication, such as glass, basalt, and crystalline powder

Metal Flow in Hot Extrusion

Metal flow varies considerably during extrusion, depending on the material, the material/tool interface friction, and the shape of the section. Figure 4 shows the four types of flow patterns that have been observed.

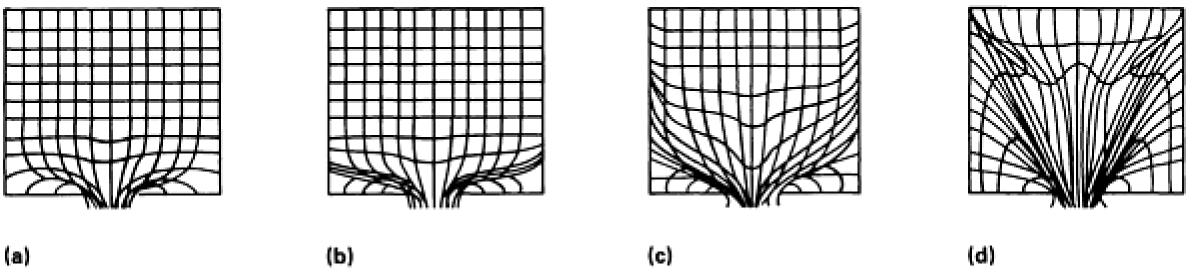

Fig. 4 Four types of flow patterns observed in the extrusion of metals. (a) Flow pattern S. (b) Flow pattern A. (c) Flow pattern B. (d) Flow pattern C. See text for details. Source: Ref 1

Flow pattern S (Fig. 4a) is characterized by the maximum possible uniformity of flow in the container. Plastic flow takes place primarily in a deformation zone directly in front of the die. The major part of the nonextruded billet, pushed as a rigid body through the die, remains undeformed; therefore, the front of the billet moves evenly into the deformation zone.

Flow pattern A (Fig. 4b) occurs in homogeneous materials when there is virtually no friction between the container and the billet but significant friction at the surface of the die and its holder. This retards the radial flow of the peripheral zones and increases the amount of shearing in this region. The result is a slightly larger dead-metal zone than that in flow type S, along with a correspondingly wider deformation zone. However, deformation in the center remains relatively uniform. Flow patterns of this type are seldom observed in nonlubricated extrusion; instead, they occur during the lubricated extrusion of soft metals and alloys, such as lead, tin, α-brasses, and tin bronzes, and during the extrusion of copper billets covered with oxide (which acts as a lubricant).

Flow pattern B (Fig. 4c) occurs in homogeneous materials if friction exists at both the container wall and at the surfaces of the die and die holder (Fig. 4c). The peripheral zones are retarded at the billet/container interface, while the lower resistance causes the material in the center to be accelerated toward the die. The shear zone between the retarded regions at the surface and the accelerated material in the center extends back into the billet to an extent that depends on the extrusion parameters and the alloy. Therefore, the dead-metal zone is large. At the start of extrusion, the shear deformation is concentrated in the peripheral regions, but as deformation continues, it extends toward the center. This increases the danger of material flowing from the billet surface--with impurities or lubricant--along the shear zone and finishing up under the surface of the extrusion. In addition, the dead-metal zone is not completely rigid and can influence, even if to a limited degree, the flow of the metal. Flow type B is found in single-phase (homogeneous) copper alloys that do not form a lubricating oxide skin and in most aluminum alloys.

Flow pattern C (Fig. 4d) occurs in the hot extrusion of materials having inhomogeneous properties when the friction is high (as in flow pattern B) and when the flow stress of the material in the cooler peripheral regions of the billet is considerably higher than that in the center. The billet surface forms a relatively stiff shell. Therefore, the conical dead-metal zone is much larger and extends from the front of the billet to the back. At the start of extrusion, only the material inside the funnel is plastic, and it is severely deformed, especially in the shear zone, as it flows toward the die. The stiff shell and the dead-metal zone are in axial compression as the billet length decreases; consequently, the displaced material of the outer regions follows the path of least resistance to the back of the billet, where it turns toward the center and flows into the funnel.

This type of flow is found in the (α + β) brasses, in which the cooling of the peripheral regions of the billet leads to an increase in flow stress, because the flow stress of the α phase is much higher than that of the β phase during hot working. As in the (α + β) brasses, flow type C will occur when there is a hard billet shell and, at the same time, the friction at the container wall is high. It can also occur without any phase change that leads to a higher flow stress if there is a large temperature difference between the billet and the container. This can take place in the extrusion of tin as well as of aluminum and its alloys.

Extrusion Speeds and Temperatures

The temperatures developed during extrusion significantly influence the speed at which the process can be carried out. This is especially true in the extrusion of hard aluminum alloys (2*xxx* and 7*xxx*). A complex thermal situation exists as soon as the heated billet is loaded into the preheated container and extrusion begins. The temperatures are influenced by:

- Heat generation due to plastic deformation
- Heat generation due to internal shear and friction between the deforming material and the tooling
- Heat transfer within the billet
- Heat transfer between the billet and the tooling
- Heat transported with the extruded product

These phenomena occur simultaneously and result in a complex relationship among the material and process variables, that is, billet material and temperature, friction, tool material and temperature, extrusion speed, shape of the extruded section, and reduction in area.

The production rate can be increased by increasing the extrusion ratio (the ratio of the cross-sectional area of the billet to that of the extruded product) and the extrusion speed while maintaining the extrusion pressure at an acceptable level. For this purpose, the flow stress of the extruded material must be kept relatively low, for example, by increasing the billet preheating temperature. The combination of high billet temperature, large reduction in area, and high extrusion speed causes a considerable rise in temperature in the extruded material, especially near the section surface, because most of the plastic deformation and frictional energy is transformed into heat. This can cause surface defects or hot shortness, especially with difficult-to-extrude 2*xxx* and 7*xxx* aluminum alloys. With a typical extrusion ratio of 40:1, exit speeds in extruding these alloys would be of the order of 0.6 to 1.2 m/min (2 to 4 ft/min). Figure 5 shows the range of exit speeds encountered in the extrusion of various aluminum alloys. The extrusion rate depends greatly on the flow stress of the alloy under the process conditions, which in turn depends on the extrusion temperature and strain rate. Exit speeds are relatively high for soft (5*xxx* and 6*xxx*) alloys, but are quite low for harder alloys such as 7075 and 2024.

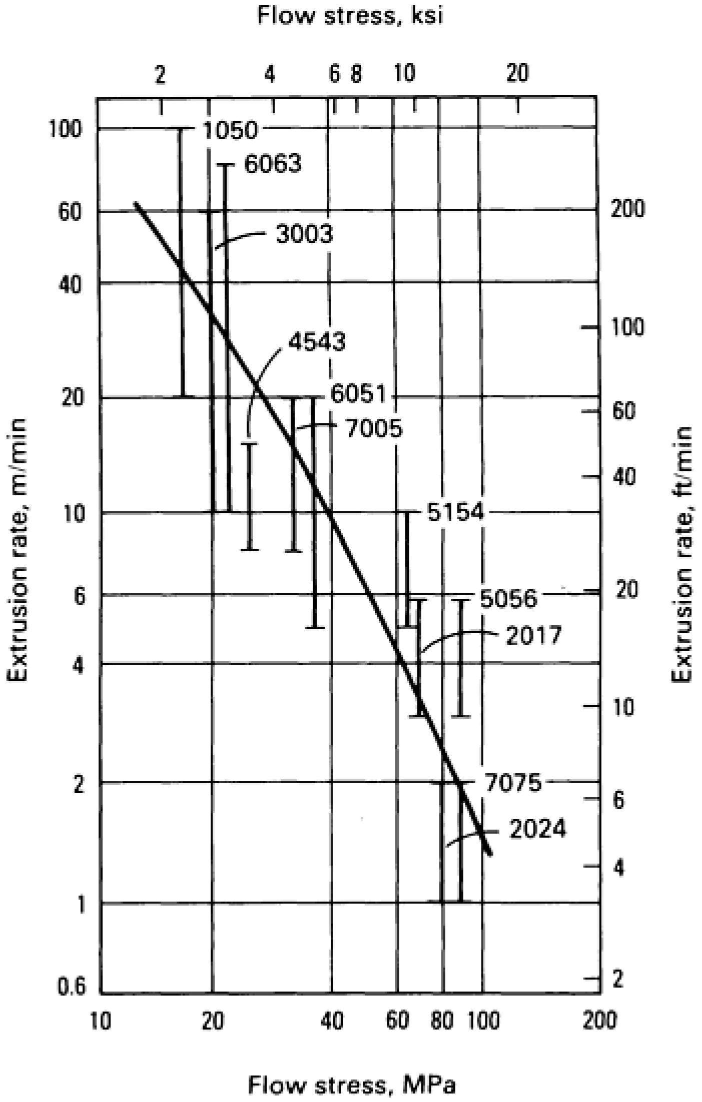

Fig. 5 Extrusion rate versus flow stress for various aluminum alloys. Source: Ref 3

Temperature increase and temperature distribution during extrusion have been investigated by many researchers (Ref 4, 5, 6, 7, 8). The emergent temperatures of aluminum, tin, and lead extruded at ram speeds from 1 to 30 m/min (3 to 100 ft/min) were measured (Ref 4). Figures 6 and 7 show the effects of extrusion ratio and ram speed on the temperature increase. A simple theoretical analysis was conducted to investigate the effect of ram speed on temperature increase (Ref 8). In this study, a billet of infinite length was assumed, container friction was neglected, and the interior of the container was assumed to be at the same temperature as the billet. The temperature of the billet varied along its length, but was assumed to be constant at any cross section. The model predicted a sigmoidal relationship between the logarithm of ram speed and the temperature rise. Based on this model, a ram speed program was devised that would give a constant emergent temperature. Experimental evaluation of this speed program resulted in maintenance of constant temperatures within ±3 K (±5 °F) for lead and ±6 K (±11 °F) for aluminum. The decrease in extrusion pressure with programmed ram speed was less than that with constant ram speed.

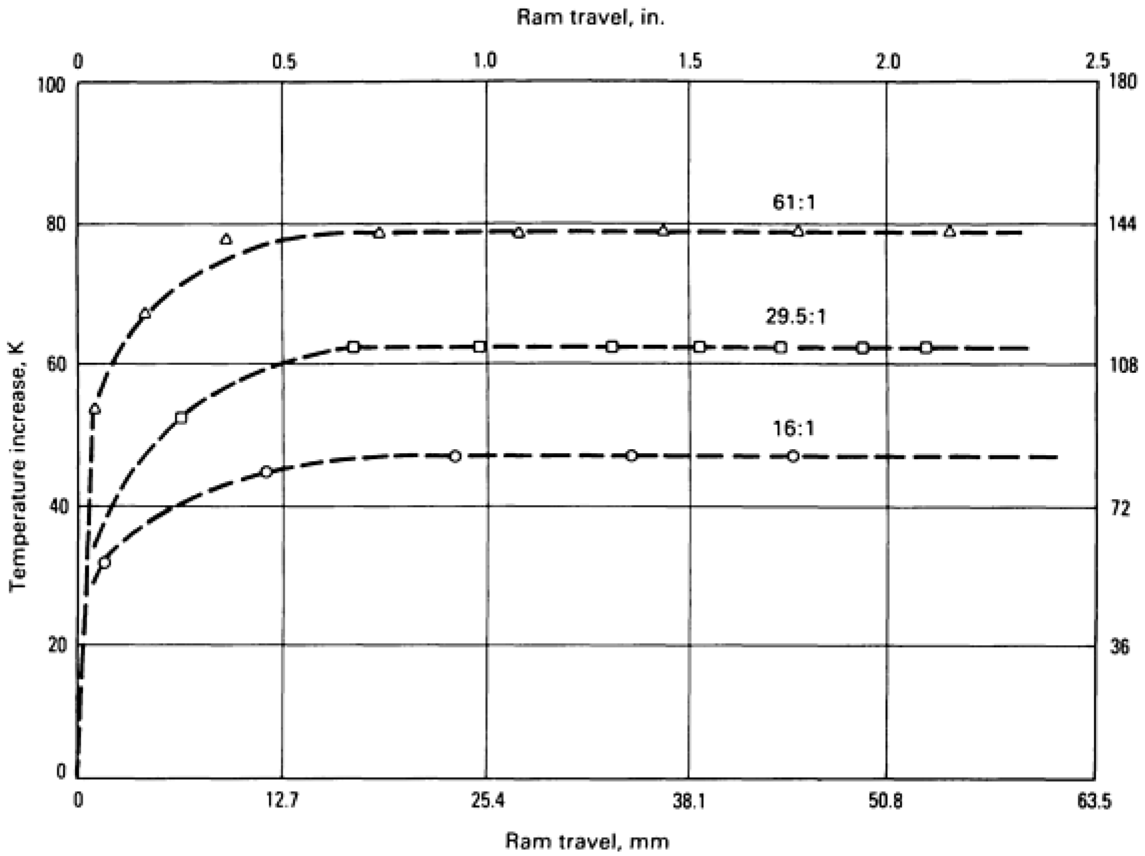

Fig. 6 Increase in emergent temperature versus extrusion ratio in the extrusion of lead. Extrusion ratios are indicated on the curves. Billet diameter: 51 mm (2 in.); billet length: 64 mm (2.5 in.); ram speed: 76 mm/min (3 in./min); starting temperature: 20 °C (70 °F). Source: Ref 4

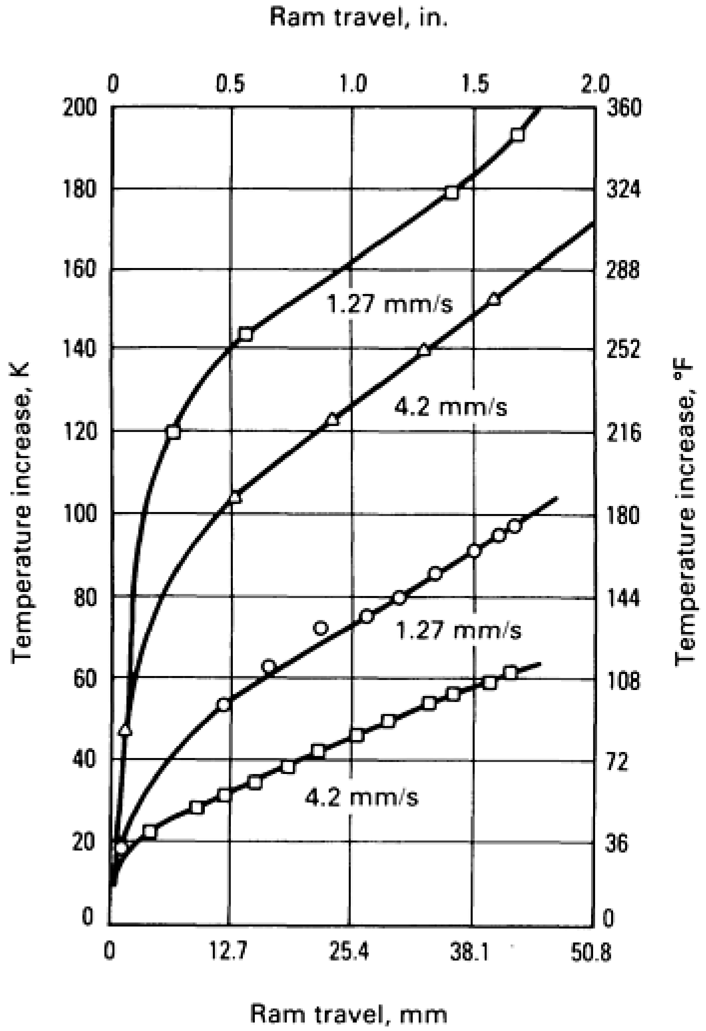

Fig. 7 Increase in emergent temperature versus ram speed in the extrusion of superpure aluminum. Ram speeds are indicated on the curves. Billet diameter: 38 mm (1.5 in.); billet length: 51 mm (2 in.); extrusion ratio: 16:1; starting temperature: 20 °C (70 °F). Source: Ref 4

Theoretical and practical studies of temperature distributions in the extrusion of aluminum alloys were conducted under conditions in which the container and tools were initially below, equal to, or above the initial billet temperature (Ref 5). For the particular experimental conditions examined, it was deduced that the increase in temperature under adiabatic conditions would be about 95 °C (205 °F). For practical purposes, it can be estimated that, in the extrusion of high-strength alloys, the maximum temperature increase likely to be encountered will not exceed 100 °C (212 °F). With the soft alloys, for which lower specific pressures are required, the temperature increase under normal production conditions is not likely to exceed 50 °C (120 °F).

Computer programs have been developed for predicting temperatures in the extrusion of rods and tubes in various materials (Ref 6, 7). As Fig. 8 shows, based on theoretical predictions and on experimental evidence, the product temperature increases as extrusion proceeds. The temperature at the product surface is higher than that at the product center. Therefore, the surface temperature of the product may approach the critical temperature at which hot shortness may occur only toward the end of the extrusion cycle. The temperature of the extruded product as it emerges from the die is one of the essential factors that influence product quality. Therefore, an ideal procedure for establishing the maximum speed of extrusion at all times would be to measure this temperature and to use it for controlling the ram speed. This procedure has been proposed by many researchers, but the problem of obtaining accurate and continuous measurement of the temperature of the extruded product remains unsolved. Methods of measuring product temperature by using various types of contact thermocouples, or by radiation pyrometry, have thus far proved to be impractical.

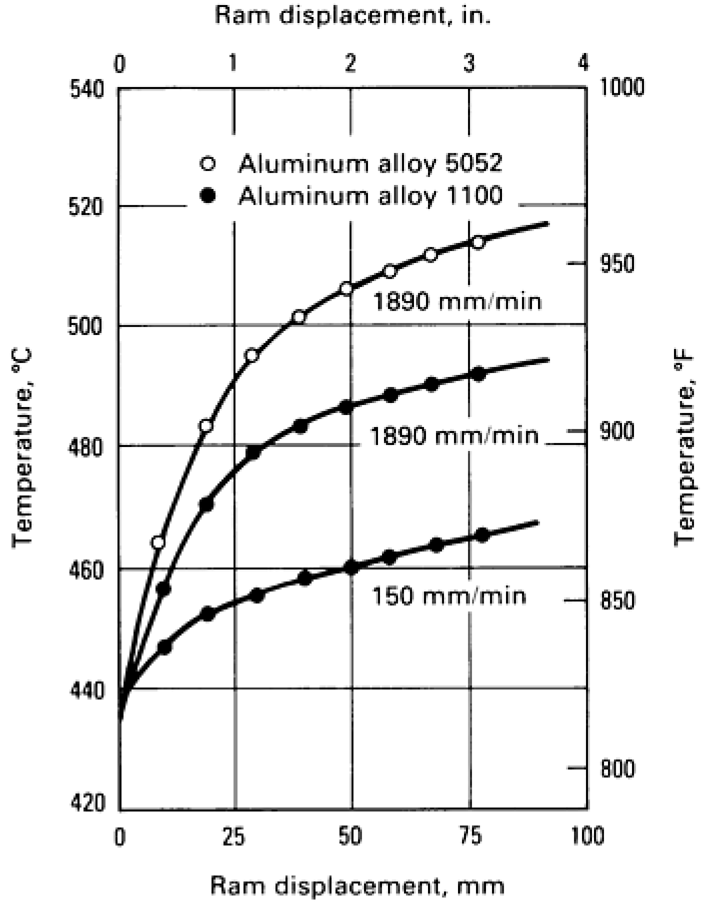

Fig. 8 Surface temperature of the extruded product versus ram displacement for two aluminum alloys. Ram velocities are indicated on the curves. Reduction ratio: 5:1; billet diameter: 71 mm (2.8 in.); billet length: 142 mm (5.6 in.); initial billet and tooling temperature: 440 °C (825 °F). Source: Ref 6

A system for isothermal extrusion was proposed in which the variation in ram speed necessary for maintaining the product temperature within the required limits was programmed (Ref 9). In presses designed to operate on this principle, the working stroke is divided into zones, each having a preset speed. In a press used for the extrusion of high-strength alloys, a time savings of 60% was claimed. Savings would be lower for more easily extrudable alloys.

In extrusion of aluminum alloys, temperature variations in the emerging product can be reduced by imposing a temperature gradient in the billet (Ref 10). The billet is inserted into the container such that the hot end is extruded first while the temperature of the cooler end increases during extrusion. This practice is not entirely satisfactory, because of the relatively high thermal conductivities of aluminum alloys; therefore, if any delays occur in the extrusion sequence, the temperatures in the billet tend to become uniform throughout the billet length. A better method consists of water quenching the feed table to the container. Another approach for increasing extrusion speed is to cool the die with water or nitrogen.

For controlling and predicting variations in ram speed during extrusion, computer simulations may be useful for predicting the temperature increase that occurs during the process (Ref 6, 7). The purpose of such computer-aided speed control is to attain maximum extrusion speeds with minimum variations in temperature in the extruded product. More information on the use of computers in die design and process simulation for hot extrusion is available in the section "Applications for Computer-Aided Design and Manufacture (CAD/CAM)" in this article.

Presses for Hot Extrusion

Horizontal and vertical presses are used for hot extrusion. Horizontal presses are the most common. Most modern extrusion presses are driven hydraulically, but mechanical drives are used in some applications, such as the production of small tubes. Two basic types of hydraulic drives are available: direct and accumulator. In the past, accumulator presses were the most widely used type, but today direct-drive presses are used more extensively.

Accumulator-Drive Presses. The hydraulic circuit of an accumulator drive press consists of one or more air-over-water accumulators charged by high-pressure water pumps. The accumulator bottle (or bank of bottles) is designed to supply the quantity of water needed to provide the necessary pressure requirements throughout the extrusion stroke--with a pressure decrease not exceeding about 10%. This decrease in pressure is often critical in applications that involve marginal, difficult-to-extrude shapes. In addition to the high cost of high-pressure water pumps, accumulators, and valves, as well as the substantial floor space requirements, this pressure decrease characteristic of accumulator drives has resulted in the increasing popularity of direct-drive presses. However, a significant advantage of accumulator water drives is higher stem speeds (up to 380 mm/s, or 15 in./s), which make these units desirable for the extrusion of steel. Water is also a non-flammable hydraulic medium--an important consideration in the extrusion of very hot billets.

Direct-Drive Presses. Figure 9 shows a typical direct-drive oil-hydraulic press for hot extrusion. The increasing use of these presses has resulted mainly from the development of reliable, high-pressure, variable-delivery oil pumps, some of which operate at pressures over 34.5 MPa (5 ksi). Direct-drive presses are self-contained, and they require less floor space and are less expensive than accumulator-drive presses. More important, direct-drive units provide a constant force during the entire extrusion stroke, with no pressure decrease. A limitation of direct-drive presses is that the stem speeds are slower than those in accumulator drives. Stem speeds to 51 mm/s (2 in./s) are typical; however, speeds to 203 mm/s (8 in./s) can be reached by using oil accumulators with oil-hydraulic drives.

Major improvements available on modern extrusion presses include simplified hydraulic circuits to facilitate troubleshooting, manifolded piping to reduce leakage and maintenance, and improved valves to minimize wear. Closed-loop constant-rate speed controls simplify the production of smooth finishes and uniform extrusion properties. In addition, the presses operate faster for increased productivity.

Solid-state programmable controllers have replaced magnetic relays on many presses for increased versatility, simplified troubleshooting, and ease of interfacing with computers. The use of computers for the presses and for the auxiliary equipment in an integrated extruding system enables the monitoring of all operations and instantaneously provides data on production, downtime, and inventory, as well as other information.

Force and Pressure Capacities. Presses for hot extrusion are usually rated in terms of force capacity, that is, the total force the press is capable of exerting upon the billet. However, press operation depends on the actual unit pressure exerted on the metal. For a press with a given force capacity, higher unit pressures can be obtained if the billet container is smaller in diameter. As the container increases in diameter, the unit pressure capability decreases, with a resultant decrease in extrusion capability.

The typical maximum unit pressure that is used on most extrusion presses is about 1035 MPa (150 ksi). This pressure is near the upper limit of the mechanical strengths of most tool steels used for extrusion. Higher pressures may result in premature tool failure.

Press Selection. The unit pressures needed for extrusion--a principal consideration in press selection--vary with the following factors:

- The metal to be extruded and its condition
- The length and temperature of the billet
- The complexity of the cross section of the product
- The speed of extrusion
- The reduction ratio

The reduction (extrusion) ratio equals the cross-sectional area of the container liner divided by the cross-sectional area of the extruded product.

Higher pressures are generally necessary at the beginning of the extrusion cycle. Pressure requirements decrease as extrusion progresses, then increase again as the butt of the billet is reduced to a thickness of about 12.7 to 25.4 mm ($\frac{1}{2}$ to 1 in.). Methods of determining press force and pressure requirements for the extrusion of various products are discussed in the section "Operating Parameters" in this article.

The advantages of using a press with sufficient capacity include the ability to use lower billet temperatures and faster speeds and the ability to obtain improved metallurgical properties in the extruded products. The use of a press having insufficient capacity can result in the inability to extrude (that is, the billets stick in the containers) or in extrusions of poor quality.

Any extrusion press requires a rigid structure as well as accurate and adjustable alignment of the stem, container, and die. Prestressed tie rod construction is used in most press structures. Modern presses permit die stack lengths that are longer than those possible with earlier models, and this provides better tool stability and improved tolerances on extruded products.

Press Accessories. Various accessories are available as standard or optional items for hot extrusion presses, including:

- Die slides or revolving die arms to facilitate changing of dies
- Indexing containers, and electrical heating elements to maintain the proper container temperature
- Piercing units and mandrel manipulators for the extrusion of tubes and hollow parts
- Internal or external billet loaders
- Cutoff shears or saws for separating the butt from the extruded product
- Mechanized butt and dummy block handling systems

Auxiliary Equipment. In addition to the press, billet heaters, stretchers, pullers, sawing equipment, and system controls are necessary for complete extrusion facilities. For many installations (especially aluminum extrusion), gas-fired log heaters have replaced gas-fired and induction billet heaters. The process of heating aluminum logs measuring 3.7 to 6.1 m (12 to 20 ft) in length and then cutting them to the required length as they emerge from the heater has eliminated the need to store billets of varying lengths. Log shears allow the press operator to tailor billet lengths to provide maximum yield from each billet with minimal scrap. Computer control ensures that the logs are sheared to the optimal billet length for the particular die being used and for the desired extrusion length.

Reliable extrusion pullers are available that reduce operator responsibilities, eliminate twisting of the extruded products, and ensure that equal-length extrusions are obtained from multiple-hole dies. These extrusion pullers also improve the efficiency of extrusion stretching operations. Fewer manipulations of the stretcher tailstock are necessary in order to accommodate unequal extrusion lengths, and the need to detwist extruded shapes prior to stretching is virtually eliminated. In many cases, stretching requires only one operator, located at the headstock; tailstock manipulation is controlled by the same operation. Several installations are equipped with completely programmed puller-stretcher combinations.

Beyond the stretcher, automatic saw tables are often provided. In many cases, cut-to-length extrusions are automatically stacked for subsequent heat treatment.

Enclosed water-filled chambers have been provided at the ends of several presses that are used to extrude copper tubing. The tubing is extruded directly into the chamber and remains submerged for the full length of the runout. A special gate prevents back-flow through the dies, and an end crimper prevents water from filling the tube. The result of this arrangement is the production of copper tubing with a refined grain structure and consistent grain orientation.

Tooling

The tooling for hot extrusion consists of such components as containers, container liners, stems (rams), dummy blocks, mandrels, spider or bridge dies for producing hollow extrusions, and flat or feeder plate dies. Flat-face and shaped dies are the two most common types (Fig. 10). Flat-face dies (also termed square dies) have one or more openings (apertures) that are similar in cross section to that of the desired extruded product. Dies for lubricated extrusion (also called shaped, converging or streamlined dies) often have a conical entry opening with a circular cross section that changes progressively to the final extruded shape required. Flat-face dies are easier to design and manufacture than shaped dies and are commonly used for the hot extrusion of aluminum alloys. Shaped dies are more difficult and costly to design and manufacture, and they are generally used for the hot extrusion of steels, titanium alloys, and other metals.

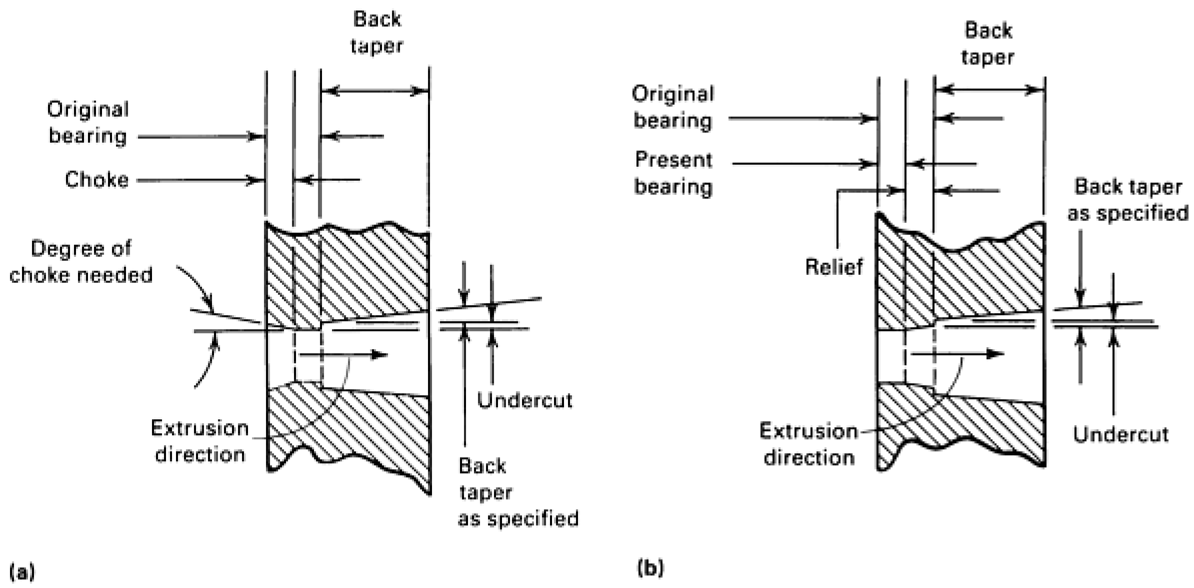

Fig. 10 Shaped die (a) and flat die (b) for hot extrusion

Die Design

Die design is a crucial aspect of the extrusion process that embodies art and science. Optimal design is influenced by such factors as the size of the shape to be produced, the maximum and minimum wall thicknesses, the press capacity, the length of the runout table, the stretcher capacity, the tool-stacking limitations, an understanding of the properties and characteristics of the metal to be extruded, and the press operating procedures and maintenance.

Computer-Aided Design and Manufacture. Computers are being used to design and manufacture dies (with computer numerical control machines) and to select process variables, such as extruding speed and billet temperatures. The software used is primarily based on an analysis of metal flow. Various design stages are displayed on a CRT screen, and the designer interacts with a computer to modify the design, based on experience. More information on the use of computers for die design is available in the section "Applications for Computer-Aided Design and Manufacture (CAD/CAM)" in this article.

Design Considerations. All metals shrink upon cooling after hot extrusion; therefore, a shrinkage allowance must be provided in the design of the dies. Deformation of the die under high pressures and expansion resulting from the high temperatures must also be considered in die design.

Another important consideration is the tendency for metal to flow faster through a larger opening than a smaller one. This must be compensated for in the design of dies to be used in extruding certain sections. For example, when a section to be extruded has a thick wall and a thin wall, various means are employed to retard metal flow through the thick section and to increase the flow rate through the thin section of the die.

The geometry of the die aperture at the front and back of the bearing surface is termed the choke and relief, respectively. A choke can be provided on certain portions of the bearing surface if the die designer anticipates difficulty in filling sharp corners or completing thin sections of the extruded product. This slows the rate of metal flow and consequently fills the die aperture. Increasing the amount of back relief at the exit side of the bearing surface increases the rate of metal flow.

For the hot extrusion of such materials as brass, bronze, and other soft metals, the dummy block is made smaller in diameter than the billet. In extruding, no lubrication is provided between the bore of the container liner and the outer surface of the billet. Consequently, friction prevents the outer surface of the billet from sliding, and the undesirable skin of the billet is left in the container as the dummy block shears the metal during its forward stroke. An additional press stroke is required to remove this retained metal before the next billet can be charged into the container.

Tool Materials

Table 2 lists typical materials and hardnesses for tools used in hot extrusion. The hot extrusion of aluminum is similar in many ways to that of magnesium; the principal difference is the pressure required. The same tool materials can often be used for the extrusion of either aluminum or magnesium.

Table 2 Typical materials and hardnesses for tools used in hot extrusion

Tooling application	**For tools used in extruding:**					
	Aluminum and magnesium		**Cooper and brass**		**Steel**	
	Tool material	**Hardness, HRC**	**Tool material**	**Hardness, HRC**	**Tool material**	**Hardness, HRC**

					H19, H21	45-50
Liners	H11, H12, H13	42-47	A-286, V-57	. . .	H11, H12, H13	42-47
Rams	H11, H12, H13	40-44	H11, H12, H13	40-44	H11, H12, H13	40-44
Containers	4140, 4150,	35-40	4140, 4150,	35-40	H13	35-40

The dies used for the extrusion of aluminum alloys and copper alloys are generally made from AISI H11, H12, or H13 tool steels. For the extrusion of copper alloys, some companies specify tungsten hot-work steels such as H14, H19, and H21. For the extrusion of steel, H13 solid dies or H13 dies with cast H21 inserts are often used.

Dummy blocks, backers, bolsters, and die rings are routinely made from H11, H12, and H13. For the extrusion of copper, brass, and steel, H14, H19, and H21 are occasionally used. Nickel alloy 718 and other superalloys are sometimes used for dummy blocks; use of these alloys often results in extremely long tool life.

Mandrels are generally made of either H11 or H13, regardless of the material being extruded. Most mandrel tips and inserts for the extrusion of aluminum are made of T1 or M2. Nickel alloy 718 mandrel tips and inserts are commonly used in the extrusion of copper and brass, but H11, H12, H13, H19, or H21 tips and inserts can be used for the extrusion of steel.

The liners used in extruding aluminum or steel are usually made of H11, H12, or H13. Liners for the extrusion of copper and brass are normally made of a nickel- or iron-base superalloy. Rams are generally made of H11, H12, or H13.

Containers for the extrusion of aluminum or copper products are usually made of 4140, 4150, or 4340 alloy steel. Containers for the extrusion of steel can also be made from alloy steels; however, H13 is generally preferred.

Special Materials. In addition to the materials listed in Table 2, special insert materials and surface treatments have been specified (particularly for tools used in extruding complex shapes) for applications requiring better resistance to wear at higher temperatures. Special insert materials include special grades of cemented tungsten carbide, nickel-bonded titanium carbides, and alumina ceramics. Special surface treatments include nitriding, aluminide coating, and application of proprietary materials by vapor deposition or sputtering.

Materials for Hot Extrusion

The numerous uses to which extrusions are applied are constantly increasing. A large portion of metal consumption is in the form of extrusions. Depending on the material used, extrusions serve the transportation, construction, mechanical, and electrical industries. Extrusions are used for durable goods, industrial equipment, heating and air conditioning applications, petroleum production, and the production of nuclear power.

Practically all metals can be extruded, but extrudability varies with the deformation properties of the metal. Soft metals are easy to extrude; hard metals require higher billet temperatures and extruding pressures as well as sturdier presses and dies.

Lead and tin exhibit high ductility and are easy to extrude. The addition of alloying elements increases the force required, but extruding does not present a problem and is carried out with billets heated to a maximum temperature of about 300 °C (575 °F). Principal applications include pipes, wire, tubes, and sheathing for cable. Molten lead is used instead of billets for many applications. Vertical extrusion presses are sometimes used to produce protective sheathings of lead on electrical conductors.

Aluminum and aluminum alloys are probably the ideal materials for extrusion, and they are the most commonly extruded. Most commercially available aluminum alloys can be extruded. Billet temperatures generally range from about 300 to 595 °C (575 to 1100 °F), depending on the alloy. Principal applications include parts for the aircraft and aerospace industries, pipes, wire, rods, bars, tubes, hollow shapes, cable sheathing, architectural and structural sections, and automotive trim. Sections can be extruded from heat-treatable high-strength aluminum alloys.

Magnesium and Magnesium Alloys. Extruded magnesium and magnesium alloy products are used in the aircraft, aerospace, and nuclear power industries. With similar billet temperatures, the extrudability of these materials is about the same as that of aluminum, but longer heating periods are usually necessary to ensure uniform temperatures throughout the billets.

Zinc and Zinc Alloys. The extrusion of zinc and zinc alloys requires pressures that are higher than those necessary for lead, aluminum, and magnesium. Billet temperatures generally range from about 205 to 345 °C (400 to 650 °F). Applications include rods, bars, tubes, hardware components, fittings, and handrails.

Copper and copper alloy extrusions are widely used for wire, rods, bars, pipes, tubes, electrical conductors and connectors, and welding electrodes. Architectural shapes are extruded from brass, but usually in limited quantities. Billet temperatures vary from about 595 to 995 °C (1100 to 1825 °F). Depending on the alloy, extrudability ranges from easy to difficult. High pressures (690 MPa, or 100 ksi, or more) are necessary for the extrusion of many copper alloys.

Steels. For the hot extrusion of steel, it is necessary to use glass as a lubricant or some other high-temperature lubricant to prevent the excessive tooling wear that can result from the high billet temperatures required (995 to 1300 °C, or 1825 to 2375 °F). In addition, high ram speeds are required in order to minimize contact time between the billets and the tooling. The products produced include structural sections (generally required in small quantities) and tubes with small bores. For economic reasons, steel structural shapes, especially those needed in large quantities, are better suited to the rolling process. Alloy and stainless steels are usually extruded in the form of either solid shapes or tubes.

Other metals that are hot extruded include titanium and titanium alloys, nickel and its alloys, superalloys, zirconium, beryllium, uranium, and molybdenum. Some titanium alloys are more difficult to extrude than steels. Nickel alloys also can be very difficult to extrude, and billet temperatures above 995 °C (1825 °F) are used. All of these metals are extruded into tubes, rods, and bars; the bars are often used as forging stock in subsequent operations.

Metal powders are extruded into long shapes by cold and hot processes, depending on the characteristics of the powders. Aluminum, copper, nickel, stainless steels, beryllium, and uranium are some of the powders that are extruded. The powders are often compressed into billets that are heated before being placed in the extrusion press. For many applications, the powders are encapsulated in protective metallic cans, heated, and extruded with the cans. Forging of metal powders is discussed in detail in the article "Powder Forging" in this Volume; *Powder Metal Technologies and Applications*, Volume 7 of the *ASM Handbook*, is devoted to all aspects of powder metallurgy.

Characterization of Extruded Shapes

Extruded shapes in aluminum alloys are generally characterized according to geometric complexity. This characterization is also useful in classifying shapes extruded from other alloys.

The size of an extruded shape is measured by the diameter of the circle circumscribing the cross section of that shape (Fig. 11). This dimension is commonly referred to as the circumscribing circle diameter (CCD).

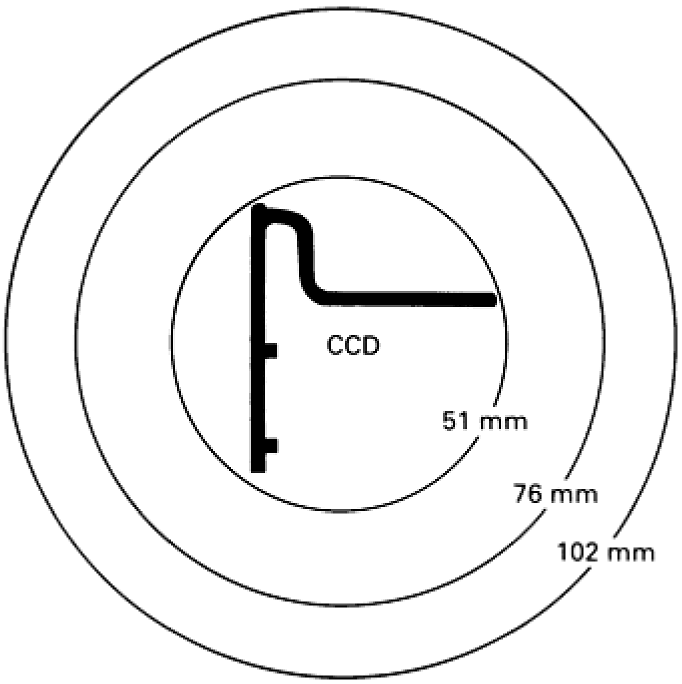

Fig. 11 Definition of size of an extruded section by circumscribing circle diameter

In extrusion, metal tends to flow more slowly at die locations that are far away from the axis of the billet. Therefore, the larger the circumscribing circle diameter, the more control required to maintain the dimensions of the extruded shape. Special care is needed in extruding large and thin shapes, especially those with thin portions near the periphery of the die. Therefore, size is one of the factors that describe the complexity of a shape.

Complexity of an Extruded Shape. Two accepted methods are available for defining the complexity of an extruded shape. One method involves the use of the shape factor, defined as follows:

$$\text{Shape factor} = \frac{\text{Perimeter}}{\text{Weight}} \quad \textbf{(Eq 1)}$$

This factor is a measure of the amount of surface generated per unit weight of metal extruded. The shape factor affects the production rate as well as the cost of manufacturing and maintaining the dies. It is used by many extruders as a basis for pricing and provides the designer with a means of comparing the relative complexities of alternate designs. The other measure of shape complexity is the classification of extruded shapes into different groups, based on the difficulty of extrusion.

Conventional Hot Extrusion

Operating Parameters

Critical parameters for successful and economical hot extrusion include the method of billet preparation and heating, the amount of pressure and rate of speed used for extruding, and the type of lubricant employed.

Billet Preparation. The more common metals that are to be extruded are generally cast in the form of cylindrical logs measuring 3.7 to 6 in (12 to 20 ft) or more in length. These logs are sawed or sheared into billets of varying length, depending on the cross-sectional area and the length of the product to be extruded.

Additional billet preparation is sometimes necessary, depending on the material to be extruded. For example, it is necessary to machine the outer surfaces of some steel billets before they are heated; the outer surfaces must then be descaled after being heated to the extrusion temperature. Best results are attained in backward extrusion by scalping the billets before extrusion to remove oxides and other impurities from the billet skin. If this is not done, these impurities would find their way onto the surfaces of the extrusion because of the inherent nature of the metal flow in backward extrusion.

Before they are extruded, aluminum billets are frequently homogenized by heat treatment. This treatment improves the extrudability of the material and the surface finish produced.

Billet temperature is important for all materials (see Table 1). A billet temperature that is too high can cause blisters or other surface defects, including cracking. A temperature that is too low increases the pressure requirements for the extrusion and shortens tool life.

Pressure Requirements. The unit pressures needed for hot extrusion are significant considerations in press selection (discussed previously). The determination of pressure requirements is difficult for the extrusion of complicated shapes and sections--especially those with thin walls. Careful judgments based on past experience must be made for estimates. Formulas have been developed for estimating pressure requirements, using shape, friction, and other parameters. However, for less complicated shapes, such as round bars and tubes, a fair approximation of pressure requirements can be calculated by:

$$P = k \ln \frac{A}{a} \quad \textbf{(Eq 2)}$$

where *P* is the extrusion pressure required (in pounds per square inch or megapascals); *k* is a numerical value representing the resistance to deformation, usually based on past experience in extruding a specific metal at a specific temperature; *A* is the cross-sectional area of the container liner or, in the case of tubes or other hollow shapes, the cross-sectional area of the liner minus the cross-sectional area of the mandrel (in square inches or square millimeters); and *a* is the total cross-sectional area of the extruded product (the shape area times the number of openings in the die) (in square inches or square millimeters).

The extrusion pressure requirements determined with Eq 2 are useful, but the values obtained are only approximations. The factor *k* varies with such factors as billet temperature, die design, type of metal extruded, amount of reduction (extrusion ratio), stem speed, and configuration of the extruded product. Billet length, nonhomogeneous metal flow, and friction also influence pressure requirements.

Unit pressures generally range from 450 to 760 MPa (65 to 110 ksi), with a maximum of about 1035 MPa (150 ksi). When practical, it is generally desirable to use a press with a capacity exceeding that actually required. This allows lower billet temperatures and faster stem speeds to be used and provides improved properties in the extruded products.

Stem Speeds. Optimal stem speeds are essential for hot extrusion. Excessive speed can cause overheating of the billet as well as tears and other surface defects. A speed that is too slow reduces productivity and increases the required extrusion pressure because of billet cooling. Slow speeds can also decrease tool life because of prolonged contact time between the tools and the hot billet. Typical stem speeds for various metals are:

Material	Stem speed	
	mm/s	in./s
Steel	152-203	**6-8**
Copper	51-76	**2-3**
Aluminum	12.7-25.4	$\frac{1}{2}$**-1**

The use of variable-delivery pumps and adjustable valves facilitates control of stem speed. Automatic control is available for maintaining constant speed throughout the extruding cycle.

Lubrication is another important operating parameter. The types of lubricants used and the effects of lubrication are discussed in the section "Lubricated Hot Extrusion" in this article.

Operating Parameters

Critical parameters for successful and economical hot extrusion include the method of billet preparation and heating, the amount of pressure and rate of speed used for extruding, and the type of lubricant employed.

Billet Preparation. The more common metals that are to be extruded are generally cast in the form of cylindrical logs measuring 3.7 to 6 in (12 to 20 ft) or more in length. These logs are sawed or sheared into billets of varying length, depending on the cross-sectional area and the length of the product to be extruded.

Additional billet preparation is sometimes necessary, depending on the material to be extruded. For example, it is necessary to machine the outer surfaces of some steel billets before they are heated; the outer surfaces must then be descaled after being heated to the extrusion temperature. Best results are attained in backward extrusion by scalping the billets before extrusion to remove oxides and other impurities from the billet skin. If this is not done, these impurities would find their way onto the surfaces of the extrusion because of the inherent nature of the metal flow in backward extrusion.

Before they are extruded, aluminum billets are frequently homogenized by heat treatment. This treatment improves the extrudability of the material and the surface finish produced.

Billet temperature is important for all materials (see Table 1). A billet temperature that is too high can cause blisters or other surface defects, including cracking. A temperature that is too low increases the pressure requirements for the extrusion and shortens tool life.

Pressure Requirements. The unit pressures needed for hot extrusion are significant considerations in press selection (discussed previously). The determination of pressure requirements is difficult for the extrusion of complicated shapes and sections--especially those with thin walls. Careful judgments based on past experience must be made for estimates. Formulas have been developed for estimating pressure requirements, using shape, friction, and other parameters. However, for less complicated shapes, such as round bars and tubes, a fair approximation of pressure requirements can be calculated by:

$$P = k \ln \frac{A}{a} \qquad \textbf{(Eq 2)}$$

where P is the extrusion pressure required (in pounds per square inch or megapascals); k is a numerical value representing the resistance to deformation, usually based on past experience in extruding a specific metal at a specific temperature; A is the cross-sectional area of the container liner or, in the case of tubes or other hollow shapes, the cross-sectional area of the liner minus the cross-sectional area of the mandrel (in square inches or square millimeters); and a is the total cross-sectional area of the extruded product (the shape area times the number of openings in the die) (in square inches or square millimeters).

The extrusion pressure requirements determined with Eq 2 are useful, but the values obtained are only approximations. The factor k varies with such factors as billet temperature, die design, type of metal extruded, amount of reduction (extrusion ratio), stem speed, and configuration of the extruded product. Billet length, nonhomogeneous metal flow, and friction also influence pressure requirements.

Unit pressures generally range from 450 to 760 MPa (65 to 110 ksi), with a maximum of about 1035 MPa (150 ksi). When practical, it is generally desirable to use a press with a capacity exceeding that actually required. This allows lower billet temperatures and faster stem speeds to be used and provides improved properties in the extruded products.

Stem Speeds. Optimal stem speeds are essential for hot extrusion. Excessive speed can cause overheating of the billet as well as tears and other surface defects. A speed that is too slow reduces productivity and increases the required extrusion pressure because of billet cooling. Slow speeds can also decrease tool life because of prolonged contact time between the tools and the hot billet. Typical stem speeds for various metals are:

Material	Stem speed

	mm/s	in./s
Steel	152-203	**6-8**
Copper	51-76	**2-3**
Aluminum	12.7-25.4	$\frac{1}{2}$ **-1**
Brass	**25-51**	**1-2**

The use of variable-delivery pumps and adjustable valves facilitates control of stem speed. Automatic control is available for maintaining constant speed throughout the extruding cycle.

Lubrication is another important operating parameter. The types of lubricants used and the effects of lubrication are discussed in the section "Lubricated Hot Extrusion" in this article.

Applications for Computer-Aided Design and Manufacture (CAD/CAM)

In current industrial practice, the design of extrusion dies, whether of the flat or conical type, is still an art rather than a science. Die design for a new extrusion is developed from previous experience and through costly experimentation and in-plant trials. Therefore, process and die development may require relatively long periods of time and may tie up extrusion presses that should be used for actual production. Automated design systems have been developed for nonlubricated and lubricated extrusion processes to reduce the costs of designing and manufacturing extrusion dies (Ref 11, 12, 13, 14).

Many years of experience lie behind the production of extrusion dies with increasing complexity of shape, thinness of section, and quality of surface. Some of this experience is rationalized in empirical design rules, but much die design still relies on personal judgment, intuition, and experience. The dies are proven out through the production of trial extrusions. Invariably, the die orifice is corrected to achieve the required control of cross-sectional dimensions, straightness, and surface quality.

The objectives of applying CAD techniques to extrusion are:

- To provide a scientific basis and to rationalize the die design procedure as much as possible
- To improve productivity by reducing the trials and corrections needed to prove out the dies
- To optimize die design in order to achieve optimal material yield and maximum productivity
- To reduce the lead time required for designing and manufacturing the die
- To reduce die manufacturing costs by using cost-effective numerical control (NC) machining techniques whenever appropriate

Computer-Aided Design and Manufacture of Flat Dies

Design. Flat dies are primarily used for the extrusion of aluminum alloys. They consist of flat disks of tool steel containing one or more shaped orifices (Ref 15). The hot metal is forced (extruded) through these orifices to produce the desired sections (Fig. 12). The detailed design of the die involves determination of the following:

- Optimal number of shaped orifices in the die
- Location of the orifices relative to the billet axis for uniform metal flow through each orifice

- Orientation of the orifices
- Modification of the shape of the orifices to correct for thermal shrinkage and die deflection under load
- Determination of bearing lengths for balancing metal flow

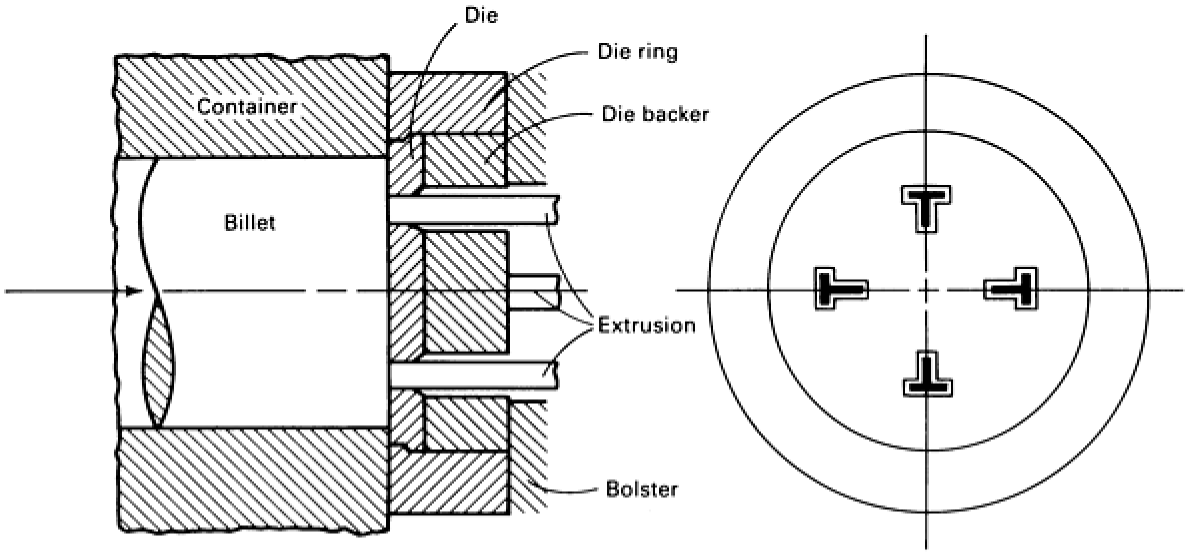

Fig. 12 Schematic of a flat die for extrusion of T-sections. Source: Ref 13

The details of a CAD technique for flat dies are given in Ref 13 and 15, in which the capabilities and application of an interactive CAD program, called ALEXTR, are described. A flow chart of the operation of this program is shown in Fig. 13. The first input into the program is the cross section of the extrusion, expressed in terms of *x*,*y* coordinates and the associated fillet or corner radii. These data are used to calculate such geometric parameters as cross-sectional area, perimeter, shape factor (perimeter/weight/length), location of centroid, and size and location of the circumscribing circle. The extrusion shape and the circumscribing circle are displayed on the graphics terminal with the calculated geometric variables.

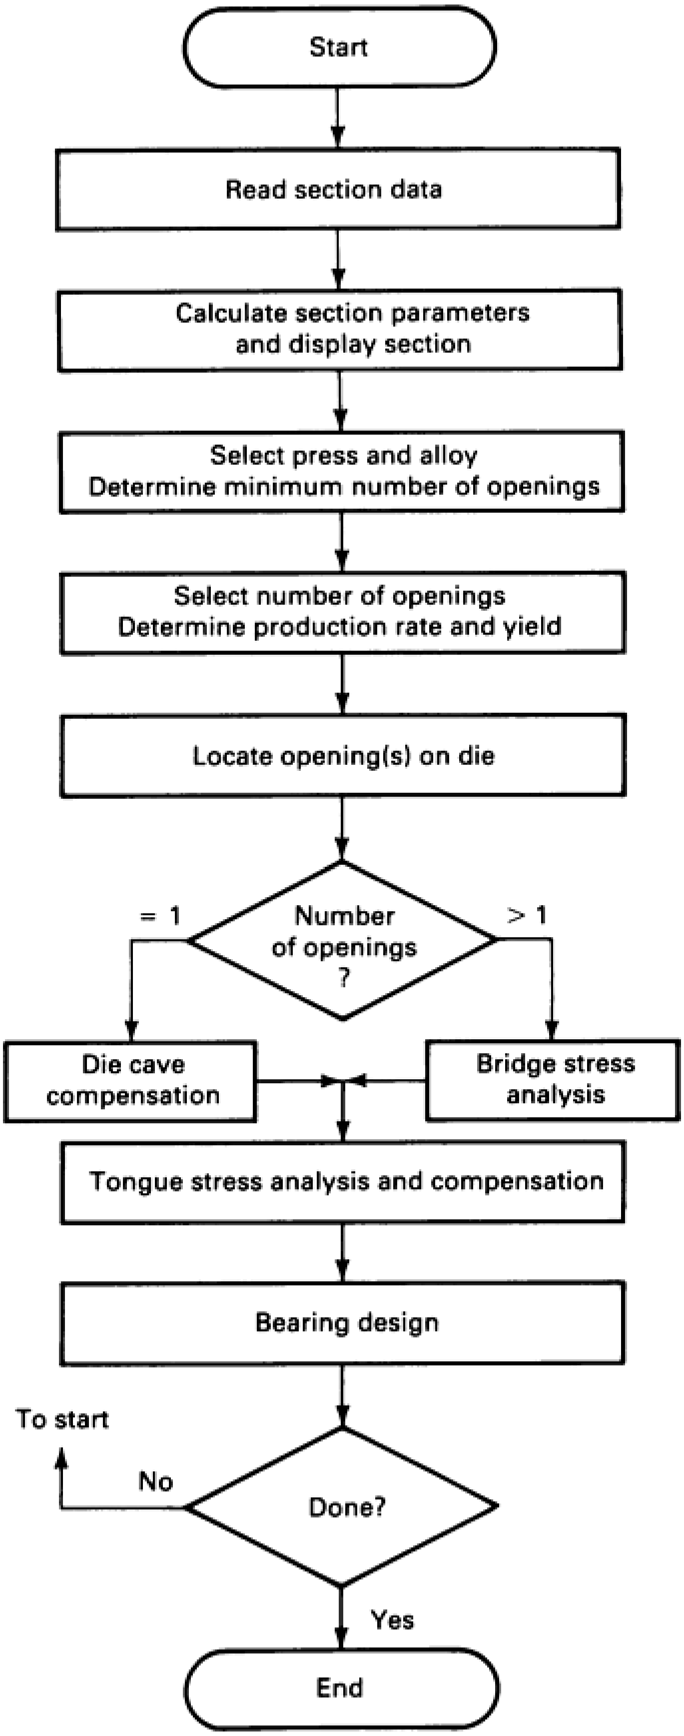

Fig. 13 Flow chart showing steps in the operation of ALEXTR. Source: Ref 13

ALEXTR then determines the number of extrusion orifices in the die (Ref 14). For this purpose, the user is asked to enter the specific press number (among several available), the alloy to be used, and the extrusion temperature. For each available press, characteristics such as press capacity, container diameter, maximum billet length, and runout length are stored in a data table. Load and yield calculations are made with the use of this information. The yield *Y*, in percent, is defined as:

$$Y = \frac{\text{Weight of usable extrusion}}{\text{Weight of billet}} \cdot 100 \qquad \textbf{(Eq 3)}$$

Because the load decreases as the number of openings increases, ALEXTR makes the first load calculation based on a single opening. If the result exceeds the press capacity, the calculation is repeated until the expected load is less than the press capacity or until the number of openings required is greater than the number allowed by the defined press characteristics. The number of openings is selected on the basis of:

- Operator specifications
- Maximum extrusion length
- Maximum material yield

The program also determines the optimal billet size for the number of openings to be used.

The next step in the design process is the layout of the extrusion orifices. Two considerations are involved. The first is that certain minimum clearances have to be maintained between the die openings (so that the die and the backup tooling have the strength to withstand the extrusion pressure) and between the die opening and the cylinder wall (to avoid flow of metal from the outside surface of the billet into the product). The second consideration is that the metal flow must be balanced by orienting the orifices such that a certain amount of symmetry is maintained, if possible.

The openings are positioned such that the center of gravity of an opening coincides with that of the billet segment feeding that opening. The opening is also rotated such that its greatest dimension is parallel to and as close as possible to the chord of the segment (Fig. 14a). If this layout is acceptable to the user, the single display is replaced with a display of the full container circle and all openings (Fig. 14b). The layout can be modified by the designer, if desired, through the use of the translate, rotate, and mirror image capabilities of the program. If unable to lay out the holes because of insufficient clearances, the designer can go back and select a different number of holes or a different press.

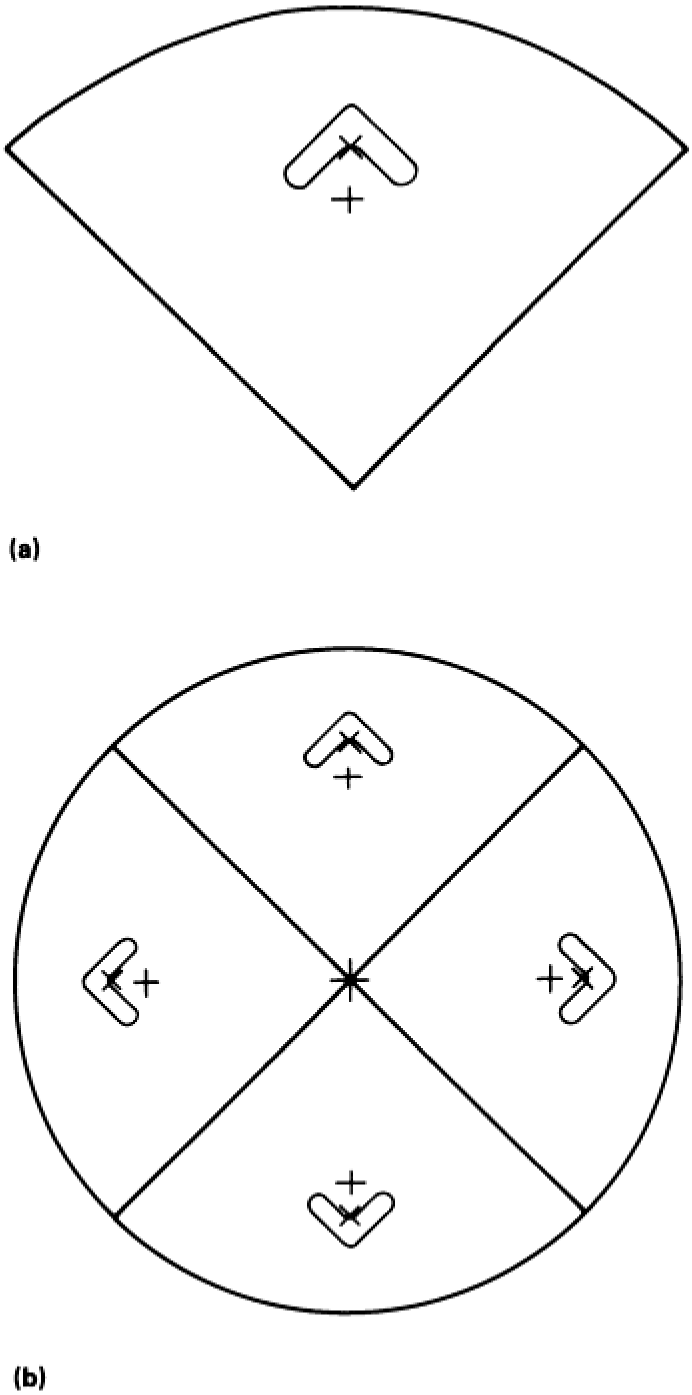

Fig. 14 Placement of openings in the die by ALEXTR. (a) Extrusion section placed on one quadrant of the die. (b) Arrangement of the entire die by repeating layout of the segment shown in (a)

After the layout is complete, ALEXTR corrects the openings for die cave and die deflection. A tool strength analysis is then performed to determine the bending and shear stresses in the die, backer, and bolster due to the extrusion pressure. The need for conforming tools to support the die is also determined by the tool strength analysis. These calculations allow the user to evaluate the need for support tooling. Die deflection analysis also includes estimation of the bending of the die at various locations. This information is helpful in predicting the dimensional changes in the die orifices under load, during extrusion. Therefore, the dimensions of the die orifices can be modified to correct for these dimensional changes to obtain the desired tolerances in the extruded shape.

The next step in the design process is the determination of die bearing lengths. The die bearing at any position is dependent on the section thickness at that position and on its distance from the die center. The designer indicates, with the light pen on the screen of the graphics terminal, the applicable thicknesses at various points on the extrusion perimeter. These dimensions are used by the computer program to calculate the die bearing lengths.

Manufacture and Evaluation. After die design has been completed, the geometric design information can be used to manufacture the dies by NC techniques. For manufacturing extrusion dies, either conventional electrical discharge machining (EDM) or wire electrical discharge machining is used. In the first case, two EDM electrodes are machined by numerical control; one electrode is used for machining the die opening(s) from the billet entry side, and the other is used for machining the die bearings from the exit side of the die. In wire electrical discharge machining, a wire electrode can be used for machining the die opening. However, the backside of the die, that is, the bearing areas, still must be machined conventionally by milling or by conventional electrical discharge machining. Numerical control programs are also used for preparing the templates for dimensional quality control of the dies and the extrusion.

In an example development study, the CAD/CAM technique was used to make flat-face dies (see Fig. 10b) and to extrude a T-shape from aluminum alloy 7075 (Ref 13). This section was extruded using a 6.2 MN (700 tonf) hydraulic press equipped with a 76 mm (3 in.) container. With an average bearing of 4.74 mm (0.187 in.), starting billet dimensions of 173 mm (2.875 in.) in diameter and 152 mm (6.0 in.) in length, and a flow stress of 52 MPa (7.5 ksi), a breakthrough load of 2.34 MN (263 tonf) was calculated. When the average bearing was specified to be 6.35 mm (0.250 in.), the expected load was 2.43 MN (273 tonf). The flow stress of 52 MPa (7.5 ksi) was estimated for the billet of aluminum alloy 7075 from data available in the literature and from preliminary extrusion tests with a round extrusion die. In these estimations, calculations were made for the average strain (4.0 for the present extrusion ratio of approximately 15 to 1) and strain rate (0.37/s for the ram speed of 406 mm/min, or 16 in./min).

The final step in the die design process was to indicate the section thicknesses and the bearing transition points. The die design data were then saved on a disk file for subsequent access by NC programs. Therefore, this geometry was used for NC machining of the EDM electrodes and the die bearings. The die opening, in H13 die steel with a hardness of 42 to 46 HRC, was machined through the die from the front. The die bearings were machined by numerical control from the back.

Computer-Aided Design and Manufacture of Dies for Lubricated Extrusion

Design. Lubrication in extrusion reduces load and energy requirements, reduces tool wear, improves surface finish, and provides a product with nearly uniform properties. This technique is commonly used in the extrusion of shapes from steels, titanium alloys, and nickel alloys. Proper die design is critical in lubricated extrusion, especially when noncircular shapes are extruded. An effective die design must ensure smooth metal flow with consistent lubrication. It is desirable to use shaped dies, which provide a smooth transition for the billet from the round or rectangular container to the shaped-die exit.

Computer-aided design techniques have been developed for the design of dies for lubricated extrusion (Ref 14, 16). For example, the design of a shaped die for extruding a T-shape from a round billet is illustrated schematically in Fig. 15. The geometry of this die should be optimized to:

- Give a defect-free extrusion requiring minimum postextrusion treatment (twisting and straightening)
- Minimize load and energy requirements
- Yield maximum throughput at minimum cost

The design procedure for determining the optimal shape of the die involves the following three steps:

- Define die geometry in a general manner
- Calculate the extrusion load as a function of the die geometry
- Optimize and determine the die shape that requires the minimum extrusion load

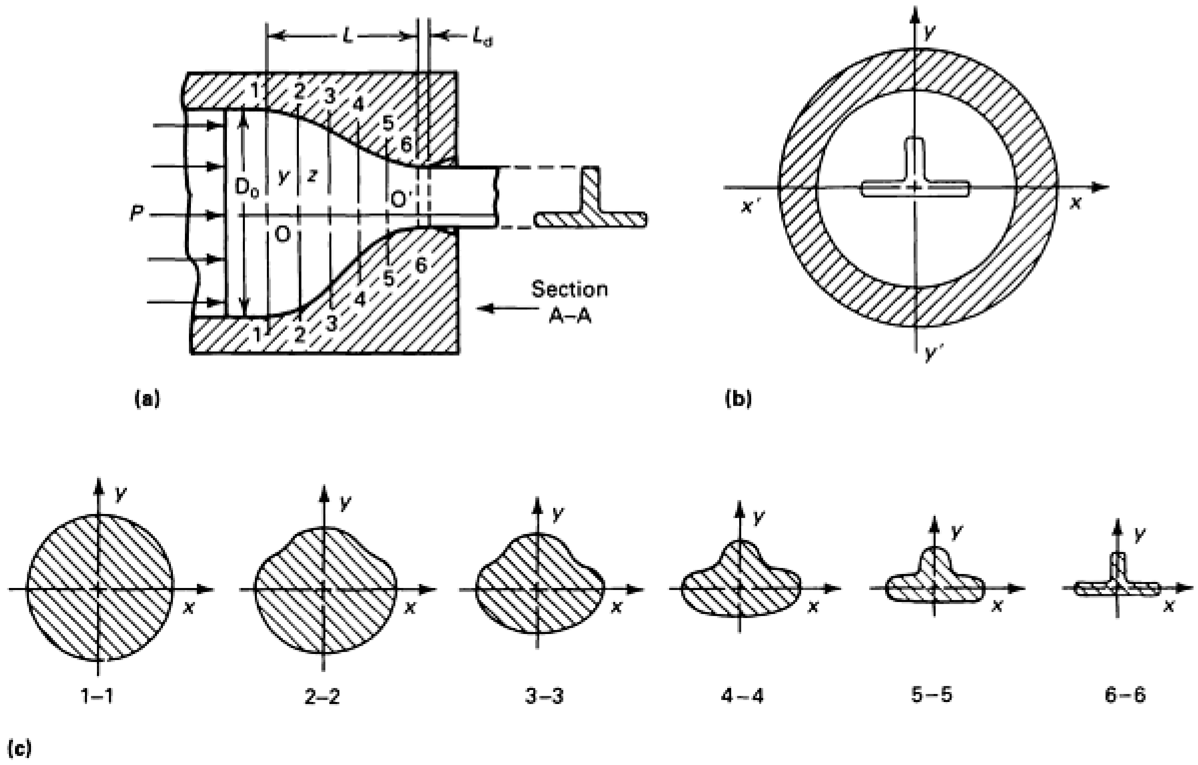

Fig. 15 Schematic of a shaped die for extrusion of a T-shape. (a) Section through *y*-*y*'. (b) Section A-A. (c) Cross sections of the billet during extrusion. Source: Ref 16

To define the die geometry for a T-extrusion, first the position of the die opening with respect to the container axis is determined. The initially circular cross section of the billet is then divided into a number of sectors. Starting from a plane of symmetry, the final cross section is divided into the same number of segments. This is done while keeping the extrusion ratios (ratio of the area of a sector in the billet to the area of the corresponding segment in the product) equal to the overall extrusion ratio. Thus, the initial and final positions of the material flow lines along the die surface are determined, and the path followed by any material point between the initial and final positions is determined by calculating and optimizing extrusion pressure.

Manufacture and Evaluation. The surface of a shaped die is defined as an array of points. The practical method of manufacturing this die is to NC machine a carbon electrode and then to electrical discharge machine the die. For this purpose, the cutter paths for machining the electrode surface must be determined. In using a ball-end mill, the position of the center of the spherical portion of the mill, with respect to any given point on the surface, can be determined by constructing a vector normal to the surface at that given point. Typically, the normal vector is calculated from the cross product of two vectors: one tangent to the surface along the material path line, and the other tangent to the cross-sectional boundary. For a tool of given radius, the coordinates of the cutter paths are determined as the tool moves, in a predetermined manner, over the array of points defining the die surface. The computer programs developed for calculating the cutter paths contain special routines to check for undercutting and gouging. The calculated cutter center points for extruding the T-section are plotted on the screen of a graphics terminal, as shown in Fig. 16.

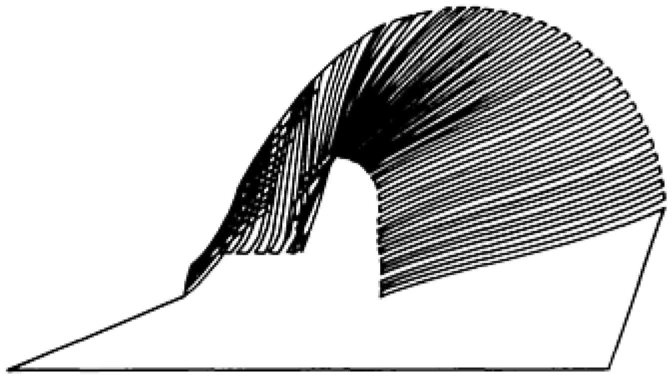

Fig. 16 Cutter path for NC machining of the EDM electrode for the streamlined die shown in Fig. 15. Source: Ref 16

The CAD/CAM technique was used to design and manufacture shaped dies for a T-shape with a 51 mm (2 in.) wide web and a 25.4 mm (1 in.) high rib. Billets 76 mm (3 in.) in diameter--from type 4340 steel and alloy Ti-6Al-4V--were extruded in a 6.2 MN (700 tonf) hydraulic extrusion press. Comparison of experimental results with computer-aided predictions showed that:

- Shaped dies for lubricated extrusion of simple structural shapes in titanium and steel can be designed and manufactured using computer-aided techniques
- Numerical control programs are adequate for machining three-dimensional streamlined surfaces (die or electrode) providing smooth transitions from round to structural sections. This was demonstrated by machining the EDM electrode for a streamlined T-section
- Straight T-sections of titanium and steel can be extruded through a streamlined die without any die modification
- Extrusion loads can be predicted with reasonable accuracy if accurate flow stress and friction data are available
- In the extrusion of simple structural shapes, the product shape does not significantly influence the extrusion load

Economic Aspects of Computer-Aided Design and Manufacture

The application of computer-aided design and manufacture in extrusion continues to increase. Several extrusion companies are using computer-aided techniques for die making and process optimization (Ref 11, 17). In addition to cost reductions, the implementation of computer-aided design and manufacture in extrusion provides the following potential benefits:

- More precise estimation, and reductions in estimation costs
- Reduction in delivery schedules
- Less dependence on skilled diemakers
- Reductions in the number of die failures and in die-design and manufacturing costs
- Improved utilization of existing press capacity by reducing die trials
- Continuous improvement of die and process technology
- Increases in material yield and press productivity

Introduction

IN HYDROSTATIC EXTRUSION, the billet in the container is extruded through the die by the action of a liquid pressure medium rather than by direct application of the load with a ram. The process of pure hydrostatic extrusion differs from conventional extrusion processes (see the articles "Cold Extrusion" and "Conventional Hot Extrusion" in this Volume) in that the billet is completely surrounded by a fluid, which is sealed off and is pressurized sufficiently to extrude the billet through the die.

Hydrostatic extrusion can be done hot, warm, or cold and can be used to extrude brittle materials that cannot be processed by conventional extrusion. Hydrostatic extrusion also allows greater reductions in area (higher extrusion ratios) than either cold or conventional hot extrusion.

The primary advantages of simple hydrostatic extrusion over conventional hot or cold extrusion methods are:

- There is no friction between the billet and the container. Therefore, the pressure at the beginning of extrusion is much lower, and billets of any length can theoretically be extruded
- Friction at the die can be significantly reduced by a film of pressurized lubricant between the deforming metal and the die surface
- The lower extrusion pressures and the reduced die friction of hydrostatic extrusion allow the use of either higher extrusion ratios or lower extrusion temperatures
- The uniform hydrostatic pressure in the container means that billets do not have to be straight; coiled wire can also be extruded

Limitations of the hydrostatic extrusion process include:

- Containment of the fluid under high pressure (up to 2 GPa, or 290 ksi) requires reliable seals between the container bore surface and both the ram and die. The technology required to achieve dependable seals at these points is widely available, however. Also, sealing between the billet nose and the die can easily be achieved by chamfering or tapering the billet nose to match the entry angle of the die
- In addition to being tapered to match the die opening angle, the billet is also usually machined all over to remove surface defects that would otherwise reappear on the extruded product. This is especially true when cast billets are being used

Other limitations of the process arise when a relatively large volume of fluid is used compared to the billet volume to be extruded. These include:

- Increased handling for injecting and removing the fluid for each extrusion cycle
- Reduced control of billet speed and stopping due to potential stick-slip and excessive stored energy in the compressed fluid
- Reduced process efficiency in terms of billet-to-container volume ratio
- Increased complications when extruding at elevated temperatures

The problems of billet speed and stopping control can be reduced by using viscous dampers and by improving lubrication at the billet/die interface. Another approach to minimizing this and the other problems cited above is to keep the amount of pressurizing fluid to an absolute minimum, as in the Hydrafilm process (see the section "The Hydrafilm Process" in this article).

Introduction

IN HYDROSTATIC EXTRUSION, the billet in the container is extruded through the die by the action of a liquid pressure medium rather than by direct application of the load with a ram. The process of pure hydrostatic extrusion differs from conventional extrusion processes (see the articles "Cold Extrusion" and "Conventional Hot Extrusion" in this Volume) in that the billet is completely surrounded by a fluid, which is sealed off and is pressurized sufficiently to extrude the billet through the die.

Hydrostatic extrusion can be done hot, warm, or cold and can be used to extrude brittle materials that cannot be processed by conventional extrusion. Hydrostatic extrusion also allows greater reductions in area (higher extrusion ratios) than either cold or conventional hot extrusion.

The primary advantages of simple hydrostatic extrusion over conventional hot or cold extrusion methods are:

- There is no friction between the billet and the container. Therefore, the pressure at the beginning of extrusion is much lower, and billets of any length can theoretically be extruded
- Friction at the die can be significantly reduced by a film of pressurized lubricant between the deforming metal and the die surface
- The lower extrusion pressures and the reduced die friction of hydrostatic extrusion allow the use of either higher extrusion ratios or lower extrusion temperatures
- The uniform hydrostatic pressure in the container means that billets do not have to be straight; coiled wire can also be extruded

Limitations of the hydrostatic extrusion process include:

- Containment of the fluid under high pressure (up to 2 GPa, or 290 ksi) requires reliable seals between the container bore surface and both the ram and die. The technology required to achieve dependable seals at these points is widely available, however. Also, sealing between the billet nose and the die can easily be achieved by chamfering or tapering the billet nose to match the entry angle of the die
- In addition to being tapered to match the die opening angle, the billet is also usually machined all over to remove surface defects that would otherwise reappear on the extruded product. This is especially true when cast billets are being used

Other limitations of the process arise when a relatively large volume of fluid is used compared to the billet volume to be extruded. These include:

- Increased handling for injecting and removing the fluid for each extrusion cycle
- Reduced control of billet speed and stopping due to potential stick-slip and excessive stored energy in the compressed fluid
- Reduced process efficiency in terms of billet-to-container volume ratio
- Increased complications when extruding at elevated temperatures

The problems of billet speed and stopping control can be reduced by using viscous dampers and by improving lubrication at the billet/die interface. Another approach to minimizing this and the other problems cited above is to keep the amount of pressurizing fluid to an absolute minimum, as in the Hydrafilm process (see the section "The Hydrafilm Process" in this article).

Simple Hydrostatic Extrusion

In the simplest method of hydrostatic extrusion, the metal is extruded through a conical die into the atmosphere in much the same way as in conventional extrusion (Fig. 1). The container with the pressure-transmitting fluid is sealed with high-pressure seals at the ram and the die. Extrusion begins as soon as the hydrostatic pressure has reached a sufficiently high value, depending on the flow stress of the material and the extrusion ratio.

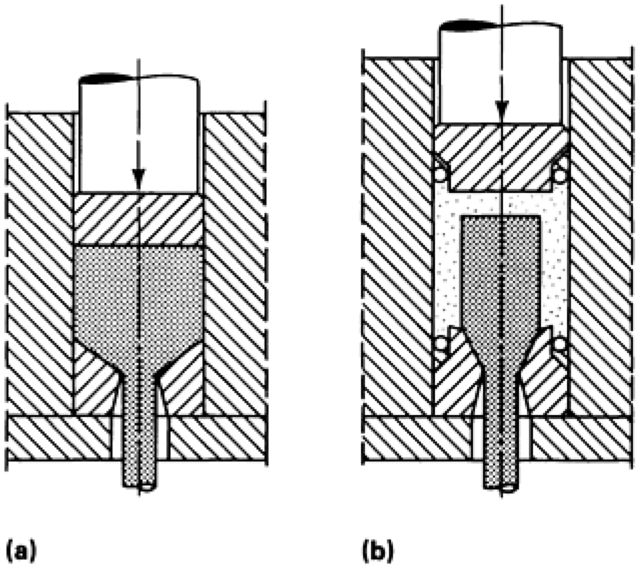

Fig. 1 Comparison of the conventional extrusion (a) and hydrostatic extrusion (b) processes

Extrusion Pressure. A pressure peak is found at the beginning of extrusion in the hydrostatic process. It is needed to initiate metal flow, which is hindered by friction at the die until a lubricating film and steady-state conditions have developed. This pressure peak can be very high, particularly if breakdown of the lubricant film occurs. The rapid decrease in pressure after extrusion begins can sometimes lead to the development of periodic oscillations in pressure; this is known as the stick-slip effect. It can be eliminated through the use of viscous dampers (Ref 1, 2) or by minimizing the amount of hydrostatic fluid used.

After the initial pressure peak, the steady-state pressure remains constant because there is no friction at the wall of the container (Fig. 2). The steady-state extrusion pressure required depends on the work material and is linearly related to the natural logarithm of the extrusion ratio R according to the empirical equation:

$$p = k_1 \ln R + k_2 \qquad \textbf{(Eq 1)}$$

where k_1 and k_2 are constants. Figure 3 illustrates this relationship for the cold extrusion of round billets to rod for several alloys. The gradient of the lines would be slightly steeper for more complex sections.

Simple Hydrostatic Extrusion of Brittle Materials

Most brittle materials are subject to circumferential (transverse) and longitudinal surface cracking during hydrostatic extrusion. This cracking can be avoided through the use of either fluid-to-fluid extrusion or double-reduction dies. In fluid-to-fluid extrusion, the billet is hydrostatically extruded into a fluid at a lower pressure. This method has several disadvantages, including high tooling and operating costs, extrusion lengths that are limited to the length of the secondary chamber, and increased fluid pressure required for extrusion. For these reasons, the fluid-to-fluid process may not be suitable for many industrial applications.

The problem of extruding low-ductility metals was approached in a different way by researchers at Battelle Columbus Division (Ref 3), who established that the cracks or fracture first developed in the rear section of the die land, immediately before the exit plane, and that the surface cracking resulted from residual tensile stresses as the product left the die. The cracks observed were either longitudinal or transverse across the extruded product, depending on whether the predominating residual stresses were longitudinal or circumferential. This phenomenon was noted much earlier in rod and tube drawing (Ref 4). It was discovered that it is possible to reverse the residual stresses at the surface to compressive stresses by a subsequent draw with a low reduction in area (<2%).

The work of these investigators led to the development of the double-reduction die (Ref 4). Figure 4 compares a standard die with a double-reduction die. The double-reduction die used for the experiments was designed to give a 2% reduction in the second step. This method has been successfully applied to the extrusion of brittle materials, including beryllium and TZM molybdenum alloy, without any cracking. The lubricant used was polytetrafluoroethylene (PTFE), and the pressurizing fluid was castor oil. The results may be applicable to conventional cold extrusion through a lubricated conical die (Ref 3).

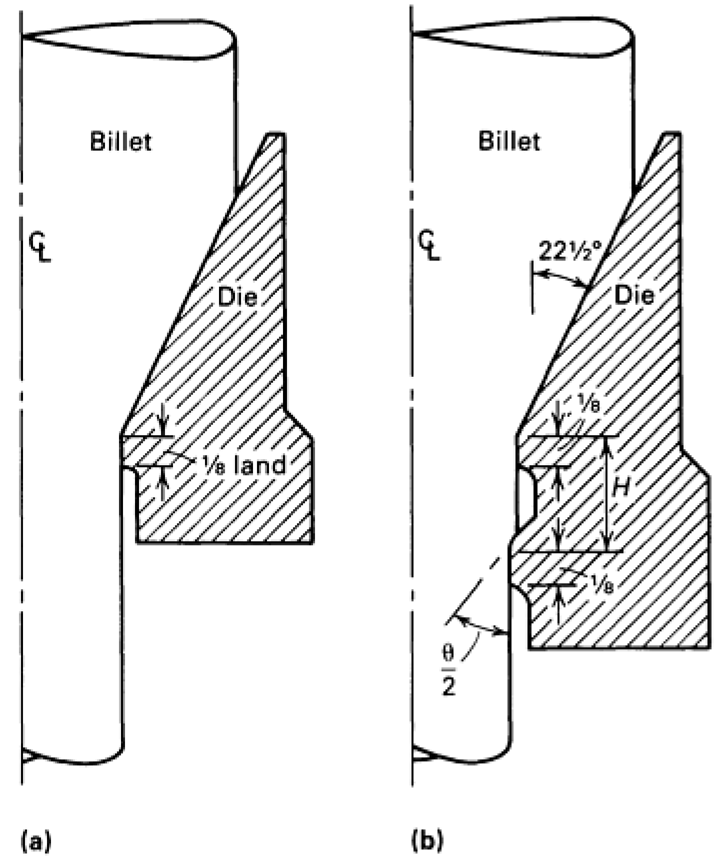

Fig. 4 Standard die (a) and double reduction die (b) for the hydrostatic extrusion of brittle materials. *H*, distance between the start of each bearing; θ, included angle at second reduction. Dimensions given in inches. Source: Ref 5

It is believed that the small second reduction prevents cracking by imposing an annular counterpressure on the extrusion as it exits the first portion of the die. This counters the axial tensile stresses arising from residual stresses, elastic bending, and friction. Prevention of circumferential cracks upon exit from the second portion of the die is believed to be associated with the favorable permanent change in residual stresses in the workpiece caused by the small second reduction (Ref 5).

Introduction

IN THE DRAWING PROCESS, the cross-sectional area and/or the shape of a rod, bar, tube, or wire is reduced by pulling through a die. One of the oldest metal-forming operations, drawing allows excellent surface finishes and closely controlled dimensions to be obtained in long products that have constant cross sections. In drawing, a previously rolled, extruded, or fabricated product with a solid or hollow cross section is pulled through a die at exit speeds as high as several thousand feet per minute (Ref 1, 2). The die geometry determines the final dimensions, the cross-sectional area of the drawn product, and the reduction in area. Drawing is usually conducted at room temperature using a number of passes or reductions through consecutively located dies. An important exception is the warm drawing of tungsten to make incandescent lamp filaments. Annealing may occasionally be necessary after a number of drawing passes before the drawing operation is continued. The deformation is accomplished by a combination of tensile and compressive stresses that are created by the pulling force at the exit from the die and by the die configuration.

In wire or rod drawing (Fig. 1 and 2), the section is usually round but could also be a shape. In the cold drawing of shapes, the basic contour of the incoming shape is established by cold-rolling passes that are usually preceded by annealing. After rolling, the section shape is refined and reduced to close tolerances by cold drawing (Ref 3). Again, a number of annealing steps may be necessary to eliminate the effects of strain hardening, that is, to reduce the flow stress and to increase the ductility.

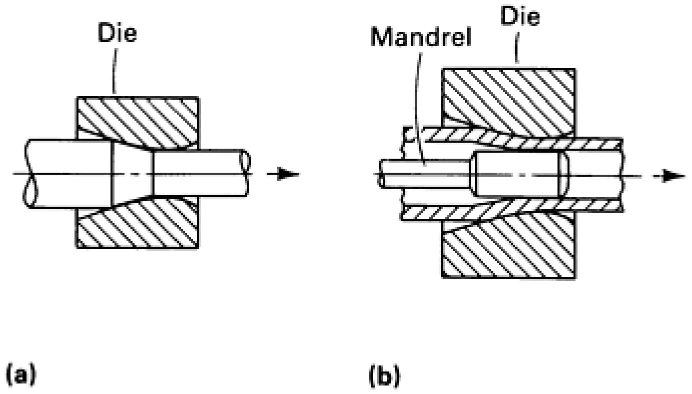

Fig. 1 Drawing of rod or wire (a) and tube (b).

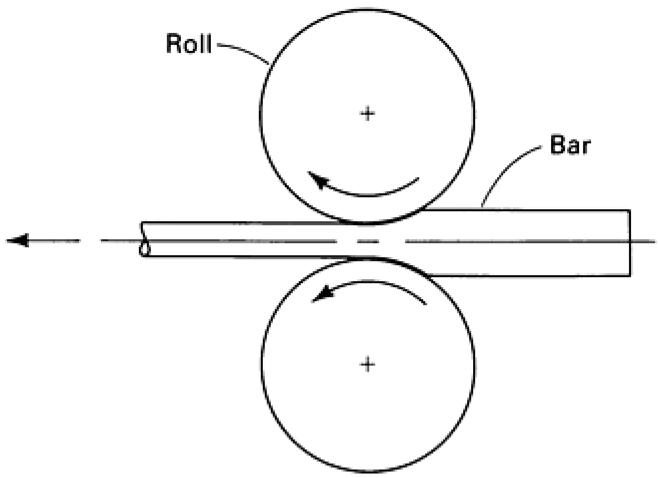

Fig. 2 Drawing of a bar through undriven rolls.

In tube drawing without a mandrel (Fig. 3), also called tube sinking, the tube is initially pointed to facilitate feeding through the die; it is then reduced in outside diameter while the wall thickness and the tube length are increased. The magnitudes of thickness increase and tube elongation depend on the flow stress of the drawn part, die geometry, and interface friction.

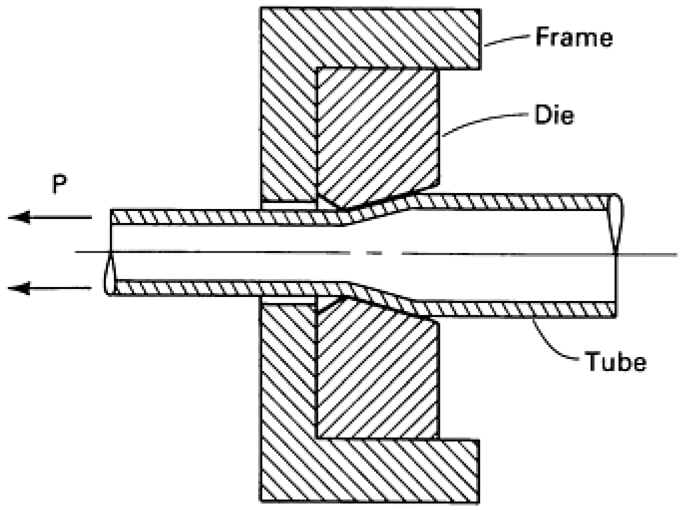

Fig. 3 Tube drawing without a mandrel (tube sinking).

Drawing with a fixed plug (Fig. 4) is widely known and used for drawing large-to-medium diameter straight tubes. The plug, when pushed into the deformation zone, is pulled forward by the frictional force created by the sliding movement of the deforming tube. Therefore, the plug must be held in the correct position with a plug bar. In drawing long and small-diameter tubes, the plug bar may stretch and even break. In such cases, it is advantageous to use a floating plug (Fig. 5). This process can be used to draw any length of tubing by coiling the drawn tube at speeds as high as 10 m/s (2000 ft/min). In drawing with a moving mandrel (Fig. 6), the mandrel travels at the speed at which the section exits the die. This process, also called ironing, is widely used for thinning the walls of drawn cups or shells in, for example, the production of beverage cans or artillery shells.

Wire, Rod, and Tube Drawing

Basic Mechanics of Drawing (Ref 4)

It is fundamental that the pulling force, or drawing stress, cannot exceed the strength of the wire or rod being drawn (otherwise, fracture or unstable deformation would occur). In fact, practical considerations often limit the drawing stress to about 60% of the as-drawn flow stress. Therefore, the area reduction per drawing pass is rarely greater than 30 to 35%. A particularly common reduction is that of an American Wire Gauge of 1, or about 20.7%. Thus, many reductions or drawing passes are needed to achieve a large overall reduction. Much larger reductions can be achieved in a single operation with extrusion. Alternatively, drawing can be used to generate larger quantities of small-diameter product (for example, 0.01 mm, or 0.0004 in.) with excellent dimensional control (assuming proper die maintenance).

Approach Angle. A typical carbide drawing die is illustrated in Fig. 7. The wire or rod makes contact in the drawing cone along the approach angle and is reduced to the dimensions of the drawing cone exit. The bearing region involves no further reduction and allows the die to be refinished without a change in the exit dimensions of the drawing cone. The back relief reduces the amount of abrasion that takes place if the drawing stops or if the die is out of alignment. A lubricant is introduced at the bell portion of the die and is pulled into the die/wire interface by the moving wire.

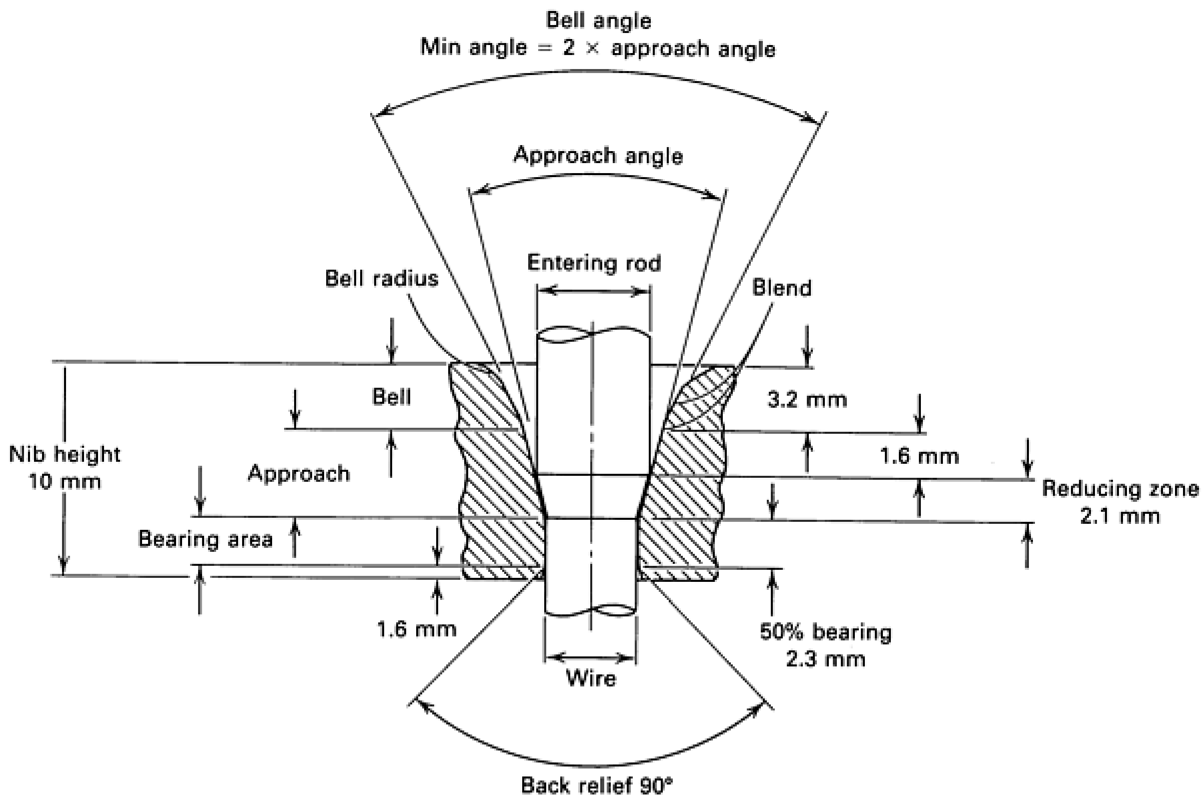

Fig. 7 Cross section of a typical wire die for drawing 5.5 mm (0.218 in.) diam rod to 4.6 mm (0.180 in.) diam wire (17% reduction per pass).

The approach angle is perhaps the most important feature of the die for most applications. The effect of the approach angle on metal flow cannot easily be considered independent of the drawing reduction, and modern drawing theory incorporates both into the Δ parameter:

$$\Delta \approx \left(\frac{\alpha}{r}\right) [1 + (1 - r)^{1/2}]^2$$

where α is the approach semiangle (one-half the included angle) in radians and r is the fractional drawing reduction, given by:

$$r = 1 - A_1/A_0$$

where A_0 and A_1 are the starting and finishing cross-sectional areas, respectively. Commercial die design often involves approach semiangles in the range of 6 to 10° and drawing reductions of about 20%. The corresponding Δ values typically range from 2 to 3, with higher values corresponding to lower reductions and higher die angles, and lower values corresponding to higher reductions and lower die angles.

Effect of Friction. Basically, low Δ values may involve excessive frictional work between the wire and the drawing cone, and high Δ values involve redundant work or plastic strain beyond that calculable from the reduction in area of the pass. Some degree of redundant work exists for Δ> 1, with redundant work increasing as Δ increases, much as frictional work can increase as Δ decreases. The net effect is that some intermediate value of Δ involves the minimum work, and therefore the minimum drawing force, because the drawing force multiplied by the drawing velocity is the work consumed per unit time. Similarly, the drawing stress equals the work per unit volume of wire drawn. The Δ for minimum drawing stress can be approximated by:

$$\Delta_{min} \simeq 4.9 \left[\frac{\mu}{\ln(1/1 - r)} \right]^{1/2}$$

where μ is the coefficient of friction between the wire and the drawing cone. The drawing stress σ_d can be usefully approximated as:

$$\sigma_d \simeq \bar{\sigma} \left(\frac{3.2}{\Delta + 0.9} \right) (\alpha + \mu)$$

where $\overline{\sigma}$ is the average strength or flow stress of the wire during the drawing pass.

Redundant Work of Deformation. Redundant work is expressed in terms of the redundant work factor or the ratio of total plastic deformation work to the work implied by dimensional change. Experimental studies suggest that the redundant work factor Φ can be estimated to be:

$$\Phi \simeq \Delta/6 + 1$$

Heat Generation During Drawing. The management of heat is of great concern in drawing; practical cold-drawing operations can involve wire temperature increases of a few hundred degrees Kelvin. Much heat is generated directly by the plastic deformation, and this heat is only partially removed by interpass cooling. The dies extract little heat under commercial conditions and become very hot. Under adiabatic conditions, the temperature increase ΔT_d associated with plastic deformation in a single pass is approximately:

$$\Delta T_d = \Phi \overline{\sigma} \ln (1/1 - r)/C\rho$$

where C and ρ are the heat capacity and density of the wire, respectively. Additional heat generation is associated with frictional work. This heat is concentrated at the die/wire interface and can lead to diminished lubrication, further heating, and catastrophic lubricant breakdown. Accompanying problems include poor wire surface quality and metallurgical changes near the wire surface. If the coefficient of friction is not influenced by Δ, frictional heating is aggravated by low Δ processing. Fortunately, there is a tendency for low approach angles (and thus low Δ) to foster hydrodynamic lubrication and a reduced coefficient of friction.

Preparation for Drawing (Ref 5)

One or more of three basic preparation steps--heat treatment, surface preparation, and pointing--are usually required prior to successful cold drawing. These three steps are naturally dependent on the state of the part before drawing and on the desired drawing results.

Heat treatment usually involves annealing or softening so that the material is ductile enough for the intended percentage of reduction. This is particularly necessary for certain metals that are hard or brittle in the hot-worked state or for previously cold-drawn parts that have already been work hardened too much to allow further reduction.

Annealing. In the wire industry, a wide variety of in-process annealing operations are available for rendering coiled material suitable for further processing that may require formability, drawability, machinability, or a combination of these characteristics. One large wire mill reported using 42 separate and distinct annealing cycles, most of which represented compromises between practical considerations and optimal properties. For example, annealing temperatures below those that might yield optimal softness sometimes must be used in order to avoid the scaling of wire coils, which can often occur even in controlled-atmosphere furnaces. Even slight scaling can cause the coil wraps to stick together, and this can impede coil payoff in subsequent operations.

Patenting is a special form of annealing that is peculiar to the rod and wire industry. In this process, which is usually applied to medium- and higher-carbon grades of steel, the rod or wire products are uncoiled, and the strands are delivered to an austenitizing station. The strands are then cooled rapidly from above the full annealing temperature (A_3) in a molten medium (usually lead at about 540 °C, or 1000 °F) for a period of time sufficient to allow complete transformation to a fine pearlitic structure. Salt baths and fluidized beds have also been used for this purpose. This treatment increases considerably the amount of subsequent wire-drawing reduction that the product can withstand and permits the production of high-strength wire. Successive drawing and patenting steps can be used to obtain the desired size and strength level.

Surface Preparation. To prevent damage to the workpiece surface or the draw die during cold drawing, the starting stock must first be cleaned of surface contaminants, such as scale, glass, and heavy rust. This cleaning usually involves the use of various pickling or shotblasting methods. In many cases, especially when tubes are being drawn, the surface can also be coated or prelubricated by phosphatizing, plating, soaping, or liming methods. If no intermediate annealing is required, some of the prelubricating methods permit several cold-drawing passes without repeated treatment. Solid bars or rods are generally lubricated by oil during the drawing process.

To provide a wire of good surface quality, it is necessary to have clean wire rod with a smooth oxide-free surface. Conventional hot-rolled rod must be cleaned in a separate operation, but with the advent of continuous casting, which provides better surface quality, a separate cleaning operation is not required. Instead, the rod passes through a cleaning station as it exits the rolling mill.

Pointing, sometimes called chamfering, involves the preparation of a short length of one end of the starting part to a size slightly smaller than the draw die. The prepared end, called the point, is thus ready for insertion through the draw die for gripping. The actual pointing operation is usually performed at room temperature by swaging, rolling, or turning. However, it can be performed after preheating and can also be done by hammering, acid etching, or grinding.

In some cases, these pointing operations can be avoided through the use of push pointing, which involves pushing the end a short distance through the die. Pushing forces, however, are much higher than pulling forces. As a result, starting parts having small diameters and slender sections may buckle during the push-pointing process. This buckling action can be minimized by proper support, but parts having a diameter of about 9.5 mm (0.37 in.) or less generally must be pointed by one of the methods previously described.

Drawing of Rod and Wire (Ref 5)

An overall view of the process by which steel wire is drawn from rods is shown in Fig. 8. Methods and equipment used for the cold drawing of rod and wire, as well as small-diameter tubing, are generally designed so that the products can be uncoiled and then re-coiled after drawing. On multiple-die continuous machines, uncoiling, drawing, and re-coiling are repeated at successive stations. Rod coils, when ready for processing, are usually butt welded together for continuous drawing.

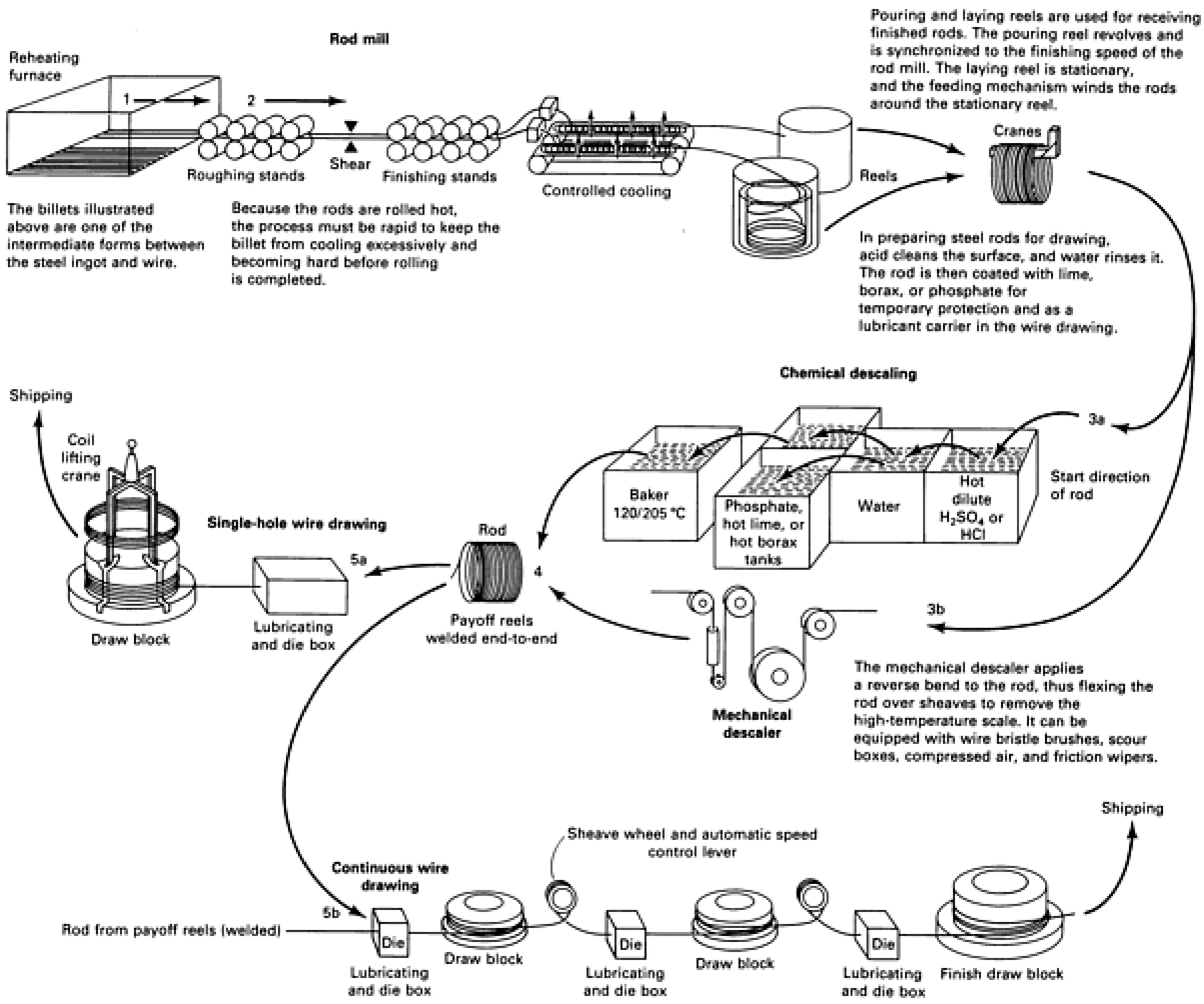

Fig. 8 Schematic diagram illustrating how steel wire is drawn from rods. Source: Ref 6.

The distinction between wire and rod (or bar) is somewhat arbitrary. The term wire generally refers to smaller-diameter products (<5 mm, or 0.2 in.) that can be rapidly drawn on multiple-die machines. Larger-diameter rod and bar stock can be drawn on single-die machines or on benches that do not require coiling of the as-drawn product.The terms rod and wire will often be defined from a marketing perspective. In both cases, the nature of the drawing process is similar (Ref 4).

In the drawing process, cleaned and coated coils of rod or wire are first placed on a payoff tray, stand, or reel; this permits free unwinding of the stock. The leading end of the rod or wire, after being pointed, is then inserted through the drawing die and seized by a gripper attached to a powered cylindrical block or capstan. On so-called dry machines, the die is mounted in an adapter within a box. This die box contains grease, dry soap, oil, or other lubricants through which the stock must pass before reaching the die.

Bull blocks are single-die drawing machines with individual drive systems. They are extensively used for breakdown, finishing, or sizing operations on large-diameter rod and wire, made from both ferrous and nonferrous metals, by firms with production requirements that do not warrant more sophisticated, continuous machines.

The spindles of these machines are generally vertical, with spindle blocks revolving in a horizontal plane. The arrangement is occasionally reversed (with the spindles horizontal and the blocks revolving in a vertical plane), particularly for applications involving large-diameter stock.

Many design variations are available with bull blocks. For example, a double-deck arrangement permits two drafts to be performed, with the second draft maintaining a fixed percentage of area reduction. Other refinements include external air cooling and internal water cooling of the block as well as riding-type block-stripping spiders for direct coiling and wire removal. These spiders, with collapsible feet, can be equipped with automatic discharging mechanisms to transfer drawn coils to wire carriers or stems.

The wire being drawn on the block is usually coiled around block pins that provide an extension to the height of the block; this is often done when large bundles are not required. A stripper, with the feet temporarily collapsed, is then inserted through the eye of the coil, with the feet fitting into stripper slots or recesses in the block flange. The feet are then locked in their extended positions, and the bundle is lifted free of the block.

Dry-Drawing Continuous Machines. For the dry drawing of ferrous metals, four types of nonslip continuous machines are in general use: accumulating-type machines, double-block accumulating-type machines, controlled-speed machines, and straight-through machines.

An accumulating-type multiblock continuous wire-drawing machine is shown in Fig. 9. This machine is equipped with electromagnetic block clutches. Photocells sense high and low wire accumulation on each block and disengage or engage appropriate block clutches. A single dc motor drives a coupled lineshaft that carries the clutches. Only the inlet block has to be stopped in the event of a payoff snarl, allowing the machine to continue production while the snarl is removed. A programmable controller enables rapid checkout and simple alteration to input and output circuits, and it serves as a continuous fault-monitoring system to simplify maintenance.

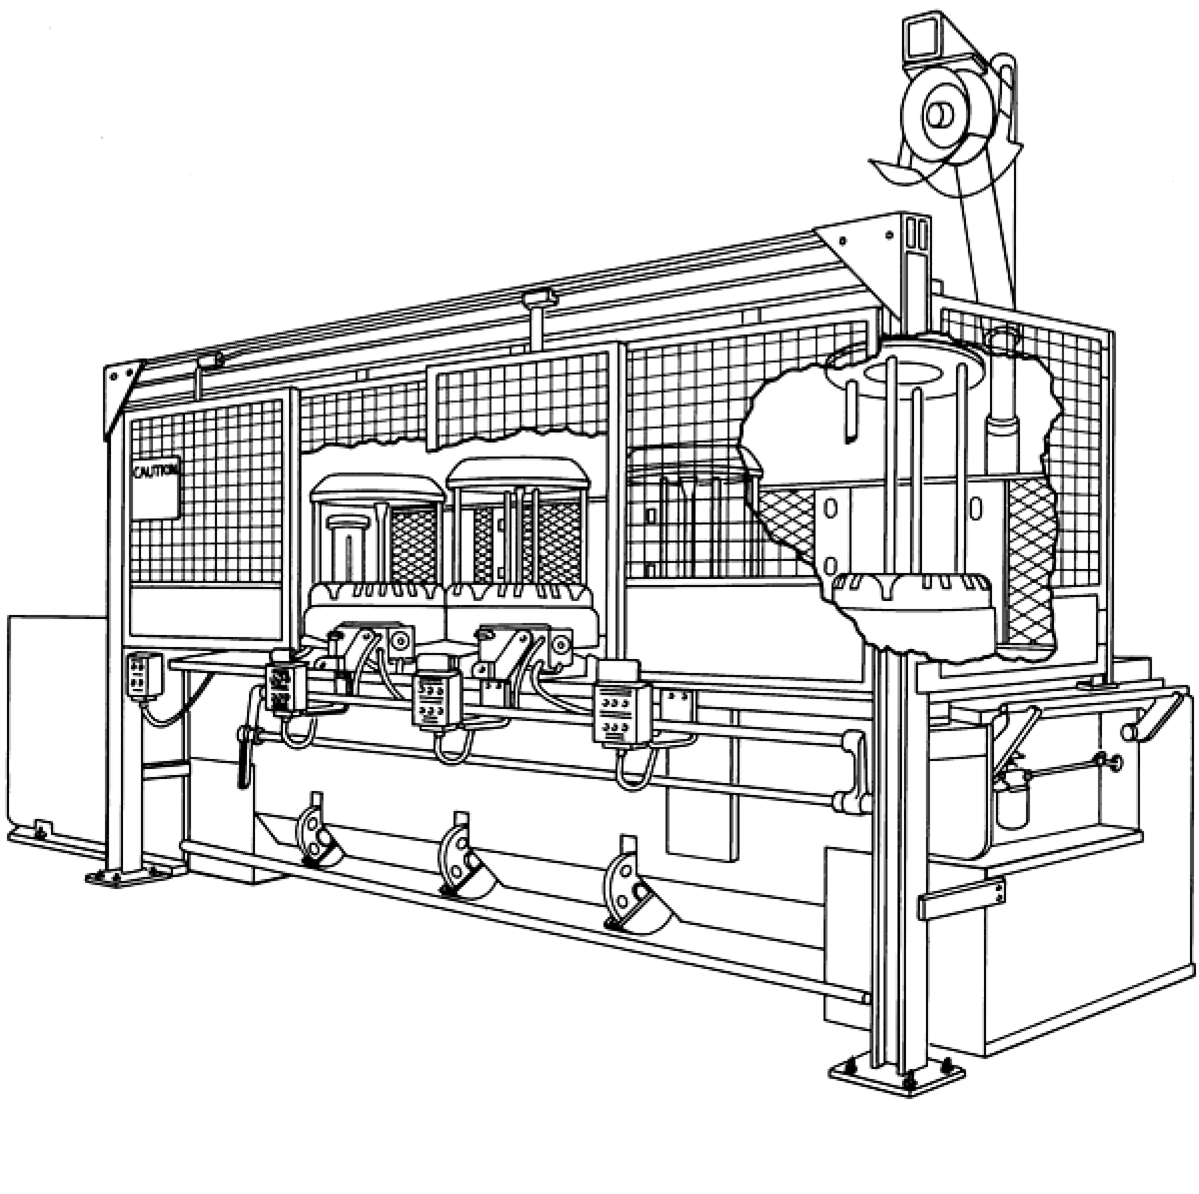

Fig. 9 Accumulating-type continuous wire-drawing machine.

Double-block accumulating machines have individually driven blocks. Wire is transferred from the first drawing block by means of an intermediate flyer sheave that reverses the direction of the wire (without twisting it) onto a coiling block mounted immediately above the first drawing block. The wire is then held temporarily in storage until demanded by the second drawing block. Fully automatic, electrical drive systems can be used to start and stop, or slowdown and speedup, the individual blocks to accumulate or deplete the wire.

On controlled-speed machines, the wire follows an essentially flat path from block to block with a constant, unvarying amount of wire storage without twisting and slipping. A tension arm between the blocks, activated by a loop of the wire being drawn, regulates the speed of the adjustable-speed dc motor on the preceding block.

Straight-through machines, without tension arms, are also available. The spindles are often canted from the vertical axis to accommodate wire buildup on the blocks and to provide unimpeded, straight entry into the succeeding die; this is usually done when large-size workpieces are required. Skillful operators are necessary because torque adjustments may need to be altered at each block when stringing up the machines in order to make the electrical system function properly.

The continuous drawing of nonferrous rod and wire, as well as some intermediate and fine sizes of ferrous wire, is generally done on wet-drawing slip-type machines. On these machines, the surface speed of the capstans, except for the final (pull-out) capstans, exceeds the speed of the wire being drawn, thus creating slip of the wire on the capstans. Brighter surface finishes are generally produced with these machines, but the machines are limited to smaller reductions per pass than with dry-drawing nonslip continuous machines.

With wet-drawing slip-type machines, the drawing operation is generally confined to an enclosed chamber, with the lubricant bathing the dies and wire as it is being drawn. These machines are less complicated electrically than nonslip machines, and only one drive system is employed. They are designed with either tandem or cone-type configurations, usually with horizontal spindles, but sometimes with a vertical spindle for the finishing capstan. Cone capstans have drawing surfaces (usually hard-faced) that are stepped outward to provide increasing peripheral speeds. This compensates for the elongation and increasing speed of the wire as it is reduced in diameter during drawing.

Drawing of Bar (Ref 5)

Bars about 32 mm (1.25 in.) and smaller in diameter are cold drawn from coil stock by various methods. With one method, cold-drawn coils of rod and wire produced on the various machines described previously are straightened and cut into bars in a separate operation on machines designed for that purpose. Some in-line methods and equipment begin by unwinding the starting coil, then pull the stock through a draw die without recoiling, and finally straighten and cut the material into bars in a continuous operation.

The continuous machine illustrated in Fig. 10 has a fixed die box with a recirculating wet-die lubricating system. Drawing is accomplished with three moving grip slides; one slide for push pointing before the die box and two opposed-motion drawing slides after the die box. The push-pointing grip runs twice as fast as the drawing grips in order to minimize production loss when push pointing. This machine also has one set each of vertical and horizontal straightening rollers, and a set of feed-out rolls. Most cold-drawn bars are produced from hot-rolled or extruded bars up to 17 in (55 ft) long by 152 mm (6 in.) in diameter, with seldom more than one cold-drawing pass performed.

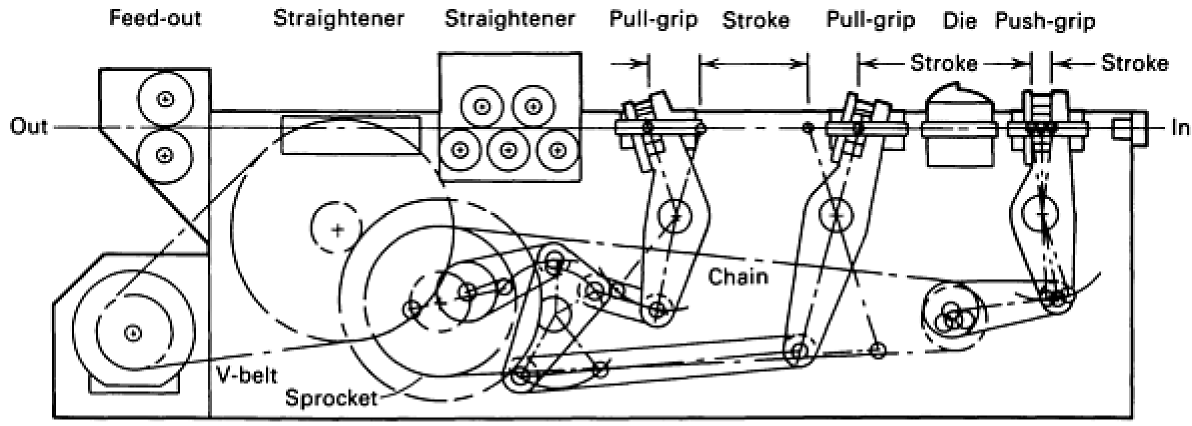

Fig. 10 In-line drawing and straightening machine for producing cold-drawn bars from hot-rolled steel coils or bars.

Drawbenches for Bars. The cold drawing of cleaned and pointed hot-rolled bars is also generally performed on a high-powered, rigidly built, long, horizontal machine called a drawbench (Fig. 11). The draw-bench consists essentially of a table of entry rollers (an elevating entry conveyor is shown), a die stand, a carriage, and an exit rack (not shown). Entry rollers support the hot-rolled bars and are usually powered to help bring the pointed ends of the bars into the draw dies. An upright head can hold as many as four dies to permit the drawing of four bars at a time. If lubrication is required, a lubricating oil system is provided on the entry side of the head.

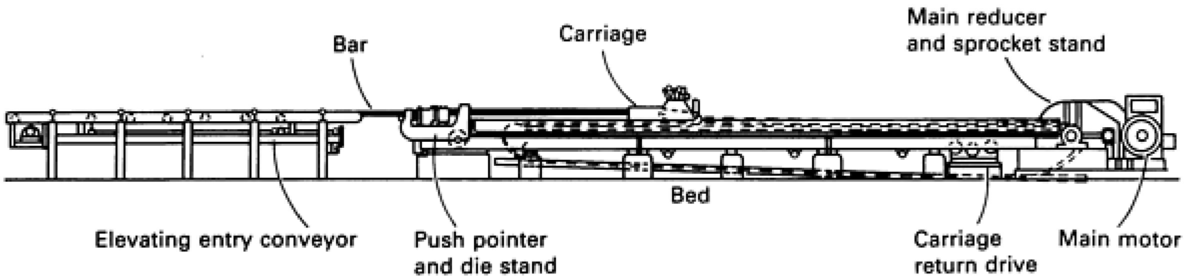

Fig. 11 Typical arrangement of a drawbench for producing cold-drawn bars from hot-rolled bars.

On most drawbenches, the entry side of the head is provided with a hydraulic pushing device, which, for a normal draft, can be used to push point the ends of the bars. Pneumatically operated grips on the carriage grasp the pointed ends of the bars protruding through the dies. The carriage is powered by a motor-driven chain(s) or hydraulic piston(s) to slide or roll along ways to pull the bar(s) through the die(s).

As soon as the bar being pulled exits the draw die, the carriage automatically releases the bar and stops. The drawn bar is then free to fall, usually onto discharge arms for removal from the drawbench. The carriage is then rapidly returned to the die stand--by a separately powered return system on chain benches or by means of a piston on hydraulic benches--for drawing the next bar. Chain-operated drawbenches are usually controlled automatically to permit low speeds at the start of the pulling action, followed by rapid acceleration to the preset pulling speed.

Drawing of Tube (Ref 5)

Tubes, particularly those having small diameters and requiring working only of their outer surfaces, are produced from cold-drawn coils on machines that straighten the stock and cut it to required lengths. As with bars, however, most tubes are produced from straight lengths rather than coiled stock. With four exceptions, the methods and equipment used for cold drawing tubes in straight lengths are basically identical to those used for bar drawing. The four exceptions are:

- Some tubes require more than one drawing pass
- Tubes are usually longer than bars. Drawbenches for tubes are usually correspondingly longer, some permitting drawn lengths of over 30 m (100 ft)
- Tube diameters are generally larger than bar diameters, ranging to about 305 mm (12 in.). The bigger tube drawbenches have larger components than do bar drawbenches
- Tubes require internal mandrels or bars for simultaneous working or support of the interior surface during drawing. Tube drawbenches are usually equipped with one of several available devices, usually powered, for ready assembly of the cleaned, coated, and pointed workpiece onto internal bars or rod-supported mandrels. If rod-supported mandrels are used, they are usually air-operated so that the mandrel can be placed and maintained in the plane of the draw die after pulling starts. Butt or electric-welded tubes are sometimes drawn to smooth the weld seams and tube walls

Drawing of Tubes and Cups With a Moving Mandrel. The principle of drawing with a moving mandrel is illustrated in Fig. 6 for a single-die draw. The process can be conducted hot or cold to manufacture a variety of discrete hollow cuplike components, such as artillery shells, shock absorber sleeves, beverage cans, and gas cylinders. Tube drawing with a moving mandrel, often called ironing, is carried out by using several drawing dies located in tandem (Fig. 12).

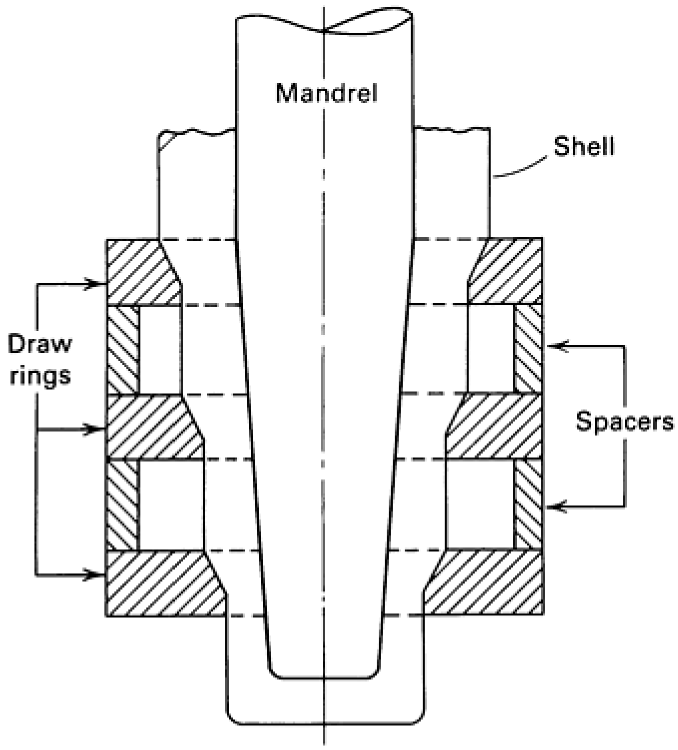

Fig. 12 Multipass ironing with tapered punch and dies in tandem.

In a typical application, a relatively thick-wall cup is first produced by extrusion or deep drawing. The wall thickness of this cup is then reduced by tandem ironing with a cylindrical punch, while the internal diameter remains unchanged. Hot and cold ironing both produce parts with good dimensional accuracy while maintaining or improving concentricity.

A very common application of tandem drawing is the production of beverage cans from steel or aluminum. The principle of a can ironing press is illustrated in Fig. 13. The press is horizontal, and the ram has a relatively long stroke and is guided by the hydrostatic bushing (A). The front seal (B) prevents mixing of the ironing lubricant with the hydrostatic bushing oil. With the ram in the retracted position, the drawn cup is automatically fed into the press, between the redraw die (D) and the redraw sleeve (C). The redraw die centers the cup for drawing and applies controlled pressure while the cup is drawn through the first die (D). As the ram proceeds, the redrawn cup is ironed by passing through the carbide dies (E), which gradually reduce the wall thickness. The ironed can is pressed against the doming punch (I), which forms the bottom shape of the can. When the ram starts its return motion, the mechanical stripper (G), assisted by the air stripper (F), removes the can from the ironing punch (H). The punch is made of carbide or cold-forging tool steel. The stripped can is automatically transported to the next machine for trimming of the top edge of the can wall to a uniform height.

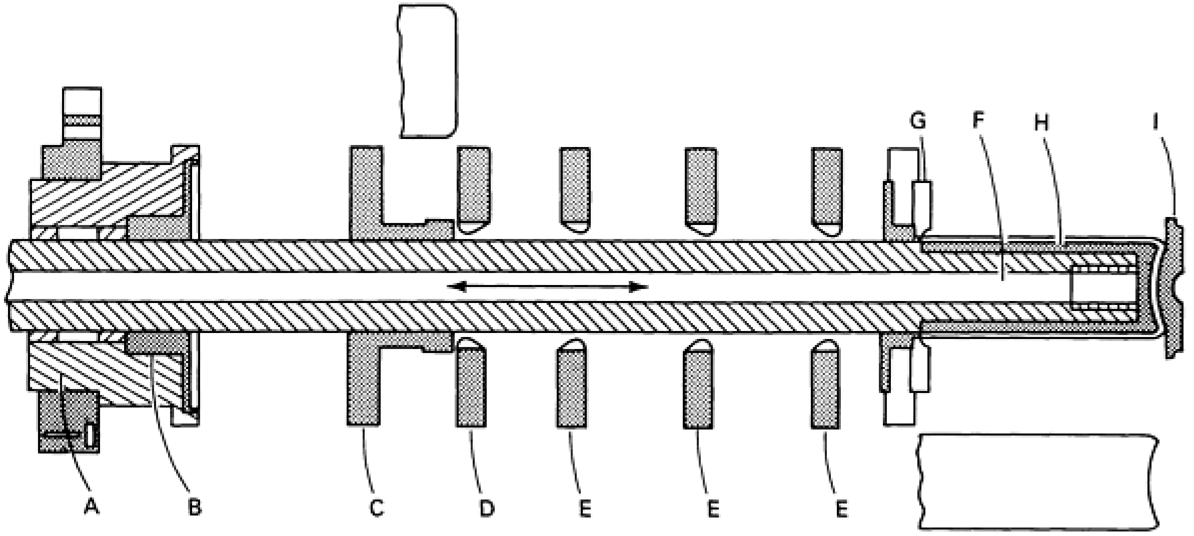

Fig. 13 Multiple-die ironing operation for the manufacture of beverage cans.

Single-Spindle Machines. With the development of floating plugs (Fig. 5), long lengths of thin-wall small-diameter nonferrous tubing can be drawn on special types of single-spindle machines. Instead of using a conventional mandrel that is attached to a rod, as is done in drawbench operations, a specially designed plug is inserted into the leading end of the tube before pointing and passing the tube through the draw die. The plug is free to ride in the throat of the die during drawing, thus controlling the inside diameter of the tube (while the die controls the outside diameter) and maintaining the desired wall thickness.

Drawing methods and machines, particularly material-handling arrangements, are generally more sophisticated for Single-spindle tube drawing than for the more conventional bull blocks used in drawing rod and wire. The machine configurations available for single-spindle tube drawing include horizontal, vertical upright, and inverted vertical designs.

Dies and Die Materials

The selection of tool materials for cold drawing metal into continuous forms such as wire, bar, and tubing depends primarily on the size, composition, shape, stock tolerance, and quantity of the metal being drawn. The cost of the tool material is also important and may be decisive.

Dies and mandrels used for cold drawing are subjected to severe abrasion. Therefore, most of the wire, bar, and tubing produced is drawn through dies having diamond or cemented tungsten carbide inserts, and tube mandrels are usually fitted with carbide nibs. Small quantities, odd shapes, and large sizes are more economically drawn through hardened tool steel dies.

Wire-Drawing Dies. Table 1 lists recommended materials for wire-drawing dies. For round wire, dies made of diamond or cemented tungsten carbide are always recommended, without regard for the composition or quantity of the metal being drawn. For short runs or special shapes, hardened tool steel is less costly, although carbide gives superior performance in virtually any application.

Table 1 Recommended materials for wire-drawing dies

Metal to be drawn	Wire size		Recommended die material	
	mm	in.	Round wire	Special shapes
Carbon and alloy steels	<1.57	<0.062	Diamond, natural or synthetic	CPM 10V, M2, or cemented tungsten carbide
	>1.57	>0.062	Cemented tungsten carbide	
Stainless steels; titanium, tungsten, molybdenum and nickel alloys	<1.57	<0.062	Diamond, natural or synthetic	CPM 10V, M2, or cemented tungsten carbide
	>1.57	>0.062	Cemented tungsten carbide	
Copper	<2.06	<0.081	Diamond, natural or synthetic	CPM 10V, D2, or cemented tungsten carbide
	>2.06	>0.081	Cemented tungsten carbide	
Copper alloys and aluminum alloys	<2.5	<0.100	Diamond, natural or synthetic	CPM 10V, D2, or cemented tungsten carbide
	>2.5	>0.100	Cemented tungsten carbide	
Magnesium alloys	<2.06	<0.081	Diamond, natural or synthetic	. . .
	>2.06	>0.081	Cemented tungsten carbide	

Die Life. In a wire-drawing die, the approach angle and the bearing area (Fig. 7) are both subjected to severe abrasion. Normal die life is defined as the length or mass of metal drawn through a die that causes the bearing area of the die to increase from minimum to maximum size. Factors that influence die wear, both singly and collectively, are drawing speed, composition of the metal being drawn, wire temperature, reduction per pass, and hardness of the die material.

Wear often begins as an angular ring on the approach angle of the die. Die life can be increased by as much as 200% if the die is removed and repolished at the first appearance of this ring; otherwise, die wear will accelerate. Redressing should never shorten the length of the bearing area to less than 30% of the product diameter.

Diamond Dies. The use of diamond dies is restricted only by limitations on the sizes of available industrial diamonds and by cost, which is extremely high for diamonds in larger sizes. These tools can outperform cemented tungsten carbide dies by 10 to 200 times, depending on the alloy being drawn; therefore, they are cost effective despite their high unit cost.

Cemented tungsten carbide is economical for wire-drawing dies in most applications above the range of size where diamond can be used. The softer cemented carbides, which contain about 8% Co, are less brittle and can withstand greater stock reductions without breaking, but wear more rapidly than lower-cobalt grades.

If not damaged or broken, carbide dies can be progressively reworked to accommodate larger wire sizes. Diamond dies can also be reworked, but greater numbers of reworkings are expected from carbide dies.

Tool steel used for wire-drawing dies should have near-maximum hardness (62 to 64 HRC) for reductions below about 20%. For greater reductions, because of the possibility of breakage, hardness should be decreased to 58 to 60 HRC, even though the rate of wear will increase.

Die breakage is usually caused by abnormal reductions, lack of mechanical support for the insert, inadequate lubrication, or use of a tool material that is too hard and brittle for the amount of reduction and speed. Some wear resistance is always sacrificed to minimize breakage.

Drawing Bars and Tubing. Table 2 lists recommended die and mandrel materials for drawing bars and tubing. Diamond is virtually never used in larger sizes; cemented tungsten carbide is recommended for three-fourths of all applications. Tool steels are rarely used to make tools for drawing commercial-quality round bars less than 90 mm (3.5 in.) in diameter. Cemented tungsten carbide is used to draw stainless steel tubes as large as 279 mm (11 in.) in outside diameter.

Table 2 Recommended tool materials for drawing bars, tubing, and complex shapes

Metal to be drawn	Round bars and tubing[a]			
	Common commercial sizes		**Maximum commercial size[c]: dies and mandrels**	Complex shapes: dies and mandrels[a][b]
	Bar and tube dies	**Tube mandrels[b]**		
Carbon and alloy steels	Tungsten carbide	W1 or carbide	D2 or CPM 10V	**CPM 10V or carbide**
Stainless steels, titanium, tungsten, molybdenum, and nickel alloys	Diamond or carbide[d]	D2 or carbide	D2, M2, or CPM 10V[a]	**F2 or carbide[e]**
Copper, aluminum, and magnesium alloys	**W1 or carbide**	**W1 or carbide**	**D2 or CPM 10V**	**O1, CPM 10V, or carbide**

(a) Tool steels for both dies and mandrels are usually chromium plated.

(b) "Carbide" indicates use of cemented carbide nibs fastened to steel rods.

(c) 10 in. OD by $\frac{3}{4}$ in. wall.

(d) Under 1.5 mm (0.062 in.), diamond; over 1.5 mm (0.062 in.), tungsten carbide.

(e) Recommendations for large tubes or complex shapes apply to stainless steel only.

Drawing of Common Sizes. Common sizes are usually drawn in sufficient quantities to warrant the investment in carbide dies. In addition, carbide bar or tube dies can be reworked to the next larger size. Die life after reworking is substantially the same as for the first run. In drawing steel bars, it is possible to increase normal die life by properly planning the sequence of compositions to be drawn.

For example, in drawing 0.45% C steel bars 25.40 mm (1.000 in.) in diameter, a minus tolerance of 0.08 mm (0.003 in.) is allowed, but for this grade it is necessary to allow for a 0.05 mm (0.002 in.) elastic expansion of the bar after it passes through the die. When the die is worn to maximum size at the bearing area, it will still be only 25.35 mm (0.998 in.) in diameter. It is then possible to draw 0.20% C steel bars, which expand less because of their lower yield strength. After the limit of tolerance has been reached for this grade (a diameter of 25.37 mm, or 0.999 in., at the bearing area), the die can be used for drawing a still lower carbon steel, such as a low-carbon free-machining grade that expands even less, until the diameter of the bearing area reaches 25.40 mm (1.000 in.). The dies can then be reworked to the next usable size.

In many cases, the planning of drawing sequences is more complicated than described above. Bell angle, approach angle, back relief, and amount of subsequent straightening all affect as-drawn size because they influence the amount of elastic growth that occurs; therefore, these factors must be taken into account when planning drawing sequences.

Drawing of Complex Shapes. When complex shapes are to be drawn, the selection of die material is somewhat uncertain. In short runs less than 300 m (1000 ft), tool steels are generally more economical. For longer runs, carbide is usually more economical unless sharp edges, which may cause the carbide to chip, are involved. In that event, tool steel dies must be used, even though they may have to be replaced more frequently because of wear. A proprietary powder metallurgy tool steel, CPM 10V, is another alternative to cemented carbide. CPM 10V has toughness equivalent to the conventional tool steels D2 and M2, and it has substantially superior wear resistance in drawing-die service.

Die Breakage. The most frequent cause of die breakage in bar and tube drawing is a die design inappropriate for the percentage of reduction. Excessive die hardness also frequently leads to breakage, particularly of dies for drawing thin-wall tubing. Lack of lubrication, excessive drawing speeds, and other extreme conditions of operation also contribute to die breakage.

Wire, Rod, and Tube Drawing

Lubrication (Ref 7)

Proper lubrication is essential in rod, tube, and wire drawing. No friction is needed for wire drawing, tube sinking, and tube drawing on a fixed plug. However, some minimum friction is essential for drawing with a floating plug, and friction is helpful on the tube/bar interface in drawing on a bar. Therefore, if at all possible, the lubricant is chosen to give lowest friction and minimum wear. It is essential, though, that the heat generated be extracted, especially in high-speed drawing; if this is not done, the lubricant may fail, and the properties of the wire may suffer.

In dry drawing, the lubricant is chosen for its tribological attributes, and the wire is cooled while it resides on the internally cooled capstans of single-hole bull blocks and of multihole machines drawing with accumulation. In addition, external air cooling of the wire coil and water cooling of the die holder are possible. If water is applied to the wire at all, it must be totally removed before the wire enters the next die. The lubricant is usually a dry soap powder, placed in a die box and picked up by the wire surface upon its passage through the box. This technique is used for steel wire larger than 0.5 to 1 mm (0.02 to 0.04 in.) in diameter, for which the relatively rough surface produced is acceptable. For the most severe draws and for tubes, the soap is often preapplied from a solution, if necessary, over a conversion coating; the soap must be allowed to dry.

With high-strength materials such as steels, stainless steels, and high-temperature alloys, the surface of the rod or wire can be coated either with a softer metal or with a conversion coating. Copper or tin can be chemically deposited on the surface of the metal. This thin layer of softer metal acts as a solid lubricant during drawing. Conversion coatings may consist of sulfate or oxalate coatings on the rod; these are then typically coated with soap, as a lubricant. Polymers are also used as solid lubricants, such as in the drawing of titanium.

In the case of steels, the rod to be drawn is first surface treated by pickling. This removes the surface scale that could lead to surface defects and therefore increases die life.

In wet drawing, the lubricant is chosen both for its tribological attributes and for its cooling power, and it can be either oil-base or aqueous. It can be applied to the die inlet, the wire, and often also to the capstan, or the entire machine can be submerged in a bath. When the machine operates with slip, the lubricant must reduce wear of the capstan while maintaining some minimum friction. This wet-drawing practice is typical of all nonferrous metals and of steel wires less than 0.5 to 1 mm (0.02 to 0.04 in.) in diameter.

A transition between the two techniques is sometimes used, particularly in the low-speed drawing of bar and tube. A high-viscosity liquid or semisolid is applied to the workpiece and/or die. Reference 8 provides additional details on the lubrication of ferrous wire.

The Manufacture of Commercial Superconductors*

The design requirements of commercial superconductors have challenged metal extrusion and composite metal-drawing technology such that superconductors with 10,000 to 40,000 filaments, several microns in diameter, are available in wire form. On an experimental basis, wires have been produced with 1 million filaments less than 1 μm (40 μin.) in diameter. Understanding the reasons for this challenge to metal-forming technology requires a brief introduction to engineering requirements for commercial superconductors.

The design and application of superconductors is mainly controlled by the critical temperature, T_c. Niobium-base superconductors are usually used at liquid helium temperatures (4.2 K). At these temperatures, specific heats of materials are typically in the 10^{-3} J range. Small mechanical or electromagnetic disturbances can provide sufficient heat to raise the temperature of the superconductor above T_c; this increase in temperature causes the normally high resistance to return. Commercial superconductors are designed to prevent and/or control the change to the nonsuperconducting state.

Copper and aluminum are usually used as the matrix; copper is the preferred matrix because of its mechanical compatibility with the niobium-base superconductors. If an event occurs that is sufficient to return the superconductor to the normal state, the copper temporarily conducts the current until the superconductor is cooled below the critical temperature.

The sizes of the filaments of the superconductor are chosen to be in the 100 μm (4000 μin.) range--small enough to prevent an electromagnetic instability called a flux jump. For applications requiring precise magnetic fields, as in dipole magnets, filaments must be in the 1 μm (40 μin.) range. Power frequency applications require filaments of less than 1 μm (40 μin.).

Commercial superconductors for power applications are manufactured by a coextrusion and composite-drawing process. The resulting wire consists of one to tens of thousands of filaments of the superconductor, each individually surrounded by a normal metal matrix. The superconductor itself is usually a ductile alloy of niobium and titanium (Fig. 14) or a brittle intermetallic of niobium and tin (Nb_3Sn) (Fig. 15 and 16).

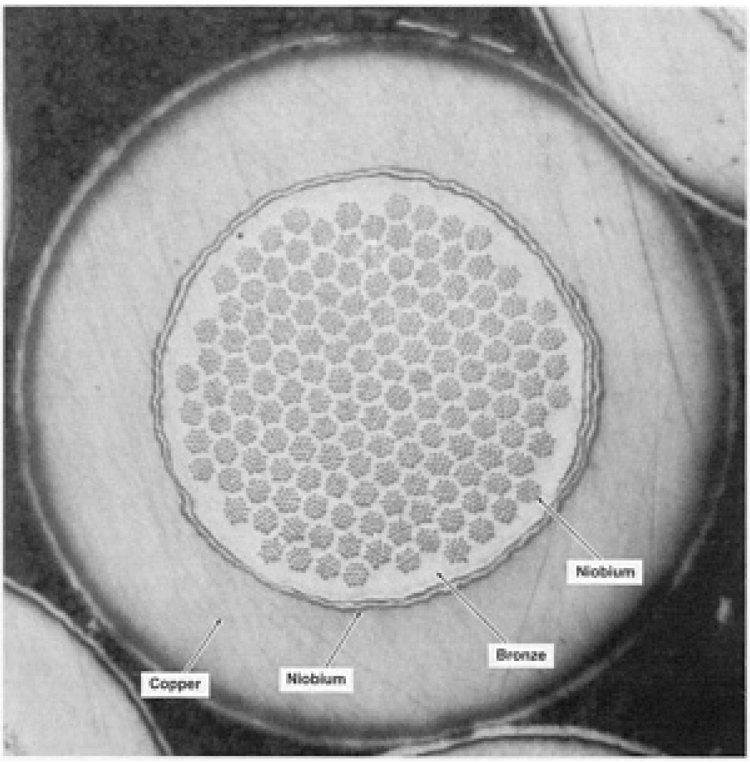

Fig. 16 Cross section of 3000 filaments of Nb_3Sn in final conductor. Courtesy of Oxford Superconducting Technology.

Superconducting multifilamentary conductors are manufactured using a combination of extrusion and wire-drawing techniques (up to 40 to 50 such separate sequences may be necessary) to make up to 1 million individual wire filaments of microscopic size enclosed within a wire having outside diameter of fractions of an inch. The two primary techniques used are billet stacking and the modified jelly-roll method.

Billet Stacking Method. The manufacture of a typical niobium-titanium superconductor with filaments in the 10 to 100 μm (400 to 4000 μin.) range begins with the assembly of a billet (Fig. 17). The billet is assembled by inserting rods of the superconductor into an array of tubes of CDA 101 copper with a hexagonal outer shape and a round inner diameter. The array approximates a circle having a diameter slightly less than the copper extrusion can placed over it. A typical billet is 305 mm (12 in.) in diameter and 762 mm 30 in. long.

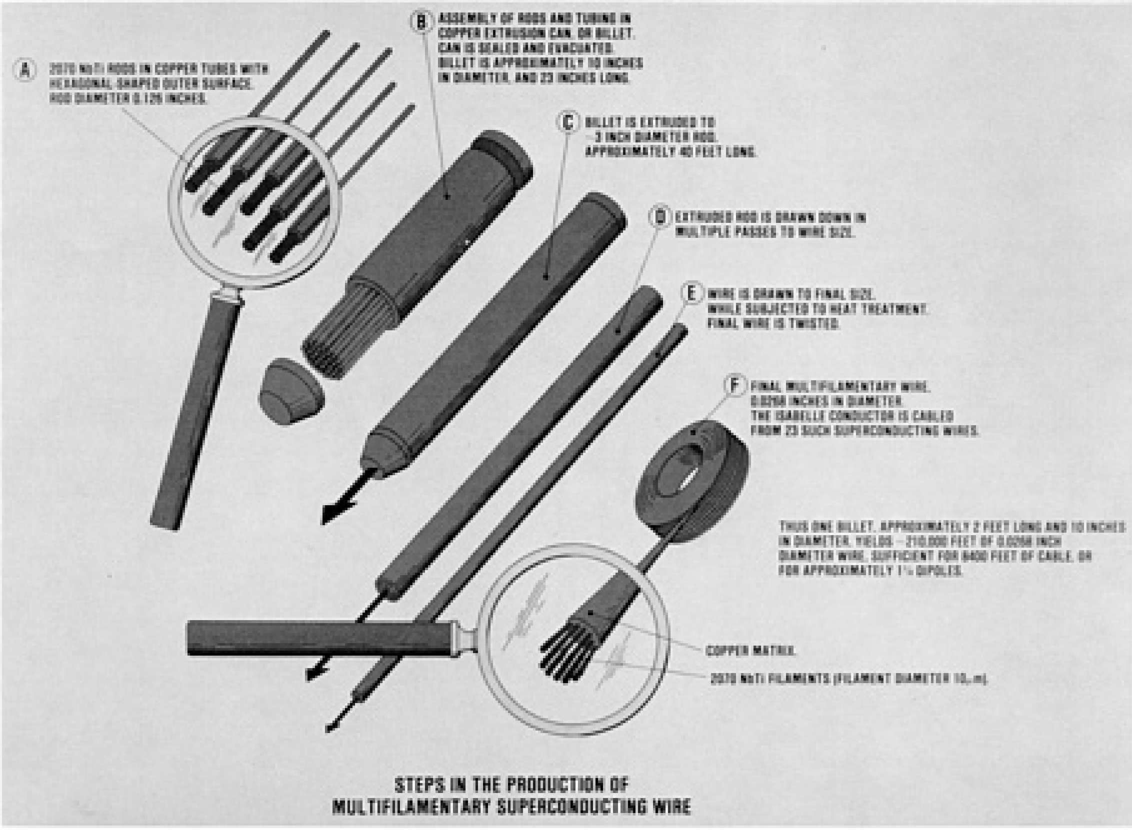

Fig. 17 Fabrication steps and process parameters required to manufacture multicore niobium-titanium filament conductors. Courtesy of Intermagnetics General Corporation.

The billet is evacuated to remove the air and electron beam welded to form a vacuum-tight seal. The elements in the billet are metallurgically bonded and uniformly reduced in area by a hot direct extrusion. Reduction ratios of 16 to 1 are generally used, requiring extrusion forces typically in the 31 to 44 MN (3500 to 5000 tonf) range. The resulting extrudate is normally 10 m (33 ft) long by 85 mm (3.3 in.) in diameter. This rod is then cold drawn using a proprietary die and reduction schedules designed to ensure uniform coreduction of the superconducting filaments. The initial draw process requires benches as long as 60 m (200 ft), with 590 kN (60,000 kgf) of draw force to be used to ensure that the rod does not have to be cut before it is coiled for further drawing. The remaining process involves performing heat treatment and draw cycles to develop the current capacity of the superconductor, annealing the matrix, and uniformly coreducing the filaments. Specially modified wire-drawing machinery is generally used. The final step is an anneal to restore the ductility and resistivity of the copper matrix. Preceding this step is a twisting operation, which twists the wire upon itself. This twists the filaments inside the composite, ensuring that the filaments act individually under electromagnetic fields.

Superconductors requiring more than 5000 or 6000 filaments or, correspondingly, filaments of sizes less than 10 μm (400 μin.) are made by coextruding a single filament, which, in the case of niobium-titanium, usually has a diffusion barrier. This ensures that no damaging intermetallics form during the extrusion or heat treatment process. This extrudate is drawn to the appropriate size and assembled into a second extrusion billet; the process is then repeated.

The extrusion and draw process can be repeated a number of times to produce wires with 20,000 to 1 million or more filaments. As shown in Fig. 18, a first-generation billet can yield 19 individual filaments in the wire configuration. Sixty one of these 19-filament wires were then stacked, extruded, and drawn to yield a 19 × 61 array of 1159 filaments in the second-generation billet. The third-generation billet, consisting of 61 of the 1159 filament wires obtained in the second-generation billet, was stacked, extruded, and drawn to yield a 70,699 filament superconducting wire. However, the problem of "sausaging," or filament nonuniformity, especially in the outer diameter of the conductor, becomes more evident as more extrusions and drawings of the wire are attempted.

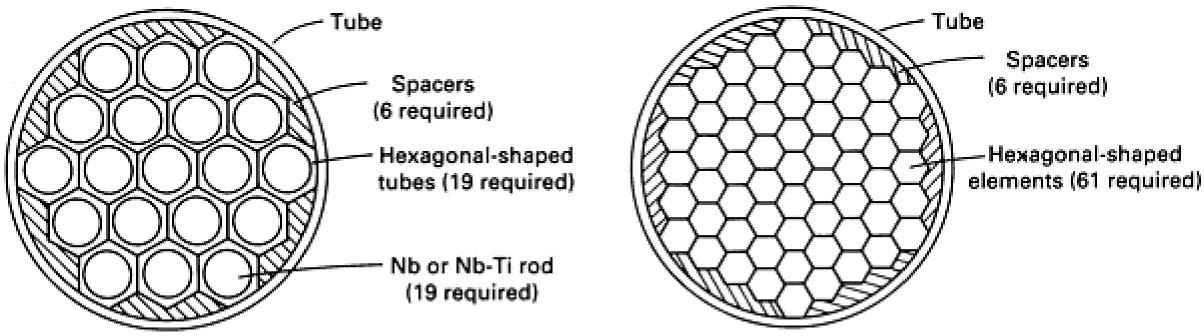

Fig. 18 Cross section of billet assembly used to produce a 70 699-filament wire using up to third-generation billets. (a) First-generation billet. (b) Second- and third-generation billets.

For these developmental conductors, the matrix is often composed of several metals or alloys of metals, such as copper nickel, or is alloyed slightly with magnetic impurities, such as manganese. This ensures that the electromagnetic and physical sizes of the micron-size filaments are the same.

The manufacture of Nb_3Sn in filamentary form has presented some unusual problems because of the brittle nature of the superconductor. The accepted processes are based on forming the brittle phase at the final stage. Early technology carried the tin in a 13 wt% bronze matrix. The manufacturing process was a multiple coextrusion and codrawing process similar to that for niobium-titanium. The work-hardening rates of bronze require many anneals, and this can lead to premature formation of the brittle phase. More recently, a process based on maintaining the tin in its pure phase has gained acceptance. This is called the internal tin process.

The standard process begins with a billet of copper and niobium filaments assembled into a tubular array (Fig. 19). The billet follows the usual procedures for niobium-titanium, but is extruded with a mandrel to maintain the hole. The resulting extrudate typically has several hundred filaments of niobium in a copper matrix with a hole of about 10% of the diameter running throughout the length at the center. Tin is inserted into the hole, and the resulting composite is drawn to a size suitable for assembly into the stabilizer tube. This tube is also formed from a hollow extrusion but is composed of copper and a diffusion barrier such as niobium or vanadium. The diffusion barrier keeps the tin from alloying with the copper in the stabilizer. Quantities of 19 to 37 composite elements are assembled and inserted into the stabilizer tube. The resulting rod is repeatedly drawn without any annealing to yield a wire having a diameter ranging from 1 mm to fractions of a millimeter. The resulting conductor frequently has several to tens of thousands of filaments in the several micron size range with multiple cores of tin. The wire is then heat treated to diffuse and then react the tin with the niobium to form the Nb_3Sn.

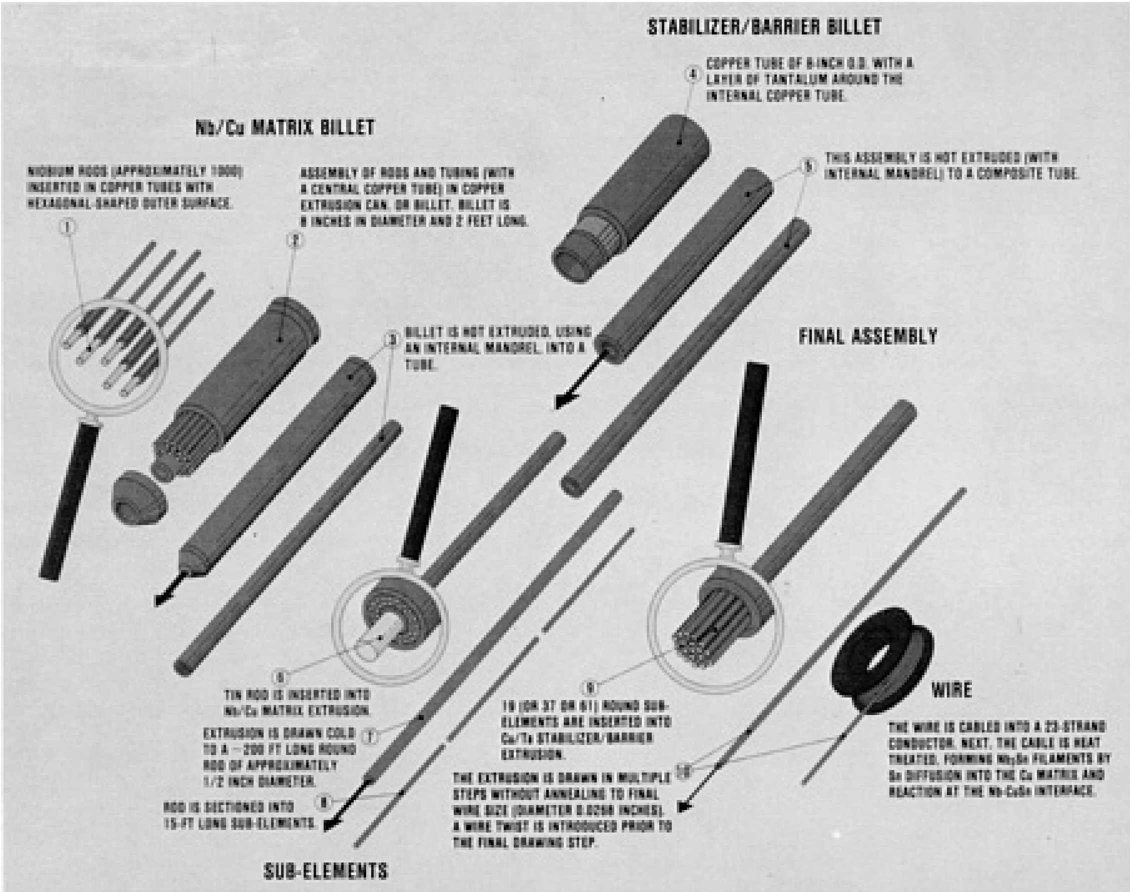

Fig. 19 Sequence of manufacturing operations involved in the formation of Nb_3Sn multifilamentary wire using the internal tin process. Courtesy of Intermagnetics General Corporation.

Modified Jelly-Roll Method. Instead of using rods, the modified jelly-roll method (Ref 9) utilizes thin (0.05 to 0.50 mm, or 0.0020 to 0.020 in., thick) niobium foil sheets that are slit with a number of discontinuous and staggered parallel slits having controlled interconnection distances, *d*, of 5 to 150 mm (0.197 to 5.9 in.), as shown in Fig. 20. This niobium sheet is subsequently stretched at right angles to the original slits to produce a diamond-shaped array of continuously connected filaments--a hexagonal matrix that is 45 to 85% open. The expanded niobium sheet is then rolled up with the designated matrix material (bronze, copper, and aluminum), inserted into a copper container, sealed, extruded, and processed as conventional wire. As area reduction of the cross section progresses, the horizontal dimension ***d*** is stretched and elongated, and the vertical dimension ***w*** is compressed by a factor of 100,000 to 1,000,000 to form the individual filaments (Fig. 21(a) and 21(b)).

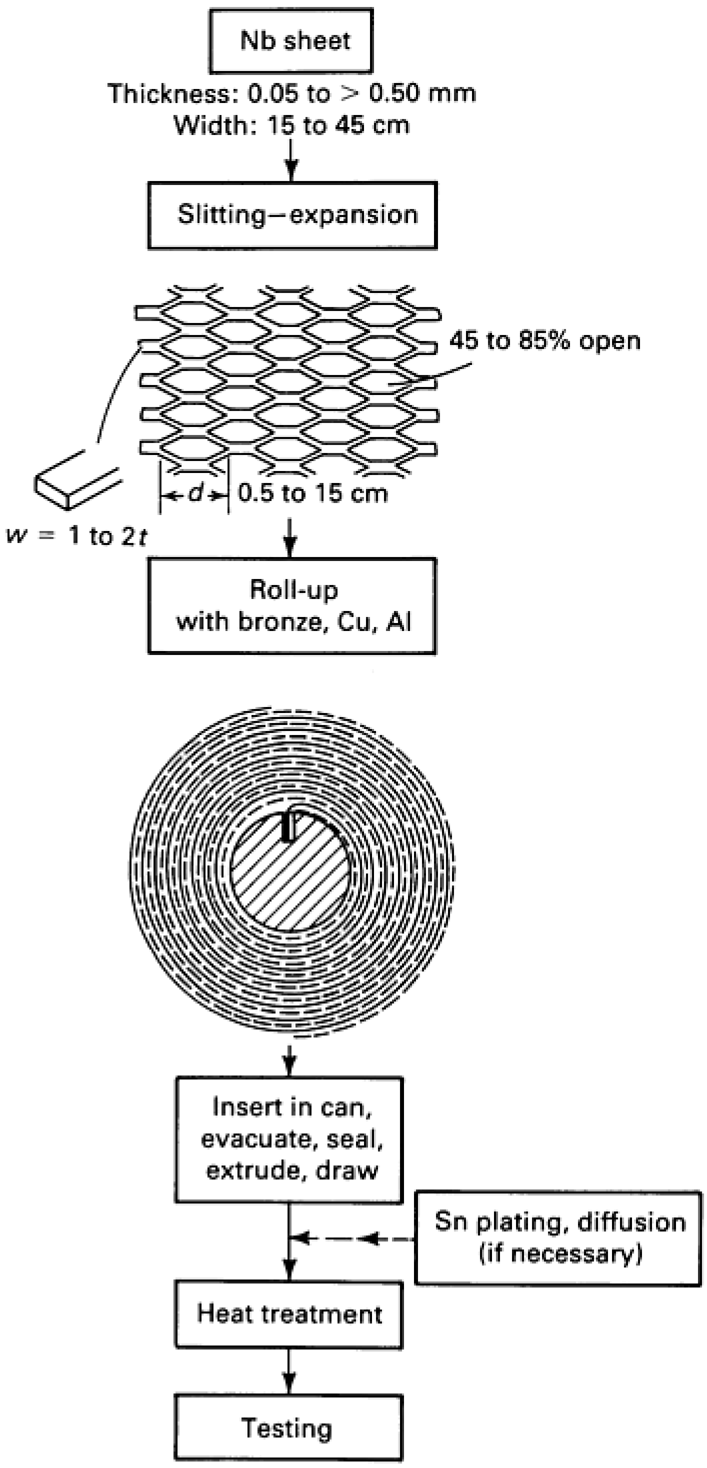

Fig. 20 Schematic of the modified jelly-roll process for producing superconducting multi-filamentary wire.

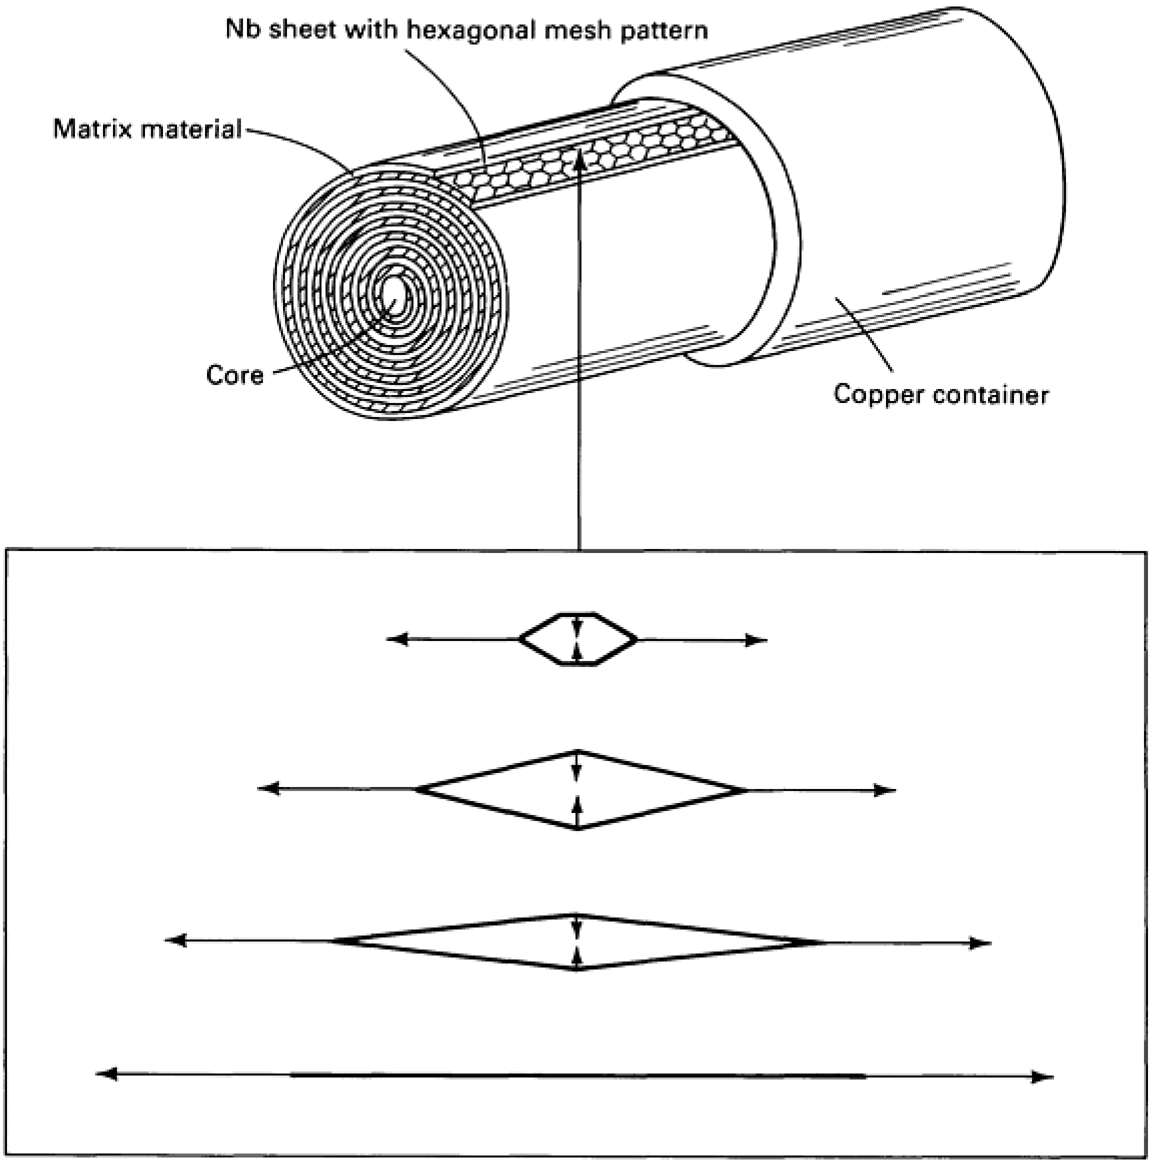

Fig. 21(a) Detail of niobium sheet mesh rolled into a jelly roll using a matrix material to show how the hexagonal mesh is transformed into an individual filament through elongation in the horizontal direction and compression in the vertical direction when subjected to extrusion and drawing.

wire consisting of 18 subelements that were produced using the modified jelly-roll method. The wire was cold worked to a 160,000 to 1 reduction in area. Left: 65×. Right: Close-up of one of the 18 subelements showing the individual niobium filaments surrounding a tin/copper alloy core and a vanadium barrier. 465× (differential interference contrast). Courtesy of P. E. Danielson, Teledyne Wah Chang Albany.

Numerous billets 75 mm (3 in.) in diameter have been produced with a final niobium filament size of 1 to 2 μm (40 to 80 μin.) in diameter. It should be possible to achieve submicron filaments. At the commercial level, the process can be used for Va_3Ga, Nb_3Al, Nb_3Sn, NbTi, and other composites.

Flat, Bar, and Shape Rolling

G. D. Lahoti, The Timken Company; S.L. Semiatin, Battelle Columbus Division

Introduction

ROLLING OF METALS is perhaps the most important metalworking process. More than 90% of all the steel, aluminum, and copper produced--in 1985, some 800 million tons of material worldwide--go through the rolling process at least one time. Thus, rolled products represent a significant portion of the manufacturing economy and can be found in many sectors. Beams and columns used in buildings are rolled from steel. Railroad tracks and cars are made from rolled steel, and airplane bodies are made from rolled aluminum and titanium alloys. The wire used in fences, elevator ropes, electrical conductors, and cables are drawn from rolled rods. Many consumer items, including automobiles, home appliances, kitchen utensils, and beverage cans, use rolled sheet materials.

In rolling, a squeezing type of deformation is accomplished by using two work rolls (Fig. 1) rotating in opposite directions. The principal advantage of rolling lies in its ability to produce desired shapes from relatively large pieces of metals at very high speeds in a somewhat continuous manner. Because other methods of metalworking, such as forging, are relatively slow, most ingots and large blooms are rolled into billets, bars, structural shapes, rods (for drawing into wire), and rounds for making seamless tubing. Steel slabs are rolled into plate and sheet.

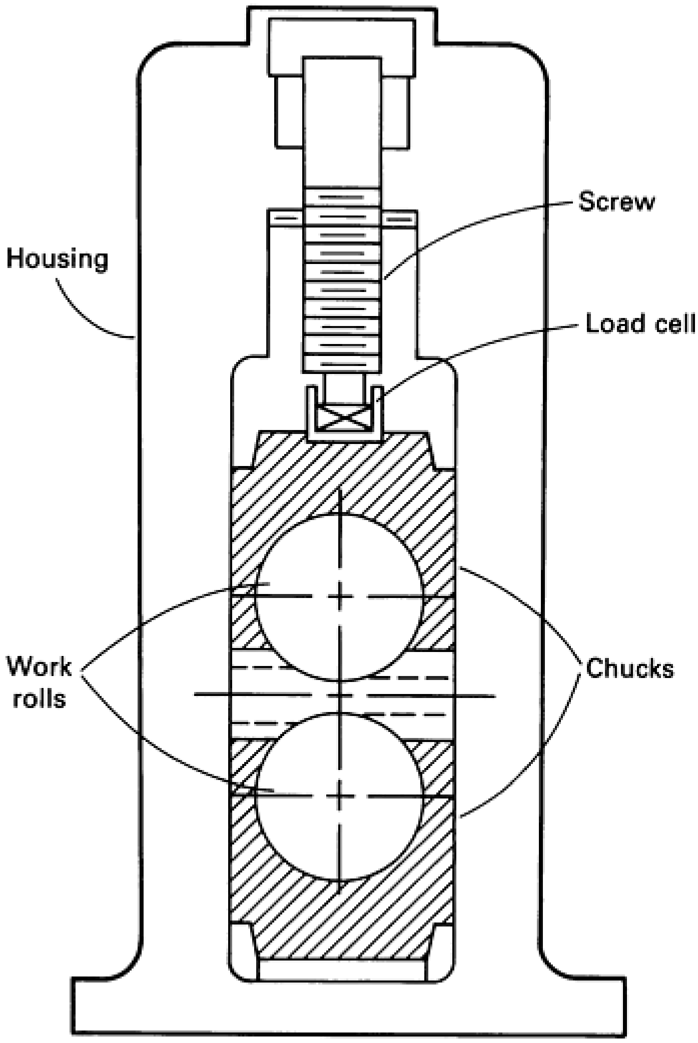

Fig. 1 Typical rolling mill stand

Although the rolling of metals has been done for some time and has been a very productive means of working large quantities of metals to a variety of shapes and sizes, the state of the technology had been somewhat stagnant until recently, when major innovations started to appear. With the advent of computer-assisted controls, highly automated, very high-speed rolling mills were installed beginning in the 1970s. One rod mill commissioned in 1980, for example, is reported to roll steel wire rod at the rate of 335 kph (210 mph). This mill has a rated output of 545,000 Mg (600,000 tons) per year, and the entire mill is operated from three climate-controlled pulpits equipped with computerized controls and closed-circuit video monitors. Another modern mill came on stream in the early 1980s. It is a 200 cm (80 in.) hot strip mill capable of producing steel coils up to 188 cm (74 in.) wide and weighing up to 33.6 Mg (37 tons). The mill features computer controls that automatically adjust water flow rates, roll speeds, and strip temperatures to meet metallurgical requirements. In addition to these developments, computer-aided modeling of the rolling process is now routinely used at several locations for design of rolls and optimization of the process parameters (see the section "Mechanics of Plate Rolling" in this article). Understanding of the materials also has improved considerably, thereby permitting development of new products such as high-strength low-alloy (HSLA) steels, which require controlled rolling. In short, significant developments are happening in this field, which was largely neglected for decades.

Flat, Bar, and Shape Rolling

G. D. Lahoti, The Timken Company; S.L. Semiatin, Battelle Columbus Division

Basic Rolling Processes

Many engineering metals, such as aluminum alloys, copper alloys, and steels, are often cast into ingots and are then further processed by hot rolling into blooms, slabs, and billets, which are subsequently rolled into other products such as plate, sheet, tube, rod, bar, and structural shapes (Fig. 2). The definitions of these terms are rather loose and are based on the traditional terminology used in the primary metal industry. For example, a bloom has a nearly square cross section with an area larger than 205 cm^2 (32 $in.^2$); the minimum cross section of a billet is about 38 × 38 mm (1.5 × 1.5 in.), and a slab is a hot-rolled ingot with a cross-sectional area greater than 103 cm^2 (16 $in.^2$) and a section width of at least twice the section thickness. Plates are generally thicker than 6.4 mm (0.25 in.), whereas sheets are thinner-gage materials with very large width-to-thickness ratios. Sheet material with a thickness of a few thousandths of an inch is referred to as foil. Rolling of blooms, slabs, billets, plates, and structural shapes is usually done at temperatures above the recrystallization temperature, that is, in the hot-forming range, where large reductions in height or thickness are possible with moderate forming pressures. Sheet and strip often are rolled cold in order to maintain close thickness tolerances.

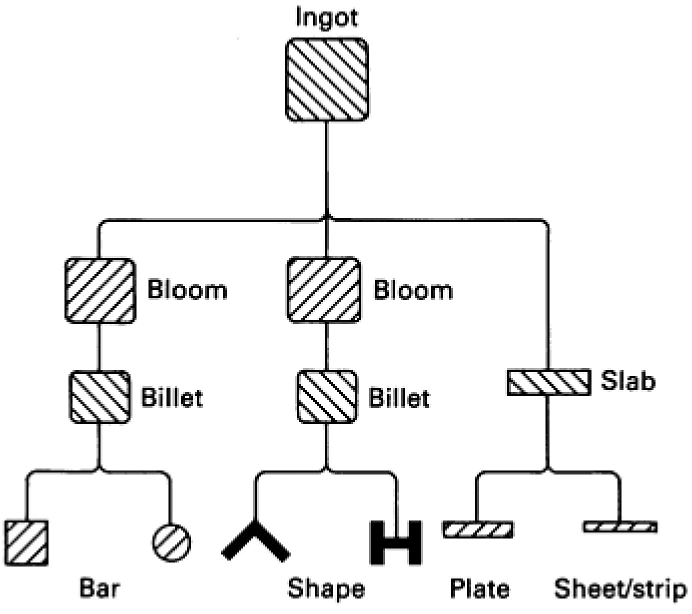

Fig. 2 Rolling sequence for fabrication of bars, shapes, and flat products from blooms, billets, and slabs

The primary objectives of the rolling process are to reduce the cross section of the incoming material while improving its properties and to obtain the desired section at the exit from the rolls. The process can be carried out hot, warm, or cold, depending on the application and the material involved. The technical literature on rolling technology, equipment, and theory is extensive because of the significance of the process (Ref 1, 2, 3, 4, and 5). Many industrial investigators prefer to divide rolling into cold and hot rolling processes. From a fundamental point of view, however, it is more appropriate to classify rolling processes on the bases of the complexity of metal flow during the process and the geometry of the rolled product. Thus, the rolling of solid sections can be divided into the categories below.

Uniform Reduction in Thickness with No Change in Width. This is the case with strip, sheet, or foil rolling where the deformation is in plane strain, that is, in the directions of rolling and sheet thickness. This type of metal flow exists when the width of the deformation zone is at least 20 times the length of that zone.

Uniform Reduction in Thickness with an Increase in Width. This type of deformation occurs in the rolling of blooms, slabs, and thick plates. The material is elongated in the rolling (longitudinal) direction, is spread in the width (transverse) direction, and is compressed uniformly in the thickness direction.

Moderately Nonuniform Reduction in Cross Section. In this case, the reduction in the thickness direction is not uniform. The metal is elongated in the rolling direction, is spread in the width direction, and is reduced nonuniformly in the thickness direction. Along the width, metal flow occurs only toward the edges of the section. The rolling of an oval section in rod rolling or of an airfoil section would be considered to be in this category.

Highly Nonuniform Reduction in Cross Section. In this type of deformation, the reduction in the thickness direction is highly nonuniform. A portion of the rolled section is reduced in thickness while other portions may be extruded or increased in thickness. As a result, in the width (lateral) direction metal flow may be toward the center. Of course, in addition, the metal flows in the thickness direction as well as in the rolling (longitudinal) direction.

The above discussion illustrates that, except in strip rolling, metal flow in rolling is in three dimensions (in the thickness, width and rolling directions). Determinations of metal flow and rolling stresses in shape rolling are very important in designing rolling mills and in setting up efficient production operations. However, the theoretical prediction of metal flow in such complex cases is nearly impossible at this time. Numerical techniques are being developed in an attempt to simulate metal flow in such complex rolling operations.

Flat, Bar, and Shape Rolling

G. D. Lahoti, The Timken Company; S.L. Semiatin, Battelle Columbus Division

Strip Rolling Theory

The most rigorous analysis was performed by Orowan (Ref 6) and has been applied and computerized by various investigators (Ref 7, 8, 9, 10, 11, 12). More recent studies consider elastic flattening of the rolls and temperature conditions that exist in rolling (Ref 9, 13). The roll-separating force and the roll torque can be estimated with various levels of approximations by such mathematical techniques as the slab method, the upper bound method (Ref 10), or the slip line method of analysis (Ref 2, 4). Most recently, computerized numerical techniques are being used to estimate metal flow, stresses, roll-separating force, temperatures, and elastic deflection of the rolls (Ref 9, 13).

Simplified Method for Estimating Roll-Separating Force. The strip-rolling process is illustrated in Fig. 3. Because of volume constancy, the following relations hold:

$$W \cdot H_0 \cdot V_0 = W \cdot H \cdot V = W \cdot H_1 \cdot V_1 \quad \textbf{(Eq 1)}$$

where W is the width of the strip; H_0, H, and H_1 are the thicknesses at the entrance, in the deformation zone, and at the exit, respectively; and V_0, V, and V_1 are the velocities at the entrance, in the deformation zone, and at the exit, respectively. In order to satisfy Eq 1. the exit velocity V_1 must be larger than the entrance velocity V_0. Therefore, the velocity of the deforming material in the *x* or rolling direction must steadily increase from entrance to exit. At only one point along the roll-strip interface is the surface velocity of the roll, V_R, equal to the velocity of the strip. This point is called the neutral point, or neutral plane, indicated by *N* in Fig. 3.

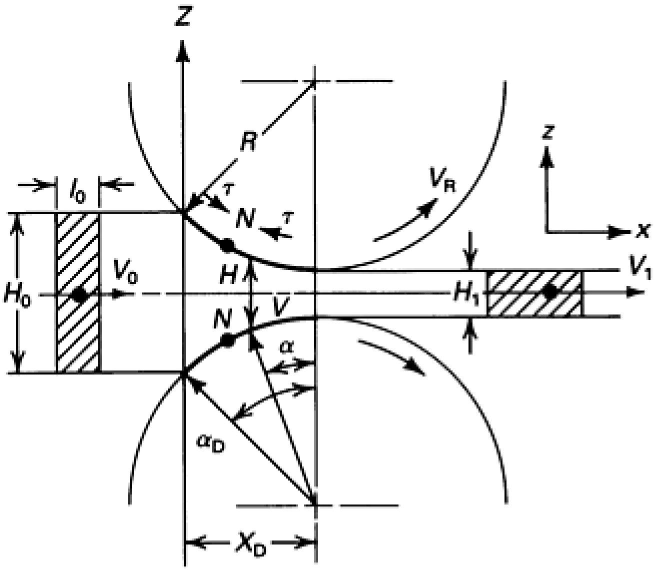

Fig. 3 Representation of strip rolling. The strip width *w* is constant in the *y* (width) direction.

The interface frictional stresses are directed from the entrance and exit planes toward the neutral plane because the relative velocity between the roll surface and the strip changes its direction at the neutral plane. This will be considered later in estimating rolling stresses.

An approximate value for the roll-separating force can be obtained by approximating the deformation zone, shown in Fig. 3, with the homogeneous plane-strain upsetting process. With this assumption, Eq 2 is valid, that is, the load per unit width of the strip is given by:

$$L = \frac{2\bar{\sigma}}{\sqrt{3}}\left(1 + \frac{ml}{4h}\right)l \qquad \textbf{(Eq 2)}$$

However, in this case the following approximations must be made:

- Average strip height $h = 0.5(H_0 + H_1)$
- Average length of the deforming strip $l = R\alpha_D$, with $\cos \alpha_D = 1 - (H_0 - H_1)2R$. In the literature, it is often recommended that the value of the projection of strip length X_D (Fig. 3) be used for *l;* however, considering the effect of friction on the roll-strip interface length, $R\alpha_D$, it is more appropriate to use $l = R\alpha_D$

To estimate average flow stress $\bar{\sigma}(\bar{\varepsilon}\ \dot{\bar{\varepsilon}}, \theta)$ at a given rolling temperature θ, the average strain $\bar{\varepsilon}$ is obtained from the thickness reduction, that is, $\bar{\varepsilon} = \ln (H_0/H_1)$. The strain rate $\dot{\bar{\varepsilon}}_\alpha$ is given by:

$$\dot{\bar{\varepsilon}}_\alpha = V_z/H = 2V_R \sin \alpha/H = [2V_R \sin \alpha]/[H_1 + 2R(1 - \cos \alpha)] \qquad \textbf{(Eq 3)}$$

where V_z is the velocity at a given plane in the z direction (see Fig. 3), H is the thickness at a given plane (roll angle α) in the deformation zone, and V_R is the roll surface velocity. At the entrance plane:

$$V_z = 2V_R \sin \alpha_D; H = H_0$$

At the exit plane:

$$V_z = 0; H = H_1$$

By taking a simple average of these two limiting values, an approximate value of strain rate is obtained:

$$\dot{\bar{\varepsilon}} = [2V_R \sin \alpha_D/H_0 + 0]/2 \qquad \textbf{(Eq 4)}$$

A more accurate value can be obtained by calculating an integrated average of $\dot{\bar{\varepsilon}}\alpha$ (Eq 3) throughout the deformation zone. Then, an average approximate value is (Ref 1):

$$\dot{\bar{\epsilon}} = \frac{V_R}{H_0}\left[\frac{2(H_0 - H_1)}{R}\right]^{1/2} \qquad \textbf{(Eq 5)}$$

The stress (roll pressure) distribution in strip rolling is illustrated in Fig. 4. The maximum stress is at the neutral plane N. These stresses increase with increasing friction and length of the deformation zone X_D. Tensile stresses applied to the strip at entrance or exit have the effect of reducing the maximum stress (by an amount approximately equal to $\Delta\sigma_z$ in Fig. 4b) and shifting the position of the neutral plane. The analogy to plane-strain upsetting is illustrated in Fig. 4(a).

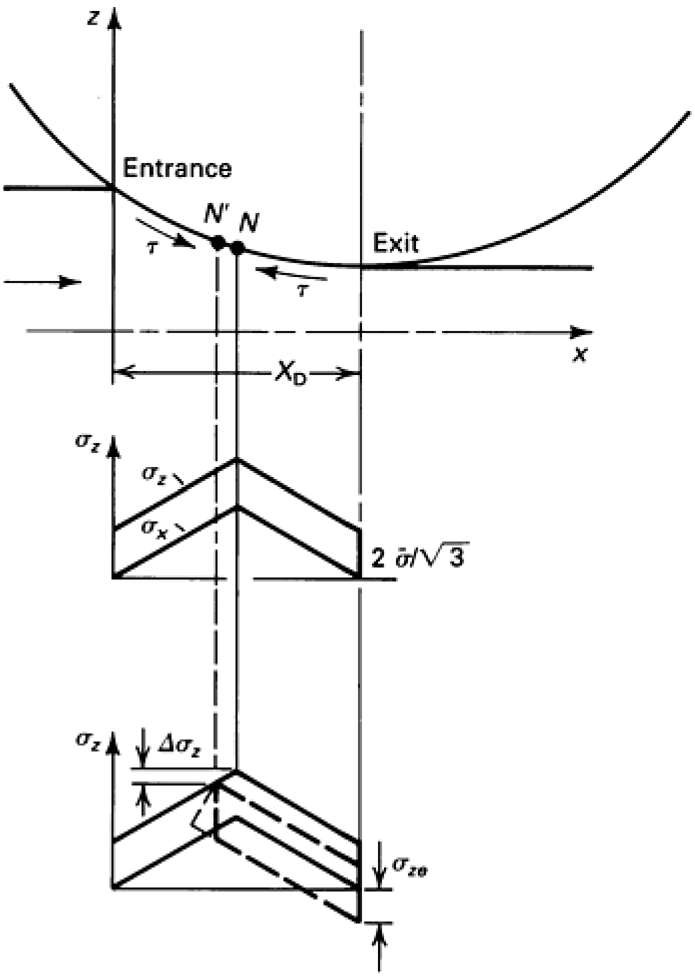

Fig. 4 Stress distribution in rolling. (a) With no tensile stresses at entry or exit. (b) With tensile stress σ_{ze} at exit.

The stress distribution can be calculated by using the equations derived in most textbooks (Ref 1, 2, 3, 4, 5) or by following the theory presented by Orowan (Ref 6). However, these calculations are quite complex and require numerical techniques in order to avoid an excessive number of simplifying assumptions. A computerized solution, with all necessary details and the listing of the FORTRAN computer program, is also given by Alexander (Ref 8).

For a numerical/computerized calculation of rolling stresses, the deformation zone can be divided into an arbitrary number of elements with flat, inclined surfaces (Fig. 5). The element, illustrated in this figure, is located between the neutral and exit planes because the frictional stress τ is acting against the direction of metal flow. When this element is located between the entrance and neutral planes, τ acts in the direction of metal flow. The stress distribution within this element can be obtained by use of the slab method, as applied to plane-strain upsetting (Ref 14):

$$\sigma_z = \frac{K_2}{K_1} \ln \left(\frac{h_1}{h_0 + K_1 X} \right) + \sigma_{z1} \quad \textbf{(Eq 6)}$$

where

$$K_1 = -2 \tan \alpha \quad \textbf{(Eq 7)}$$

$$K_2 = -\frac{2\bar{\sigma}K_1}{\sqrt{3}} + 2\tau(1 + \tan^2 \alpha) \quad \textbf{(Eq 8)}$$

$$\tau = m\bar{\sigma}/\sqrt{3} \quad \textbf{(Eq 9)}$$

Following Fig. 5, for $x = \Delta x$, $h_0 + K_1x = h_1$, and therefore Eq 6 gives $\sigma_z = \sigma_{z1}$, the boundary condition at $x = \Delta x$, which is known. For $x = 0$:

$$\sigma_z = \sigma_{z0} = \frac{K_2}{K_1} \ln\left(\frac{h_1}{h_0}\right) + \sigma_{z1}$$

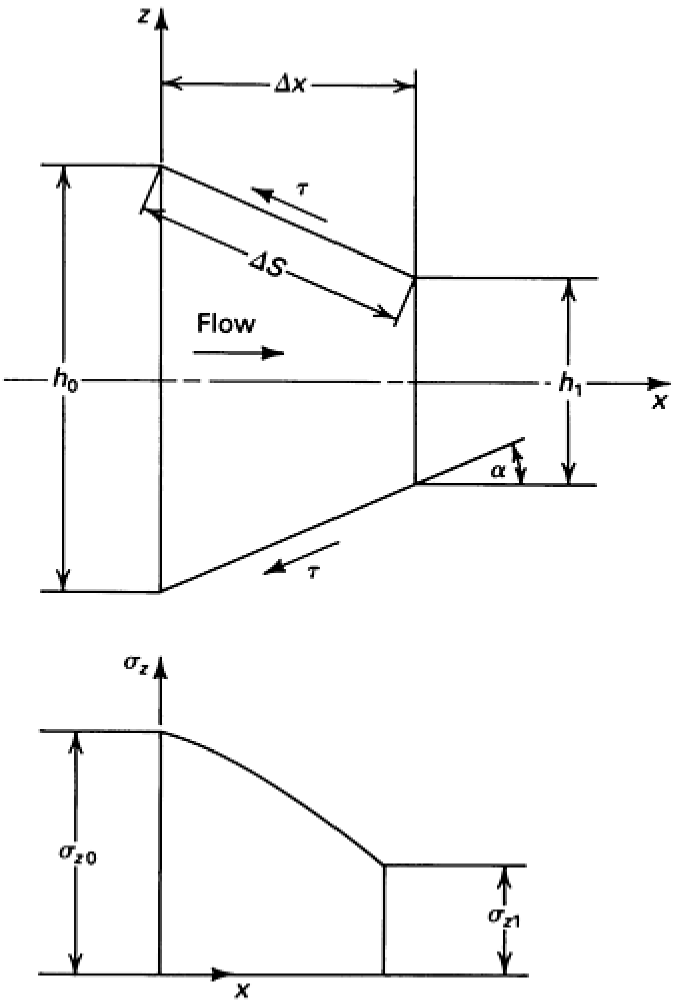

Fig. 5 Stresses in a deformation element used in computerized calculation of rolling stresses

If the element shown in Fig. 5 is located between the entrance and neutral planes, then the sign for the frictional shear stress τ must be reversed. Thus, Eq 6 and 7 are still valid, but:

$$K_2 = -\frac{2\bar{\sigma}}{\sqrt{3}} K_1 - 2\tau(1 + \tan^2 \alpha) \quad \textbf{(Eq 10)}$$

In this case, the value of the boundary condition at $x = 0$, that is, σ_{z0}, is known, and σ_{z1}, can be determined from Eq 6:

$$\sigma_{z1} = \sigma_{z0} - \frac{K_2}{K_1} \ln\left(\frac{h_1}{h_0 + K_1\Delta x}\right) \quad \textbf{(Eq 11)}$$

The stress boundary conditions at exit and entrance are known. Thus, to calculate the complete stress (roll pressure) distribution and to determine the location of the neutral plane, the length of the deformation zone X_D (see Fig. 3 and 4) is divided into n deformation elements (Fig. 6). Each element is approximated by flat top and bottom surfaces (Fig. 5). Starting from both ends of the deformation zone, that is, entrance and exit planes, the stresses are calculated for each element successively from one element to the next. The calculations are carried out simultaneously for both sides of the neutral plane. The location of the neutral plane is the location at which the stresses, calculated progressively from both exit and entrance sides, are equal. This procedure has been computerized and extensively used in cold and hot rolling of sheet, plane-strain forging of turbine blades (Ref 15) and in rolling of plates and airfoil shapes (Ref 16, 17).

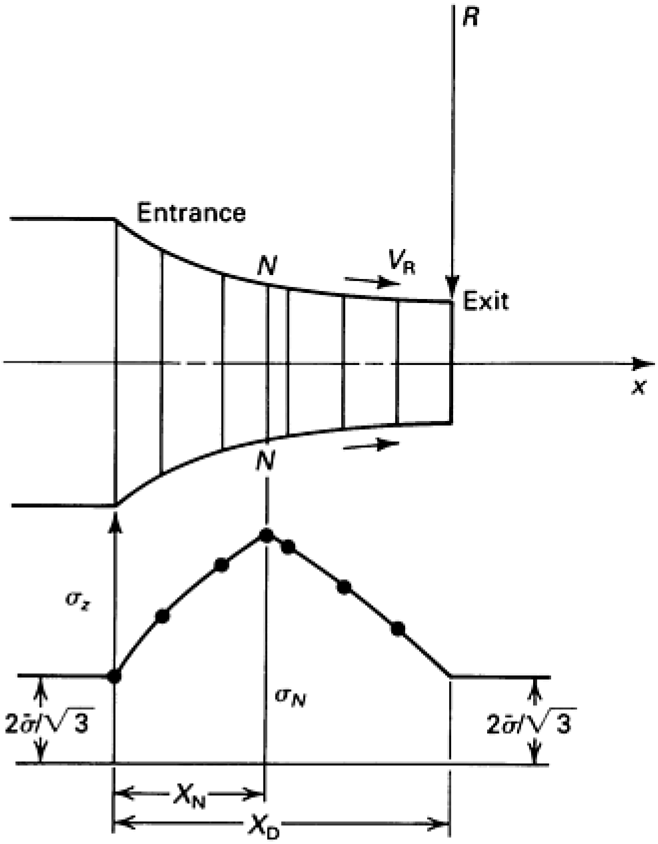

Fig. 6 Calculation of stress distribution by dividing the deformation zone into a number of tapered elements. In this case, tensile stresses in the strip are zero at both entrance and exit.

Roll-Separating Force and Torque. The integration of the stress distribution over the length of the deformation zone gives the total roll-separating force per unit width in strip rolling. In addition, the total torque is given by:

$$T = \int_0^{X_D} R\, dF \qquad \textbf{(Eq 12)}$$

where X_D is the length of the deformation zone (Fig. 6), R is roll radius, and F is the tangential force acting on the roll. Assuming that all energy is transmitted from the roll to the workpiece by frictional force:

$$dF = \tau\, dS \qquad \textbf{(Eq 13)}$$

In Fig. 5, it can be seen that:

$$dS = dx/\cos\alpha = \sqrt{1+\tan^2\alpha}\, dx \qquad \textbf{(Eq 14)}$$

In the deformation zone, the frictional force is in the rolling direction between entry and neutral planes. It changes direction between the neutral and exit planes. Thus, the total roll torque per unit width is:

$$T = R\tau \left[\int_0^{X_N} (1 + \tan^2 \alpha) dx - \int_{X_N}^{X_D} (1 + \tan^2 \alpha) dx \right] \quad \textbf{(Eq 15)}$$

where τ equals $m\bar{\sigma}/\sqrt{3}$; *R* is roll radius; α is roll angle (Fig. 3); X_N is the *x* distance of the neutral plane from the entrance (Fig. 6); and X_D is the length of the deformation zone (Fig. 6).

Elastic Deflection of Rolls. During rolling of strip, especially at room temperature, a considerable amount of roll deflection and flattening may take place. In the width direction, the rolls are bent between the roll bearings, and a certain amount of crowning, or thickening of the strip, occurs at the center. This can be corrected by either grinding the rolls to a larger diameter at the center or by using backup rolls.

In the thickness direction, roll flattening causes the roll radius to "enlarge," increasing the contact length. There are several numerical methods for calculating the elastic deformation of the rolls (Ref 9). A method for approximate correction of the force and torque calculations for roll flattening entails replacement of the original roll radius *R* with a larger value *R*'. A value of *R*' is suggested by Hitchcock (Ref 18) and is referred to extensively in the literature (Ref 2, 4). This is given as:

$$R' = R \left[1 + \frac{16(1 - \nu^2)p}{\pi E(H_0 - H_1)} \right] \quad \textbf{(Eq 16)}$$

where ν is Poisson's ratio of the roll material, *p* is the average roll pressure, and *E* is the elastic modulus of the roll material.

It is obvious that *R*' and *p* influence each other. Therefore, a computerized iteration procedure is necessary for consideration of roll flattening in calculating rolling force or pressure. Thus, the value of *p* is calculated for the nominal roll radius *R*. Then *R*' is calculated from Eq 16. If $R'/R \neq 1$, the calculation of *p* is repeated with the new *R*' value, and so on, until *R*'/*R* has approximately the value of 1.

Mechanics of Plate Rolling

In rolling of thick plates, metal flow occurs in three dimensions. The rolled material is elongated in the rolling direction as well as spread in the lateral or width direction. Spread in rolling is usually defined as the increase in width of a plate or slab expressed as a percentage of its original width. The spread increases with increasing reduction and interface friction, decreasing plate width-to-thickness ratio, and increasing roll-diameter-to-plate thickness ratio. In addition, the free edges tend to bulge with increasing reduction and interface friction. The three-dimensional metal flow that occurs in plate rolling is difficult to analyze. Therefore, most studies of this process have been experimental in nature, and several empirical formulas have been established for estimating spread (Ref 19, 20, 21). Recently, attempts were also made to predict elongation or spread theoretically (Ref 22, 23, 24). Once the spread has been estimated, the elongation can be determined from the volume constancy, or vice versa.

An Empirical Method for Estimating Spread. Among the various formulas available for predicting spread, Wusatowski's formula (Ref 20) is used most extensively and is given as:

$$W_1/W_0 = abcd(H_0/H_1)^P \quad \textbf{(Eq 17)}$$

where W_1 and W_0 are the final and initial widths of the plate, respectively; H_1 and H_0 are the final and initial thicknesses of the plate, respectively; P equals $10^{(-1.269)}\ (W_0/H_0)(H_0/D)^{0.556}$; D is the effective roll diameter; and $a, b, c,$ and d are constants that allow for variations in steel composition, rolling temperature, rolling speed and roll material, respectively. These constants vary slightly from unity, and their values can be obtained from the literature (Ref 16, 20, 24).

An empirical formula for predicting spread such as Eq 17 gives reasonable results within the range of conditions for the experiments from which the formula was developed. There is no formula that will make accurate predictions for all the conditions that exist in rolling. Thus, it is often necessary to attempt to estimate spread or elongation by theoretical means.

The theoretical prediction of spread involves a rather complex analysis and requires the use of computerized techniques (Ref 16, 22, 23). A modular upper-bound method has been used to predict metal flow, spread, elongation and roll torque (Ref 16). The principles of this method are described below. Figure 7 illustrates the coordinate system, the division of the deformation zone into elements, and the notations used. The spread profile is defined in terms of a third-order polynomial $w(x)$ with two unknown coefficients a_1 and a_2. The location of the neutral plane x_n is another unknown quantity. The following kinematically admissible velocity field, initially suggested by Hill (Ref 25), is used:

$$V_x = 1/[w(x)h(x)] \quad \textbf{(Eq 18)}$$

$$V_y = \frac{1}{h(x)} \frac{d}{dx}\left[\frac{1}{w(x)}\right] \quad \textbf{(Eq 19)}$$

$$V_z = \frac{1}{w(x)} \frac{d}{dx}\left[\frac{1}{h(x)}\right] \quad \textbf{(Eq 20)}$$

Using Eq 18, 19, and 20, the upper-bound method can be applied to predict spread. A computer program, SHPROL, can be used for some steps in the analysis. More information on SHPROL is available in the section "Shape Rolling" in this article.

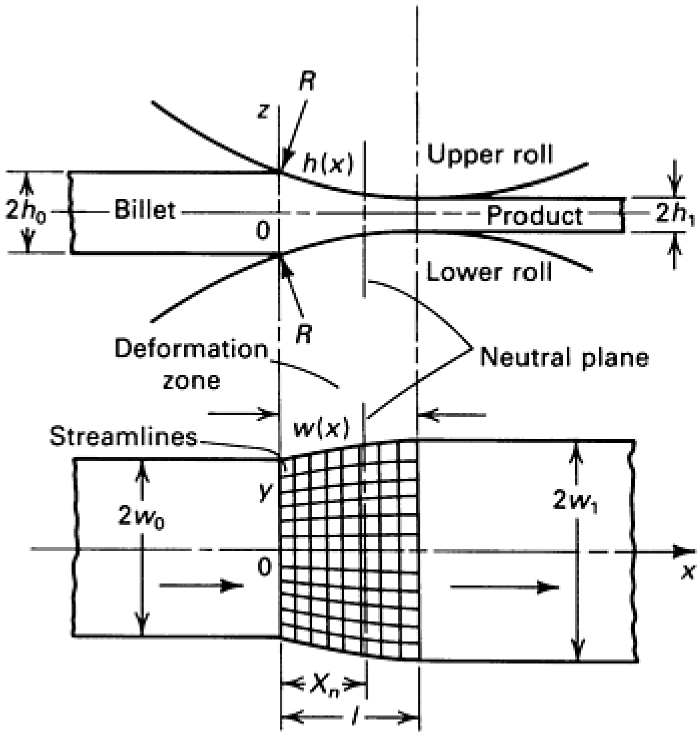

Fig. 7 Configuration of deformation and the grid system used in the analysis of the rolling of thick plates. Source: Ref 16

Prediction of Stresses and Roll-Separating Force. Once the spread (the boundaries of the deformation zone) has been calculated, this information can be used to predict the stresses and the roll-separating force. The computerized procedure used here is in principle the same as the method discussed earlier for predicting the stresses in strip rolling (Ref 16).

The deformation zone under the rolls is divided into trapezoidal slabs by planes normal to the rolling direction and along the stream tubes, as illustrated in Fig. 5 and 8. The stresses acting on strips in the rolling and transverse directions are illustrated in Fig. 8(b) and 8(c), respectively. As expected from the slab analysis, the stress distributions are very similar to those illustrated for strip rolling in Fig. 4, 5, and 6. By use of a numerical approach similar to that discussed for strip rolling, detailed predictions of stresses, in both the longitudinal and lateral directions, can be made. The stresses are calculated by assuming the frictional shear stress τ to be constant, as in the case of upper-bound analysis. Thus, the stress distribution at various planes along the width, or y, direction (Fig. 8) is linear on both sides of the plane of symmetry. The stress distribution in the rolling, or x, direction is calculated along the streamlines of metal flow (Fig. 7). At each node of the mesh, the lower of the σ_z values is accepted as the actual stress. Thus, a tentlike stress distribution is obtained (Fig. 9). Integration of the stresses acting on the plane of contact gives the roll-separating force.

Flat, Bar, and Shape Rolling

G. D. Lahoti, The Timken Company; S.L. Semiatin, Battelle Columbus Division

Shape Rolling

Rolling of shapes, also called caliber rolling, is one of the most complex deformation processes. A round or round-cornered square bar, billet, or slab is rolled in several passes into relatively simple sections such as rounds, squares, or rectangles; or complex sections such as L, U, T, H, or other irregular shapes (Ref 26). For this purpose certain intermediate shapes or passes are used, as shown in Fig. 10 for the rolling of angle sections (Ref 27). The design of these intermediate shapes, that is, roll pass design, is based on experience and differs from one company to another, even for the same final rolled section geometry. Relatively few quantitative data on roll pass design are available in the literature. Good summaries of references on this subject are given in several books (Ref 24, 26, 28, 29, 30, 31) and in a few recent articles (Ref 32, 33).

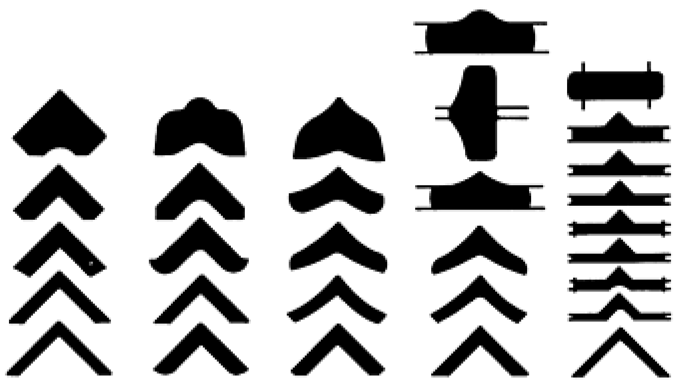

Fig. 10 Five possible roll pass designs for the rolling of a steel angle section. Source: Ref 27.

Basically, there are two methods for rolling shapes or sections. The first method is universal rolling (Fig. 11). The second method is caliber rolling (Fig. 10, 12). In universal rolling, the mill and stand constructions are more complex. However, in the rolling of I-beams or other similar sections, this method allows more flexibility than does caliber rolling and requires fewer passes. This is achieved because this method provides appropriate amounts of reductions, separately in webs and flanges.

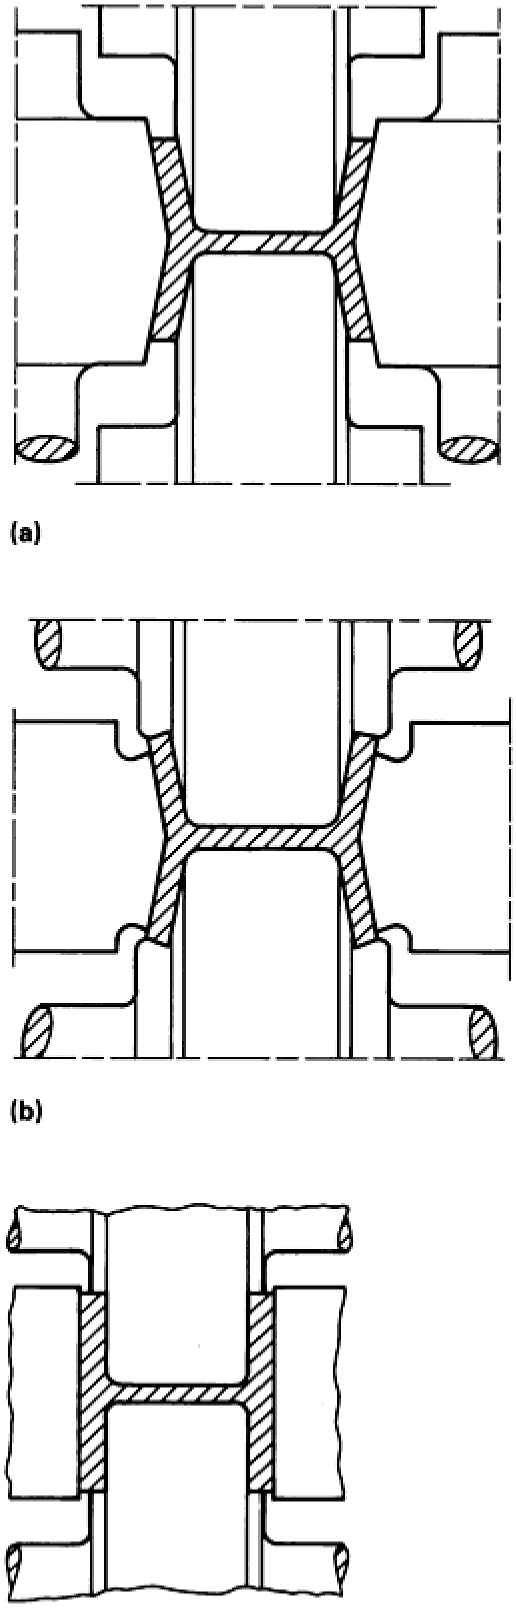

Fig. 11 Universal rolling of flanged beams. (a) Universal roll stand. (b) Edging stand. (c) Finishing stand. Source: Ref 34

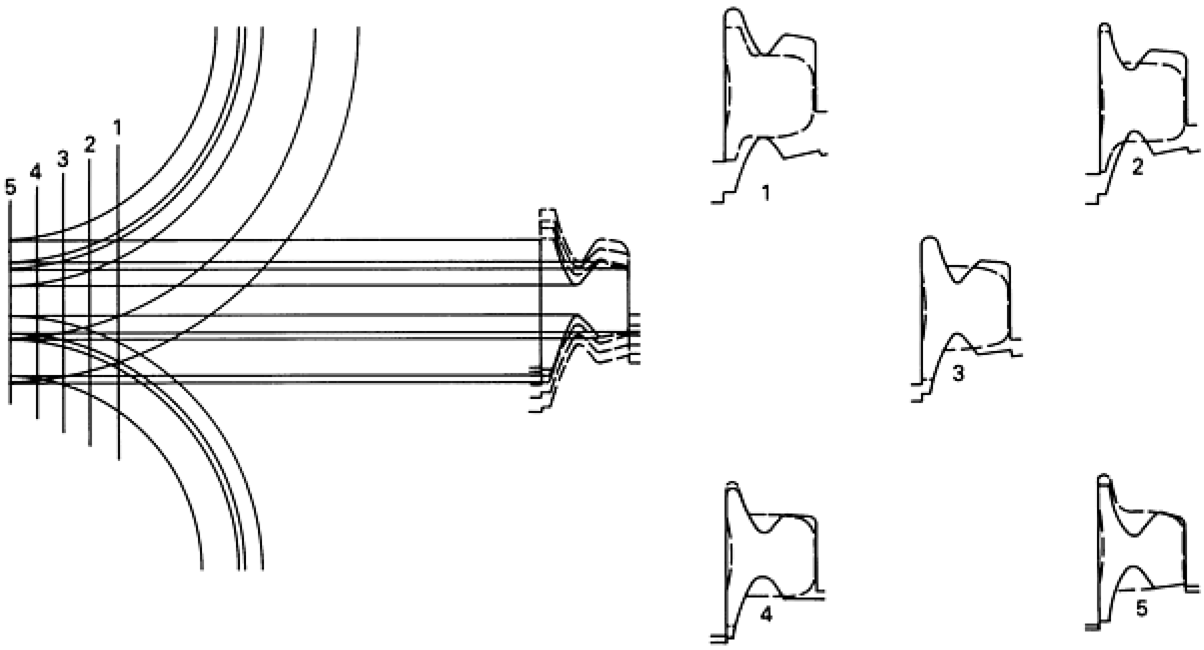

Fig. 12 Analysis of a roll stand used in rolling of rails. Sketches 1 through 5 illustrate the stock in broken lines and the roll in solid lines at various positions in the deformation zone. Source: Ref 35

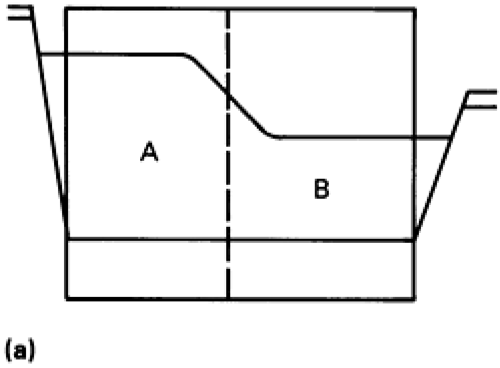
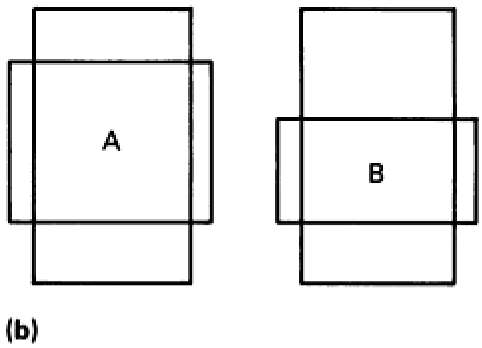
For successful rolling of shapes, it is necessary to estimate for each stand: the roll separating force and torque, the spread and elongation, and the appropriate geometry of the roll cavity or caliber. The force and torque can be estimated either by using empirical formulas or by approximating the deformation in shape rolling with that occurring in an "equivalent" plate rolling operation. In this case, the "equivalent" plate has initial and final thicknesses that correspond to the average initial and final thicknesses of the rolled section. The load and torque calculations can be performed for the "equivalent" plate, as discussed earlier in this chapter for plate rolling. The results are approximately valid for the rolled shape being considered.

Estimation of Elongation. During the rolling of a given shape or section, the cross section is not deformed uniformly, as can easily be seen in Fig. 12. This is illustrated further in Fig. 13 for a relatively simple shape. The reductions in height for zones A and B are not equal (Fig. 13a). Consequently, if these two zones, A and B, were completely independent of each other (Fig. 13b), zone B would be much more elongated than zone A. However, the two zones are connected and, as part of the rolled shape, must have equal elongation at the exit from the rolls. Therefore, during rolling, metal must flow from zone B into zone A so that a uniform elongation of the overall cross section is obtained (Fig. 13c). This lateral flow is influenced by the temperature differences that exist in the cross section because of variations in material thickness and heat flow.





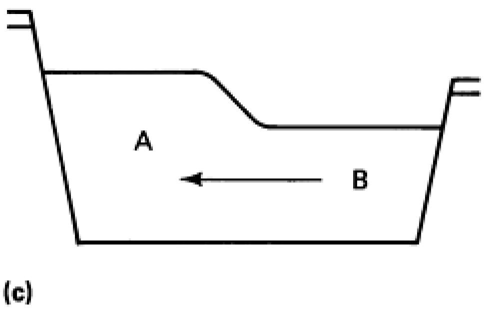


Fig. 13 Nonuniform deformation in the rolling of a shape. (a) Initial and final sections. (b) Two zones of the section considered as separate plates. (c) Direction of lateral metal flow. Source: Ref 24

To estimate the overall elongation, it is necessary to divide the initial section into a number of "equivalent" plates (A, B, C, and so forth), as shown in Fig. 13. The elongation for an individual section, without the combined influence of other portions of the section, can be estimated by using both the plate-rolling analogy and the techniques discussed in this article. The combined effect can be calculated by taking a "weighted average" of the individual elongations. For example, if the original section is to be divided into an equivalent system consisting or two plate sections (A and B in Fig. 13), with individual cross-sectional areas A_a and A_b, then the following weighted-average formula can be used:

$$\lambda_m = \frac{A_0}{A_1} = \frac{A_{a0} + A_{b0}}{A_{a1} + A_{b1}} = \frac{A_{a1}\lambda_a + A_{b1}\lambda_b}{A_{a1} + A_{b1}} \quad \textbf{(Eq 21)}$$

where λ is the elongation coefficient (that is, the cross-sectional area at the entrance divided by the cross-sectional area at the exit); *A* is the cross-sectional area; m is a subscript denoting average; a and b are subscripts denoting section portions A and B; and 0 and 1 are subscripts denoting entrance and exit values, respectively.

Computer-Aided Roll Pass Design. Estimation of the number of passes and of the roll geometry for each pass is the most difficult aspect of shape rolling. Ideally, to accomplish this, certain factors, discussed below, must be considered.

The Characteristics of the Available Installation. These include diameters and lengths of the rolls, bar dimensions, distance between roll stands, distance from the last stand to the shear, and tolerances that are required and that can be maintained.

The reduction per pass must be adjusted so that the installation is used at a maximum capacity, the roll stands are not overloaded, and roll wear is minimized. The maximum value of the reduction per pass is limited by the excessive lateral metal flow, which results in edge cracking; the power and load capacity of the roll stand; the requirement for the rolls to bite in the incoming bar; roll wear; and tolerance requirements.

At the present stage of technology, the above factors are considered in roll pass design by using a combination of empirical knowledge, some calculations, and some educated guesses. A methodical way of designing roll passes requires not only an estimate of the average elongation, as discussed earlier, but also the variation of this elongation within the deformation zone. The deformation zone is limited by the entrance, where a prerolled shape enters the rolls, and by the exit, where the rolled shape leaves the rolls. This is illustrated in Fig. 12. The deformation zone is cross sectioned with several planes (for example, planes 1 to 5 in Fig. 12; 1 is at the entrance, 5 is at the exit). The roll position and the deformation of the incoming billet are investigated at each of these planes. Thus, a more detailed analysis of metal flow and an improved method for designing the configuration of the rolls are possible. It is evident that this process can be drastically improved and made extremely efficient by the use of computer-aided techniques.

In recent years, most companies that produce shapes have computerized their roll pass design procedures for rolling rounds (Ref 33, 36, 37, 38, 39, 40) or structural shapes (Ref 36, 40, 41, 42, 43). In most of these applications, the elongation per pass and the distribution of the elongation within the deformation zone for each pass are predicted by using an empirical formula. If the elongation per pass is known, it is then possible, by use of computer graphics, to calculate the cross-sectional area of a section for a given pass, that is, the reduction and the roll geometry. The roll geometry can be expressed parametrically (in terms of angles, radii, and so forth). These geometric parameters can then be varied to optimize the area reduction per pass and obtain an acceptable degree of fill of the roll caliber used for that pass.

Computer-Aided Roll Pass Design of Airfoil Sections. To analyze metal flow and predict force and torque in the rolling of airfoils, two computer programs have been developed in a recent study (Ref 17). The first of these programs, SHPROL, uses upper bound analysis in a numerical form to predict spread and roll torque. SHPROL is based on the following simplifying assumptions:

- The initial contact between the rolls and the entrance section can be approximated as a straight line. (This is only correct if the upper and lower surfaces of the initial section already have the shape of the rolls.)
- An airfoil shape can be considered as an aggregate of slabs, as shown in Fig. 14.
- Plane sections perpendicular to the rolling direction remain plane during rolling. Thus, the axial velocity (velocity in the rolling, or *x*, direction) at any section perpendicular to the rolling direction is uniform over the entire cross section.
- The velocity components in the transverse, or *y*, direction and in the thickness, or *z*, direction are functions of *x* and linear in the *y* and *z* coordinates, respectively.

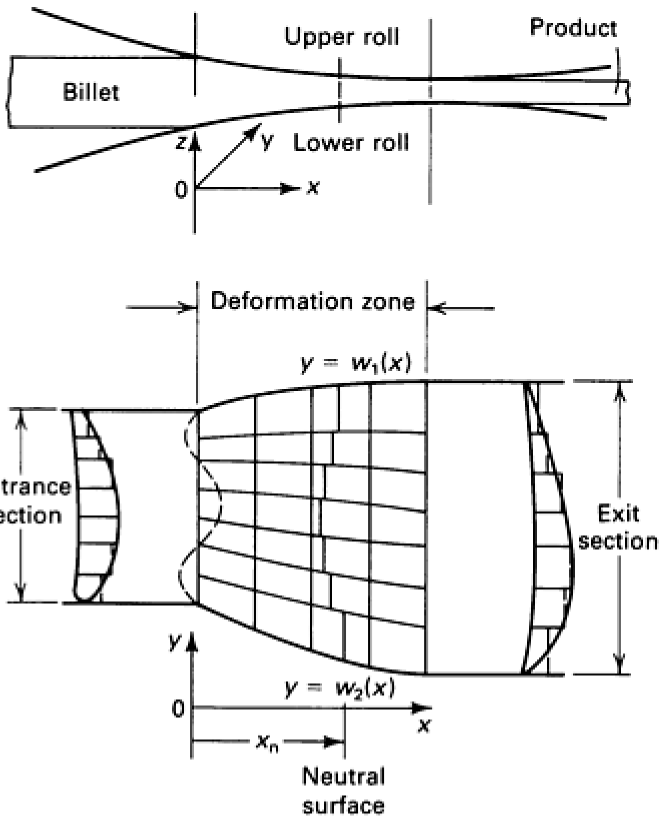

Fig. 14 Configuration of deformation zone in the application of numerical upper-bound analysis to the rolling of airfoil shapes. Source: Ref 17

In Fig. 14 each element is considered to be a plate for which it is possible to derive a kinematically admissible velocity field. The total energy dissipation rate of the process $\dot{E}_T$ is:

$$\dot{E}_T = \dot{E}_P + \dot{E}_D + \dot{E}_F \quad \textbf{(Eq 22)}$$

where $\dot{E}_P$ is the energy rate of plastic deformation, and is calculated for each element by integrating the product of flow stress and the strain rate over the element volume; $\dot{E}_D$ represents the energy rates associated with velocity discontinuities and is due to internal shear between the elements; and $\dot{E}_F$ is the energy rate due to friction between the rolls and the deforming material.

The total energy dissipation rate $\dot{E}_T$ is a function of unknown spread profiles w_1 and w_2 (Fig. 14) and the location of the neutral plane x_n. As in the analysis discussed earlier for plate rolling, the unknown coefficients of w_1, w_2, and x_n are determined by minimizing the total energy rate.

The computer program SHPROL uses as input data: roll and incoming-shape geometry, friction, flow stress, and roll speed. SHPROL can predict the energy dissipation rates, the roll torque, and, most important, the amounts of elongation and spread within one deformation zone, in the rolling of any airfoil shape.

The second program, called ROLPAS, uses interactive graphics and is capable of simulating the metal flow in the rolling of relatively simple shapes, such as rounds, plates, ovals, and airfoils (Fig. 15). ROLPAS uses as input: the geometry of the initial section, the geometry of the final section, the flow stress of the rolled material and the friction factor, and the variations in elongation and spread in the rolling direction, as calculated by the SHPROL program.

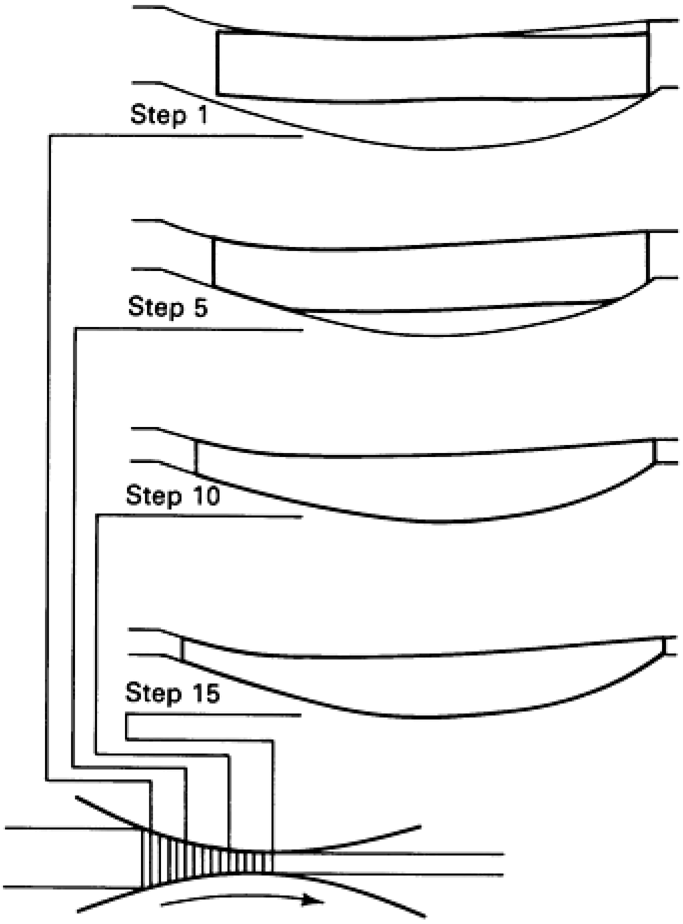

Fig. 15 Selected simulation steps as displayed by ROLPAS for a test airfoil shape cold rolled from rectangular steel stock

To simulate the rolling process, ROLPAS divides the deformation zone into a number of cross sections parallel to the roll axis (Fig. 7, 15). The simulation is initiated by considering the cross-sectional area, stresses present, and the roll-separating force and torque for the first section. These same analyses can then be performed on any succeeding section.

Computer-Aided Roll Pass Design for Round Sections. Several computer-aided methods for designing caliber rolls for rod rolling have been discussed in the literature (Ref 33, 36, 37, 38, 39, 40). One of these methods is a computer program called RPDROD for establishing roll cross sections and pass schedules interacting with a graphics terminal (Ref 33). RPDROD uses an empirical formula for estimating the variation of the spread in the roll bite and parametrically described alternative roll caliber designs. When using this program, the designer obtains an optimum roll pass schedule by evaluating a number of alternatives in which individual pass designs are selected from a variety of caliber shapes commonly used in rod rolling.

The computer program RPDROD consists of four modules, called STOCK, SCHEDULE, GROOVE, and METAL FLOW. The STOCK design module allows the user to design/specify the entry cross section for the first pass in the schedule. A square, rectangular, or round stock cross section can be defined. The SCHEDULE design module allows the user to design the roll pass schedule by providing specific functions:

- Add a new pass to the roll pass schedule, by estimating alternative roll cross section dimensions from design data provided by spread/elongation calculations
- Delete pass design data from the schedule in order to investigate alternative pass designs
- Review and/or provide hard copy of existing pass design data

The SCHEDULE design module allows the user to design an optimum roll pass schedule by investigating various alternative pass design and/or shape combinations. In principle, any roll cross section shape considered by the program could be used for a given pass in the schedule. However, RPDROD has facilities for checking input data and thus for preventing the selection of an illogical pass design or the inappropriate selection of roll cross-sectional shape combinations.

The GROOVE design module can be used to change the initially suggested roll cross section dimensions, as the user deems appropriate. As in the SCHEDULE module, input checking facilities ensure that specified roll cross-sectional dimensions are consistent with the chosen roll cross-sectional shape and bar entry cross section.

The METAL FLOW design module provides the user with details of metal flow simulation, including the calculated cross sections of the deforming bar in the roll bite, stresses in the deforming material, roll separating load, and roll torque. For this purpose, this module uses the ROLPAS program discussed earlier for the rolling of airfoil shapes.

As an example, a pass schedule calculated with RPDROD is given in Table 1. Comparison of these results with laboratory experiments indicated that these predictions were reasonably accurate, and RPDROD can be used for practical roll pass design for rolling of round sections (Ref 33).

Table 1 Summary of pass schedule information for the laboratory experiments as simulated by RPDROD

Computer-Aided Roll Pass Design of Structural and Irregular Sections. Computer graphics is being used by many companies for the design and manufacture of the caliber shapes for the rolling of structural sections (Ref 36, 40, 41, 42, 43). A publication on this subject gives an excellent summary of the practical use of computer graphics for roll caliber and roll pass design (Ref 43). In this case, the cross section of a rolled shape is described in general form as a polygon. Each corner or fillet point of the polygon is identified with the *x* and *y* coordinates and with the value of the corresponding radius (Fig. 16). Thus, any rolled section can be represented by a sequence of lines and circles. This method of describing a rolled section is very general and can define a large number of sections with a single computer program. Lines or circles that are irrelevant in a specific case can be set equal to zero. Thus, a simpler section, with a smaller number of corner and fillet points, can be obtained. For example, in the rolling of the symmetric-angle section shown in Fig. 10, several intermediate section passes are required. Such an intermediate section is shown in parametric representation in Fig. 17. In this figure, all the geometric variables can be modified to change the cross-sectional area and/or the amount of reduction per pass. These variables, which fully describe this section, are SELA = length (of one leg) at centerline, BETAG = angle at top corner, RK = radius at top corner, AL = length of straight portion at top, RD = radius of leg at top, PRST = projection of draft angle, RRU = radius at lower tip of leg, and RH = radius at bottom corner.

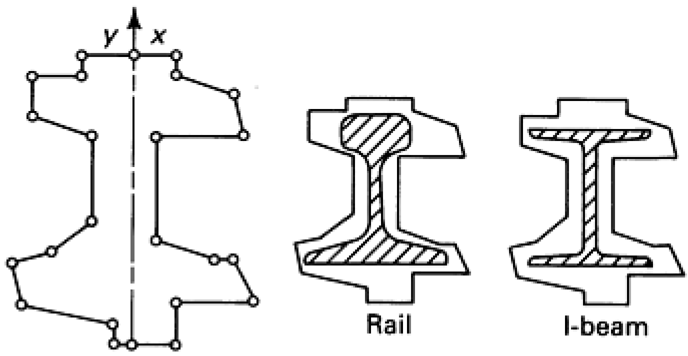

Fig. 16 Geometric representation of a rolled section as a polygon. Source: Ref 43

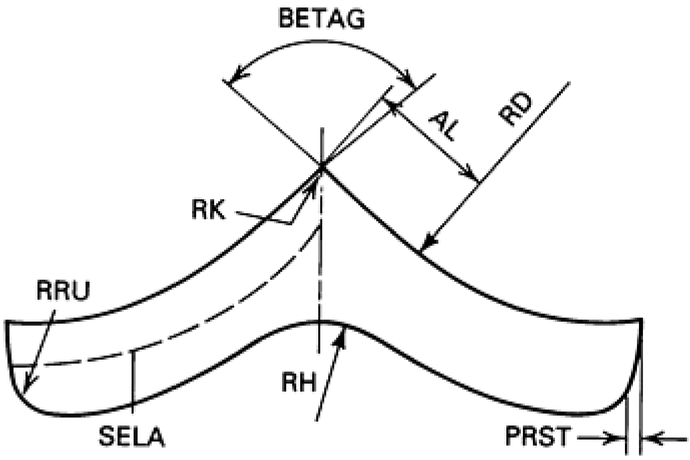

Fig. 17 Parametric representation of an intermediate-shape rolling pass for a symmetric angle section. See also Fig. 18. Source: Ref 43

In establishing the final section geometry, the designer assigns desired values to the variables listed above and, in addition, inputs the desired cross-sectional area and the degree of caliber fill, for example, the desired ratio of rolled section area versus section area on the caliber rolls. Thus, there is only one geometric variable that is calculated by the computer program, and that is the thickness of the leg of the angle section. In the example shown in Fig. 18(a), the leg thickness is calculated to be 18.2 mm (0.72 in.). The designer compares this section geometry (Fig. 18a) with the caliber geometry of the next pass that has been generated in a similar way. Let us assume that the section shown in Fig. 18(a) appears to be too long, that is, SELA is 67.5 mm (2.66 in.) and should be reduced to 65 mm (2.56 in.) without modifying the other variables. The interactive program is rerun with the new value for SELA. The modified section, shown in Fig. 18(b), is slightly thicker than the original section in order to maintain the same cross-sectional area.

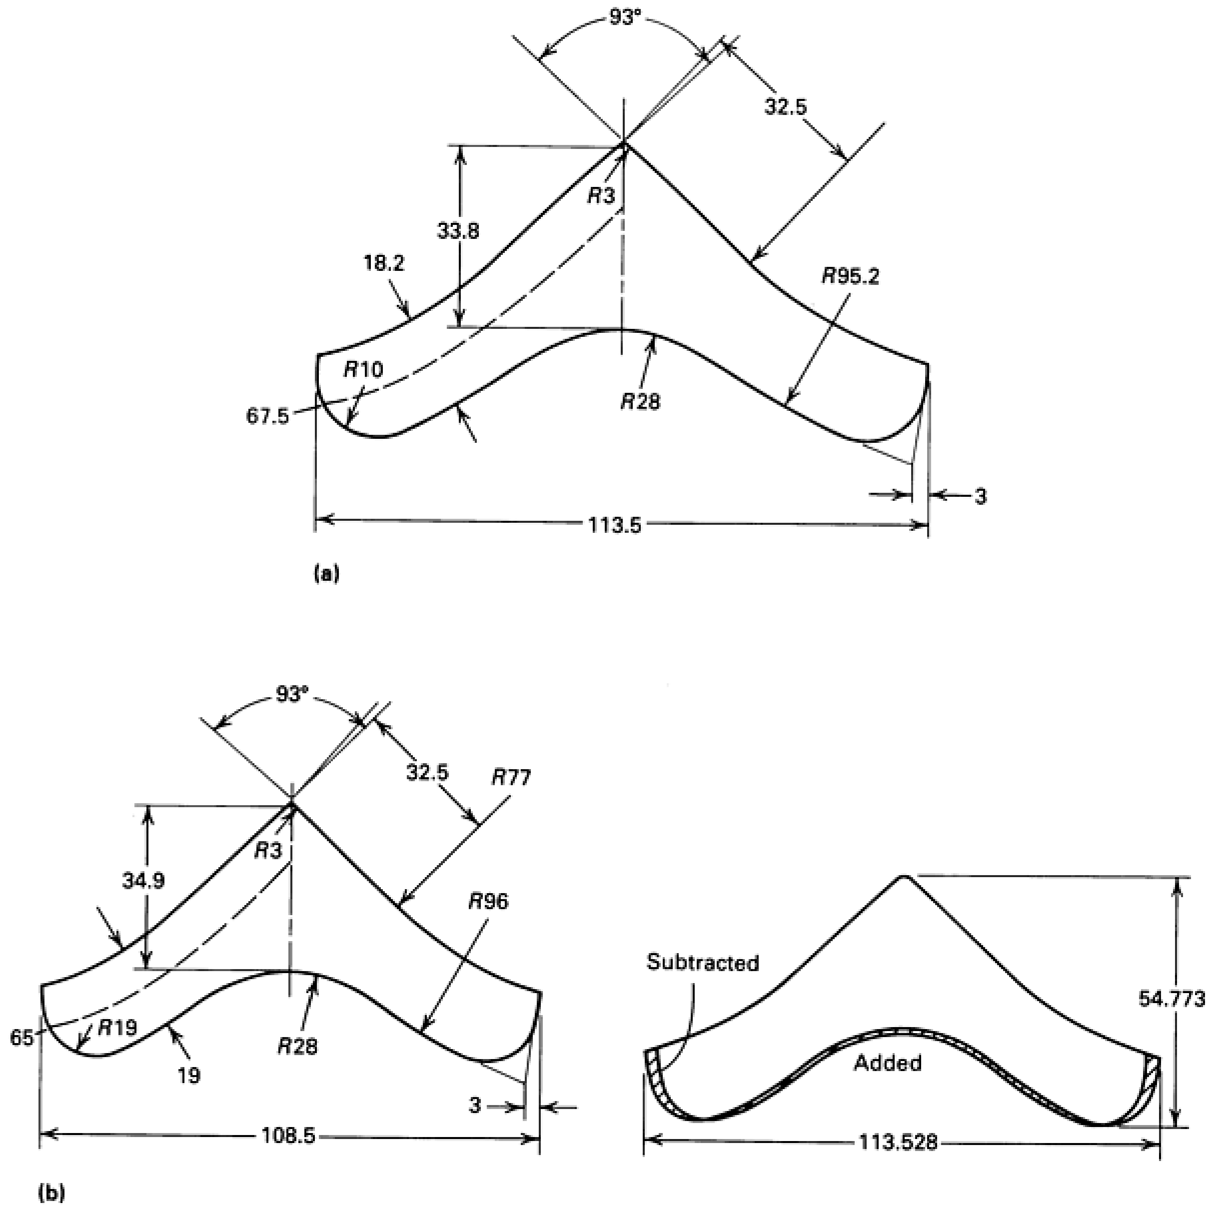

Fig. 18 (a) Alternative design for an intermediate-angle pass obtained by assigning values to the parameters given in Fig. 17. (b) Modified design of the intermediate-angle pass shown in (a), with new dimensions (left) and added and subtracted areas (right). Source: Ref 43

This interactive graphics program does not involve any analysis of metal flow or stresses. Nevertheless, it is extremely useful to the designer for modifying section geometries quickly and accurately, calculating cross-sectional areas, and cataloging all this geometrical information systematically. The program also automatically prepares engineering drawings of the sections and the templates for quality control as well as tapes for numerically controlled milling of the templates and the graphite EDM electrodes used in manufacturing the necessary cutting tools for roll machining (Ref 43).

Finite-element modeling has been used in the analysis of three-dimensional metal flow and of stress and strain distributions in shape rolling (Fig. 19, 20). By this so-called FEM method, the complex shape under the roll gap is divided into cells or elements with simple three-dimensional shapes. Through the analysis of these elements one at a time, the deformation pattern in a complex shape can be determined. Such calculations take hours on most computers; however, as new generations of computer hardware that perform calculations at greater speed become available, the laborious task of designing rolls for complex shapes will be greatly simplified.

Rolling Mills (Ref 44)

Mills are classified by descriptive dimensions that indicate the size of the mill, by the arrangement of roll stands, and by the type of product that is rolled. The dimensions used to indicate size vary depending on the type of mill and the product. (More information on classification and other aspects of rolling mills is available in Ref 44.)

However, there are three principal types of rolling mills, referred to as two-high, three-high, and four-high mills (Fig. 21). This classification, as the names indicate, is based on the way the rolls are arranged in the housings. A two-high stand consists of two rolls, one positioned directly above the other; a three-high mill has three rolls, and a four-high mill has four rolls, also arranged one on top of the other.

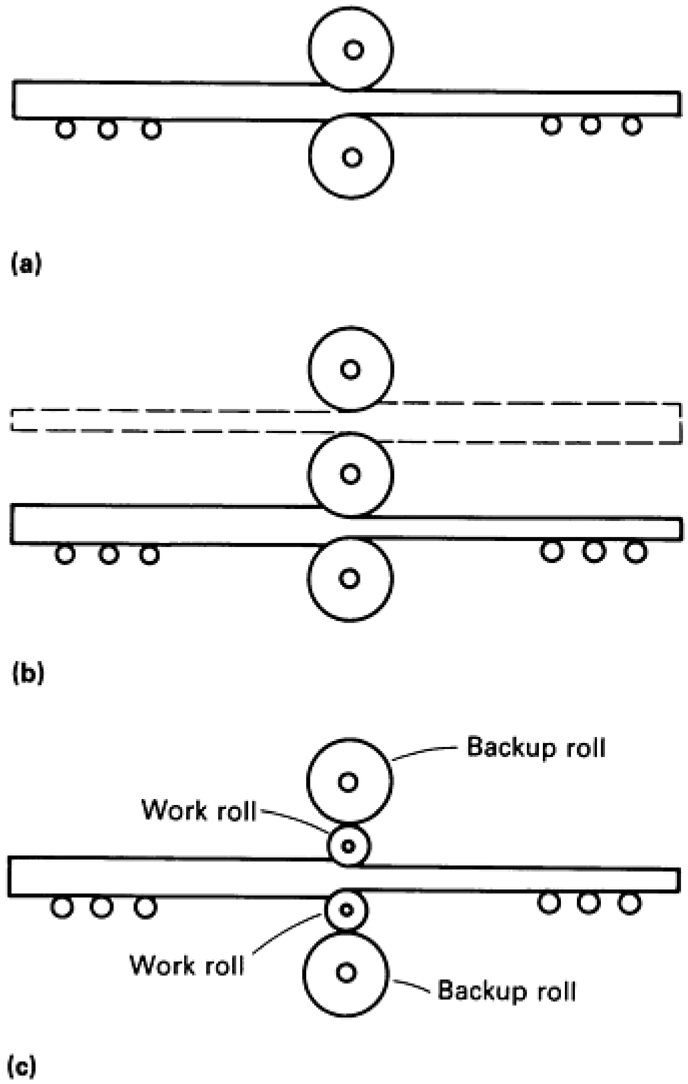

Fig. 21 The most common types of rolling mills. (a) Two-high. (b) Three-high. (c) Four-high

Two-high mills (Fig. 21a) may be either pull-over (drag-over) mills or reversing mills. In pull-over-type mills, the rolls run in only one direction. The workpiece must be returned over the top of the mill for further rolling, hence the name pull-over. Reversing mills employ rolls on which the direction of rotation can be reversed. Rolling then takes place alternately in two opposite directions. Reversing mills are among the most widely used in industry, and can be used to produce slabs, blooms, plates, billets, rounds, and partially formed sections suitable for rolling into finished shapes on other mills.

In three-high mills (Fig. 21b), the top and bottom rolls rotate in the same direction, while the middle roll rotates in the opposite direction. This allows the workpiece to be passed back and forth alternately through the top and middle rolls and then through the bottom and middle rolls without reversing the direction of roll rotation.

Four-high mills (Fig. 21c) are used for rolling flat material such as sheet and plate. This type of mill uses large backup rolls to reinforce smaller work rolls, thus obtaining fairly large reductions without excessive amounts of roll deflection. Four-high mills are used to produce wide plates and hot-rolled or cold-rolled sheet, as well as strip of uniform thickness.

Specialty Mills. Two other types of mills that are used are cluster mills and planetary mills. The most common type of cluster mill is the Sendzimir mill. In a typical Sendzimir mill design (Fig. 22a), each work roll is supported through its entire length by two rolls, which in turn are supported by three rolls. These rolls transfer roll-separating forces through four large backup rolls to a rigid, cast steel housing. Sendzimir mills are used for the cold rolling of sheet and foil to precise thicknesses.

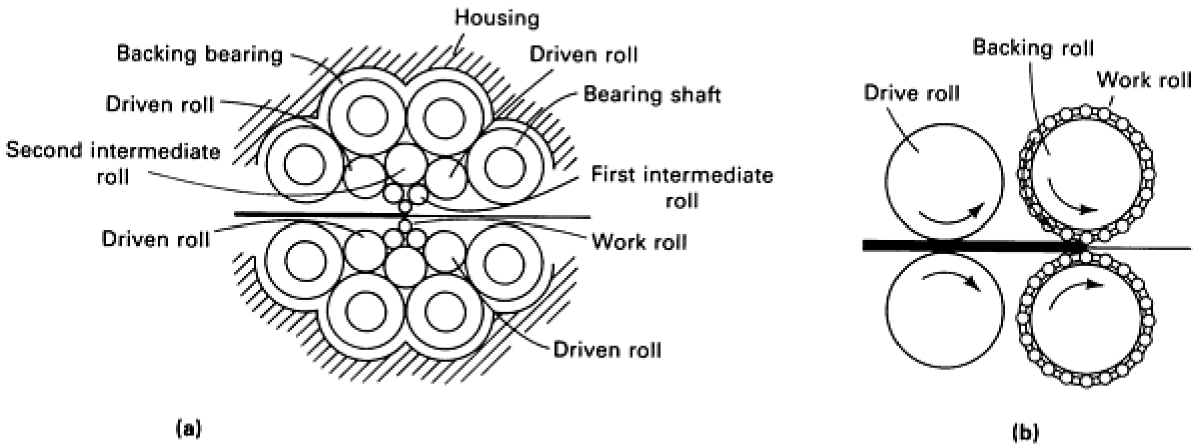

Fig. 22 Two types of specialty mills. (a) Sendzimir mill, used for precision cold rolling of thin sheet and foil. (b) Planetary mill, used to accomplish large reductions in a single pass

Planetary mills were developed in Germany to reduce slabs to hot-rolled strip in a single pass. This is accomplished by the use of two backup rolls surrounded by a number of small work rolls (Fig. 22b). Planetary mills are capable of reductions of up to 98% in a single pass, and have been designed up to 2030 mm (80 in.) in width.

Flat, Bar, and Shape Rolling

G. D. Lahoti, The Timken Company; S.L. Semiatin, Battelle Columbus Division

Rolls and Roll Materials

Of all the components of a rolling mill, the rolls are probably of primary interest, because they control the reduction and shaping of the work metal. There are three main parts of a roll: the body (the part on which the actual rolling takes place), the necks (which support the body and take the rolling pressure), and the driving ends, commonly known as wobblers (where the driving force is applied). These parts are shown in Fig. 23.

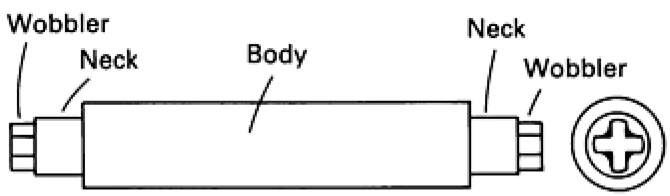

Fig. 23 Principal parts of a rolling mill roll

Rolls must have good wear resistance; sufficient strength to withstand the bending, torsional, and shearing stresses to which they are subjected; and, for hot rolling, ability to withstand elevated temperatures without heat checking (thermal fatigue) and oxidation.

Roll Design

Rolls are designed by engineering companies and builders of rolling mills, except for pass and groove designs on grooved rolls, which generally are engineered in the user's roll shop. The proportions of rolls are based on application and mill design. The width of the metal to be rolled, or the length of the billet where cross rolling is required, determines the width of the body face. Body diameter is selected to provide the required bite and pass angle to accomplish reduction and to provide sufficient mass to resist roll deflection and breakage. Rolls of smaller diameter result in less spread of the work metal and require less rolling pressure, separating force, and power for a given reduction. In designing rolls for shape rolling, deep grooves should be placed as far as possible from the center, in a location where the bending moment is at a minimum.

The size of a roll is generally designated by body diameter and body length, in that order; for example, a 600 × 1200 mm (24 × 48 in.) roll would have a body diameter of 600 mm and a body length of 1200 mm. For rolls used in processing shapes, the body diameter given is the nominal, or pitch, diameter.

Journal, or neck, dimensions are determined by imposed bending loads and by bearing design. The abrupt change in diameter from roll body to roll neck intensifies bending and torsional stresses at this location. To prevent breakage, the neck diameter should be as large a proportion of the body diameter as is feasible. Safe ratios of neck diameter to body diameter vary with type of bearing, type of mill, and conditions of service. In any event, neck diameter should never be smaller than 50% of body diameter. More information on roll design and manufacture is available in Ref 44.

Roll Materials

Cast iron rolls are used in the as-cast condition or after stress relief. Some high-alloy iron rolls are heat treated by holding at high temperature, then subjected to several lower-temperature treatments. Cast irons used for rolls are metastable and may be white or gray depending on composition, inoculation (if any), cooling rate, and other factors. Because of the number of elements present, determination of transformation diagrams is complicated.

Development of proper roll specifications to meet widely varying rolling requirements is an extremely complicated, technical undertaking; for example, when specifying radial hardness penetration, roll manufacturers must consider the requirements dictated by the design of each particular mill. Because of these factors, each roll must be more or less tailored for its intended use, and close cooperation between manufacturer and user is necessary to obtain maximum roll life and performance.

In American practice, cast iron rolls are classified as chilled iron rolls, grain rolls, sand iron rolls, ductile iron rolls, or composite rolls.

Chilled iron rolls (hardness 50 to 90 HSc) have a definitely formed, clear, homogeneous, chilled white iron body surface and a fairly sharp line of demarcation between the chilled surface and the gray iron interior portion of the body. Clear, chilled iron rolls can be made in unalloyed or alloyed grades, as shown in Table 2. The depth of chill is measured visually as the distance between the finished surface of the body and the depth at which the first graphitic specks appear. Below this, there is an area consisting of a mixture of white and gray iron known as mottle, which gradually becomes more gray and more graphitic, until it merges with the main gray iron structure of the roll interior.

Table 2 Applications of cast iron rolls

Type of roll	Applications
Chilled iron rolls	
Unalloyed	

(50-72 HSc)	**Hot and cold rolls for sheet mills, tin mills, two-high and three-high plate mills, and jobbing mills; wet and dry work rolls for four-high hot strip mills and for intermediate and finishing stands in rod, merchant, sheet, bar, and skelp mills**
Alloy iron (60-90 HSc)	**Hot rolls for sheet and strip mills in ferrous, nonferrous, rubber, plastic, and paper industries, two-high and three-high plate mills, and universal mills; work rolls for four-high hot strip mills and for finishing stands in sheet, bar, skelp, strip, and merchant mills; cold rolls for finishing ferrous and nonferrous sheet and strip**
Grain rolls (40-90 HSc)	
Mild hard	**Light-duty roughing rolls for small merchant and bar mills**
Medium hard	**Intermediate rolls for merchant and bar mills and for large structural mills**
Hard	**Finishing rolls for merchant, bar, and structural mills; flat finishing rolls for sheet, bar, and skelp mills; sizing, high-mill, reeler, and welding rolls for tube mills**
Sand iron rolls (35-45 HSc)	**Mild-duty rolls for roughing stands in small mills and finishing stands in large structural mills**
Ductile iron rolls (50-80 HSc)	**Roughing and intermediate rolls for bar and merchant mills and for tube mills and various other uses**

Alloy chilled iron rolls have hardnesses ranging from 60 to 90 HSc that are controlled by carbon and alloy contents. Customary maximum percentages of alloying elements are 1.25 Mo, 1.00 Cr, and 5.5 Ni. Many different combinations are used to produce desired properties. Rolls of this type, particularly in the harder grades, are used chiefly for rolling flat work, both hot and cold. The softer, machinable grades are used for rolling rod and small shapes.

Grain rolls are "indefinite chill" iron rolls (hardness 40 to 90 HSc) that have an outer chilled face on the body. There is finely divided graphite at the surface, which gradually increases in amount and in flake size, with a corresponding decrease in hardness, as distance from the surface increases. These rolls have high resistance to wear and good finishing qualities, to considerable depths. The harder grades are used for hot and cold finishing of flat rolled products, and the softer grades are for deep sections (even with small rolls). Alloying elements such as chromium, nickel, and molybdenum are usually added, either singly or in combination, to develop specific levels of hardness and toughness similar to those of chilled iron rolls.

Sand iron rolls (no chill; hardness 35 to 45 HSc) are cast in sand molds, in contrast to chilled iron rolls and grain rolls, the bodies of which are cast directly against chills. In a sand iron roll, the metal in the grooves of the body may be mildly hardened by use of cast iron ring inserts set in the sand mold. Sand iron rolls are used chiefly for intermediate and finishing stands on mills that roll large shapes. They are also used for roughing operations in primary mills.

Ductile iron rolls (hardness 50 to 65 HSc) are made of iron of restricted composition to which magnesium or rare-earth metals are added under controlled conditions to cause the graphite to form, during solidification, as nodules instead of the flakes common to gray iron. The resulting iron has strength and ductility properties between those of gray iron and steel.

Composite rolls, sometimes called double-pour rolls (hardness: bodies, 70 to 90 HSc; necks, 40 to 50 HSc) are rolls in which the body surface is made of a richly alloyed, hard, wear-resistant cast iron, and the necks, wobblers, and central areas of the body are of a tougher and softer material. The metals are firmly bonded together during casting to form an integral structure that produces a wearing surface of high hardness, along with a tougher body and neck. Composite rolls are thus better able to withstand impact and thermal stresses. The outer rolling surface may be of either chilled or grain iron. The chief application of composite rolls in the rolling of steel has been for work rolls in four-high hot and cold strip mills and in plate mills; in the rolling of nonferrous metals, the chief application has been for rolls for hot breakdown and cold reduction of sheet and strip.

Cast Steel Rolls. Differentiation between cast iron rolls and cast steel rolls cannot be made strictly on the basis of carbon content. Iron rolls are usually of compositions that produce free graphite in unchilled portions; steel rolls do not exhibit free graphite.

The harder cast alloy steel rolls have hardnesses equivalent to those of the softer cast iron rolls, and the superior toughness of cast steel rolls often makes them preferable to cast iron rolls.

Composition. Alloy steel rolls have almost entirely superseded carbon steel rolls in use. Compositions of most alloy steel rolls are within the following limits: 0.40 to 2.0 C; less than 0.012 S, usually 0.06 max; less than 0.012 P, usually 0.06 max; up to 1.25 Mn; up to 1.50 Cr; up to 1.50 Ni; and up to 0.60 Mo. Higher carbon contents increase hardness and wear resistance. Some rolls have higher alloy contents, but these are usually employed for special purposes.

Applications. Cast steel rolls are graded according to carbon content. The general applications of these rolls are listed in Table 3. This table does not constitute a rigid classification, because conditions vary widely from mill to mill. Adjustments in carbon and alloy content are commonly made to suit individual conditions.

Table 3 Applications of cast steel rolls

Carbon, %	Applications
0.50-0.65	**Applications in which strength is the only requirement**
0.70-0.85	**Blooming mills; roughing stands in jobbing, plate, and sheet mills; muck mills**
0.90-1.05	**Blooming mills; slab mills; roughing stands in continuous bar mills; backing rolls**
1.10-1.25	**Blooming and slab mills where breakage is not great; piercing mills; roughing stands in billet, bar, rail, and structural mills**
1.35-1.55	**Intermediate stands for rail mills; structural, continuous-billet, and continuous-bar mills**
1.60-1.80	**Intermediate stands for continuous-bar and billet mills; middle rolls for three-high mills**
1.85-2.05	**Middle rolls for rail and structural mills; finishing mills where housing design is too limited for iron rolls**
2.10-2.60	**Finishing rolls for unusual conditions**
2.65 and up	**Special applications**

Hardened forged steel rolls are principally used for cold rolling various metals in the form of coiled sheet and strip. Extremely high pressures are used in cold rolling, and forged rolls have sufficient strength, surface quality, and wear resistance for cold-rolling operations. Forged rolls are sometimes employed in nonferrous hot mills in preference to iron rolls because of their higher bending strength and resistance to metal pickup.

Type and Design. Forged steel rolls are generally flat-bodied (or plain-bodied) rolls designed to close dimensional tolerances and concentricity. They vary widely in size from a few kilograms to as much as 45 Mg (50 tons). During manufacture, holes are bored through the centers of larger rolls for heat treatment and inspection purposes. New design developments include tapered journals with drilled holes to accommodate a special type of roller bearing, and somewhat greater use of fully hardened bearing journals for direct roller-bearing contact. Forged rolls have been specified for work rolls, backup rolls, auxiliary rolls, and special rolls.

Composition. The most commonly used composition for forged steel rolls, sometimes known as regular roll steel, averages 0.85 C, 0.30 Mn, 0.30 Si, 1.75 Cr, and 0.10 V. About 0.25% Mo is sometimes added to this basic composition, and the chromium content may be varied to obtain specific characteristics. For rolling nonferrous metals, a forged steel containing 0.40 C and 3.00 Cr is preferred. In Sendzimir mills, the work rolls and first and second intermediate supporting and drive rolls usually are made from high-carbon high-chromium tool steel with 1.50 or 2.25% C and 12.00% Cr (AISI D1 or D4). For more severe service, work rolls of M1 are used. The powder metallurgy (P/M) alloy CPM 10V has wear resistance approaching that of cemented carbide, which makes it attractive for some special forged steel rolls. The composition of CPM 10V is 2.45 C, 5.25 Cr, 10.0 V, and 1.30 Mo.

Hardness. Selection of the proper hardness for the body of the roll is essential for successful service performance. The hardness range varies with the specific application and is developed with the cooperation of mill operators. Most forged rolls are heat treated to high hardness, but they may be processed to lower values for specific purposes. Because of their high hardness, hardened steel rolls require careful handling in shipping, storage, mill service, and grinding.

Hardness of work rolls for rolling thin strip averages about 95 HSc; lower hardnesses are employed for rolling thicker strip. In temper and finishing mills, work roll hardness is sometimes higher than 95 HSc, and for special applications such as foil rolls, it is up to 100 HSc. In nonferrous rolling, especially in aluminum plate mills, work roll hardness generally ranges from 60 to 80 HSc. Hardness of backing rolls varies from 55 to 95 HSc; values on the high side of this range are specified for rolls in small mills and foil mills.

For Sendzimir mills, customary hardness is 61 to 64 HRC for D1 and D4 steel work rolls and 64 to 66 HRC for high-speed steel work rolls. Customary hardness of intermediate rolls is 58 to 62 HRC.

Only the body section of a forged roll is hardened. Journals are usually not hardened, except those for direct-contact roller-bearing designs, for which a minimum hardness of 80 HSc is specified. In normal practice, the journals of forged rolls range in hardness from 30 to 50 HSc.

Sleeve Rolls. Use of forged and hardened sleeve-type rolls in certain hot strip and cold reduction mills has become common because such rolls are more economical. Sleeves are forged from high-quality alloy steel. Chromium-molybdenum-vanadium and nickel-chromium-molybdenum-vanadium compositions are generally used. Sleeves are heat treated by liquid quenching in either oil or water and are tempered to hardnesses of 50 to 85 HSc, depending on application.

The mandrel over which the sleeve is slipped may be made from a cast roll that has been worn below its minimum usable diameter, from a new casting made specifically for use as a mandrel, or from an alloy steel forging.

The outside diameter of the mandrel and the inside diameter of the sleeve are accurately machined or ground for a shrink fit. Mounting is accomplished by heating the sleeve to obtain the required expansion and then either slipping the sleeve over the mandrel or inserting the mandrel in the sleeve. This operation is performed with the mandrel in a vertical position. A locking device prevents lateral movement of the sleeve. Final machining is done after the sleeve is mounted.

Forged sleeves provide the hard, dense, spall-resistant surface required for the severe service encountered in hot and cold reduction mills. Another economical advantage of this type of roll is that the mandrel may be resleeved four or five times.

Instruments and Controls

Early rolling mills used few, if any, sensing and monitoring devices and were manually controlled by the operators. However, in modern high-speed mills, instrumentation and process controls are essential to ensure a correct set, the proper operation of mills, and an acceptable product quality. At a rolling speed of 1500 m/min (4900 ft/min), for example, 1200 mm (48 in.) wide sheet that is rolled 0.01 mm (0.0004 in.) too thick can result in a loss of one ton of steel every 5 min. Therefore, at each mill stand, instruments are used to measure roll force, drive motor current, roll speed, and roll gap. In addition, other devices measure workpiece temperature, size, and shape. Furthermore, microprocessors and computers are being used to program the mill operation, based on mathematical models. In slower mills, such as blooming, billet, and slab mills, the operator often acts as the controller, adjusting the mill operation based on feedback from instrumentation. However, for high-speed mills (bar, sheet, and strip mills), this is best accomplished by computer control.

The principal components of a computer-controlled system are:

- Mathematical models that adequately describe the process
- Instrumentation to measure the required variables of the system
- Control equipment, including a digital computer, to perform the required functions for control of the system

Process Models. A computer-controlled system can only follow orders; it is necessary to tell the computer what to do. This instruction is provided by programming the computer in accordance with mathematical formulations or process models that describe the relationships between the process variables. The mathematical form of these relationships depends on the specific application and might include differential equations derived from theoretical considerations, empirical equations developed from experimental data, statistical analysis, logical decisions, or some combination of these. The chosen treatment of the processing data must provide the processing parameters to be controlled and the desired degree of control. In addition to inputting the computational instructions, the computer must be programmed for the logic to be used, the time sequence of required events, priorities of control actions under certain circumstances, and other decisions necessary for proper process control.

Instrumentation. A computer-controlled system accepts the quantitative values of the many processing variables and executes its control function based on these values. A prime requisite of such a system is adequate, reliable instrumentation for translating a process variable from its physical or chemical units to a form suitable for use by the computer. Many instruments are presently available to provide rapid on-line measurements of such variables as width, thickness, position, force, temperature, and flow. Instruments that measure other physical and chemical properties of both raw materials and finished products are available. However, this kind of measurement generally involves the taking of a sample and subsequent analysis in an off-line laboratory.

Control Equipment. The final component of a computer control system is the digital computer system, including hardware and software, and process regulating devices. The computer hardware includes a central processing unit that has the arithmetical and logical capability needed to run the mathematical models, a storage (memory) unit for accumulation of process measurement data and other information, and a computer interface to allow the central processing unit and memory to communicate with the instrumentation, with process regulators such as screw position regulators and speed regulators, with operators, and with other computers, including a business computer system.

Software consists of all the computer programs needed to accomplish the desired functions of the computer controlled system.

G. D. Lahoti, The Timken Company; S.L. Semiatin, Battelle Columbus Division

Materials for Rolling

A large number of metals are rolled using the methods and equipment described above, or slight variations of them. By far the largest amount of rolled material falls under the general category of ferrous metals, or materials whose major constituent is iron. Included in this group are carbon and alloy steels, stainless steels, and specialty steels. Nonferrous metals, including aluminum alloys, copper alloys, titanium alloys, and nickel-base alloys also are processed by rolling.

Steels

Conventional primary and secondary rolling of steels is usually conducted at elevated (hot-rolling) temperatures. In a typical hot-rolling operation involving multiple passes through a reversing or multistand mill, the temperature of the work metal drops considerably. For carbon steels, the initial rolling temperature may be about 1200 °C (2190 °F); it may drop to 900 °C (1650 °F) or lower by the final pass. Because the size of recrystallized grains decreases with temperature, hot rolling results in a fine grain size.

The control of grain size and other microstructural features during rolling is especially important in low-carbon and low-alloy steels. Higher-carbon and high-alloy steels produced in the form of plates, bars, or shapes often undergo subsequent mechanical (for example, forging or extrusion) or thermal (such as hardening or tempering) processing in which the final properties are tailored to the end-use. Two products in which rolling is used almost exclusively to control structure and properties are low-carbon steel (used in automotive and appliance applications) and high-strength low-alloy steels (used in various structural applications).

Low-carbon steel is produced in the form of sheet by a combination of hot and cold rolling. The starting steel is either rimmed or killed. In these steels, it is not possible to obtain very fine grain sizes by means of controlling the rolling process (Fig. 24). This is because of the absence of alloying elements, which could retard the rapid grain growth that occurs between passes. Nevertheless, grain size and strength are of secondary importance in this product. The most important property is cold formability, because the sheet metal is often subsequently stamped into complex shapes at room temperature.

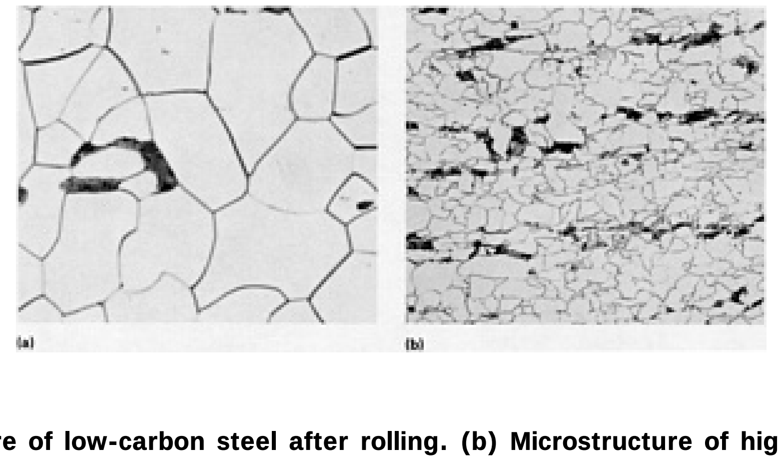

Fig. 24 (a) Microstructure of low-carbon steel after rolling. (b) Microstructure of high-strength low-alloy steel after rolling. See text for details. Courtesy of L. Cuddy, Pennsylvania State University

High-strength low-alloy steels, in contrast to the low-carbon steels discussed above, are designed to have high strength and a relatively modest amount of cold formability. These grades are typically produced as hot-rolled sheet, bar, and plate with 0.05 to 0.10% C and small amounts of niobium, vanadium, and titanium.

The correct thermomechanical treatment is extremely important in determining the final properties of high-strength low-alloy steels. For these materials, controlled rolling (Fig. 25) is used to refine the relatively coarse austenite structure by a series of high-temperature rolling and recrystallization steps. A moderate to heavy reduction is imposed on the material below the recrystallization temperature (T_r in Fig. 25) to achieve the desired fine grain size and the associated properties. More information on controlled rolling of high-strength low-alloy steels is available in Ref 45.

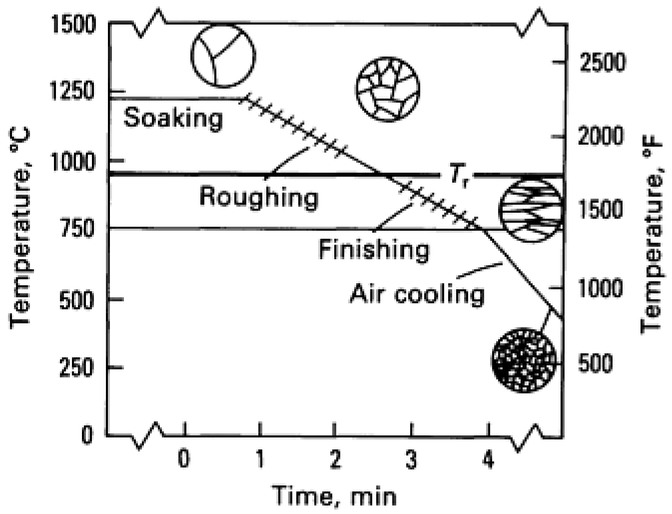

Fig. 25 Temperature/time profile for controlled rolling of high-strength low-alloy steel plate. Ar_3, austenite-to-ferrite transformation temperature. Source: Ref 45

Stainless steels are available in the same product forms as carbon and low-alloy steels. Mills of more rugged construction are required for the rolling of stainless steels than are needed for plain carbon and alloy steels because of the higher strengths of the stainless alloys; otherwise, rolling practice is similar to that used for carbon and alloy steels.

Stainless steel mill products are normally obtained in the annealed condition, but strength or hardness higher than that in the annealed condition can be attained by controlled cold rolling.

Nonferrous Materials

A number of nonferrous metals are also rolled into a variety of product forms using methods similar to those described above for steels. These include aluminum, copper, titanium, and nickel-base alloys.

Aluminum Alloys. Aluminum alloy sheet and plate are also hot rolled from slabs. As for steels, the slabs are frequently fabricated from cast ingots. In many cases, it is first necessary to remove surface defects from the ingots by means of a machining operation known as scalping. Also, the ingots are given a preliminary high-temperature homogenization heat treatment to eliminate chemical nonuniformities inherent in aluminum alloy castings. Such a treatment expands the temperature regime over which rolling can be successfully conducted without fracture. Aluminum slabs are finished by hot rolling alone on continuous mills (thicker gages) or by a combination of hot and cold rolling (thinner gages). Aluminum foil is one of the most common of rolled aluminum products, and is produced by cold rolling to thicknesses as small as 6 μm (0.00024 in.) (Ref 46). Aluminum alloy blooms are hot rolled from square ingots on two-high reversing mills, with scalping and homogenization heat treatments being used as for the slabbing operation. Bars, shapes, and wire are subsequently hot rolled from reheated blooms.

Copper Alloys (Ref 47). Production of copper alloy strip and sheet begins with semicontinuous cast slabs or continuous cast strip. Initial breakdown of these products is usually by hot rolling on two-high reversing mills equipped with vertical edging rolls. After rolling, the strip is scalped (milled) to remove any oxides remaining from the casting and rolling operations. After milling, the strip has a thickness of about 7.6 to 10.2 mm (0.300 to 0.400 in.).

Copper alloy sheet is cold rolled to final thickness using either four-high or Sendzimir mills to obtain the necessary reduction while maintaining flatness. The finished thickness of the sheet can be as low as 0.1 mm (0.004 in.).

Titanium and titanium alloys are considerably more difficult to roll than are either steels or copper and aluminum alloys. Most titanium alloys have very narrow working temperature ranges. To overcome this problem, titanium alloys are often rolled in packs, or layers of sheets, that are sometimes encased in a steel envelope (Fig. 26). The envelope, called a can, is evacuated to minimize oxidation of the work metal, and also serves to minimize heat loss to the relatively cold rolls upon deformation. The narrow working temperature range of titanium alloys makes the rolling of these materials labor intensive. Rolling passes are done by hand on relatively small pieces, and many intermediate reheating steps are required. Some β titanium alloys, however, are being continuously rolled on hot and cold strip mills.

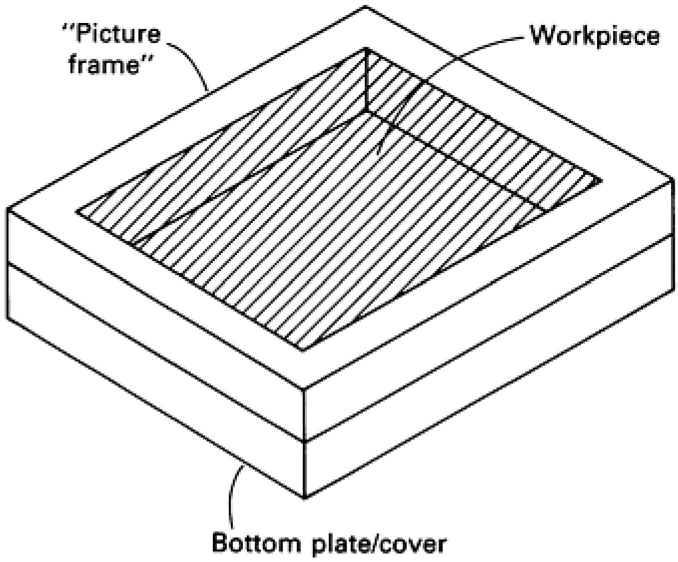

Fig. 26 Pack ("can") used for rolling titanium and nickel-base alloys. The top cover, which would be welded in place before rolling, is not shown.

Nickel-base superalloys are the most difficult materials to roll. Primary rolling of these materials is usually done at temperatures near the melting point on rugged, powerful mills built to withstand the high stresses encountered in the working of these alloys. Like titanium alloys, nickel-base alloys have narrow working temperature ranges, are often rolled in packs or cans, and must be reheated frequently between passes. Mill products include sheets, bars, and shapes.

Flat, Bar, and Shape Rolling

G. D. Lahoti, The Timken Company; S.L. Semiatin, Battelle Columbus Division

Heated-Roll Rolling

Heated-roll rolling is a process that was developed at Battelle Columbus Laboratories to roll difficult-to-work materials. Heated-roll rolling is an isothermal or near-isothermal process in which the work rolls are heated to the same or nearly the same temperature as the work metal. Heated-roll rolling is analogous to isothermal and hot-die forging (see the article "Isothermal and Hot-Die Forging" in this Volume).

Heated-Roll Rolling of Sheet and Strip

In conventional hot rolling of high temperature materials, such as titanium and nickel alloys, the hot metal is deformed between cold or warm rolls. This causes chilling on the surface of the rolled metal, resulting in higher working loads and stresses than would be required if chilling were avoided. Further, chilling limits the maximum possible reduction per pass and the minimum thickness attainable in conventional hot sheet rolling. From a materials viewpoint, conventional hot rolling often requires rolling temperatures that are higher than optimal, which cause more workpiece contamination and can result in microstructure and property variations in rolled products. To overcome some of the problems associated with conventional hot rolling, the techniques of isothermal and near-isothermal hot rolling have been developed.

The technique has been demonstrated for sheet rolling on modified conventional rolling mills with either two-high or four-high arrangements (Ref 48, 49, 50). In the two-high arrangement, where the rolls are relatively large, a composite roll design has often been employed (Fig. 27). This consists of rolls with outer sleeves made of a high-temperature superalloy and with cores of hot-work tool steels (such as AISI H13). Such a design satisfies the need for a roll with good hot hardness at temperatures in the 815 °C (1500 °F) range at a cost less than a solid roll made from an expensive superalloy. This setup is improved by induction heating the roll surfaces and by internal water cooling of the core of the rolls and roll bearings. The viability of heated-roll rolling also has been demonstrated on a four-high mill (Ref 49). In this case, the work rolls and the backup rolls were heated by banks of radiant heaters and had a design maximum operating surface temperature of 815 °C (1500 °F) for the work rolls.

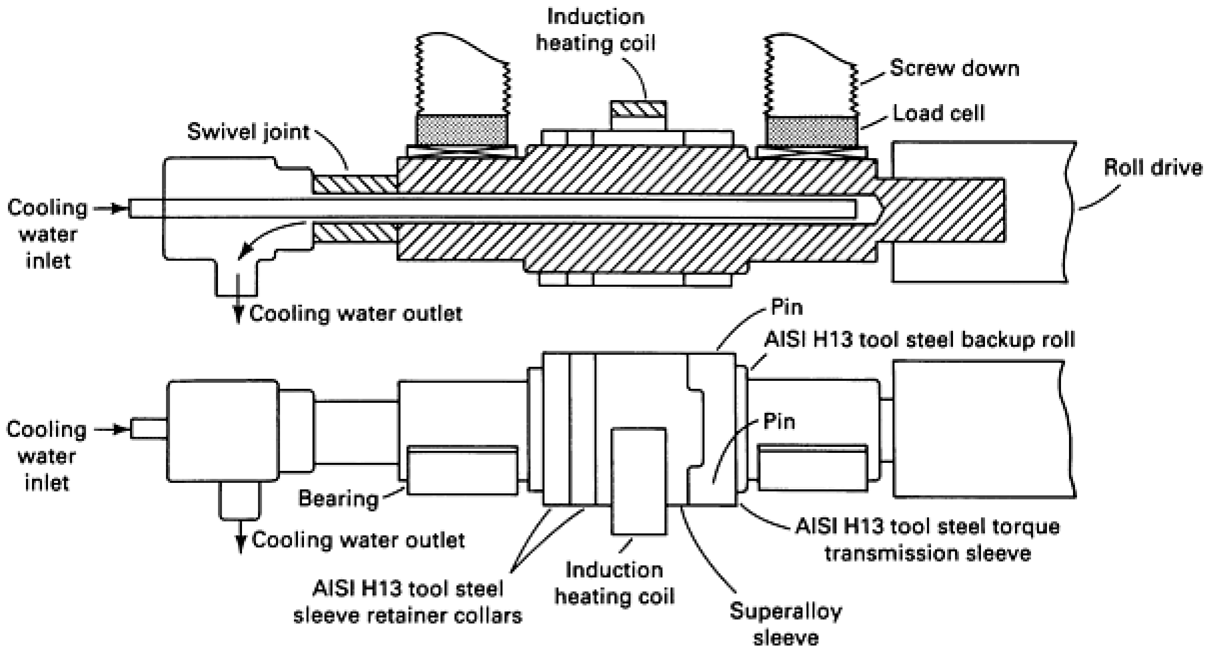

Fig. 27 Schematic showing composite roll construction and auxiliary equipment for heated-roll rolling. Source: Ref 48, 50

In studies conducted at Battelle Columbus Division, rolling was not performed at low deformation rates, and therefore did not rely on the superplastic characteristics of the workpiece materials, which are often used in isothermal and hot-die forging. Rather, these studies concentrated on determination of the workability of and uniformity obtainable in difficult-to-work and temperature sensitive alloys in the absence of chilling. Thus, attention was focused on a much wider range of alloys than those used in isothermal forging, including tungsten, beryllium, Ti-6Al-4V, alloy 718, and several alloy steels and oxide-dispersion strengthened alloys. For powder metallurgy (P/M) consolidated and stress relieved tungsten, for instance, workability was shown to be greatly improved with heated-roll rolling (Ref 48). This material is difficult to hot work conventionally because of its ductile-to-brittle transition at temperature of 230 to 250 °C (445 to 480 °F). With rolls at a temperature of 150 °C (300 °F) or lower, strip preheated to 260 °C (500 °F) and rolled at a speed of 6 m/min (20 ft/min) developed severe laminations and edge cracking because of chilling. In contrast, when the roll temperature was raised to the preheat temperature of the strip (260 °C, or 500 °F), none of these problems was encountered.

The effect of heated rolls on temperature uniformity in rolling of strip from high-temperature alloys was quantified through a series of heat transfer simulations performed on a digital computer (Ref 48, 49, 50). An example result is shown in Fig. 28 for thin beryllium strip preheated to 540 °C (1000 °F) and rolled to 20% reduction in thickness at a rolling speed of 30 m/min (100 ft/min). In this case, when the rolls are at room temperature, the temperature of the hot strip decreases significantly during rolling, and large temperature gradients are present. Both of these factors may cause workability problems. On the other hand, temperature decreases and thermal gradients through the strip thickness are calculated to be comparatively small when the rolls are heated to a surface temperature of 540 °C (1000 °F).

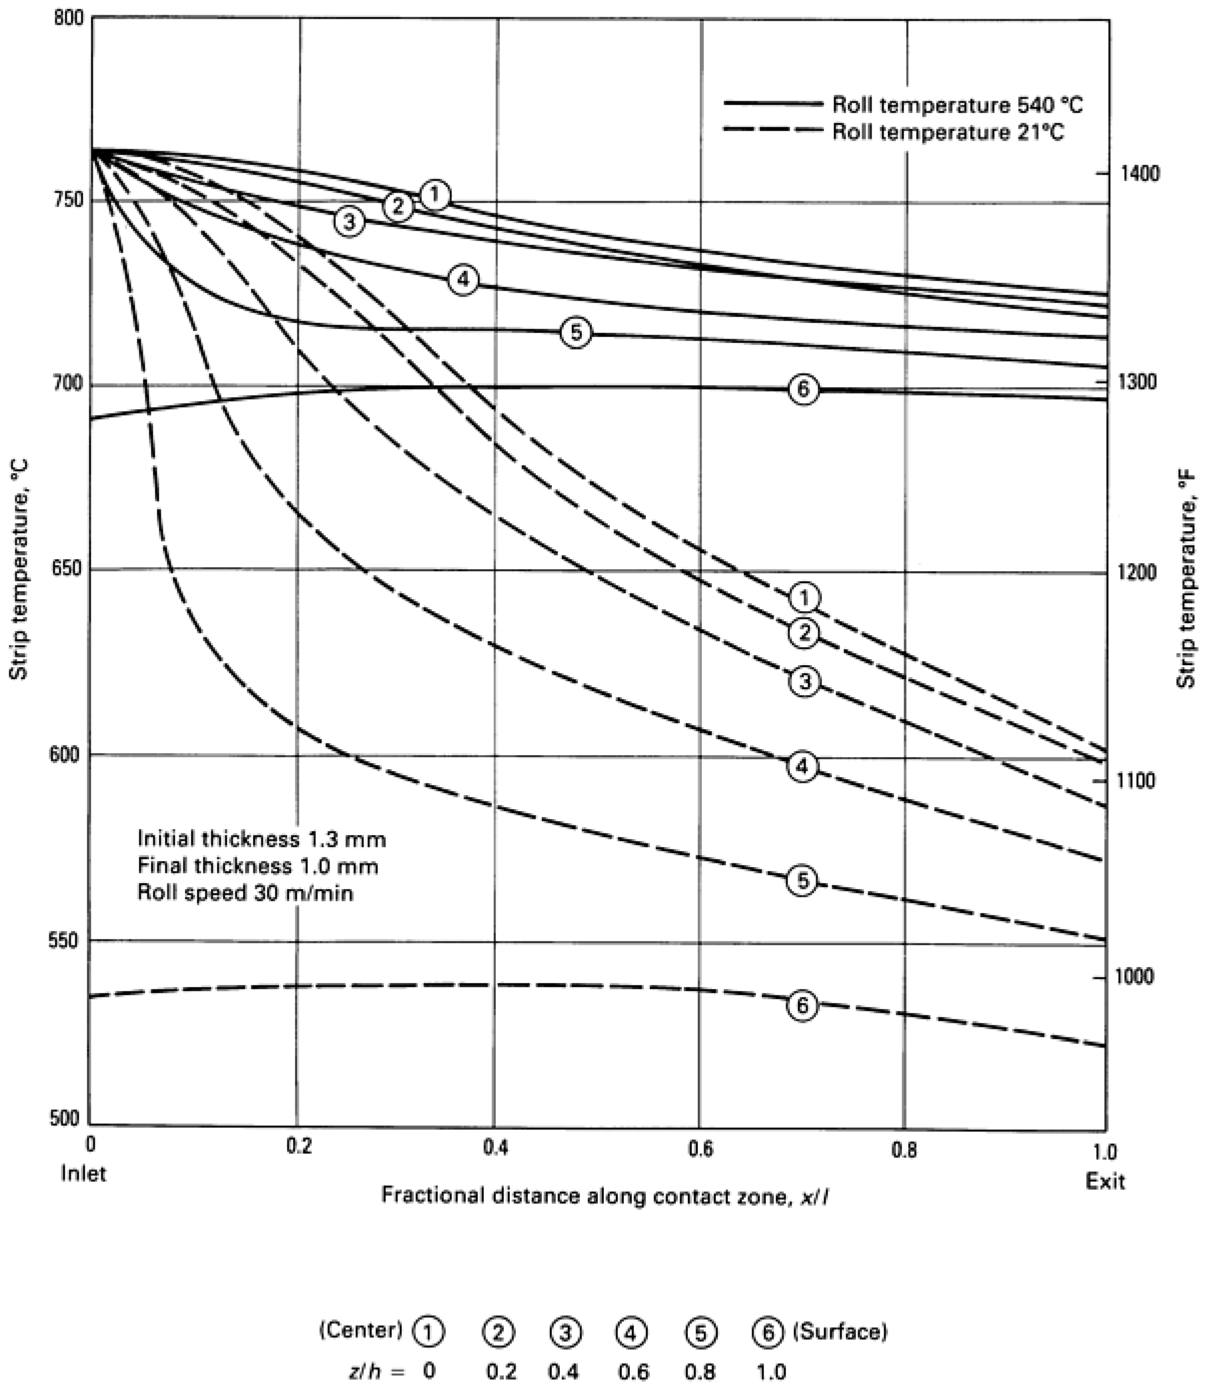

Fig. 28 Predicted temperature profiles for beryllium strip preheated to 760 °C (1400 °F). Source: Ref 48, 50

Experiments at Battelle have also shown that heated-roll rolling lowers roll separating forces and enables larger reductions per pass by eliminating or minimizing chilling effects. This is illustrated by the data on the rolling of Ti-6Al-4V shown in Table 4. For example, an 80% reduction at a strip preheat temperature of 995 °C (1825 °F) required a roll separating force of 28.9 kN (6500 lbf) at a roll temperature of 540 °C (1000 °F). With the rolls at 27 °C (80 °F) and the strip at the same preheat temperature, a 62% reduction required more than twice the roll separating force measured in the first case (Table 4).

Table 4 Rolling loads required for Ti-6Al-4V

Initial sheet thickness was 3.1 mm (0.12 in.); rolling speed was 32 m/min (105 ft/min).

Reduction, %	**Workpiece preheat temperature**		**Roll surface temperature**		Rolling load per inch of sheet width	
	°C	**°F**	**°C**	**°F**	**kN**	lbf
43	650	1200	27	80	95.7	**21,500**
53	840	1550	27	80	66.8	**15,000**
62	995	1825	27	80	75.7	**17,000**
51	650	1200	540	1000	77.9	**17,500**

Source: Ref 49

Like the microstructures obtained in isothermal forging, microstructures in isothermally rolled sheet have been found to be very uniform. Thus, it has been suggested that in some cases one or more post-rolling heat treating steps may be eliminated. This was demonstrated in the processing of 8670 alloy steel strips that were preheated to 840 °C (1550 °F), rolled, quenched upon exit from the mill, and tempered for 2 h at 175 °C (350 °F) (Ref 51). At 840 °C (1550 °F), this steel is totally austenitic. When the rolls were unheated, a coarse martensitic structure at the strip center, microstructural non-uniformity near the surface, and rolling directionality were evident. However, when the rolls were heated to 840 °C (1550 °F) to produce isothermal metalworking conditions, a fine, uniform martensitic microstructure with no directionality was obtained. Therefore, heated-roll rolling of steel sheet and shapes which are to be subsequently hardened may offer the advantage of eliminating the austenitizing and quenching stages.

Heated-Roll Rolling of Shapes

The application of the isothermal and heated-roll rolling concept to shapes also has met with success, although the commercialization of the process, like that for flat rolling, has yet to be fully realized and accepted. One company, in cooperation with Battelle Columbus Division, modified an existing two-high production rolling mill with 250-mm (10-in.) diameter rolls into a heated-roll rolling setup. This setup was used to produce a structural L-shape to close tolerances from Ti-6Al-4V and a high-temperature superalloy (Ref 49). Similar to designs used in Battelle's work, the company used a composite roll design consisting of an AISI A9 tool steel core and a superalloy sleeve. Further, the rolls were heated by banks of quartz-tube radiant heaters which Battelle had also shown to be feasible. With this tooling, 150 m (500 ft)--a production-size quantity, of the structural shape--were successfully rolled for each of the two alloys. Compared to conventional rolling practice, the heated-roll rolling of the superalloy required fewer rolling and other major operations.

A different isothermal rolling concept has been developed and applied for the rolling of structural shapes (channels, Z sections, T sections, I sections, etc.) of various titanium and nickel-base alloys (Ref 52). In this method, molybdenum alloy rolls are heated only locally by an electric current which is passed from one roll to another through the workpiece. Thus, the workpiece can be heated by resistance heating during or just prior to rolling. It may also be preheated to a temperature lower than the actual rolling temperature prior to being fed into the mill. Thus, oxidation and heating times are reduced. In this scheme, local resistance heating aids in producing very thin sections found in many structural parts and allows very large reductions (up to 90%) to be taken in a single pass. However, to obtain large reductions, it is necessary to apply a "feed force," in addition to the "squeeze force" supplied by the rolls.

Flat, Bar, and Shape Rolling

G. D. Lahoti, The Timken Company; S.L. Semiatin, Battelle Columbus Division

Defects In Rolling

A number of defects or undesirable conditions can develop in the rolling of flat, bar, or shaped products. Very broadly, these problems can be attributed to one of four sources: melting and casting practice, metallurgical sources, heating practice, and rolling practice.

Melting and Casting Practice. The major problems associated with melting and casting practice are the development of porosity and a condition known as scabs. Porosity is developed in cast ingots when they solidify and is of two types: pipe and blow holes. Pipe is a concave cavity formed at the top of the ingot due to nonuniform cooling and shrinkage. If not cropped off, pipe can be rolled into the final product to form an internal lamination (Fig. 29). These laminations may not be immediately evident following rolling, but may become apparent during a subsequent forming operation. The occurrence of laminations is most prevalent in flat-rolled sheet products. Blow holes are usually a less serious defect. They are the result of gas bubbles entrapped in the metal as the ingot solidifies. If the surfaces of holes are not oxidized, they may be welded closed during the rolling operation.

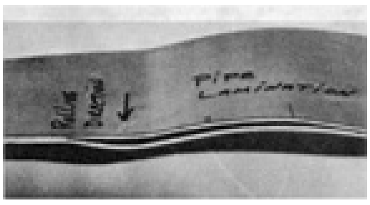

Fig. 29 Laminations in rolled steel sheet resulting from insufficient cropping of the pipe from the top of a

conventionally cast ingot. Courtesy of V. Demski, Teledyne Rodney Metals

Scabs are caused by improper ingot pouring, in which metal is splashed against the side of the mold wall. The splashed material, or scab, tends to stick to the wall and become oxidized. Scabs usually show up only after rolling and, as can be expected, give poor surface finish.

Metallurgical Sources. Defects such as poor surface finish may also result from a metallurgical source, nonmetallic inclusions. In steels, inclusions are of two types, refractory and plastic. Refractory inclusions are often metallic oxides such as alumina in aluminum-killed steels or complex oxides of manganese and iron in rimmed steels. When near the surface, such inclusions give rise to defects known as seams and slivers (Fig. 30).

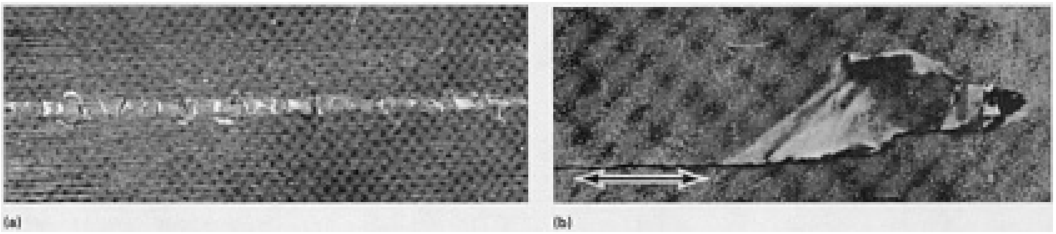

Fig. 30 (a) Seams and (b) slivers caused in rolled material by the presence of surface inclusions. Courtesy of V. Demski, Teledyne Rodney Metals

Plastic inclusions, such as manganese sulfides, elongate in the rolling direction during hot forming. The presence of these elongated inclusions (stringers) produces fibering, which causes directional properties. For example, ductility transverse to the fiber is frequently lower than that parallel to it. In high-strength low-alloy steels, sulfide shape control elements, such as cerium, are often added to prevent the development of such fibering, which is especially undesirable from the viewpoint of subsequent forming operations or service behavior.

Another rolling defect whose source is metallurgical is alligatoring (Fig. 31). This defect, found most frequently in rolled slabs of aluminum-magnesium, zinc, and copper-base alloys, is manifested by a gross midplane fracture at the leading edges of the rolled metal.

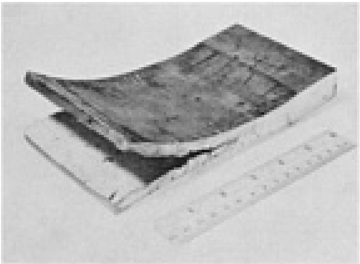

Fig. 31 Alligatoring in a rolled slab. This defect is thought to be caused by nonhomogeneous deformation and nonuniform recrystallization during primary rolling of such metals as zinc alloys, aluminum-magnesium alloys, and copper-base alloys. Courtesy of J. Schey, University of Waterloo

Heating Practice. Two rolling defects that stem from heating practice are rolled-in scale and blisters. The development of scale during preheating of ingots, slabs, or blooms is almost inevitable, particularly for steels. Sometimes descaling operations involving hydraulic sprays or preliminary light rolling passes are not totally successful; scale may get rolled into the metal surface and become elongated into streaks during subsequent rolling. The other defect, blistering, is a raised spot on the surface caused by expansion of subsurface gas during heating. Blisters may break open during rolling and produce a defect that looks like a gouge or surface lamination.

Rolling practice can cause defects also. In bar and shape rolling, for example, excessive reduction in the finishing pass may cause metal to extrude laterally in the roll gap, leading to a defect known as finning. Finning in an intermediate pass causes folds or laps in subsequent passes. Excessive reduction in the leader pass (the pass prior to the finishing pass) also may wrinkle open the sides of a bar, which after turning 90° in the finishing pass can result in a series of hairline cracks. In the rolling of slabs and plates, two defects that affect yield are fishtail and overlaps, both of which need to be trimmed off (Fig. 32). The former results from nonuniform reduction in the width, and the latter results from nonuniform reduction in thickness. These defects can be reduced by proper design of the blooming and rolling sequence. Several defects, such as wavy edges, center buckle, herringbone, and quarter buckle can be created in cold rolling of sheets and strips. These defects are primarily due to localized overrolling, which can occur because of improper roll profiles or variations in the properties or shape of the incoming strip.

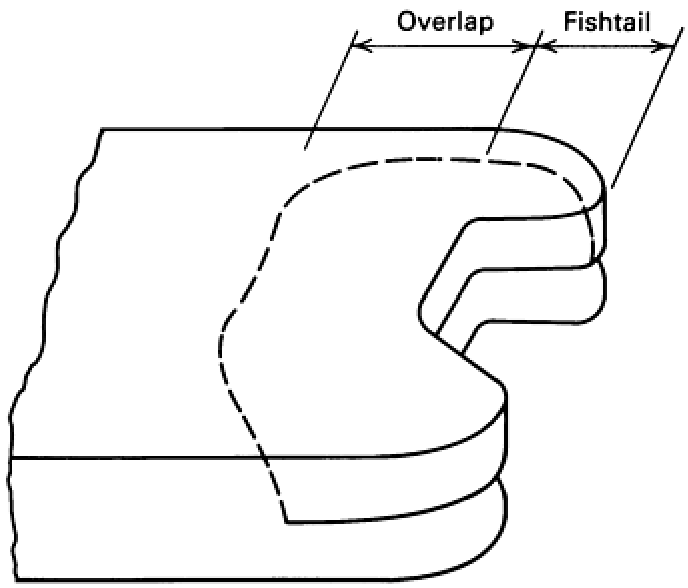

Fig. 32 Overlap and fishtail formed during rolling of slabs and plates. Overlap is the result of nonuniform deformation in thickness, while fishtail is caused by nonuniform deformation in width.

Introduction to Workability

George E. Dieter, University of Maryland

Introduction

WORKABILITY refers to the relative ease with which a metal can be shaped through plastic deformation. The term workability is often used interchangeably with the term formability, which is preferred when referring to the shaping of sheet metal parts (see the Section "Evaluation of Formability for Secondary (Sheet) Forming" in this Volume). However, workability is usually used to refer to the shaping of materials by such bulk deformation processes as forging, extrusion, and rolling.

The characterization of the mechanical behavior of a material by tension testing measures two different types of mechanical properties: strength properties (such as yield strength and ultimate strength) and ductility properties (such as percentage of elongation and reduction in area). Similarly, the evaluation of workability involves both measurement of the resistance to deformation (strength) and determination of the extent of possible plastic deformation before fracture (ductility). Therefore, a complete description of the workability of a material is specified by its flow stress dependence on processing variables (for example, strain, strain rate, preheat temperature, and die temperature), its failure behavior, and the metallurgical transformations that characterize the alloy system to which it belongs.

However, the major emphasis in workability is on measurement and prediction of the limits of deformation before fracture.Therefore, the emphasis in this article is on methods for determining the extent of deformation a metal can withstand before cracking or fracture occurs. It is important, however, to allow for a more general definition in which workability is defined as the degree of deformation that can be achieved in a particular metalworking process without creating an undesirable condition. Generally, the undesirable condition is cracking or fracture, but it may be another condition, such as poor surface finish, buckling, or the formation of laps, which are defects created when metal folds over itself during forging.In addition, in the most general definition of workability, the creation by deformation of a metallurgical structure that results in unsatisfactory mechanical properties, such as poor fracture toughness or fatigue resistance, can be considered to be a limit on workability.

In the restricted context of the forging process, the relative ability of a material to deform without fracture is termed forgeability.Because the ability of the material to flow readily and to fill the die recesses completely is important, this is another aspect of forgeability. This aspect of forgeability is measured by the flow stress of the material. Methods of measuring flow stress are briefly discussed in this article and are treated in more detail in the Section "Computer-Aided Process Design for Bulk Forming".

Generally, workability depends on the local conditions of stress, strain, strain rate, and temperature in combination with material factors, such as the resistance of a metal to ductile fracture. In addition to a review of the many process variables that influence the degree of workability, the mathematical relationships that describe the occurrence of room-temperature ductile fracture under workability conditions are summarized in this article. The most common testing techniques for workability prediction are discussed in the article "Workability Tests" in this Section.

Introduction to Workability

George E. Dieter, University of Maryland

Material Factors Affecting Workability

Fracture Mechanisms. Fracture in bulk deformation processing usually occurs as ductile fracture, rarely as brittle fracture.However, depending on temperature and strain rate, the details of the ductile fracture mechanism will vary. Figure 1 illustrates the different modes of ductile fracture obtained in a tension test over a wide range of strain rates and temperatures. At temperatures below about one-half the melting point of a given material (below the hot-working region), a typical dimpled rupture type of ductile fracture usually occurs. A more commonly found representation of possible fracture mechanisms is the fracture mechanism (Ashby) map (Fig. 2). Such a map shows the area of dominance of each fracture mechanism. The maps are constructed chiefly by using the best mechanistic models of each fracture process.

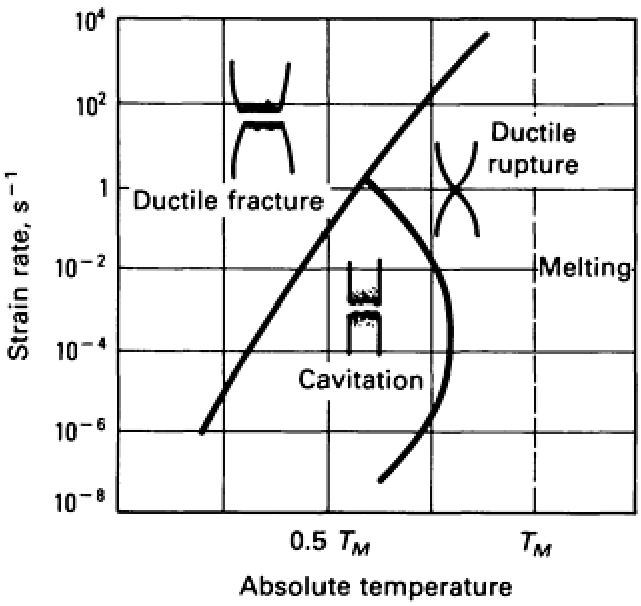

Fig. 1 Tensile fracture modes as a function of temperature (measured on the absolute temperature scale) and strain rate.

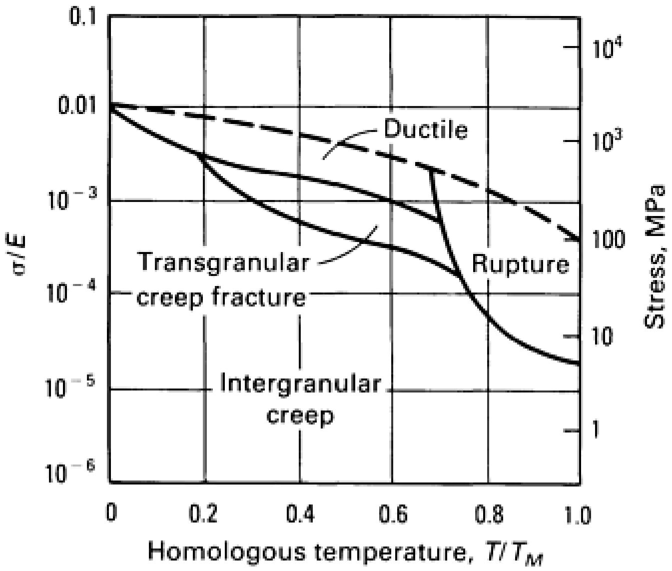

Fig. 2 Fracture mechanism map for nickel.

The three stages of ductile fracture are shown schematically in Fig. 3. The first stage is void initiation, which usually occurs at second-phase particles or inclusions.Voids are initiated because particles do not deform, and this forces the ductile matrix around the particle to deform more than normal. This in turn produces more strain hardening, thus creating a higher stress in the matrix near the particles. When the stress becomes sufficiently large, the interface may separate, or the particle may crack. As a result, ductility is strongly dependent on the size and density of the second-phase particles, as shown in Fig. 4.

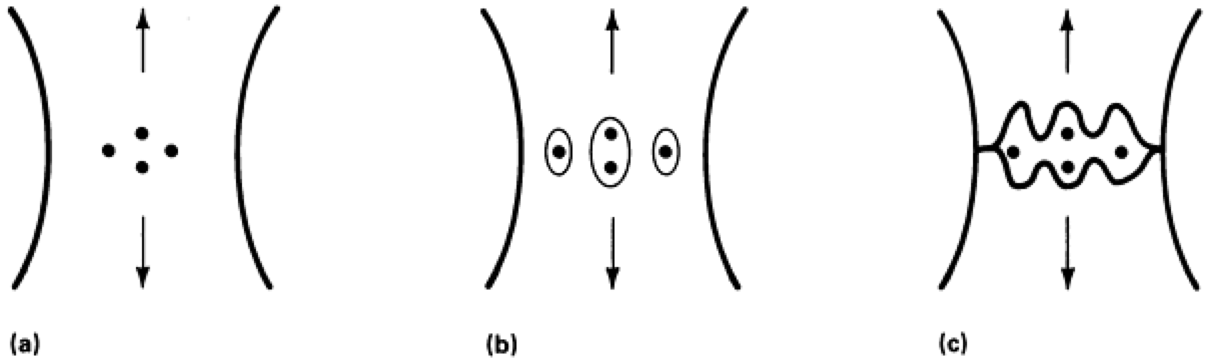

Fig. 3 Stages in the dimple rupture mode of ductile fracture. (a) Void initiation. (b) Void growth. (c) Void linking.

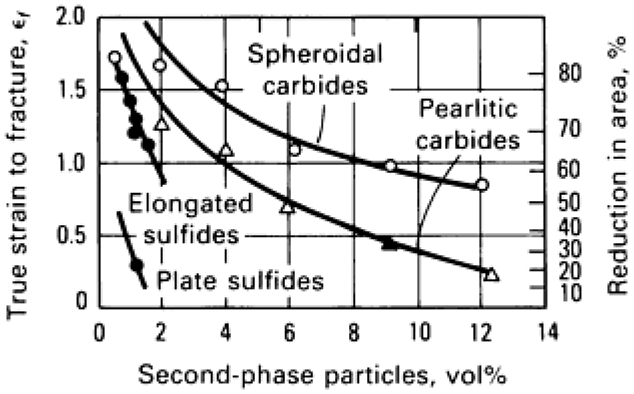

Fig. 4 Effect of volume fraction of second-phase particles on the tensile ductility of steel. Source: Ref 1.

The second stage of ductile fracture is void growth, which is a strain-controlled process. Voids elongate as they grow, and the ligaments of matrix material between the voids become thin. Therefore, the final stage of ductile fracture is hole coalescence through the separation of the ligaments, which links the growing voids.

Ductile fracture by void growth and coalescence can occur by two modes. Fibrous tearing (Mode I) occurs by void growth in the crack plane that is essentially normal to the tensile axis. In Mode II void growth, voids grow in sheets at an oblique angle to the crack plane under the influence of shear strains. This type of shear band tearing is found on the surface of the cone in a ductile cup-and-cone tensile fracture. It commonly occurs in deformation processing, in which friction and/or geometric conditions produce inhomogeneous deformation, leading to local shear bands. Localization of deformation in these shear bands leads to adiabatic temperature increases that produce local softening.

Increasing the temperature of deformation leads to significant changes in deformation behavior and fracture mode. At temperatures above one-half the melting point, particularly at low strain rates, grain-boundary sliding becomes prominent. This leads to wedge-shaped cracks that propagate along grain boundaries and result in low ductility (Fig. 5).

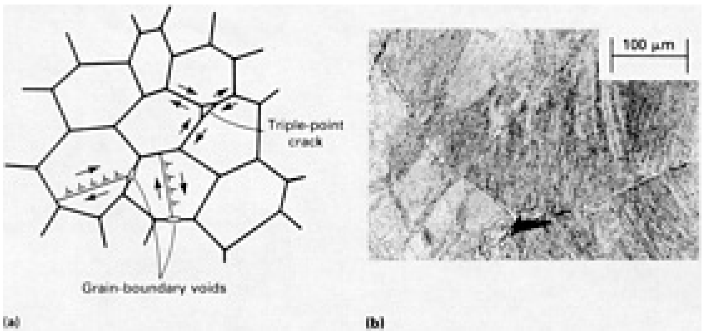

Fig. 5 Formation of grain-boundary voids (cavitation) and triple-point cracks at warm- and hot-working temperatures. (a) Schematic showing how grain-boundary voids are formed under the action of matrix deformation and how grain-boundary sliding in the absence of grain-boundary migration and recrystallization may cause cracks to open at triple points. (b) Examples of grain-boundary voids and triple-point cracking at the prior β grain boundaries in hot-forged Ti-6Al-2Sn-4Zr-2Mo-0.1Si with a Widmanstätten α starting microstructure. Source: Ref 2, 3.

The probability of wedge cracking varies with the applied strain rate. If the strain rate is so high that the matrix deforms at a faster rate than the boundaries can slide, then grain-boundary sliding effects will be negligible, and wedge cracking will not occur. If the strain rate is very low, sufficient time is available to relax the high stresses at the triple points, and a different fracture mechanism comes into play.

Round or elliptical cavities form in grain boundaries at high temperatures, but form at lower stresses than those that produce wedge-shaped cracks. Nevertheless, like wedge cracks, these cavities are formed by grain-boundary shearing. With low strain rates (<1 s^{-1}), the initiation of voids by grain-boundary sliding and the reduced rate of dynamic recrystallization can result in extensive internal void formation, or cavitation. Cavitation is germane with respect to ductility in creep, but it is generally not a factor in fracture in hot working.

For high-temperature fracture initiated by grain-boundary sliding, the processes of void growth and coalescence, rather than void initiation, are the primary factors that control ductility. When voids initiated at the original grain boundaries have difficulty in linking because boundary migration is high as a result of dynamic recrystallization, hot ductility is high. In extreme cases, this can lead to highly ductile rupture, as shown in Fig. 1.

Compressive stresses superimposed on tensile or shear stresses by the deformation process can have a significant influence on closing small cavities or limiting their growth and thus enhancing workability. Because of this important role of the stress state, it is not possible to express workability in absolute terms. Workability depends not only on material characteristics but also on process variables, such as strain, strain rate, temperature, and stress state.

A processing map can be developed considering all of the failure mechanisms that can operate in a material over a range of strain rates and temperatures. The processing map is a useful concept that should gain wider acceptance in the study of material response in deformation processing.

Figure 6 illustrates a processing map for aluminum that is based on theoretical models; however, it agrees well with experimental work. A safe region is indicated in which the material should be free from cavitation damage or flow localization. The processing map predicts that, at constant temperature, there should be a maximum in ductility with respect to strain rate. For example, at 500 K (227 °C, or 440 °F), ductility should be at a maximum at a strain rate of 10^{-3} to 1 s^{-1}. Below the lower value, wedge cracking will occur; above this level, ductile fracture would reduce ductility.

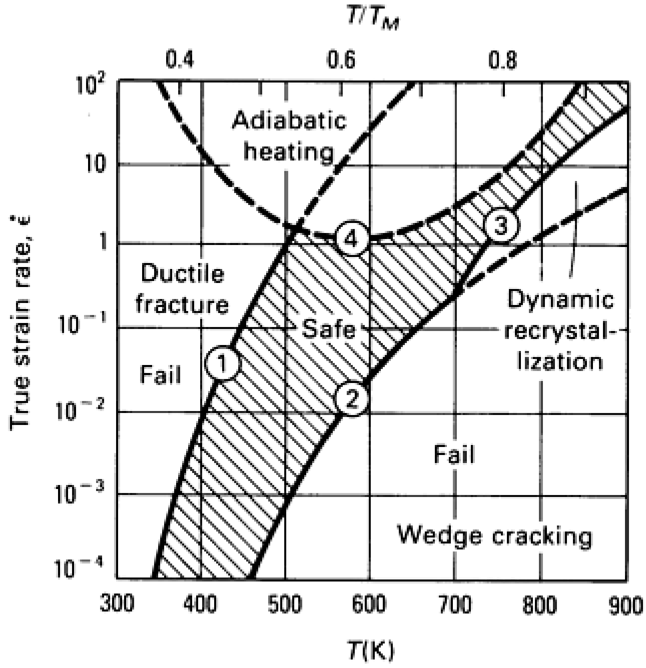

Fig. 6 Composite processing map for aluminum showing the safe region for forming. Boundaries shift with microstructure. Instabilities due to purely continuum effects, such as shear localization in sheet metal forming, are not considered. Source: Ref 4.

The safe region shown in Fig. 6 is sensitive to the microstructure of the metal. Decreasing the size and volume fraction of hard particles would move boundary 1 to the left. Increasing the size or fraction of hard particles in the grain boundary would make sliding more difficult and would move boundary 2 to the right. More detailed information on fracture mechanisms can be found in the article "Modes of Fracture" in *Fractography*, Volume 12 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

Flow Localization. Workability problems can arise when metal deformation is localized to a narrow zone. This results in a region of different structures and properties that can be the site of failure in service. Localization of deformation can also be so severe that it leads to failure in the deformation process. In either mode, the presence of flow localization needs to be recognized.

Flow localization is commonly caused by the formation of a dead-metal zone between the workpiece and the tooling. This can arise from poor lubrication at the workpiece/tool interface. Figure 7 illustrates the upsetting of a cylinder with poorly lubricated platens. When the workpiece is constrained from sliding at the interface, it barrels, and the friction-hill pressure distribution is created over the interface. The inhomogeneity of deformation throughout the cross section leads to a dead zone at the tool interface and a region of intense shear deformation.

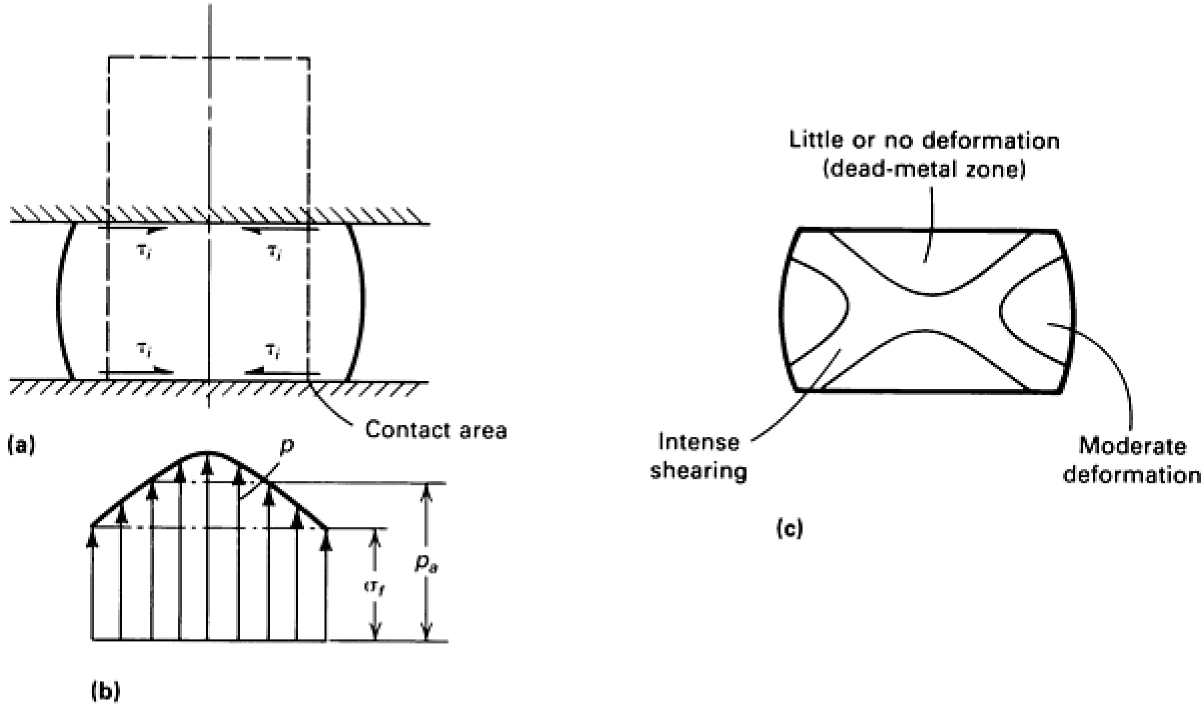

Fig. 7 Consequences of friction illustrated in the upsetting of a cylinder. (a) Direction of shear stresses. (b) Consequent rise in interface pressure. (c) Inhomogeneity of deformation. τ_i, average frictional shear stress; *p*, normal pressure; σ_f, flow stress; p_a, average die pressure.

A similar situation can arise when the processing tools are cooler than the workpiece; in this case, heat is extracted at the tools. Consequently, the flow stress of the metal near the interface is higher because of the lower temperature.

However, flow localization may occur during hot working in the absence of frictional or chilling effects. In this case, localization results from flow softening (negative strain hardening). Flow softening arises during hot working as a result of structural instabilities, such as adiabatic heating, generation of a softer texture during deformation, grain coarsening, or spheroidization. Flow softening has been correlated with materials properties (Ref 5) by the parameter:

$$\alpha = -\frac{(\gamma - 1)}{m} \quad \textbf{(Eq 1)}$$

for upset compression and

$$\alpha = -\frac{\gamma}{m} \quad \textbf{(Eq 2)}$$

for plane-strain compression where $\gamma = (1/\sigma)d\sigma/d\varepsilon$ is the normalized flow-softening rate, and $m = d \log \sigma / d \log \dot{\epsilon}$ is the strain rate sensitivity. In $\alpha + \beta$ titanium alloys and other materials that exhibit a strong tendency toward flow localization, this phenomenon is likely to occur when the parameter α is greater than 5. Figure 8 shows a crack that initiated in a shear band during the high-energy-rate forging of a complex austenitic stainless steel.

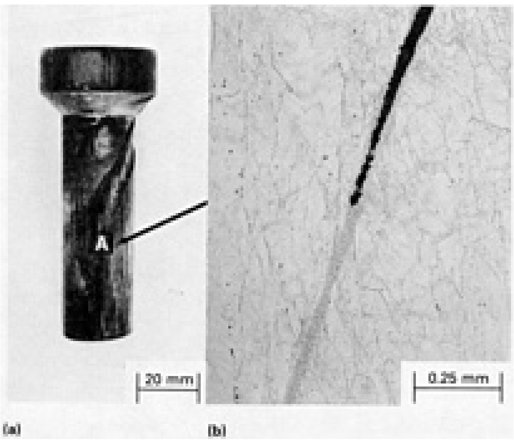

Fig. 8 Austenitic stainless steel high-energy-rate-forged extrusion. Forging temperature: 815 °C (1500 °F); 65% reduction in area; $\dot{\epsilon}$ = 1.4 × 10^3 s^{-1}. (a) View of extrusion showing spiral cracks. (b) Optical micrograph showing the microstructure at the tip of one of the cracks in the extrusion (area A). Note that the crack initiated in a macroscopic shear band that formed first at the lead end of the extrusion. Etchant: Oxalic acid. Source: Ref 6.

Metallurgical Considerations. The common failure modes occurring in deformation processing are summarized in Table 1. Three temperature regions are common: cold working, warm working, and hot working. Two types of ductile fracture are distinguished in cold working, depending on the stress state. Free surface fracture occurs at a free surface when there is no stress normal to the surface, while centerburst-type failure occurs at the center of the bar or forging because of high hydrostatic tension.

Table 1 Common failure modes in deformation processing

Temperature regime	Metallurgical defects in:	
	Cast grain structure	Wrought (recrystallized) grain structure
Cold working	(a)	Free surface fracture, dead metal zones (shear bands, shear cracks), centerbursts, galling
Warm working	(b)	Triple-point cracks/fractures, grain-boundary cavitation/fracture
Hot working	Hot shortness, centerbursts, triple-point cracks/fractures,	Shear bands/fractures, triple-point cracks/fractures,

(a) Cold working of cast structures is typically performed only for very ductile metals (such as dental alloys) and usually involves many stages of working with intermediate recrystallization anneals.

(b) Warm working of cast structures is rare.

Workability problems depend greatly on grain size and grain structure. When the grain size is large relative to the overall size of the workpiece, as in conventionally cast ingot structures, workability is lower, because cracks may initiate and propagate easily along the grain boundaries. Moreover, with cast structures, impurities are frequently segregated to the center and top or to the surface of the ingot, creating regions of low workability. Because chemical elements are not distributed uniformly on either a micro- or a macroscopic scale, the temperature range over which an ingot structure can be worked is rather limited.

Typically, cast structures must be hot worked. The melting point of an alloy in the as-cast condition is usually lower than that of the same alloy in the fine-grain, recrystallized condition because of chemical inhomogeneities and the presence of low melting point compounds that frequently occur at grain boundaries. Deformation at temperatures too close to the melting point of these compounds may lead to grain-boundary cracking when the heat developed by deformation increases the workpiece temperature and produces local melting.

This fracture mode is called hot shortness. This type of fracture can be prevented by using a sufficiently low deformation rate that allows the heat developed by deformation to be dissipated by the tooling, by using lower working temperatures, or by subjecting the workpiece to a homogenization heat treatment prior to hot working. The relationship between the workability of cast and wrought structures and temperatures is shown in Fig. 9.

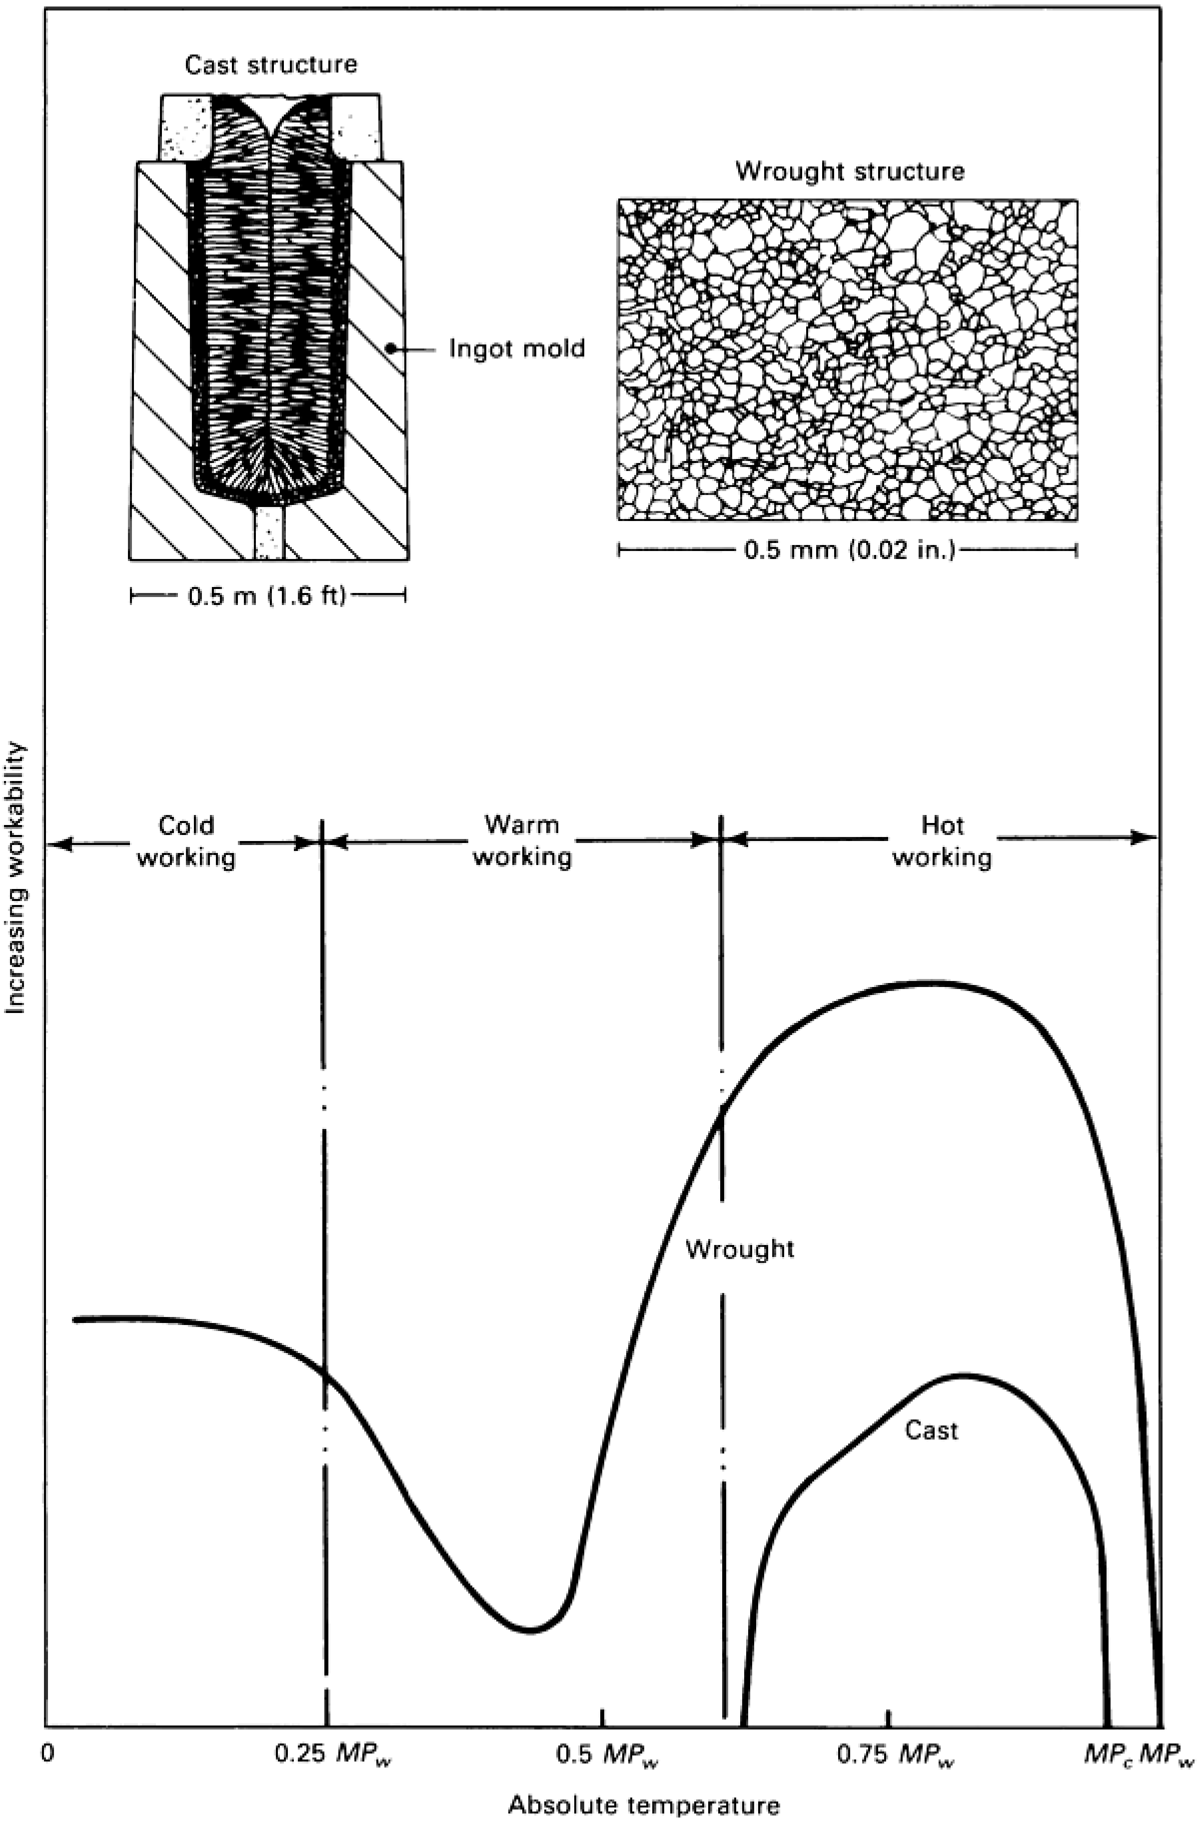

Fig. 9 Relative workabilities of cast metals and wrought recrystallized metals at cold-, warm-, and hot-working temperatures. The melting point (or solidus temperature) is denoted as MP_c (cast metals) or MP_w (wrought and

recrystallized metals).

The intermediate temperature region of low ductility shown in Fig. 9 is found in many metallurgical systems (Ref 7). This occurs at a temperature that is sufficiently high for grain-boundary sliding to initiate grain-boundary cracking, but not so high that the cracks are sealed off from propagation by a dynamic recrystallization process.

The relationship between workability and temperature for various metallurgical systems is summarized in Fig. 10. Generally, pure metals and single-phase alloys exhibit the best workability, except when grain growth occurs at high temperatures. Alloys that contain low melting point phases (such as γ'-strengthened nickel-base superalloys) tend to be difficult to deform and have a limited range of working temperature. In general, as the solute content of the alloy increases, the possibility of forming low melting point phases increases, while the temperature for precipitation of second phases increases. The net result is a decreased region for good forgeability (Fig. 11).

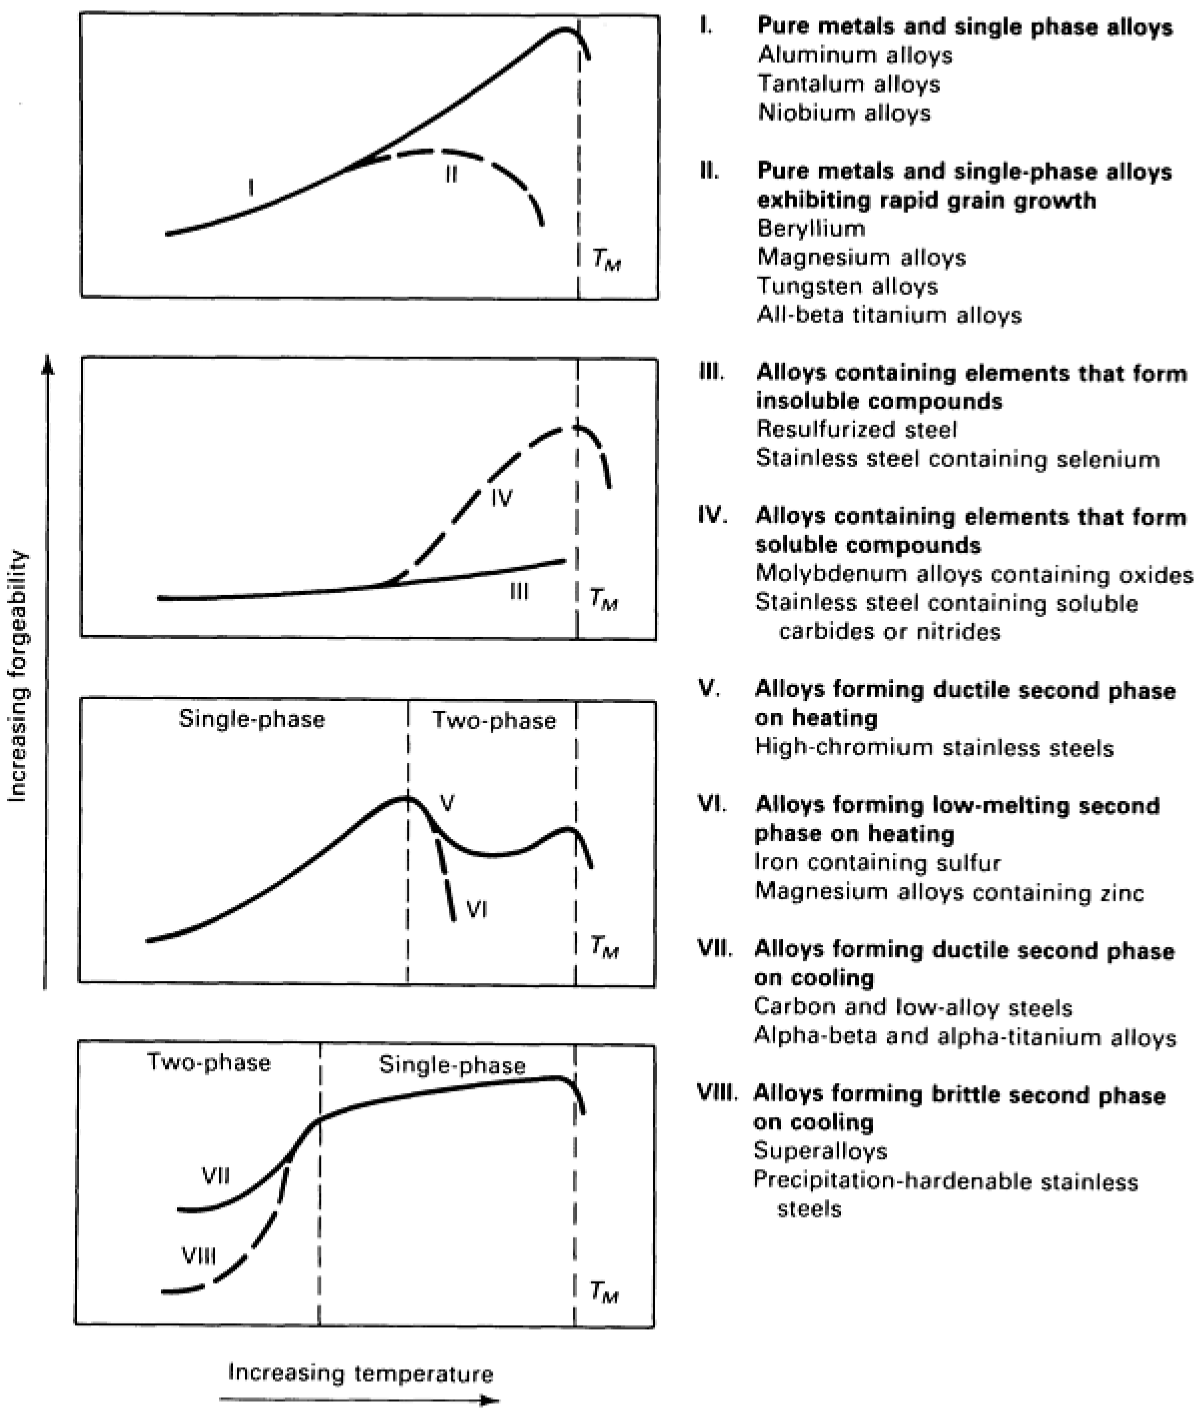

Fig. 10 Typical workability behavior exhibited by different alloy systems. T_M: absolute melting temperature. Source: Ref 8.

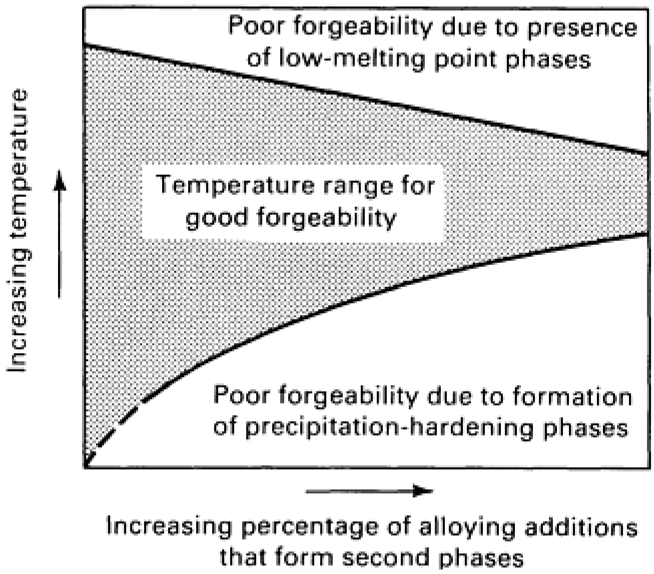

Fig. 11 Influence of solute content on melting and solution temperatures and therefore on forgeability.

During the breakdown of cast ingots and the subsequent working by forging nonuniformities in alloy chemistry, second-phase particles, inclusions, and the crystalline grains themselves are aligned in the direction of greatest metal flow. This directional pattern of crystals and second-phase particles is known as the grain flow pattern. This pattern is responsible for the familiar fiber structure of forgings (Fig. 12). It also produces directional variation in such properties as strength, ductility, fracture toughness, and resistance to fatigue. This anisotropy in properties is greatest between the working (longitudinal) direction and the transverse direction (Fig. 13). In a properly designed forging, the largest stress should be in the direction of the forging fiber, and the parting line of the dies should be located so as to minimize disruption to the grain flow lines.

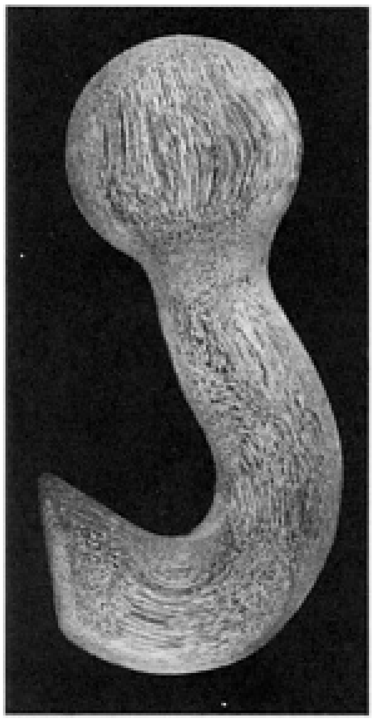

Fig. 12 Flow lines in a forged 4140 steel hook. Specimen was etched using 50% HCl. 0.5×.

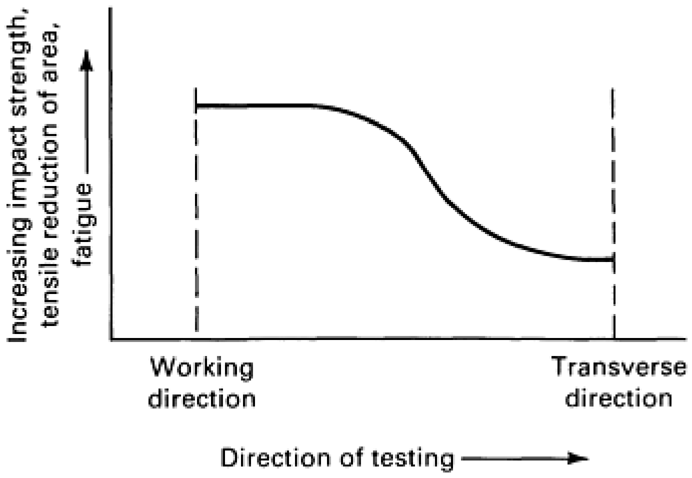

Fig. 13 Anisotropy in wrought alloys.

In closed-die forging, an important consideration is for the metal to flow during forging to fill the cavities of the impression die. The forgeability of the metal is a way of expressing this capability. Poor forgeability can be caused by rupture before the die is filled or by a high flow strength, which causes the metal to flow past recesses without filling them or causes underfilling with the maximum loads available. A shop floor evaluation of forgeability is provided in Table 2. Different alloys were hammer forged into a connecting rod for an automobile engine in a set of dies ordinarily used for 1030 steel rods. The forgeability of the materials is indicated by the number of blows needed to complete the forging and the remarks about die filling.

Table 2 Forging data on connecting rods forged from eight different materials representing increasing forging difficulty

Material	**Forging temperature**		**Number of times heated**	**Total number of blows to complete forging**	Remarks
	°C	**°F**			
1030 steel	1260	2300	1	<20	**Completely filled**
Type 304 stainless steel	1200	2200	1	40	**Completely filled**
Type 347 stainless steel	1200	2200	1	50	**Completely filled**
Monel	1120	2050	2	51	**Completely filled**
16-25-6	1100	2000	5	76	**Incomplete fill on shaft end**
N-155	1100	2000	5	89	**Incomplete fill on both ends and ribs**

Alloy B (UNS N10001)	1200	2200	3	. . .	**Extreme difficulty in drawing and fullering shape; experiment discontinued**
Alloy C (UNS N10002)	**1180**	**2150**	**4**	**. . .**	**Same as for Alloy B**

Introduction to Workability

George E. Dieter, University of Maryland

Process Variables Controlling Workability

Strain. The principal objective in plastic deformation processes is to change the shape of the deformed product. A secondary objective is to improve or control the properties of the deformed product. In dense metals, unlike porous powder compacts, the volume of the workpiece remains constant as it increases in cross-sectional area, *A*, and decreases in length, *L*:

$$A_0L_0 = A_1L_1 \qquad \textbf{(Eq 3)}$$

The strain produced in a deformation process is described by the engineering strain:

$$e = \frac{L_1 - L_0}{L_0} = \frac{A_0 - A_1}{A_1} \qquad \textbf{(Eq 4)}$$

or alternatively by the true strain:

$$\epsilon = \ln \frac{L_1}{L_0} = \ln \frac{A_0}{A_1} = \ln (e + 1) \quad \textbf{(Eq 5)}$$

Deformation in metalworking is often expressed by the cross-sectional area reduction, *R*:

$$R = \frac{A_0 - A_1}{A_0} \quad \textbf{(Eq 6)}$$

but from constancy of volume (Eq 3), $A_0L_0 = A_1L_1$, and:

$$\epsilon = \ln \frac{L_1}{L_0} = \ln \frac{A_0}{A_1} = \ln \frac{1}{1 - R} \quad \textbf{(Eq 7)}$$

The relationship between area reduction and the various measures of strain is given in Table 3.

Table 3 Relationships among area reduction (*R*), engineering strain (*e*), and true strain (ϵ)

	Area reduction (*R*), %											
	5	**10**	**15**	**20**	**25**	**30**	**40**	**50**	**60**	**70**	**80**	90
e	0.052	0.111	0.176	0.250	0.333	0.428	0.667	1.000	1.500	2.333	4.000	**9.000**
ε	**0.051**	**0.105**	**0.162**	**0.223**	**0.287**	**0.356**	**0.511**	**0.693**	**0.916**	**1.204**	**1.609**	**2.303**

Strain rate is the time rate of change of strain, that is, the rate at which deformation proceeds. It can be an important variable in workability experiments and may be difficult to control. The true strain rate for a cylinder of height *h* upset in compression at a deformation velocity *v* at time *t* is:

$$\dot{\epsilon} = \frac{d\epsilon}{dt} = \frac{1}{h}\frac{dh}{dt} = \frac{v}{h} \quad \textbf{(Eq 8)}$$

Temperature. Metalworking processes are commonly classified as hot-working or cold-working operations. Hot working refers to deformation under conditions of temperature and deformation velocity such that recovery processes occur simultaneously with deformation. Cold working refers to deformation carried out under conditions for which recovery processes are not effective during the process. In most hot working, the strain hardening and the distorted grain structure produced by deformation are eliminated rapidly by the formation of new strain-free grains as a result of recrystallization during or immediately after deformation.

Very large deformations are possible in hot working, because the recovery processes keep pace with the deformation. Hot working occurs at essentially constant flow stress. Flow stress decreases with the increasing temperature of deformation. In cold working, strain hardening is not relieved, and the flow stress increases continuously with deformation. Therefore, the total deformation possible before fracture is less for cold working than for hot working, unless the effects of strain hardening are relieved by annealing.

About 95% of the mechanical work expended in deformation is converted into heat. Some of this heat is conducted away by the tools or lost to the environment. However, a portion remains to increase the temperature of the workpiece. The faster the deformation process, the greater the percentage of heat energy that goes to increase the temperature of the workpiece.

Friction. An important concern in all practical metalworking processes is the friction between the deforming workpiece and the tools and/or dies that apply the force and constrain the shape change. Friction occurs because metal surfaces, at least on a microscale, are never perfectly smooth and flat. Relative motion between such surfaces is impeded by contact under pressure.

The existence of friction increases the value of the deformation force and makes deformation more inhomogenous (Fig. 7c), which in turn increases the propensity for fracture. If friction is high, seizing and galling of the workpiece surfaces occur, and surface damage results.

The mechanics of friction at the tool/workpiece interface are very complex; therefore, simplifying assumptions are usually used. One such assumption is that friction can be described by Coulomb's law of friction:

$$\mu = \frac{\tau_i}{p} \qquad \textbf{(Eq 9)}$$

where μ is the Coulomb coefficient of friction, τ_i is the shear stress at the interface, and p is the stress (pressure) normal to the interface.

Another simplification of friction is to assume that the shear stress at the interface is directly proportional to the flow stress σ_0 of the material:

$$\tau_i = m \frac{\sigma_0}{\sqrt{3}} \qquad \textbf{(Eq 10)}$$

where m, the constant of proportionality, is the interface friction factor. For given conditions of lubrication and temperature and for given die and workpiece materials, m is usually considered to have a constant value independent of the pressure at the interface. Values of m vary from 0 (perfect sliding) to 1 (no sliding). In the Coulomb model of friction, τ_i increases with p up to a limit at which interface shear stress equals the yield stress of the workpiece material.

Control of friction through lubrication is an important aspect of metalworking. High friction leads to various defects that limit workability. However, for most workability tests, conditions are selected under which friction is either absent or easily controlled. Most workability tests make no provision for reproducing the frictional conditions that exist in the production process; consequently, serious problems can result in the correlation of test results with actual production conditions.

Stress State. Because of the different geometries of the tools and workpiece and the different manners in which the forces of deformation are applied, different metalworking processes produce different stress states. A common system of classifying the stress state found in metalworking processes is:

Tensile-compressive systems

- Biaxial tension-uniaxial compression, such as under the roll of a two-roll rotary piercer
- Uniaxial tension-uniaxial compression, such as in the flange of a cup in deep drawing
- Uniaxial tension-biaxial compression, such as in the deformation zone in wire and rod drawing

Compressive stress systems

- Uniaxial stress, such as in forging and upsetting in closed dies
- Biaxial stress, such as between the rolls of a rolling mill when operating without front or back tension
- Triaxial stress, such as in extrusion and in certain parts of a forging deformed in a die

Tensile stress systems

- Biaxial stress, such as stretch forming

Two states that occur frequently in structural or metalworking applications--plane stress and plane strain--deserve special mention. The use of the adjective plane implies that the condition is confined to a two-dimensional situation. Plane stress occurs when the stress state lies in the plane of the member. This typically occurs when one dimension of the member is very small compared to the other two, and the member is loaded by a force lying in the plane of symmetry of the body. Examples are thin, plate-type structures, such as thin-wall pressure vessels.

Plane strain occurs when the strain in one of the three principal directions is zero (for example, $e_3 = 0$), as in an extremely long member subjected to lateral loading or a thick plate with a notch loaded in tension. A common plane-strain condition in metalworking is the rolling of a wide sheet. In this case, there is no strain in the width direction. Although $e_3 = 0$ for plane strain, there is a stress acting in that direction. For plastic deformation, the stress in the principal direction for which strain is zero is the average of the other two principal stresses, that is, $\sigma_3 = (\sigma_1 + \sigma_2)/2$.

Stress systems in metalworking are usually complex. To describe a complex stress system rather briefly, it is necessary to calculate an effective stress, σ:

$$\bar{\sigma} = \frac{1}{\sqrt{2}}[(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2]^{1/2} \qquad \textbf{(Eq 11)}$$

where $\sigma_1 > \sigma_2 > \sigma_3$ are the three principal stresses. Tensile stresses are positive, and compressive stresses are negative. Another important stress term is the mean or hydrostatic component of stress, σ_m:

$$\sigma_m = \frac{1}{3}(\sigma_1 + \sigma_2 + \sigma_3) \qquad \textbf{(Eq 12)}$$

In general, the greater the level of tensile stress, the more severe the stress system is with regard to workability. For a given material, temperature, and strain rate of deformation, the workability is much improved if the stress state is highly compressive. A general workability parameter has been proposed that allows for the stress state (Ref 9):

$$\beta = \frac{3\sigma_m}{\bar{\sigma}} \qquad \textbf{(Eq 13)}$$

where σ_m is the hydrostatic stress component, and $\bar{\sigma}$ is the effective stress. Figure 14 shows the β parameter plotted for various mechanical tests and metalworking processes. The curve is evaluated by three basic tests: tension, torsion, and compression. Table 4 gives the pertinent values for each test. Figure 14 shows that workability is enhanced when β is predominately compressive.

Table 4 Evaluation of β parameter

Test	**Principal stresses**	**Effective stress**	**Mean stress**	**β**	Strain-to-fracture measurement
Tension	σ_1; $\sigma_2 = \sigma_3 = 0$	σ_1	$\frac{\sigma_1}{3}$	1.0	$\epsilon_f = \ln \frac{A_0}{A_n}$ at necking
Torsion	$\sigma_1 = -\sigma_2$; $\sigma_3 = 0$	$\sqrt{3}\sigma_1$	0	0	$\epsilon_f = \frac{r\theta}{\sqrt{3}L}$

Compression	**$-\sigma_1$; $\sigma_2 = \sigma_3 = 0$**	**$-\sigma_1$**	$-\frac{\sigma_1}{3}$	**-1.0**	$\epsilon_f = \ln \frac{A_f}{A_0}$

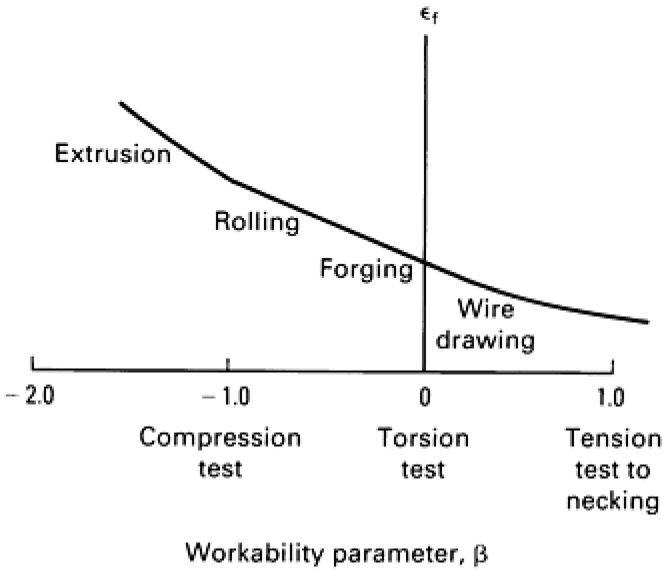

Fig. 14 Influence of stress state on strain to fracture.

Yielding Criteria. The ease with which a metal yields plastically or flows is an important factor in workability. If a metal can be deformed at low stress, as in superplastic deformation, then the stress levels throughout the deforming workpiece are low, and fracture is less likely. The dominant metallurgical conditions and temperature are important variables, as is the stress state. Plastic flow is produced by slip within the individual grains, and slip is induced by a high resolved shear stress. Therefore, the beginning of plastic flow can be predicted by a maximum shear stress, or Tresca, criterion:

$$\tau_{max} = \frac{1}{2}(\sigma_1 - \sigma_3) = \frac{\sigma_0}{2} \quad \textbf{(Eq 14)}$$

where τ_{max} is the maximum shear stress and σ_0 is the yield (flow) stress measured in either a uniaxial tension or uniaxial compression test. Although adequate, this yield criterion neglects the intermediate principal stress σ_2. A more complete and generally applicable yielding criterion is that proposed by von Mises:

$$2\sigma_0^2 = (\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2 \quad \textbf{(Eq 15)}$$

where $\sigma_1 > \sigma_2 > \sigma_3$ are the three principal stresses, and σ_0 is the uniaxial flow stress of the material. This is the same equation given earlier for effective stress.

The significance of yield criteria is best illustrated by examining a simplified stress state, in which $\sigma_3 = 0$ (plane stress). The Tresca yield criterion then defines a hexagon, and the von Mises criterion an ellipse (Fig. 15).

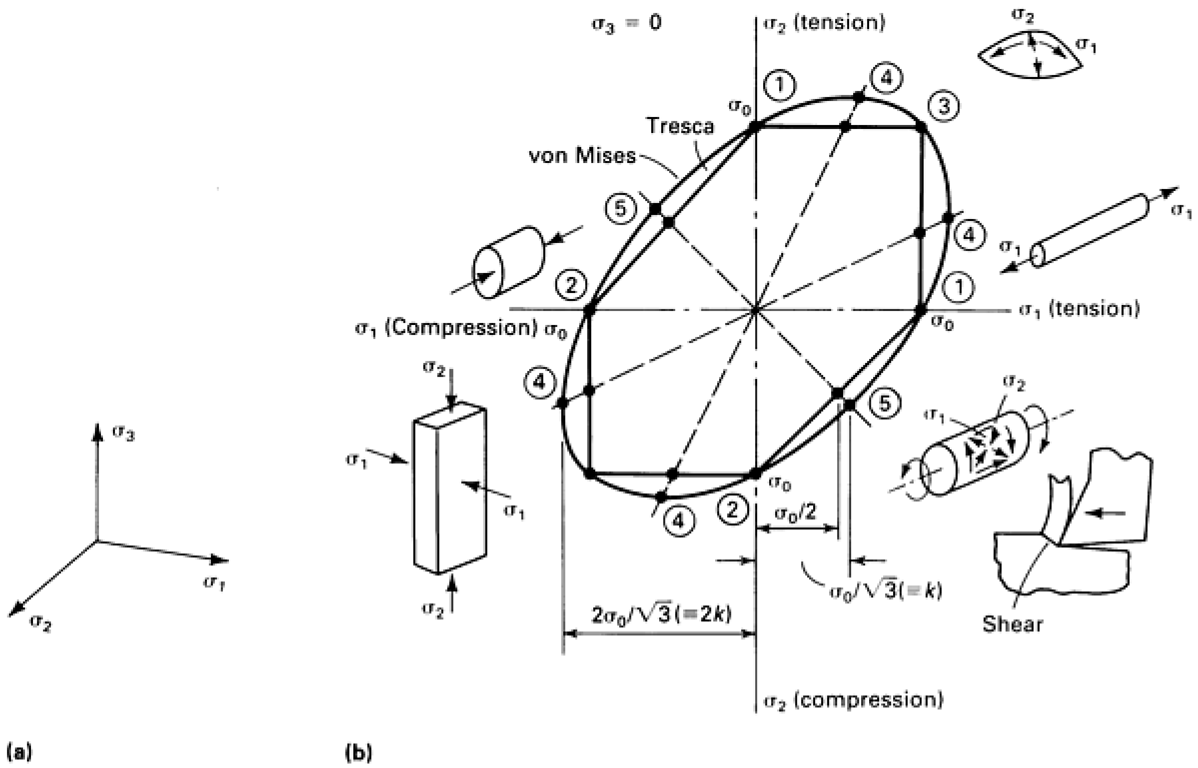

Fig. 15 Directions of principal stresses (a) and yield criteria (b) with some typical stress states.

Yielding (plastic flow) can be initiated in several modes. In pure tension, flow occurs at the flow stress σ_0 (points 1 in Fig. 15 corresponding to two directions in the plane of a sheet). In pure compression, the material yields at the compressive flow stress, which, in ductile materials, is usually equal to the tensile flow stress σ_0 (points 2, Fig. 15). When a sheet is bulged by a punch or a pressurized medium, the two principal stresses in the surface of the sheet are equal (balanced biaxial tension) and must reach σ_0 (point 3, Fig. 15).

A technically important condition is reached when deformation of the workpiece is prevented in one of the principal directions (plane strain). This occurs because a die element keeps one dimension constant; or only one part of the workpiece is deformed, and adjacent nondeforming portions exert a restraining influence. In either case, the restraint creates a stress in that principal direction; the stress is the average of the two other principal stresses (corresponding to points 4, Fig. 15). The stress required for deformation is still σ_0 according to Tresca, but is $1.15\sigma_0$ according to von Mises. The latter is usually regarded as the plane-strain flow stress of the materials. It is sometimes called the constrained flow stress.

Another important stress state is pure shear, in which the two principal stresses are of equal magnitude but of the opposite sign (points 5, Fig. 15). Flow now occurs at the shear flow stress τ_0, which is equal to $0.5\sigma_0$ according to Tresca and $0.577\sigma_0$ according to von Mises. The shear flow stress according to von Mises is often denoted as *k.* Figure 15 illustrates how the stress required to produce plastic deformation varies significantly with the stress state and how it can be related to the basic uniaxial flow stress of the material through a yield criterion.

Workability Fracture Criteria

Workability is not a unique property of a given material. It depends on such process variables as strain, strain rate, temperature, friction conditions, and the stress system imposed by the process. For example, metals can be deformed to a greater extent by extrusion than by drawing because of the compressive nature of the stresses in the extrusion process that makes fracture more difficult. Therefore, workability can be expressed as:

$$\text{Workability} = f_1 \text{ (material)} \cdot f_2 \text{ (process)} \quad \textbf{(Eq 16)}$$

where f_1 is a function of the basic ductility of the material, and f_2 is a function of the stress and strain imposed by the process. Because f_1 depends on the material condition and the fracture mechanism, it is a function of temperature and strain rate. Similarly, f_2 depends on such process conditions as lubrication (friction) and die geometry.

Therefore, to describe workability in a fundamental sense, a fracture criterion must be established that defines the limit of strain as a function of strain rate and temperature. Also required is a description of stress, strain, strain rate, and temperature history at potential fracture sites. The application of computer-aided finite-element analysis of plastic deformation and heat flow has facilitated this goal (see the Section "Computer-Aided Process Design for Bulk Forming" in this Volume). The forming limit diagrams illustrated and discussed in the article "Workability Theory and Application in Bulk Forming Processes" in this Volume are a direct outgrowth of the above concept of workability.

The simplest and most widely used fracture criterion is that discussed in Ref 10. This fracture criterion is not based on a micromechanical model of fracture, but simply recognizes the joint roles of tensile stress and plastic strain in producing fracture:

$$\int_0^{\epsilon_f} \bar{\sigma}\left(\frac{\sigma^*}{\bar{\sigma}}\right) d\bar{\epsilon} = C \quad \textbf{(Eq 17)}$$

where $\overline{\sigma}$ is the effective stress; σ^* is the maximum tensile stress; $d\bar{\epsilon}$ is the effective strain, which is equal to $(\sqrt{2}/3)[(d\varepsilon_1 - d\varepsilon_2)^2 + (d\varepsilon_2 - d\varepsilon_3)^2 + (d\varepsilon_3 - d\varepsilon_1)^2]^{1/2}$; and C is a material constant evaluated from the compression test. This fracture criterion indicates that fracture occurs when the tensile strain energy per unit volume reaches a critical value.

Use of this fracture criterion is shown in Fig. 16. The values of the reduction ratio at which centerburst fracture occurs in the cold extrusion of two aluminum alloys are illustrated. The energy conditions for different die angles are given by the three curves that reach a maximum. The fracture curves for the two materials slope down to the right. Centerburst occurs in the regions of reduction, for which the process energies exceed the material fracture curve. No centerburst occurs at small or large reduction ratios.

Dynamic Material Modeling

A processing map, such as that shown in Fig. 6, is a very useful guide for the selection of deformation processing conditions. However, processing maps that are constructed from mechanistic models of fracture modes are limited in practical application as a design tool. The analyses are valid only for pure metals and simple alloys, not for complicated engineering materials in which strain-rate sensitivity is a function of temperature and strain rate. Moreover, the numerous material parameters, such as diffusivity, that must be introduced into the models, are difficult to obtain for complicated engineering alloys. Perhaps most important, the location of the boundaries in the processing map is very sensitive to microstructure and to prior thermomechanical history. It is difficult to account for these factors in the mechanistic models.

A top-down approach has been developed that begins with macroscopic determination of flow stress as a function of temperature, strain rate, and strain and ends with a microscopic evaluation of the microstructure and the final properties of the forging (Ref 12). The technique, called dynamic material modeling (DMM), maps the power efficiency of the deformation of the material in a strain rate/temperature space (Fig. 17). At a hot-working temperature, the power per unit volume P absorbed by the workpiece during plastic flow is:

$$P = \bar{\sigma}\,\dot{\bar{\epsilon}} = \int_0^{\dot{\bar{\epsilon}}} \bar{\sigma}\, d\dot{\bar{\epsilon}} + \int_0^{\bar{\sigma}} d\bar{\sigma} \qquad \textbf{(Eq 18)}$$

or

$$P = G + J \qquad \textbf{(Eq 19)}$$

where *G* is the power dissipated by plastic work (most of it converted into heat), and *J* is the dissipator power co-content, which is related to the metallurgical mechanisms that occur dynamically to dissipate power. A strong theoretical basis for this position has been developed from continuum mechanics and irreversible thermodynamics (Ref 13). Figure 18 illustrates the definitions of *G* and *J*. At a given deformation temperature and strain:

$$J = \int_0^{\bar{\sigma}} \dot{\bar{\epsilon}}\, d\,\bar{\sigma} = \frac{\bar{\sigma}\,\dot{\bar{\epsilon}}\,m}{m+1} \qquad \textbf{(Eq 20)}$$

where *m* is the strain rate sensitivity of the material. The value of *J* reaches its maximum when *m* = 1:

$$J_{max} = \frac{\bar{\sigma}\,\dot{\bar{\epsilon}}}{2} \qquad \textbf{(Eq 21)}$$

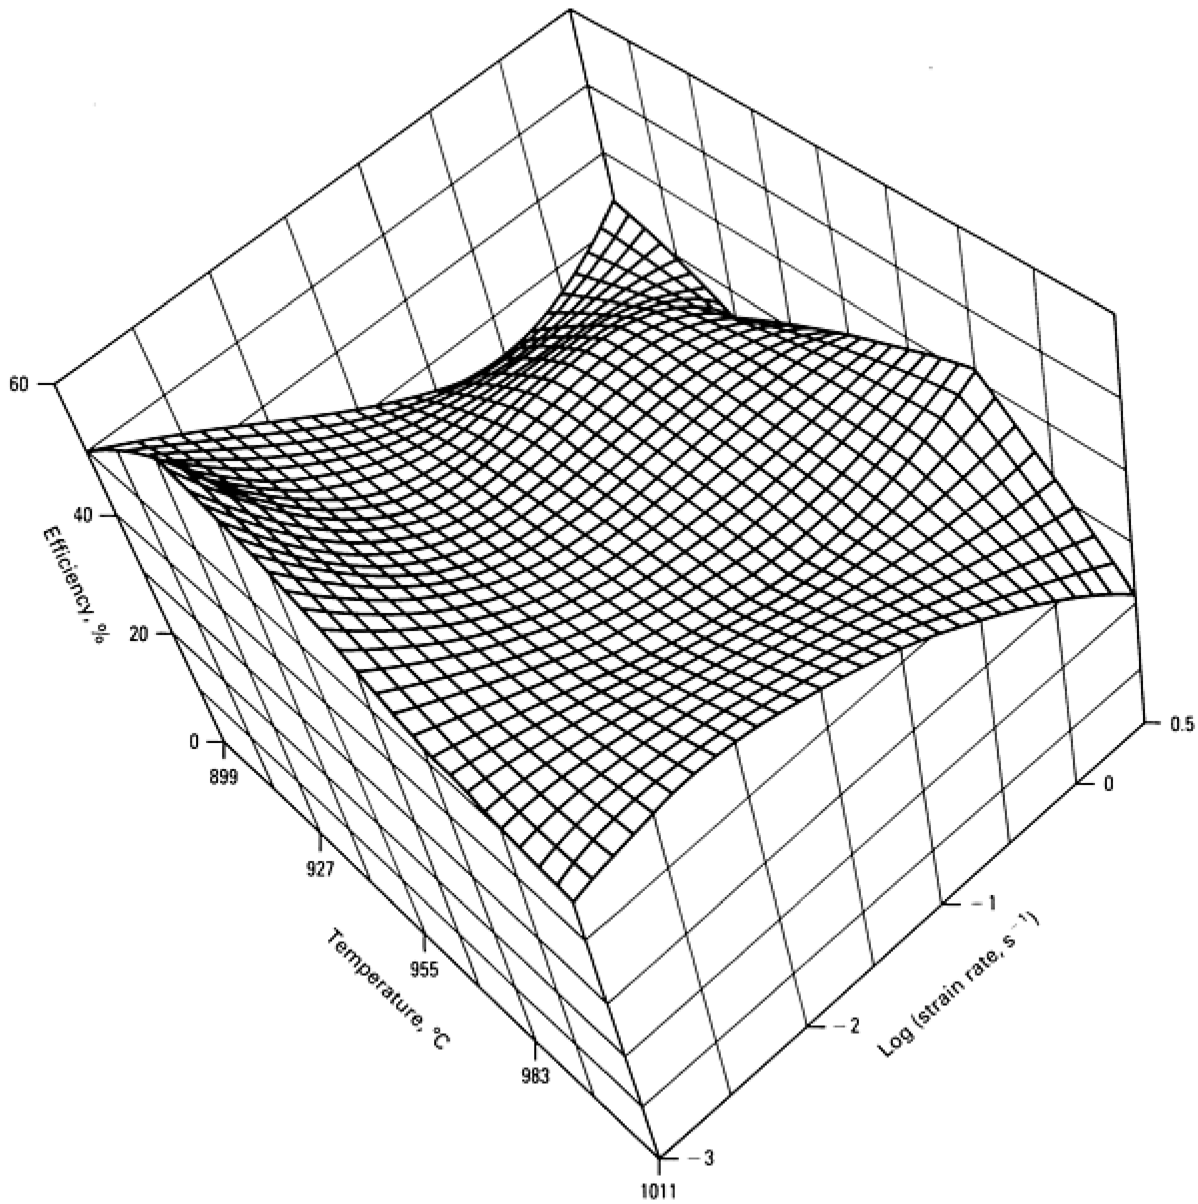

Fig. 17 Three-dimensional plot showing variation of efficiency of power dissipation with temperature and strain rate for Ti-6242 $\alpha + \beta$ preform at 0.6 strain. Source: Ref 13.

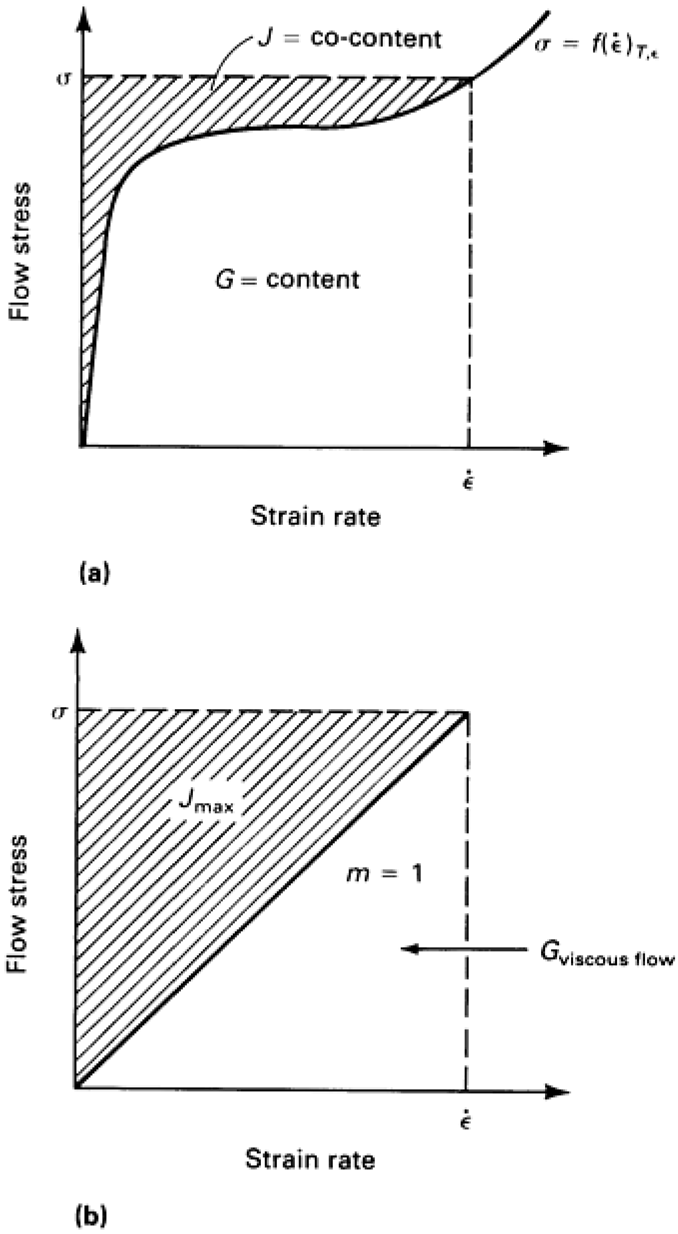

Fig. 18 Schematic of constitutive relation of material system as energy converter (dissipator). (a) Material system as nonlinear (general case) energy dissipater. (b) Material system as linear (special case) dissipator. Source: Ref 13.

A convenient measure of the power dissipation capacity of the materials is the efficiency of dissipation, η:

$$\eta = \frac{J}{J_{max}} = \frac{2m}{m+1} \quad \textbf{(Eq 22)}$$

where $m = (d \ln \overline{\sigma})/(d \ln \dot{\overline{\varepsilon}})$.

By measuring flow stress as a function of strain, strain rate, and temperature and by calculating strain rate sensitivity at each T and $\dot{\epsilon}$(Ref 14, 15) it is possible to determine η from Eq 22. By applying stability theory (Ref 13), it is then possible to establish the loci of bifurcation points as boundaries between safe and unsafe regions on a processing map (Fig. 19). The boundaries, which are determined by Liapunov stability analysis, correspond to a narrow region in which the energy dispersal processes of the material are in a steady state. Processing conditions should be designed to operate in the regions identified as stable. The DMM methodology describes the dynamic path a material element takes in response to an instantaneous change in $\dot{\epsilon}$ at a given T and $\bar{\epsilon}$. As such, it is a map that graphically describes power dissipation by the material in stable and unstable ways. These boundaries correspond to safe and unsafe regions on a processing map. The use of the DMM methodology is in its infancy, but it appears to be a powerful tool for evaluating workability and controlling microstructure by thermomechanical processing in complex alloy systems. More detailed information can be found in the Section "Computer-Aided Process Design for Bulk Forming" in this Volume.

Workability Tests

George E. Dieter, University of Maryland

Introduction

WORKABILITY is a complex property of a material, as indicated in the article "Introduction to Workability" in this Section. It is difficult to isolate the intrinsic workability because this property is strongly influenced by stress state, which is in turn affected by friction and by the geometry of the tools and the workpiece. It has also been shown that the workability of a material is strongly influenced by metallurgical structure and that workability can be a complex function of temperature and strain rate. At the current state of development, the ability to model a forging process by calculating stress, strain, strain rate, and temperature throughout a deforming workpiece with a computer-based finite-element technique exceeds the ability to predict the workability of the material.

A large number of tests are currently used to evaluate the workability of a material. The primary tests--tension, torsion, compression, and bend--will be discussed in this article. These are tests for which the state of stress is well defined and controlled. Of these four tests, the compression test has been the most highly developed as a workability test. The cold upset (compression) test will be described in detail in the article "Workability Theory and Application in Bulk Forming Processes" in this Section.

Specialized workability tests that have been developed from the four primary tests will also be covered. Each of these tests provides information that is not readily available from the primary tests.

A number of workability tests will be discussed that are especially applicable to the forging process. These forgeability tests are used because they lend themselves to the form of material or the particular forging process. Although most workability tests seek to determine the extent of large-scale deformation that is possible before fracture, one class of test is concerned with the propensity for localized deformation and fracture.

Finally, this article will conclude with a discussion of typical forging defects. Although not strictly related to workability tests, forging defects certainly represent a limitation to workability.

Workability Tests

George E. Dieter, University of Maryland

Primary Tests

The primary tests for workability are those for which the stress state is well-known and controlled. Generally, these are small-scale laboratory simulation tests.

The tension test is widely used to determine the mechanical properties of a material (Ref 1). Uniform elongation, total elongation, and reduction in area at fracture are frequently used as indices of ductility. However, the extent of deformation possible in a tension test is limited by the formation of a necked region in the tension specimen. This introduces a triaxial tensile stress state and leads to fracture.

For most metals, the uniform strain that precedes necking rarely exceeds a true strain of 0.5. For hot-working temperatures, this uniform strain is frequently less than 0.1. Although tension tests are easily performed, necking makes control of strain rate difficult and leads to uncertainties about the value of strain at fracture because of the complex stresses that result from necking. Therefore, the utility of the tension test is limited in workability testing. This test is primarily used under special high strain rate, hot tension test conditions to establish the range of hot-working temperatures. A description of this test method can be found later in this article.

In the torsion test, deformation is caused by pure shear, and large strains can be achieved without the limitations imposed by necking (Ref 2, 3). Because the strain rate is proportional to rotational speed, high strain rates are readily obtained (Table 1). Moreover, friction has no effect on the test, as it does in compression testing. The stress state in torsion may represent the typical stress in metalworking processes, but deformation in the torsion test is not an accurate simulation of metalworking processes, because of excessive material reorientation at large strains.

Table 1 Torsional rotation rates corresponding to various metalworking operations

Operation	**von Mises effective strain rate ($\dot{\bar{\epsilon}}$)[a], s^{-1}**	**Corresponding surface shear strain rate in torsion ($\dot{\Gamma}$), s^{-1}**	Rotation rate[b], rpm
Isothermal forging	10^{-3}	1.73×10^{-3}	**0.02**
Hydraulic press forging	1	1.73	**16.5**
Extrusion	20	34.6	**330.4**
Mechanical press forging	50	86.6	**827.0**
Sheet rolling	200	346.4	**3307.9**

Wire drawing	**500**	**866.0**	**8269.7**

(a) $\dot{\epsilon} = \dot{\Gamma}\sqrt{3}$

(b) Assuming specimen geometry with $r/L = 1.0$

Because of the above advantages, the torsion test is frequently used to measure the flow stress and the stress-strain curve (flow curve) under hot-working conditions. Figure 1 shows typical flow curves as a function of temperature and strain rate. In the torsion test, measurements are made of the torque, *M*, to deform the specimen and the angle of twist θor number of turns ($\theta = 2\pi$ rad per turn). The shear stress τ on the outer surface of the specimen is given by:

$$\tau = \frac{M(3 + m + n)}{2\pi r^3}$$

where *r* is the specimen radius, *m* is the strain rate sensitivity found from plots of log *M* versus log $\dot{\theta}$at fixed values of θ, and *n* is the strain-hardening exponent obtained from the instantaneous slope of log *M* versus log θ.

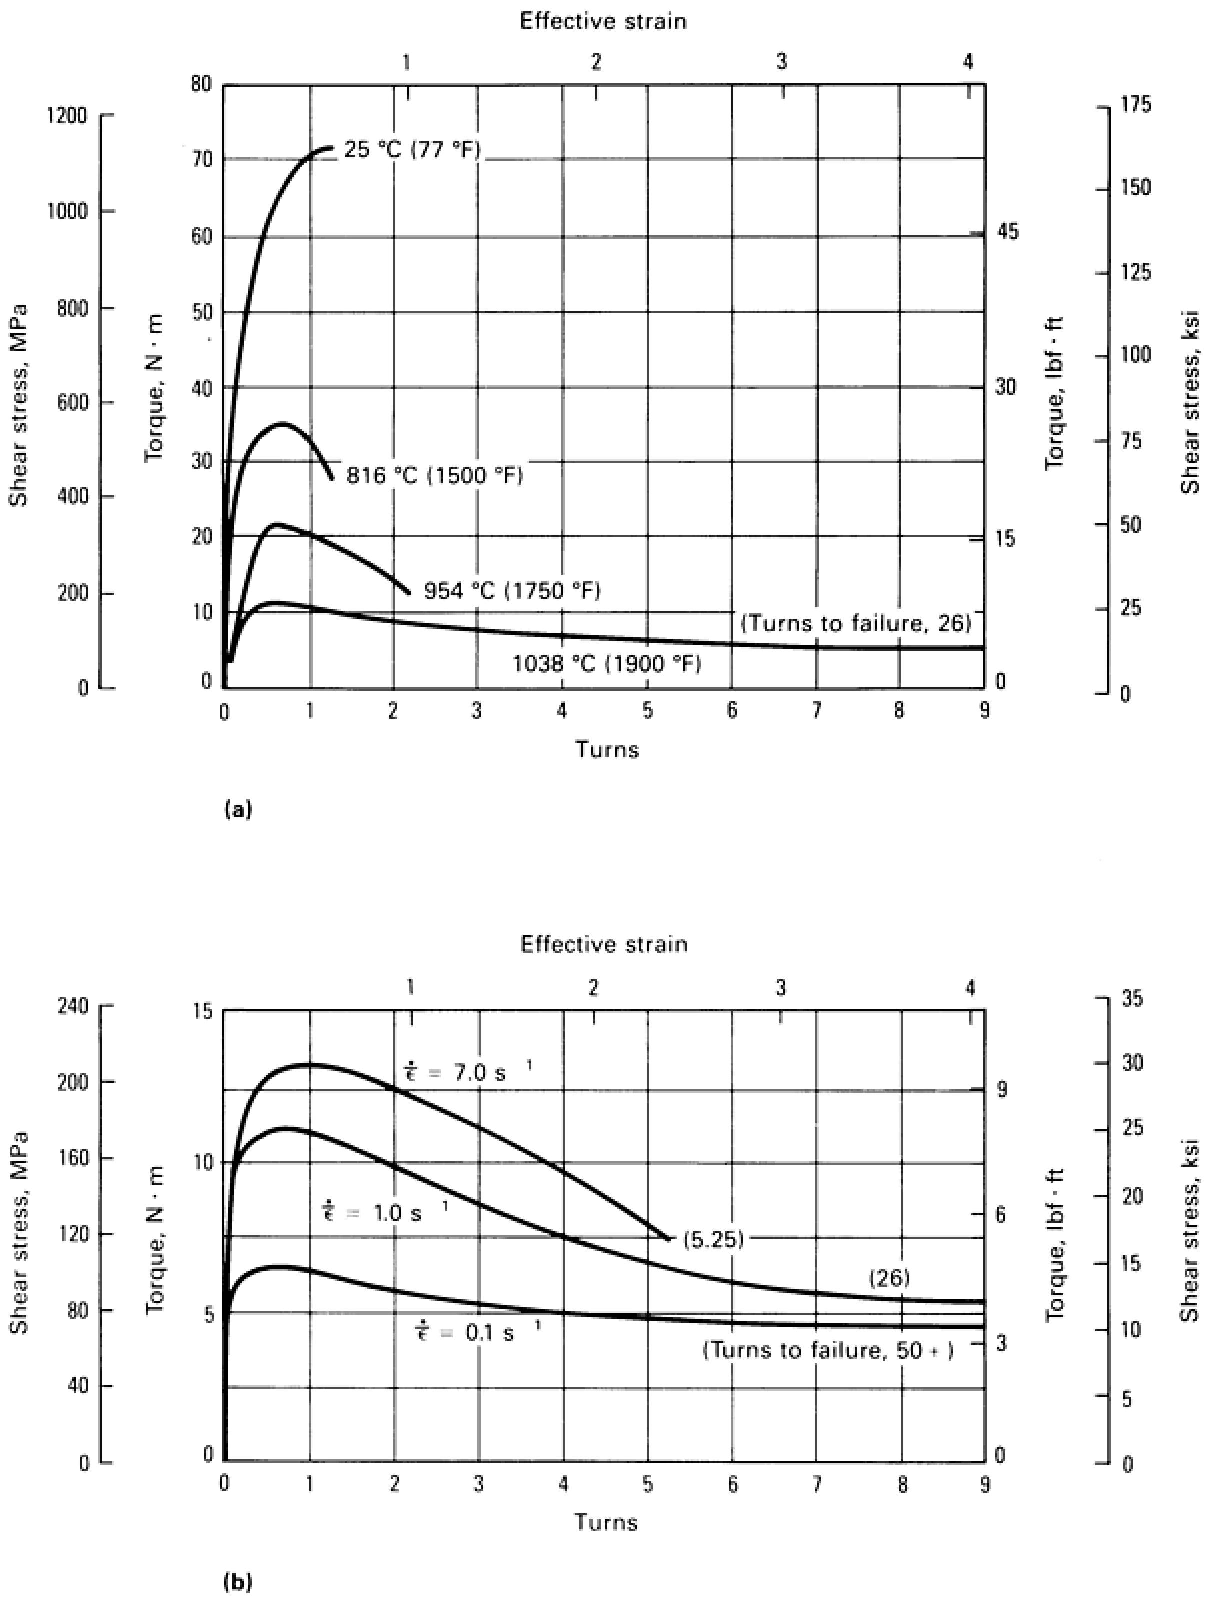

Fig. 1 Flow curves for Waspaloy. (a) Effect of temperature at a fixed effective strain rate of 1 s^{-1}. (b) Effect of strain rate at a fixed test temperature of 1038 °C (1900 °F). Flow softening at the higher temperature is a result of dynamic recrystallization. Source: Ref 4.

The engineering shear strain Γ and shear strain rate $\dot{\Gamma}$ are given by:

$$\Gamma = \frac{r\theta}{L}$$

and

$$\dot{\Gamma} = \frac{r\dot{\theta}}{L}$$

where *r* is the radius of the specimen and *L* is the gage length. These values of shear stress and shear strain are typically converted to effective stress $\overline{\sigma}$ and effective strain $\overline{\epsilon}$ by means of the von Mises yielding criterion (see the article "Introduction to Workability" in this Section):

$$\overline{\sigma} = \sqrt{3}\tau$$

and

$$\bar{\epsilon} = \frac{\Gamma}{\sqrt{3}}$$

Figure 2 shows agreement in plots of $\overline{\sigma}$ versus $\overline{\epsilon}$ for stress-strain data determined in torsion, tension, and compression. The agreement becomes much better at hot-working temperatures.

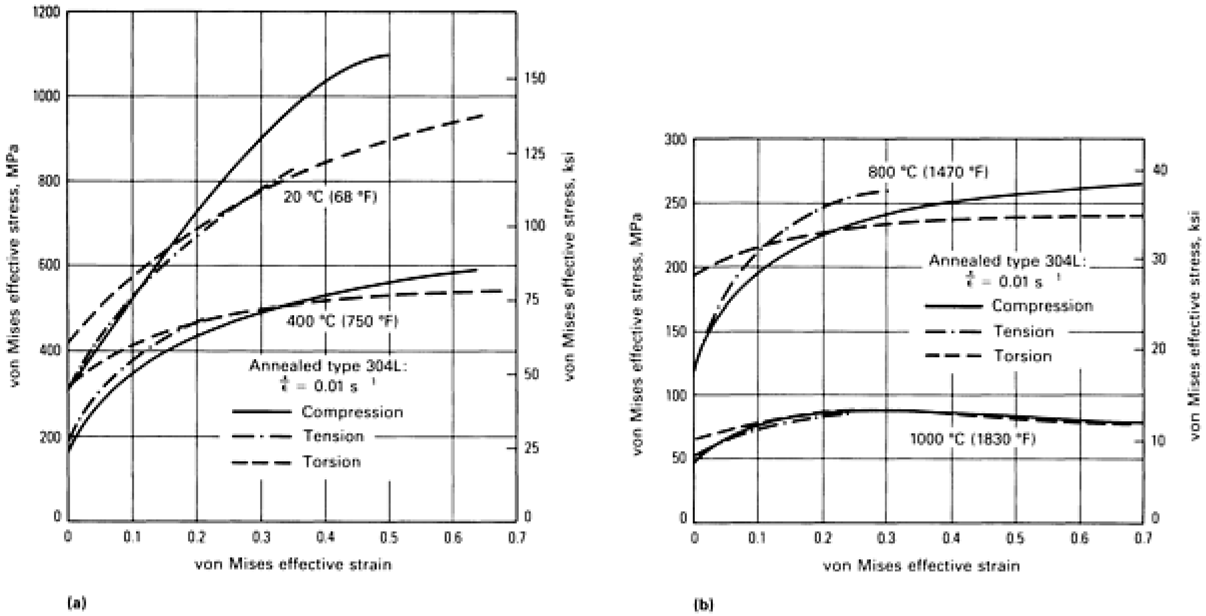

Fig. 2 Comparison of effective stress-strain curves determined for type 304L stainless steel in compression, tension, and torsion. (a) Cold- and warm-working temperatures. (b) Hot-working temperatures. Source: Ref 2.

Fracture data from torsion tests are usually reported in terms of the number of twists to failure or the surface fracture strain to failure. Figure 3 shows the relative hot workability of a number of steels and nickel-base superalloys, as indicated by the torsion test. The test identifies the optimal hot-working temperature.

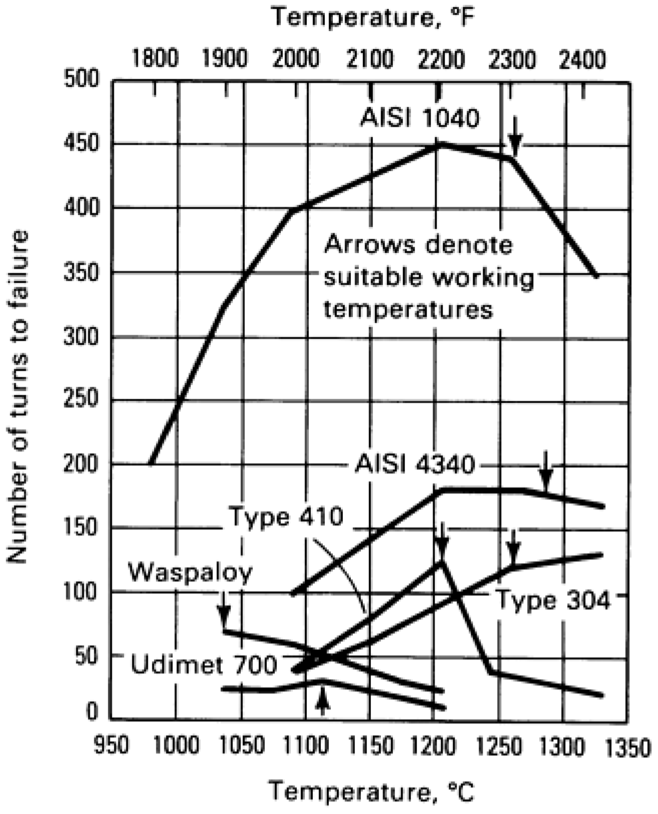

Fig. 3 Ductility determined in hot torsion tests. Source: Ref 2.

The compression test, in which a cylindrical specimen is upset into a flat pancake, is usually considered to be a standard bulk workability test. The average stress state during testing is similar to that in many bulk deformation processes, without introducing the problems of necking (in tension) or material reorientation (in torsion). Therefore, a large amount of deformation can be achieved before fracture occurs. The stress state can be varied over wide limits by controlling the barreling of the specimen through variations in geometry and by reducing friction between the specimen ends and the anvil with lubricants.

Compression testing has developed into a highly sophisticated test for workability in cold upset forging, and it is a common quality control test in hot-forging operations. Compression forging is a useful method of assessing the frictional conditions in hot working. The principal disadvantage of the compression test is that tests at a constant, true strain rate require special equipment.

Compression Test Conditions. Unless the lubrication at the ends of the specimen is very good, frictional restraint will retard the outward motion of the end face, and part of the end face will be formed by a folding over of the sides of the original cylinder onto the end face in contact with the platens. The barreling that results introduces a complex stress state, which is beneficial in fracture testing but detrimental when the compression test is used to measure flow stress. The frictional restraint also causes internal inhomogeneity of plastic deformation. Slightly deforming zones develop adjacent to the platens, while severe deformation is concentrated in zones that occupy roughly diagonal positions between opposing edges of the specimen (see Fig. 7 in the article "Introduction to Workability" in this Section).

Figure 4 shows the hot upsetting of a cylinder under conditions of poor lubrication in which the platens are cooler than the specimen. The cooling at the ends restricts the flow so that the deformation is concentrated in a central zone, with dead-metal zones forming adjacent to the platen surfaces (Fig. 4a).

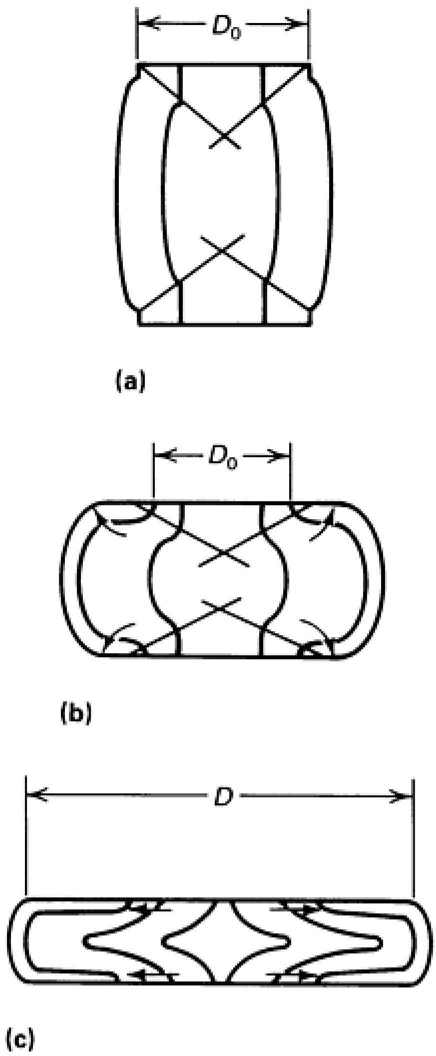

Fig. 4 Deformation patterns in nonlubricated, nonisothermal hot forging. (a) Initial barreling. (b) Barreling and folding over. (c) Beginning of end face expansion. Source: Ref 5.

As deformation proceeds, severe inhomogeneity develops, and the growth of the end faces is attributed entirely to the folding over of the sides (Fig. 4b). When the diameter-to-height ratio, D/h, exceeds about 3, expansion of the end faces occurs (Fig. 4c).

The conditions described above are extreme and should not be allowed to occur in hot compression testing unless the objective is to simulate cracking under forging conditions. Adequate lubrication cannot improve the situation so that homogeneous deformation occurs; however, with glass lubricants and isothermal conditions, it is possible to conduct hot compression testing without appreciable barreling (Ref 6). Isothermal test conditions can be achieved by using a heated subassembly, such as that shown in Fig. 5, or heated dies that provide isothermal conditions (Ref 8).

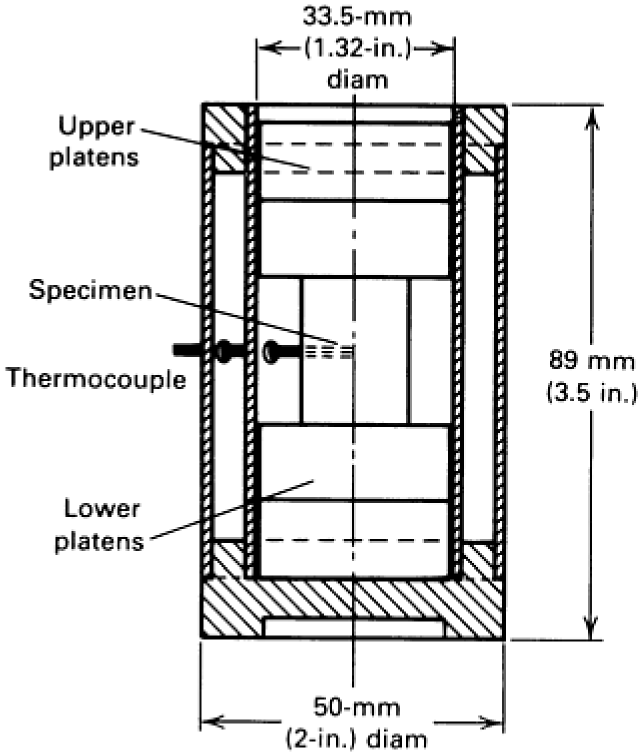

Fig. 5 Heated subassembly with specimen in position used to achieve isothermal test conditions. Thermocouple is removed prior to compression. Source: Ref 7.

The true strain rate in a compression test is:

$$\dot{\epsilon} = \frac{d\epsilon}{dt} = \frac{-dh/h}{dt} = -\frac{1}{h}\frac{dh}{dt} = -\frac{v}{h}$$

where *v* is the velocity of the platen and *h* is the height of the specimen at time *t*. Because *h* decreases continuously with time, the velocity must decrease in proportion to (-*h*) if $\dot{\epsilon}$is to be held constant. In a normal test, if *v* is held constant, the engineering strain rate $\dot{e}$will remain constant:

$$\dot{e} = \frac{de}{dt} = \frac{-dh/h_0}{dt} = -\frac{1}{h_0}\frac{dh}{dt} = \frac{-v}{h_0}$$

The true strain rate, however, will not be constant. A machine called a cam plastometer can be used to cause the bottom platen to compress the specimen through cam action at a constant true strain rate to a strain limit of ϵ= 0.7 (Ref 9). The use of cam plastometers is limited; there probably are not more than ten in existence. However, an essentially constant true strain rate can be achieved on a standard closed-loop servo-controlled testing machine. Strain rates up to 20 s^{-1} have been achieved (Ref 6, 10). The history of the cam plastometer, the basic principles involved in the technique, and the equipment used are discussed in the article "High Strain Rate Compression Testing" in *Mechanical Testing*, Volume 8 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

When a constant true strain rate cannot be obtained, the mean strain rate may be adequate. The mean true strain rate, $\langle\dot{\bar{\epsilon}}\rangle$, for constant velocity v_o, when the specimen is reduced in height from h_0 to *h*, is given by:

$$\langle\dot{\epsilon}\rangle = \frac{v_0}{2}\frac{\ln(h_0/h)}{(h_0 - h)}$$

Flow Stress in Compression. Ideally, the determination of flow stress in compression should be carried out under isothermal conditions (no die chilling) at a constant strain rate and with a minimum of friction in order to minimize barreling. These conditions can be met with conventional servohydraulic testing machines. For an essentially homogeneous upsetting test, a cylinder of diameter D_0 and initial height h_0, will be compressed to height h and spread out to diameter D_1 according to the law of constancy of volume:

$$D_0^2 h_0 = D^2 h$$

If friction can be neglected, the uniaxial compressive stress (flow stress) corresponding to a deformation force P is:

$$\sigma_0 = \frac{P}{A} = \frac{4P}{\pi D^2} = \frac{4Ph}{\pi D_0^2 h_0}$$

If substantial friction is present, the average pressure, $\overline{p}$, required to deform the cylinder is greater than the flow stress of the material, σ_0:

$$\frac{\overline{p}}{\sigma_0} = \left(\frac{h}{4\mu a}\right)^2 \left(e^{2\mu a/h} - \frac{2\mu a}{h} - 1\right)$$

where a is the radius of the cylinder, and μ is the Coulomb coefficient of friction. The true compressive strain is given by:

$$\epsilon = \ln\left(\frac{h_0}{h}\right)$$

The effects of friction and die chilling can be minimized through the use of a long, thin specimen. Therefore, most of the specimen volume is unaffected by the dead-metal zones at the platens. However, this approach is limited, because buckling of the specimen will occur if h/D exceeds about 2.

An extrapolation method involves testing cylinders of equal diameters but varying heights so that the D_0/h_0 ratio ranges from about 0.5 to 3.0 (Ref 11). A specific load is applied to the specimen, the load is removed, and the new height is determined in order to calculate a true strain. Upon relubrication, the specimen is subjected to an increased load, unloaded, and measured. The cycle is then repeated.

The same test procedure is followed with each specimen so that the particular load levels are duplicated. The results are illustrated in Fig. 6. For the same load, the actual strain (due to height reduction) is plotted against the D_0/h_0 ratio for each test cylinder. A line drawn through the points is extrapolated to a value of $D_0/h_0 = 0$. This would be the anticipated ratio for a specimen of infinite initial height for which the end effects would be restricted to a small region of the full test height. The true stress corresponding to each of these true strains is given by:

$$\sigma_0 = \frac{4Ph}{\pi D_0^2 h_0}$$

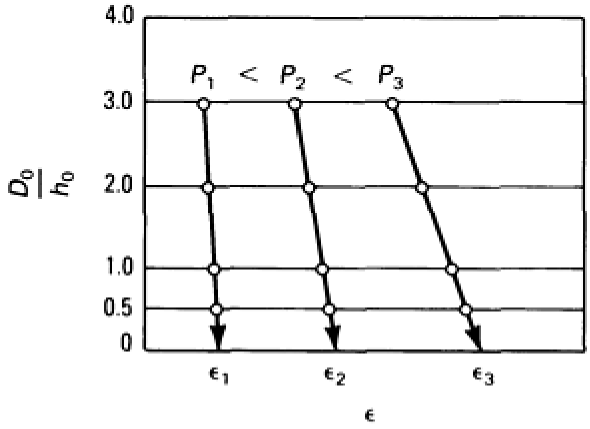

Fig. 6 Extrapolation method to correct for end effects in compressive loading. Source: Ref 11.

Ductility Testing. The basic hot ductility test consists of compressing a series of cylindrical or square specimens to various thicknesses, or to the same thickness with varying specimen length-to-diameter (length-to-width) ratios. The limit for compression without failure by radial or peripheral cracking is considered to be a measure of workability. This type of test has been widely used in the forging industry. Longitudinal notches are sometimes machined into the specimens before compression, because the notches apparently cause more severe stress concentrations, thus providing a more reliable index of the workability to be expected in a complex forging operation.

Plastic Instability in Compression. Several types of plastic instabilities can be developed in the compression test. The first type is associated with a maximum in the true stress-strain curve. The second type concerns inhomogeneous deformation and shear band formation. Figure 7 shows the type of plastic instability that occurs in some materials in hot compression testing. At certain temperatures and strain rates, some of the typical strengthening mechanisms become unstable. Because the rate of flow softening exceeds the rate of area increase as the specimen is compressed, a maximum results in the flow stress curve.

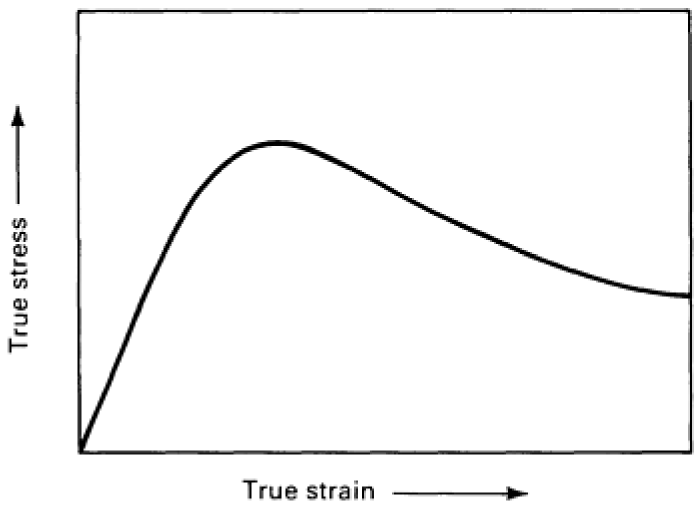

Fig. 7 Example of compressive flow stress curve showing strain softening.

Analysis of the compression process indicates that the plastic deformation is stable (no maximum in the flow curve) as long as $(\gamma + m) \leq 1$, where γ is the dimensionless work-hardening coefficient, and m is strain rate sensitivity. Both of these material parameters are defined below (Ref 12, 13). A material with a high strain rate sensitivity is more resistant to flow localization in the tension test (necking), but in compression testing, a higher rate sensitivity leads to earlier flow localization.

Flow softening or negative strain hardening can also produce flow localization effects in compression independently of the effects of die chilling or high friction. The constant strain rate, isothermal hot compression test is useful for detecting and predicting flow localization. Nonuniform flow in compression is likely if a flow parameter α_c exceeds a certain value:

$$\alpha_c = -\frac{(\gamma - 1)}{m} \geq 5$$

where

$$\gamma = \left(\frac{1}{\sigma}\right)\left(\frac{d\sigma}{d\epsilon}\right)$$

and

$$m = \frac{\partial \ln \sigma}{\partial \ln \dot{\epsilon}}\bigg|_{T,\epsilon} \simeq \frac{\Delta \log \sigma}{\Delta \ln \dot{\epsilon}}\bigg|_{T,\epsilon}$$

Figure 8 illustrates the differences in deformation of titanium alloy samples. The specimens in Fig. 8(a) to (c) were deformed at a temperature at which α_c was high. In Fig. 8(a), $\dot{\epsilon} = 10^{-3}$ s^{-1} and $\alpha_c = 2$. In Fig. 8(b), $\dot{\epsilon} = 10^{-1}$ s^{-1} and $\alpha_c = 5$. In Fig. 8(c), $\dot{\epsilon} = 10$ s^{-1} and $\alpha_c = 5$. However, the specimens in Fig. 8(d) to (f) were deformed at a temperature at which α_c was less than 0.

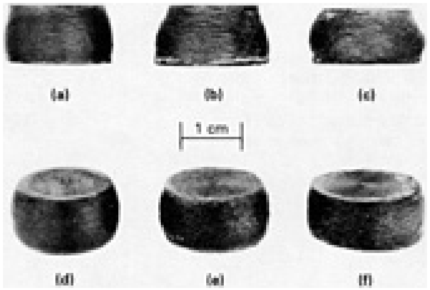

Fig. 8 Specimens of Ti-10V-2Fe-3Al from isothermal hot compression tests. (a) to (c) Tested at 704 °C (1300 °F). (d) to (f) Tested at 816 °C (1500 °F). Strain rates were 10^{-3} s^{-1} (a, d), 10^{-1} s^{-1} (b, e), and 10 s^{-1} (c, f). Before testing, the alloy had been β annealed to yield an equiaxed β starting microstructure. Source: Ref 14.

The bend test is useful for assessing the workability of thick sheet and plate. Generally, this test is most applicable to cold-working operations. Figure 9 shows a plate deformed in three-point bending. The principal stress and strains developed during bending are defined in Fig. 10. The critical parameter is width-to-thickness ratio (w/t). If $w/t > 8$, bending occurs under plane-strain conditions ($\epsilon_2 = 0$) and $\sigma_2/\sigma_1 = 0.5$. If $w/t > 8$, the bend ductility is independent of the exact w/t ratio. If $w/t < 8$, then stress state and bend ductility depend strongly on the width-to-thickness ratio.

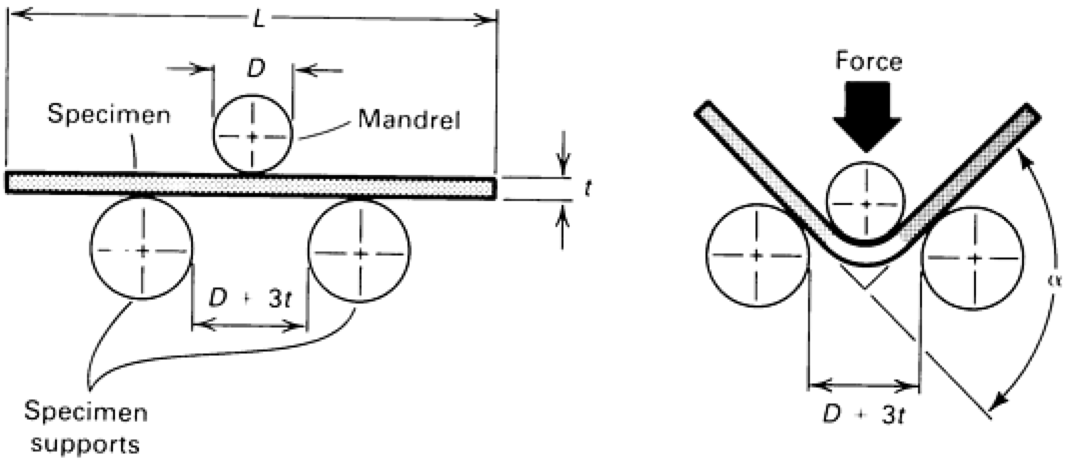

Fig. 9 Three-point bend test.

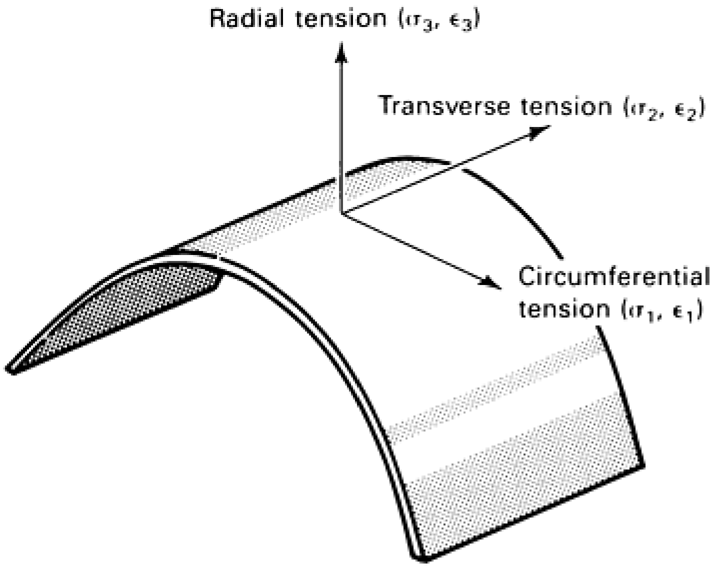

Fig. 10 Schematic of the bend region defining direction of principal stresses and strains.

For pure plastic bending, in which elastic deformation can be ignored, the maximum tensile fiber strain is (Ref 15):

$$\epsilon_0 = \ln \sqrt{\frac{R_o}{R_i}}$$

where R_o is the radius of curvature on the outer (tensile) surface and R_i is the radius of curvature on the inner (compressive) surface. When this strain is entered into the stress-strain equation or curve for the material, it gives the flow stress for the material $\overline{\sigma}$. Because of the plane-strain condition, the maximum fiber stress is $2\overline{\sigma}/\sqrt{3}$.

Workability Tests

George E. Dieter, University of Maryland

Specialized Tests

In the plane-strain compression test, the difficulties encountered with bulging and high friction at the platens in the compression of cylinders can be minimized (Ref 11). As shown in Fig. 11, the specimen is a thin plate or sheet that is compressed across the width of the strip by narrow platens that are wider than the strip. The elastic constraints of the undeformed shoulders of material on each side of the platens prevent extension of the strip in the width dimension; hence the term plane strain.

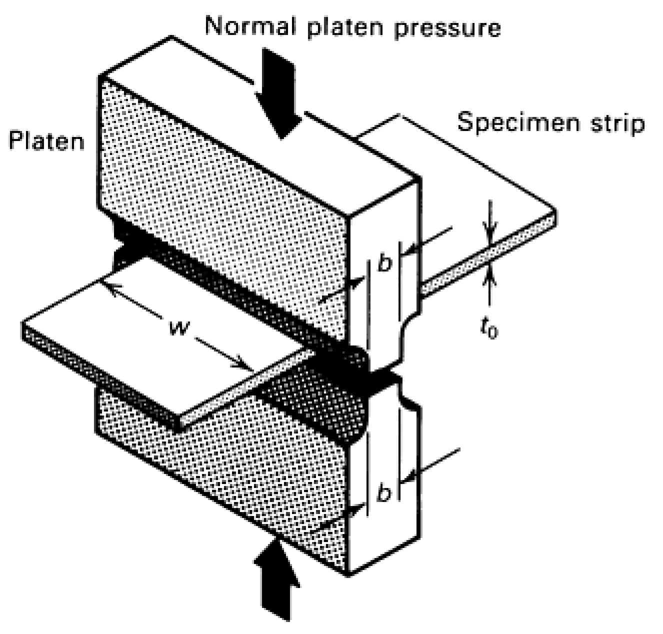

Fig. 11 Plane-strain compression test.

Deformation occurs in the direction of platen motion and in the direction normal to the length of the platen. To ensure that lateral spread is negligible, the width of the strip should be at least six to ten times the breadth of the platens. To ensure that deformation beneath the platens is essentially homogeneous, the ratio of platen breadth to strip thickness (*b*/*t*) should be between 2 and 4 at all times. It may be necessary to change the platens during testing to maintain this condition. True strains of 2 can be achieved by carrying out the test in increments in order to provide good lubrication and to maintain the proper *b*/*t* ratio. Although the plane-strain compression test is primarily used to measure flow properties at room temperature, it can also be used for elevated-temperature tests (Ref 16, 17).However, because of its geometry, this test is more applicable to rolling operations than to forging.

The true stress and true strain determined from the plane-strain compression test can be expressed as:

$$p = \frac{P}{wb}$$

$$\epsilon_{pc} = \ln \frac{t_0}{t}$$

Because of the stress state associated with plane-strain deformation, the mean pressure on the platens is 15.5% higher in the plane-strain compression test than in uniaxial compression testing. The true stress-strain curve in uniaxial compression (σ_0 versus ε) can be obtained from the corresponding plane-strain compression curve (p versus ϵ_{pc}) by:

$$\sigma_0 = \frac{\sqrt{3}}{2} p = \frac{p}{1.155}$$

and

$$\epsilon = \frac{2}{\sqrt{3}} \epsilon_{pc} = 1.155\ \epsilon_{pc}$$

The partial-width indentation test is a new test for evaluating the workability of metals. It is similar to the plane-strain compression test, but it does not subject the test specimen to true plane-strain conditions (Ref 18). In this test, a simple slab-shaped specimen is deformed over part of its width by two opposing rectangular anvils having widths smaller than that of the specimen.Upon penetrating the workpiece, the anvils longitudinally displace metal from the center, creating overhangs (ribs) that are subjected to secondary, nearly uniaxial tensile straining. The material ductility under these conditions is indicated by the reduction in the rib height at fracture. The test geometry has been standardized (Fig. 12).

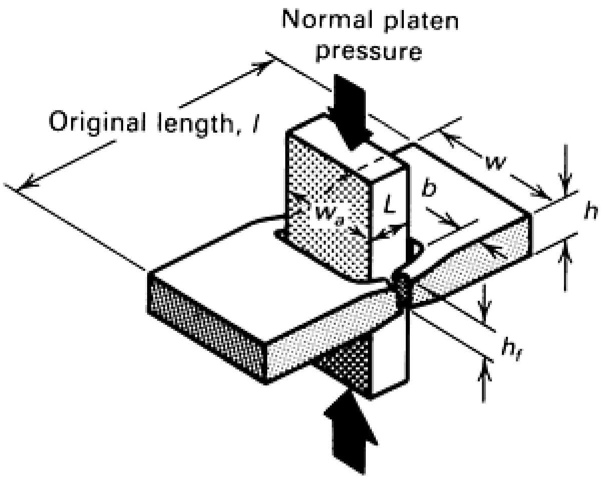

Fig. 12 Partial-width indentation test. $L \simeq h$; $b = h/2$ $w_a = 2L$; $l = 4L$.

One advantage of this test is that it uses a specimen of simple shape. In addition, ascast materials can be readily tested. One edge of the specimen can contain original surface defects. The test can be conducted hot or cold. Therefore, the partial-width indentation test is suitable not only for determining the intrinsic ductilities of materials but also for evaluating the inhomogeneous aspects of workability. This test has been used to establish the fracture-limit loci for ductile metals (Ref 19).

The secondary-tension test, a modification of the partial-width indentation test, imposes more severe strain in the rib for testing highly ductile materials. In this test, a hole or a slot is machined in the slab-type specimen adjacent to where the anvils indent the specimen. Preferred dimensions of the hole and slot are given in Fig. 13. With this design, the ribs are sufficiently stretched to ensure fracture in even the most ductile materials. The fracture strain is based on reduction in area where the rib is cut out, so that the fracture area can be photographed or traced on an optical comparator.

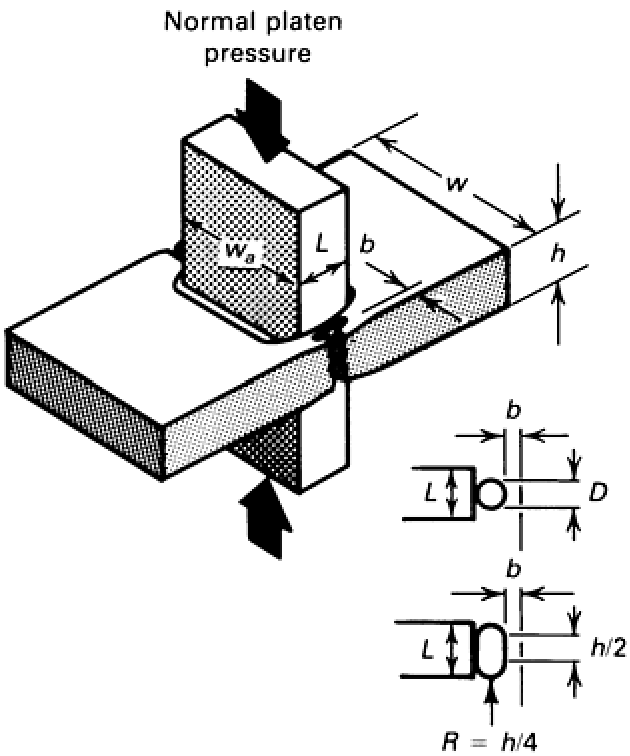

Fig. 13 Secondary-tension test showing the geometries of holes and slots $L \simeq h$; $w_a \geq 2h$; $b = h/4$; $D = h/2$.

Ring Compression Test. When a flat ring-shaped specimen is upset in the axial direction, the resulting change in shape depends only on the amount of compression in the thickness direction and the frictional conditions at the die/ring interfaces. If the interfacial friction were zero, the ring would deform in the same manner as a solid disk, with each element flowing outward radially at a rate proportional to its distance from the center.

In the case of small, but finite, interfacial friction, the outside diameter is smaller than in the zero-friction case. If the friction exceeds a critical value, frictional resistance to outward flow becomes so high that some of the ring material flows inward to the center. Measurements of the inside diameters of compressed rings provide a particularly sensitive means of studying interfacial friction, because the inside diameter increases if the friction is low and decreases if the friction is higher (Fig. 14).

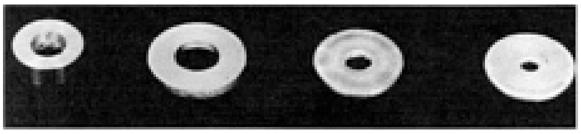

Fig. 14 Variation in shape of ring test specimens deformed the same amount under different frictional conditions. Left to right: undeformed specimen; deformed 50%, low friction; deformed 50%, medium friction; deformed 50%, high friction.

The ring test, then, is a compression test with a built-in frictional measurement. Therefore, it is possible to measure the ring dimensions and compute both the friction value and the basic flow stress of the ring material at the strain under the given deformation conditions.

Analysis of Ring Compression. The mechanics of the compression of flat ring-shaped specimens between flat dies have been analyzed using an upper bound plasticity technique (Ref 20, 21). Values of p/σ_0 (where p is the average forging pressure on the ring, and σ_0 is the flow stress of the ring material) can be calculated in terms of ring geometry and the interfacial shear factor, m. In these calculations, neither σ_0 nor the interfacial shear stress, τ, appears in terms of independent absolute values, but only as the ratio m (see the article "Introduction to Workability" in this Section).

The analysis assumes that this ratio remains constant for a given material and deformation conditions. If the analysis is carried out for a small increment of deformation, σ_0 and τ can be assumed to be approximately constant for this increment, and the solution is valid. Therefore, if the shear factor m is constant for the entire operation, the mathematical analysis can be continued in a series of small deformation increments, using the final ring geometry from one increment as the initial geometry for the subsequent increment. As long as the ratio of the interfacial shear stress, τ, to the material flow stress, σ_0, remains constant, strain hardening of the ring material during deformation has no effect if the increase in work hardening in any single deformation increment can be neglected.

The progressive increase in interfacial shear stress accompanying strain hardening is also immaterial if it can be assumed to be constant over the entire die/ring interface during any one deformation increment. Therefore, the analysis can be justifiably applied to real materials even though it was initially assumed that the material would behave according to the von Mises stress-strain rate laws, provided the assumption of a constant interfacial shear factor, m, is correct. However, it has been shown that a highly strain rate sensitive material requires a different analysis (Ref 22).

Based on these assumptions, the plasticity equations have been solved for several ring geometries over a complete range of m values from 0 to unity (Ref 23), as shown in Fig. 15. The friction factor can be determined by measuring the change in internal diameter of the ring.

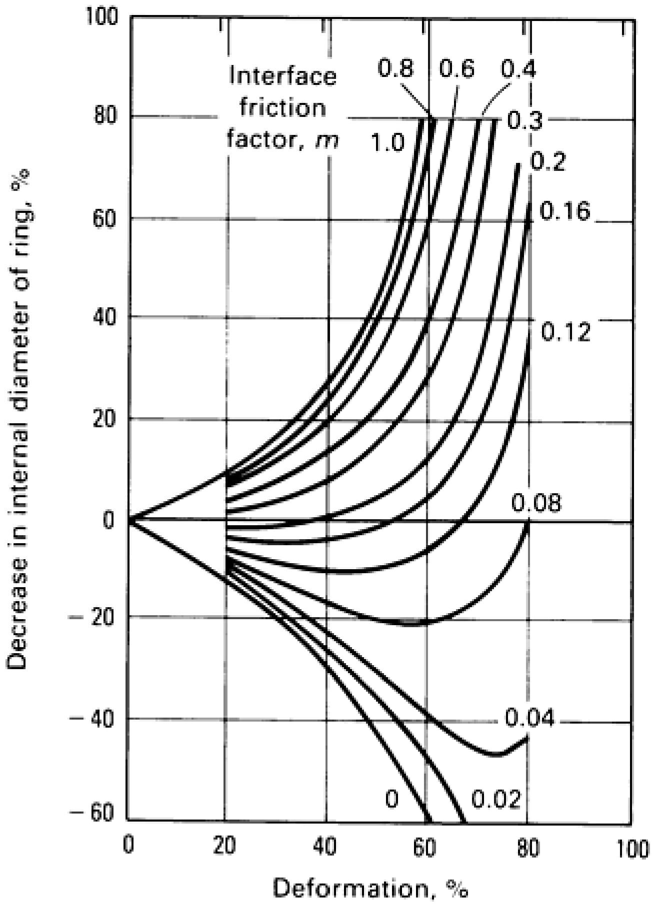

Fig. 15 Theoretical calibration curve for standard ring with an OD:ID:thickness ratio of 6:3:2.

The ring thickness is usually expressed in relation to the inside and outside diameters. The maximum thickness that can be used while still satisfying the mathematical assumption of thin-specimen conditions varies, depending on the actual friction conditions. Under conditions of maximum friction, the largest usable specimen height is obtained with rings of dimensions in the OD:ID:thickness ratio of 6:3:1. Under conditions of low friction, thicker specimens can be used while still satisfying the above assumption. For normal lubricated conditions, a geometry of 6:3:2 can be used to obtain results of sufficient accuracy for most applications.

For experimental conditions in which specimen thicknesses are greater than those permitted by a geometry of 6:3:1 and/or the interface friction is relatively high, the resulting side barreling or bulging must be considered. Analytical treatment of this more complex situation is available in Ref 24.

The ring compression test can be used to measure the flow stress under high-strain practical forming conditions. The only instrumentation required is that for measuring the force needed to produce the reduction in height. The change in diameter of the 6:3:1 ring is measured to obtain a value of the ratio p/σ_0 by solving the analytical expression for the deformation of the ring or by using computer solutions for the ring (Ref 25). Measurement of the area of the ring surface formerly in contact with the die and knowledge of the deformation load facilitate calculation of p and therefore the value of the material flow stress, σ_o, for a given amount of deformation. Repetition of this process with other ring specimens over a range of deformation allows the generation of a complete flow stress-strain curve for a given material under particular temperature and strain rate deformation conditions.

Hot Tension Testing. Although necking is a fundamental limitation in tension testing, the tension test is nevertheless useful for establishing the temperature limits for hot working. The principal advantage of this test for industrial applications is that it clearly establishes maximum and minimum hot-working temperatures (Ref 26).

Most commercial hot tensile testing is done with a Gleeble unit, which is a high strain rate, high-temperature testing machine (Ref 27). A solid buttonhead specimen that has a reduced diameter of 6.4 mm (0.250 in.) and an overall length of 89 mm (3.5 in.) is held horizontally by water-cooled copper jaws (grips), through which electric power is introduced to resistance heat the test specimen (Fig. 16). Specimen temperature is monitored by a thermocouple welded to the specimen surface at its midlength. The thermocouple, with a function generator, controls the heat fed into the specimen according to a programmed cycle. Therefore, a specimen can be tested under time-temperature conditions that simulate hot-working sequences.

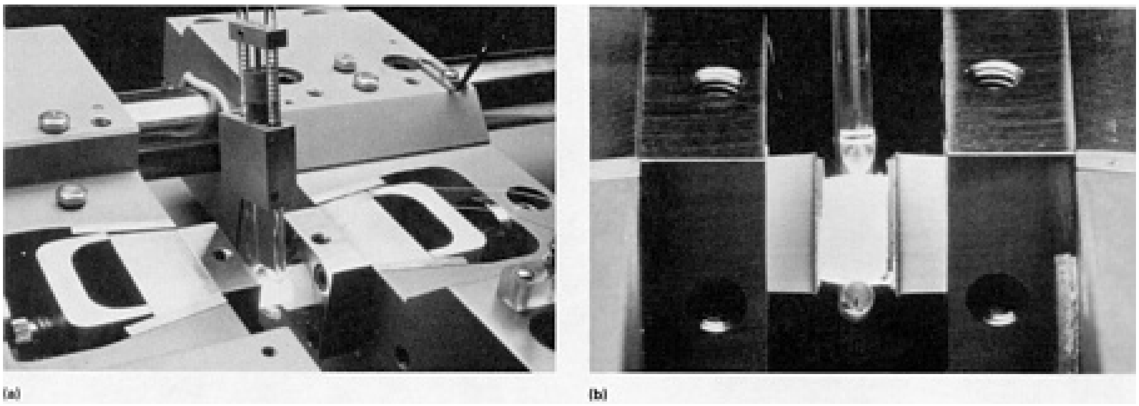

Fig. 16 The Gleeble test unit used for hot tension and compression testing. (a) Specimen in grips showing attached thermocouple wires and linear variable differential transformer for measuring strain. (b) Close-up of a compression test specimen. Courtesy of Duffers Scientific, Inc.

The specimen is loaded by a pneumatic-hydraulic system. The load can be applied at any desired time in the thermal cycle. Temperature, load, and crosshead displacement are measured as a function of time. In the Gleeble test, the crosshead speed can be maintained constant throughout the test, but the true strain rate decreases until necking occurs, according to the relationship:

$$\dot{\epsilon} = \frac{d\epsilon}{dt} = \frac{1}{L}\frac{dL}{dt}$$

When the specimen necks, the strain rate increases suddenly in the deforming region, because deformation is concentrated in a narrow zone. Although this variable strain rate history introduces some uncertainty into the determination of strength and ductility values, it does not negate the utility of the hot tension test. Moreover, a procedure has been developed that corrects for the change in strain rate with strain so that stress-strain curves can be constructed (Ref 28).

The percent reduction in area is the primary result obtained from the hot tension test. This measure of ductility is used to assess the ability of the material to withstand crack propagation. Reduction in area adequately detects small ductility variations in materials caused by composition or processing when the material is of low-to-moderate ductility. It does not reveal small ductility variations in materials of very high ductility.

A general qualitative rating scale between reduction in area and workability is given in Table 2. This correlation was originally based on superalloys. In addition to ductility measurement, the ultimate tensile strength can be determined with the Gleeble test. This gives a measure of the force required to deform the material.

Table 2 Qualitative hot-workability ratings for specialty steels and superalloys

Hot tensile reduction in area[a], %	**Expected alloy behavior under normal hot reductions in open-die forging or rolling**	Remarks regarding alloy hot-working practice
<30	Poor hot workability, abundant cracks	**Preferably not rolled or open-die forged; extrusion may be feasible; rolling or forging should be attempted only with light reductions, low strain rates, and an insulating coating.**
30-40	Marginal hot workability, numerous cracks	**This ductility range usually signals the minimum hot-working temperature; rolled or press forged with light reductions and lower-than-usual strain rates**

40-50	Acceptable hot workability, few cracks	**Rolled or press forged with moderate reductions and strain rates**
50-60	Good hot workability, very few cracks	**Rolled or press forged with normal reductions and strain rates**
60-70	Excellent hot workability, occasional cracks	**Rolled or press forged with heavier reductions and higher strain rates than normal if desired**
>70	**Superior hot workability, rare cracks. Ductile ruptures can occur if strength is too low.**	**Rolled or press forged with heavier reductions and higher strain rates than normal if alloy strength is sufficiently high to prevent ductile ruptures**

(a) Ratings apply for Gleeble tension testing of 6.4-mm (0.250 in.) diam specimens with 25-mm (1 in.) head separation.

Hot Tension Test Procedure Variations. Two variations of the hot tension test can be used to establish the temperature limits of hot working: on-heating tests and on-cooling tests. The on-heating test method is used for a material for which little or no hot-working information is available. The specimens are resistance heated to the test temperature, held for 1 to 10 min, and pulled to fracture at a crosshead rate approximating the strain rate of plant practice.

The reduction in area versus test temperature obtained by the on-heating testing of a heat-resistant alloy is shown in Fig. 17. The optimal reheat temperature for working lies between the peak ductility temperature and the zero-ductility temperature. The test clearly distinguishes between ingots prepared by electroslag remelting (ESR) and vacuum arc remelting (VAR) practices.

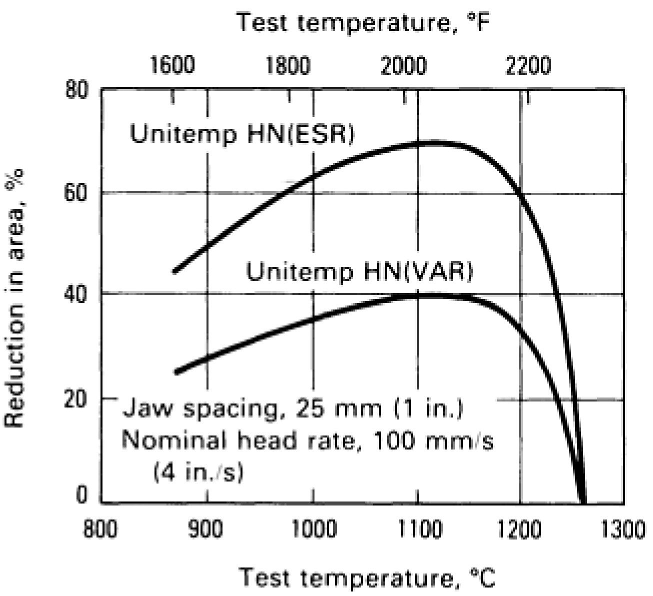

Fig. 17 Reduction in area versus test temperature obtained by hot tension testing on heating. Specimens were heated to the test temperature, held 5 min, and pulled to fracture.

The on-cooling test procedure is used to establish the optimal preheat temperature in this range. The objective is to determine which hot-working temperature provides the highest ductility over the broadest temperature range without risking permanent damage to the material from overheating. Unmachined specimen blanks are heat treated in a furnace at a given preheat temperature and duration to duplicate a furnace soak commensurate with the workpiece size and the hot-working operation. Samples are water quenched from the soak temperature to retain the high-temperature structure.

After machining, tensile specimens are heated to the preheat temperature in the Gleeble unit and held for 1 to 10 min to dissolve any phases that may have precipitated during cooling. Specimens are then cooled to a series of temperatures below the preheat temperatures at 28 to 55 °C (50 to 100 °F) intervals, held 5 s at the test temperature, and pulled to fracture at the appropriate head speed.

Data obtained from on-cooling tests conducted on three test specimens that were subjected to varying preheat temperatures are shown in Fig. 18. A preheat temperature of 1205 °C (2200 °F) was selected as optimal in this example, because it produced a slightly higher and rather broad band of high ductility. The minimum hot-working temperature was established as the temperature at which the reduction in area decreases to the 50% level for typical workpiece reductions.

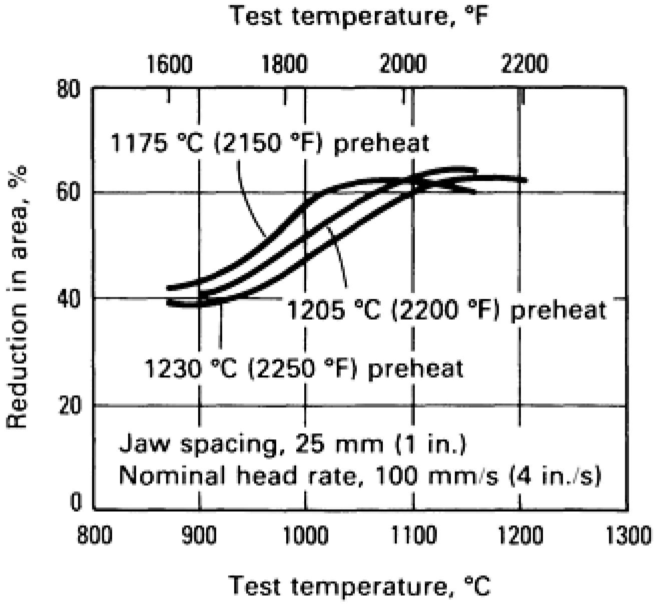

Fig. 18 Reduction in area versus testing temperature for Unitemp HN (ESR) generated by testing on cooling. Specimen blanks were furnace soaked 2 h at the preheat temperatures. The specimens were then heated to the preheat temperatures in the Gleeble unit, held 5 min, cooled to the test temperature, held 5 s, and pulled to fracture.

On-cooling hot tension testing is useful, because the brief hold times for on-heating tests may not develop a grain size representative of that temperature, or they may be insufficient to dissolve or precipitate a phase that will occur during an actual furnace soak prior to hot working. In addition, most industrial hot-working operations are performed while the workpiece temperature cools slowly. On-cooling tests also indicate how closely the zero-ductility temperature can be approached before hot ductility is severely reduced.

Workability Tests

George E. Dieter, University of Maryland

Forgeability Tests

Basically, all forging processes consist of the compressive deformation of a metal workpiece between a pair of dies (Ref 14). The two broad categories of forging processes are open-die and closed-die modes. The simplest open-die forging operation is the upsetting of a cylindrical billet between two flat dies. The compression test is a small-scale prototype of this process. As the metal flows laterally between the advancing die surfaces, there is less deformation at the die interfaces (because of the friction forces) than at the midheight plane. Therefore, barreling occurs on the sides of the upset cylinder. Generally, metal flows most easily toward the nearest free surface because this path presents the least friction.

Closed-die forging is done in closed or impression dies that impart a well-defined shape to the workpiece. The degree of lateral constraint varies with the shape of the dies and the design of the peripheral areas where flash is formed, as well as with the same factors that influence metal flow in open-die forging (amount of reduction, frictional boundary conditions, and heat transfer between the dies and the workpiece).

Because forging is a complex process, a single workability test cannot be relied on to determine forgeability. However, several testing techniques have been developed for predicting forgeability, depending on alloy type, microstructure, die geometry, and process variables. This section will summarize some of the common tests for determining workability in open-die and closed-die forging.

Wedge-Forging Test. In this test, a wedge-shaped piece of metal is machined from a cast ingot or wrought billet and forged between flat, parallel dies (Fig. 19). The dimensions of the wedge must be selected so that a representative structure of the ingot is tested. Coarse-grain materials require larger specimens than fine-grain materials. The wedge-forging test is a gradient test in which the degree of deformation varies from a large amount at the thick end (h_2) to a small amount or no deformation at the thin end (h_1). The specimen should be used on the actual forging equipment in which production will occur to allow for the effects of deformation velocity and die chill on workability.

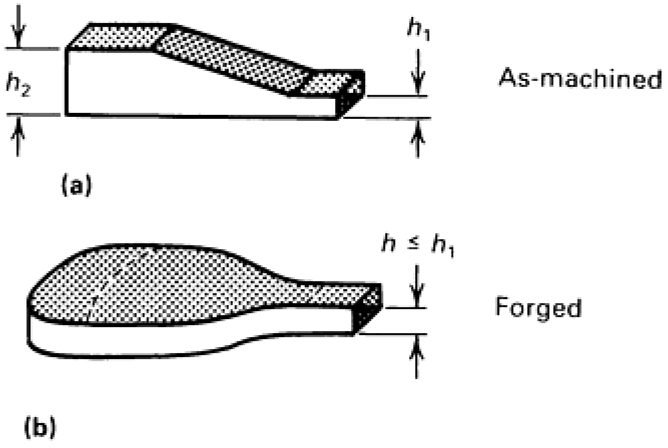

Fig. 19 Specimens for the wedge test. (a) As-machined specimen. (b) Specimen after forging.

Tests can be made at a series of preheat temperatures, beginning at about nine-tenths of the solidus temperature or the incipient melting temperature. After testing at each temperature, the deformation that causes cracking can be established. In addition, the extent of recrystallization as a function of strain and temperature can be determined by performing metallographic examination in the direction of the strain gradient.

The sidepressing test consists of compressing a cylindrical bar between flat, parallel dies where the axis of the cylinder is parallel to the surfaces of the dies. Because the cylinder is compressed on its side, this testing procedure is termed sidepressing. This test is sensitive to surface-related cracking and to the general unsoundness of the bar, because high tensile stresses are created at the center of the cylinder (Fig. 20).

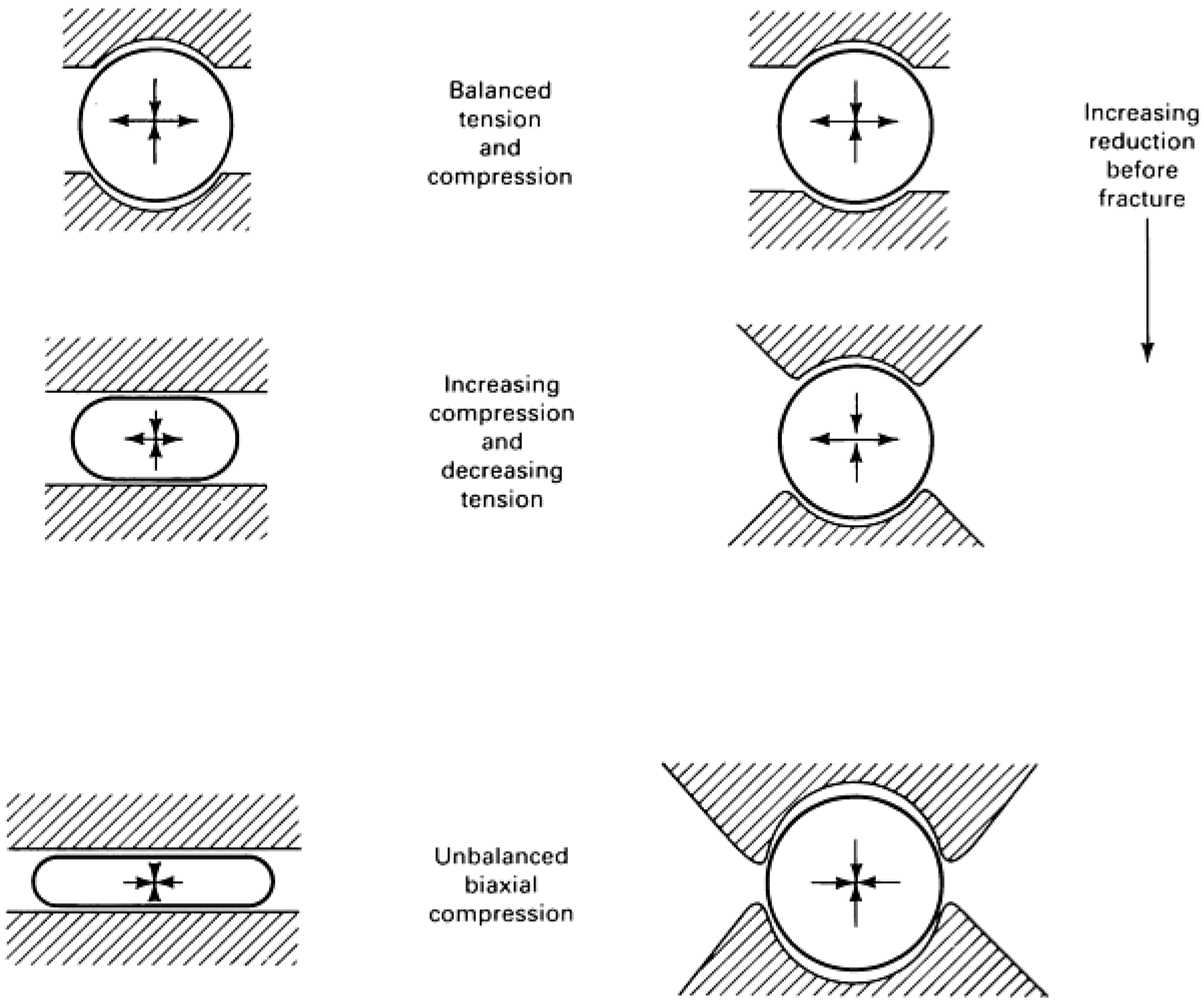

Fig. 20 Effects of billet shape and degree of enclosure on stress state in forging with good lubrication and no chilling. Source: Ref 29.

For a cylindrical bar deformed against flat dies, the tensile stress is greatest at the start of deformation and decreases as the bar assumes more of a rectangular cross section. As shown in Fig. 20, the degree of tensile stress can be reduced at the outset of the tests by changing from flat dies to curved dies that support the bar around part of its circumference.

The typical sidepressing test is conducted with unconstrained ends. In this case, failure occurs by ductile fracture on the expanding end faces. If the bar is constrained to deform in plane strain by preventing the ends from expanding, deformation will be in pure shear, and cracking will be less likely. Plane-strain conditions can be achieved if the ends are blocked from longitudinal expansion by machining a channel or cavity into the lower die block.

The notched-bar upset test is similar to the conventional upset test, except that axial notches are machined into the test specimens (Ref 30). The notched-bar test is used with materials of marginal forgeability for which the standard upset test may indicate an erroneously high degree of workability. The introduction of notches produces high local stresses that induce fracture. The high levels of tensile stress in the test are believed to be more typical of those occurring in actual forging operations.

Test specimens are prepared by longitudinally quartering a forging billet, thus exposing center material along one corner of each test specimen (Fig. 21). Notches with 1.0 or 0.25 mm (0.04 or 0.01 in.) radii are machined into the faces as shown. A weld button is frequently placed on one corner to identify the center and surface material of alloys that are difficult to forge because of segregation.

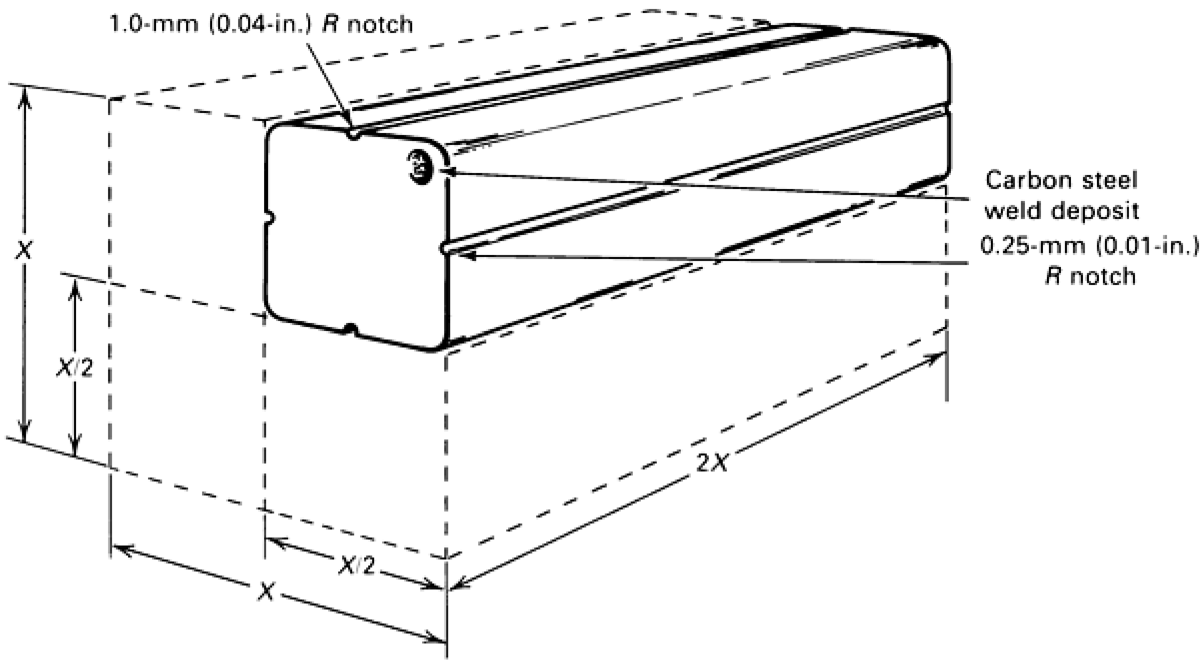

Fig. 21 Method of preparing specimens for notched-bar upset forgeability test. Source: Ref 30.

Specimens are heated to predetermined temperatures and upset about 75%. The specimen is oriented with the grooves (notches) in the vertical direction. Because of the stress concentration effect, ruptures are most likely to occur in the notched areas. These ruptures can be classified according to the rating system shown in Fig. 22. A rating of 0 indicates that no ruptures are observed, and higher numbers indicate an increasing frequency and depth of rupture.

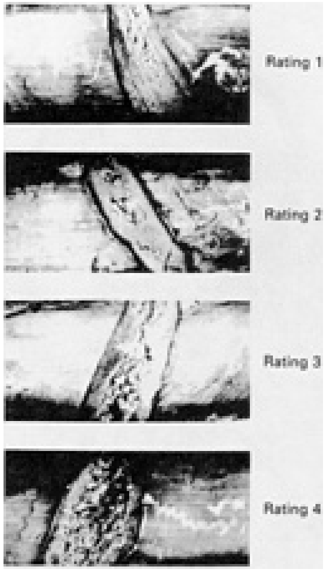

Fig. 22 Suggested rating system for notched-bar upset test specimens that exhibit progressively poorer forgeability. A rating of 0 indicates freedom from ruptures in the notched area. Source: Ref 30.

Figure 23 shows roll-forged rings made from two heats of type 403 stainless steel. The ring shown in Fig. 23(a) came from a billet with a notched-bar forgeability rating of 0. The billet shown in Fig. 23(b) had a forgeability rating of 4.

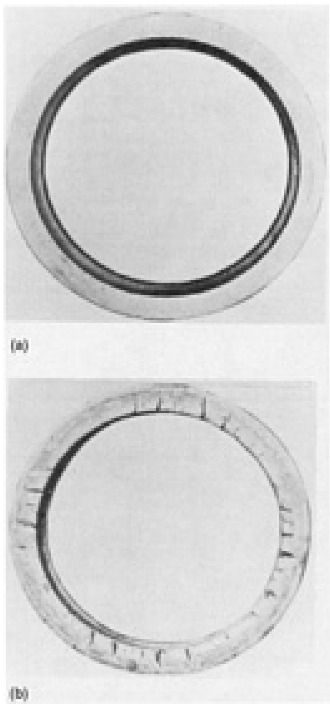

Fig. 23 Rolled rings made from two heats of type 403 stainless steel exhibiting different forgeability ratings in notched-bar upsetting tests. (a) Forgeability rating is 0. (b) Forgeability rating is 4. Courtesy of Ladish Company.

Truncated Cone Indentation Test. This test involves the indentation of a cylindrical specimen by a conical tool (Fig. 24). As a result of the indentation, cracking is made to occur beneath the surface of the testpiece at the tool/material interface. The reduction (measured at the specimen axis) at which cracking occurs can be used to compare the workability of different materials. Alternatively, the reduction (stroke) at which a fixed crack width is produced or the width of the crack at a given reduction can be used as a measure of workability.

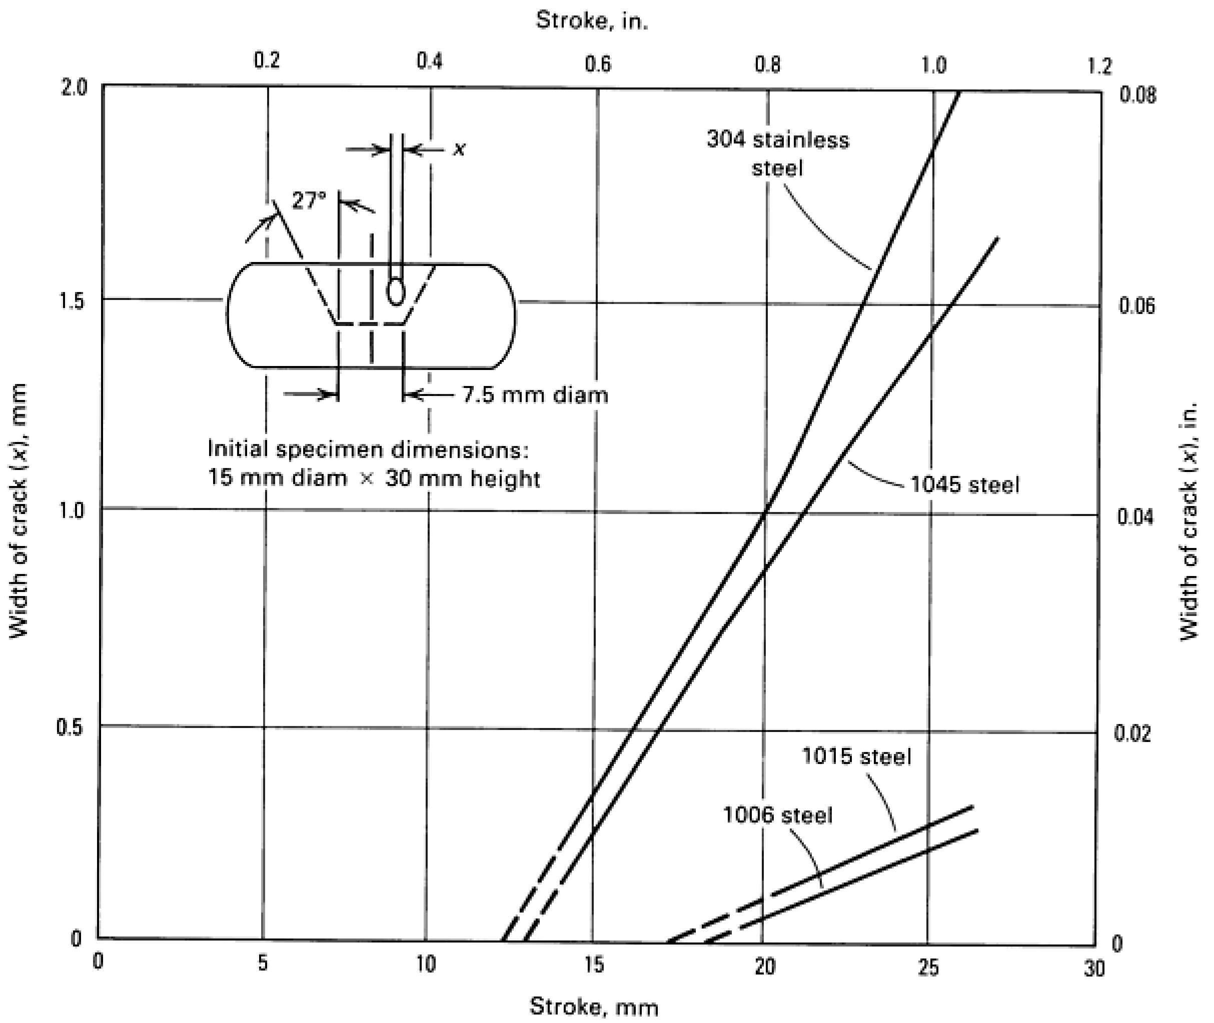

Fig. 24 Relationship between crack width and stroke in truncated cone indentation test for workability of various steels at cold-forging temperatures.
