This momentum transfer between the waterjet and the abrasive is a complex phenomenon. There is a limited dynamic stability of the high-pressure waterjet, and it breaks into droplets that accelerate the solid particles. In addition, the solid particles impose drag forces on the waterjet.

The result of this momentum transfer between the water and the abrasive particles is a focused high-velocity stream of abrasive. The cutting rate is controlled by changing the feed rate, the standoff distance, the waterjet pressure, or the abrasives.

Abrasive System Components

The primary components of an abrasive waterjet cutting system are the dual intensifier pump, the nozzle assembly, and the abrasive catcher assembly. These components are connected by a network of hoses and swivels and are controlled by a system of control valves and sensors (Fig. 3).

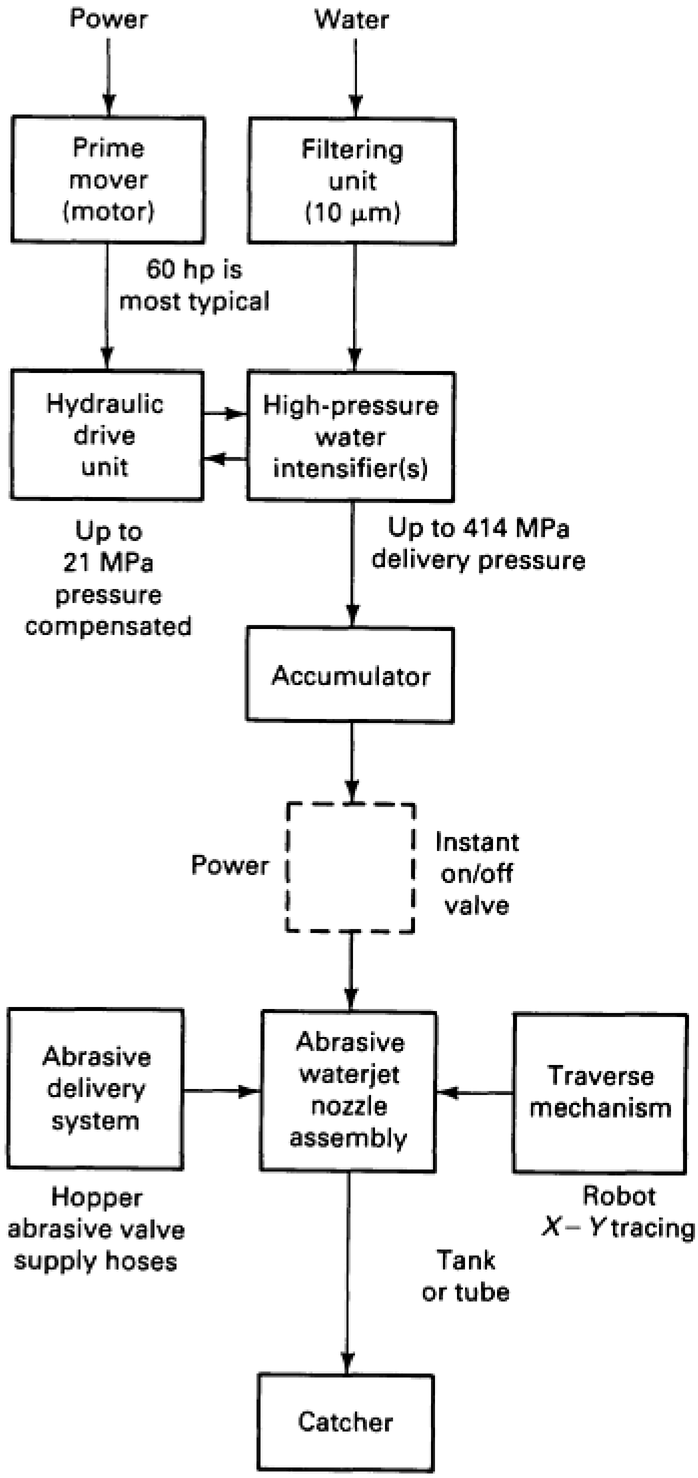

Fig. 3 Block diagram of abrasive waterjet system components.

Dual Intensifier Pump. A single or dual intensifier pump driven by a 45 kW (60 hp) motor creates a water pressure of 207 to 414 MPa (30 to 60 ksi) and a flow rate to 13 L/min (3.5 gal./min). The motor drives a hydraulic radial piston pressure compensated pump. With a hydraulic oil reservoir of approximately 140 L (37 gal.), the pump pressurizes the hydraulic oil to 19.0 MPa (3 ksi). This drives two dual water intensifiers with an intensification ratio of 20 to 1; that is, the water pressure is twenty times the oil pressure.

The pressure intensifier principle is best illustrated by the force equilibrium of the double-acting piston (Fig. 4). Hydraulic oil pressure acting on the piston results in a force on the plunger pressurizing the water in the small chamber. Force equilibrium is achieved when the water pressure equals the hydraulic oil pressure multiplied by the effective area of the piston divided by the area of the plunger (assuming no friction losses). The ratio of the effective piston area to the plunger area is termed the pressure intensification ratio. Because the intensification ratio is constant by virtue of the fixed piston-to-plunger-diameter ratio, water pressure can be regulated by controlling the hydraulic oil pressure.

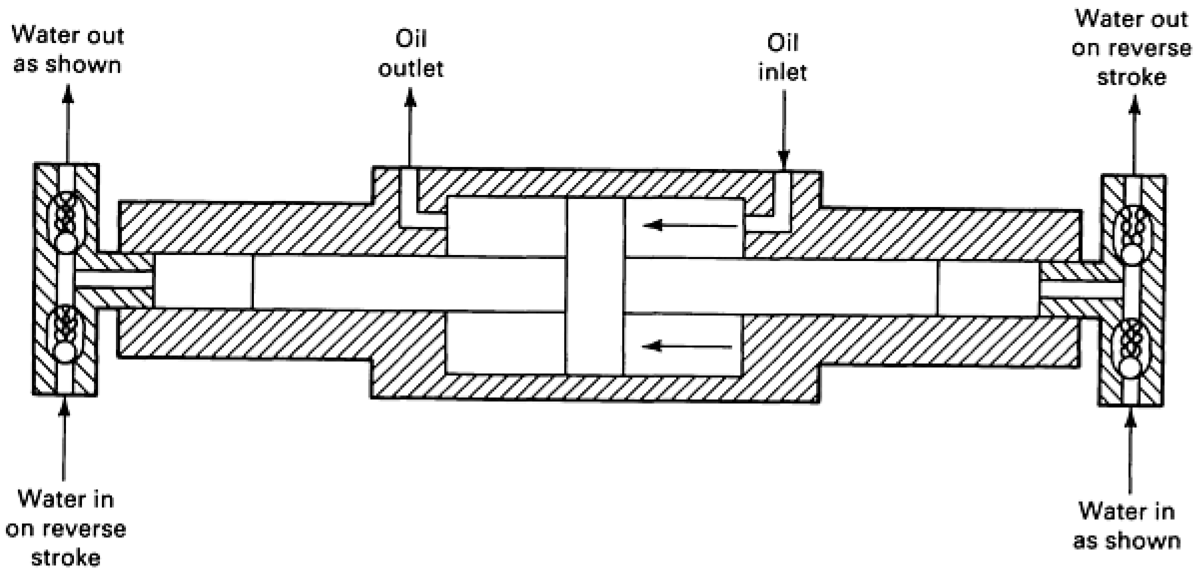

Fig. 4 Cross-sectional view of the pressurization of water to 414 MPa (60 ksi) using the fluid pressure intensifier principle.

To dampen pressure oscillations in the high-pressure output, the high-pressure water is routed to a shock attenuator. Sensors are installed throughout the intensifier pump to monitor strategic flow rates, temperatures, fluid levels, and operating conditions. Before the water enters the intensifier pumping system, it is filtered in three stages from 10 to 1 to 0.05 μm (400 to 40 to 2 μin.) to remove small particles of matter and minerals that could damage seals and valves of the pump. It is necessary to prevent cavitation of the water as it enters the intensifier pump systems. The inlet water pressure is increased to a minimum of 410 kPa (60 psi).

The microprocessor-based controller, through operator-actuated keypad commands, determines the oil pressure delivered to the intensifier by the electric motor driven hydraulic pump. Incoming filtered water is pressurized through the principle of water intensification and routed to the waterjet cutting equipment. Figure 5 illustrates the principal parts of the intensifier pump.

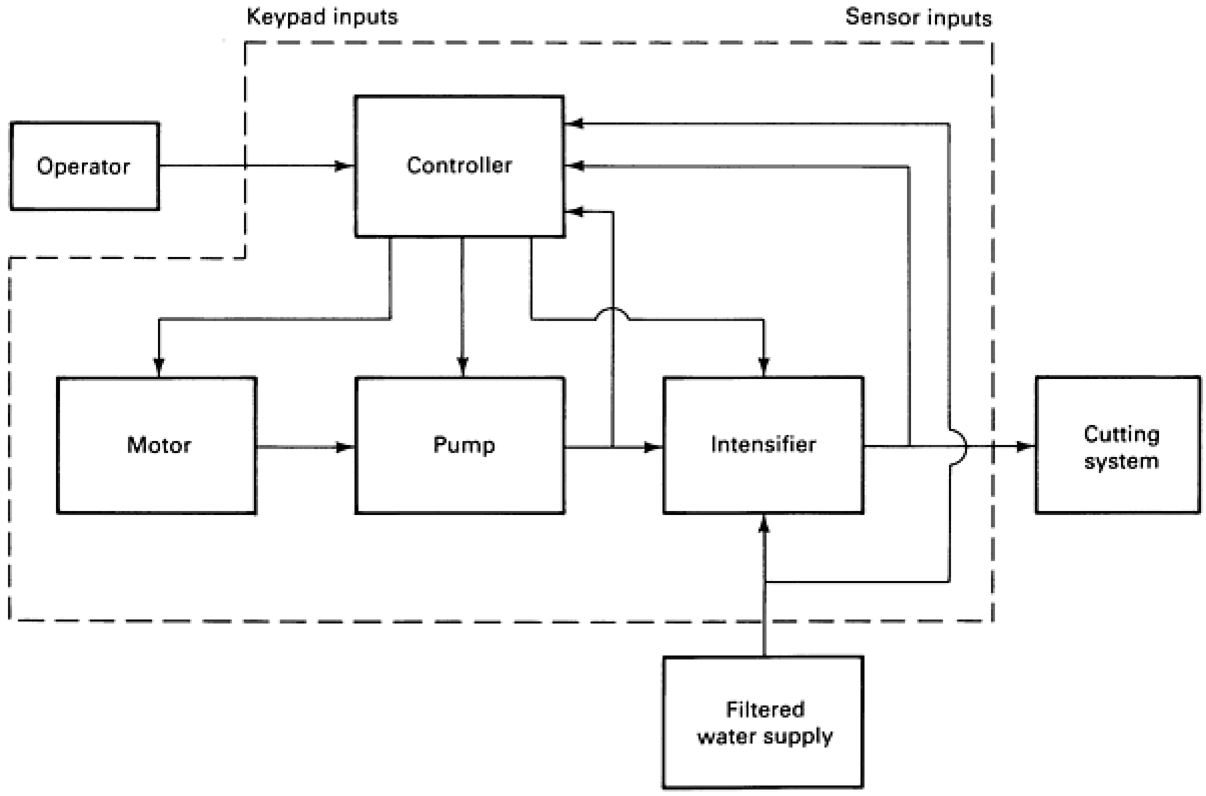

Fig. 5 Block diagram of intensifier pump assembly and its relationship to the microprocessor-based controller and cutting system.

Particle Stream Erosion Nozzle. The high-pressure water is directed through stainless steel lines and swivel joints to the particle stream erosion nozzle assembly. Here the water flows through a 0.13 to 0.51 mm (0.005 to 0.020 in.) diam sapphire jewel orifice in the mixing chamber. The dry abrasive particles are fed into the mixing chamber to become entrained in the water stream (due to the venturi effect created) and then directed through a 0.51 to 2.23 mm (0.020 to 0.090 in.) diam tungsten carbide nozzle. At this point, cutting of material takes place directly under the nozzle as both water and abrasives exit the nozzle at velocities of approximately 640 m/s (2100 ft/s) in a coherent, focused stream ranging in diameter from 1.0 to 1.5 mm (0.040 to 0.060 in.).

Operating life of the synthetic sapphire orifice, which has a 5-min replacement time, is 250 to 500 h. The operating life of the tungsten carbide abrasive nozzle is limited to 0.50 to 6 h because of the erosive effects of the accelerated water/abrasive stream.

The abrasive waterjet catcher system collects the spent fluid after it passes through the material being cut. The design of the catcher system is based on whether the cutting system uses a stationary nozzle or a moving nozzle. For a stationary nozzle, the workpiece is fed to the cutting operation, and a tank is used to collect the spent fluid (Fig. 6). A moving nozzle can be used with the same type of setup if the cutting area is contained within the tank area. The tank should be lined with ceramic pieces to suppress the cutting or piercing of the tank lining by the abrasive waterjet. Multiple pieces of concrete block, brick, thick slate, and white iron have been used to alleviate this problem. The pieces work well with a moving nozzle, but must be moved or replaced at varied intervals. Abrasives settle to the bottom, and the tank requires periodic cleaning. The accumulated water is drawn off through a valve placed low in the tank wall.

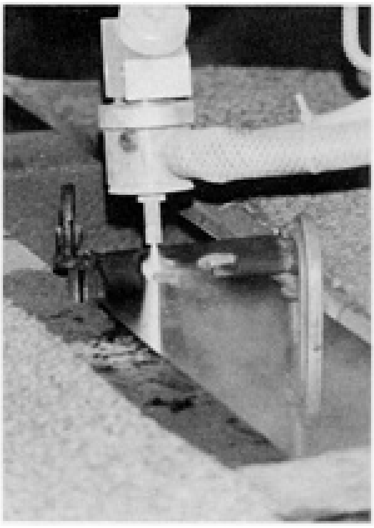

Fig. 6 Stationary waterjet nozzle cutting through a movable workpiece (René 100 alloy gating contacts). Courtesy of Department of Industrial and Manufacturing Engineering, University of Rhode Island.

A system incorporating a funnel-shaped catcher containing metallic shot to disperse the energy of the liquid has been designed for use with a movable nozzle. This device has a relatively long life expectancy as a catcher.

Abrasive Waterjet Cutting

J. Gerin Sylvia, Department of Industrial and Manufacturing Engineering, University of Rhode Island

Abrasives

Surface finish is an important part of the performance, wear, and appearance of a product. Parts may perform better or may have a higher fatigue strength or a better appearance with a higher degree of surface finish.

Two distinct surface textures are produced when cutting with an abrasive waterjet. The top half of the thickness may have a surface roughness of 3.3 to 10 μm (130 to 400 μin.). The bottom half of the cut may have striations formed by the exit of the garnet from the workpiece (Fig. 7).

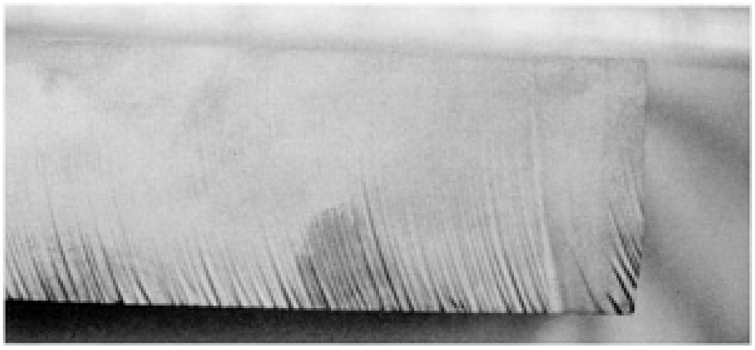

Fig. 7 Striations formed by the exit of garnet abrasives at the bottom of a workpiece. Material is 22 mm ($\frac{7}{8}$ in.) thick 4340 steel cut at 38 mm/min ($1\frac{1}{2}$ in./min). Top surface has a 3.6 μm (140 μin.) surface finish; bottom surface has a 4.7 μm (185 μin.) surface finish. Courtesy of Department of Industrial and Manufacturing

Engineering, University of Rhode Island.

Garnet Versus Silica. Tables 1 and 2 list surface finish ranges for garnet and silica abrasives. The following conclusions can be drawn from these data:

- Traverse cutting speed is the most important variable affecting surface finish
- Flow rate is the second most significant variable affecting surface finish
- Pressure is an important variable affecting surface finish, but is dependent on the specific garnet size
- Garnet will cut faster than a comparably sized silica abrasive
- A 60 grit garnet will cut 23.5% faster than a 60 to 80 grit silica abrasive
- Silica sands produce a higher-quality surface finish than garnet
- The highest-quality surface finish occurs with the slowest comparable cutting speed and at the highest flow rate for both garnet and silica

All surface finish values read off 300-unit scale.

Thus, garnet is an effective abrasive. Silica sand may be adequate for cleaning operations involving the cutting of thin metals or composites. Abrasives such as aluminum oxide or silicon carbide should be used for tough materials such as ceramics. However, these harder abrasives generally decrease the life of the nozzle.

Angular grain shapes will shear the workpiece much more efficiently than round grain abrasives. The abrasive particles should be of uniform size.

Reclaiming of abrasives is not feasible, because much time and effort would be required in drying and then regrading the particle sizes. The amount of abrasive that would be reusable does not warrant the expense. New graded garnet and silicon sands are readily available and inexpensive.

Cleanup and disposal of the abrasive fluid can be a problem. Because the spent abrasive slurry has the consistency of mud, it is advisable to wait until the slurry is dry before attempting cleanup and disposal. Garnet is environmentally safe to dispose of. However, the particles mixed in with it from the material being cut may be classified as hazardous waste, and their disposal may be subject to both state and federal EPA regulations.

Abrasive Waterjet Cutting

J. Gerin Sylvia, Department of Industrial and Manufacturing Engineering, University of Rhode Island

Calculation of Abrasive Waterjet Speeds

The following parameters are assumed:

- Sand flow rate of 0.68 kg/min (1.5 lb/min)
- Water flow rate of 4.5 L/min (1.2 gal./min)
- Jewel size of 0.46 mm (0.018 in.) diameter

Using the continuity of momentum equation and assuming that the water is not compressed at all, the theoretical (ideal) velocity of the water exiting the jewel orifice is 461 m/s (1513 ft/s), and the theoretical velocity of the garnet and water at the nozzle is 402 m/s (1319 ft/s).

If, instead of 4.5 L/min (1.2 gal./min), it is assumed that the water flow rate is 3.84 L/min (1 gal./min)* and that the water is compressed by 8%, the actual flow rate is 3.5 L/min (0.92 gal./min). Therefore, the actual velocity of the water exiting the jewel orifice is 354 m/s (1160 ft/s), and the actual velocity of the garnet and water at the nozzle is 297 m/s (973 ft/s). The speed of sound under normal atmospheric conditions is about 335 m/s (1100 ft/s).

The following examples illustrate the effect of different water pressures and garnet flow rates on a single thickness of two different metals as well as the effects of these variables on different thicknesses of one metal.

Example 1: Analysis of Varying Water Pressures and Garnet Flow Rates on 9.5 mm ($\frac{3}{8}$ in.) Thick 6061T6 Aluminum and 6.4 mm ($\frac{1}{4}$ in.) Thick Type 304 Stainless Steel.

All piercings were made with a 3.2 mm ($\frac{1}{8}$ in.) nozzle standoff having a 1.6 mm (0.062 in.) nozzle diameter. The garnet flow rates were 0.23, 0.45, 0.68, 0.79, and 0.91 kg/min (0.5, 1.0, 1.5, 1.75, and 2.0 lb/min). The water pressures were 55, 69, 103, 138, 172, and 207 MPa (8, 10, 15, 20, 25, and 30 ksi). The water pressure was held constant at 207 MPa (30 ksi) for the cutting, and the garnet flow rates were varied at 0.45, 0.68, and 0.91 kg/min (1.0, 1.5, and 2.0 lb/min).

Figures 8 and 9 show that much more time is required for piercing stainless steel than for aluminum at low water pressure. This reflects the hardness of the stainless steel. Although the two metals are not the same thickness, similarities between Fig. 8 and 9 are evident.

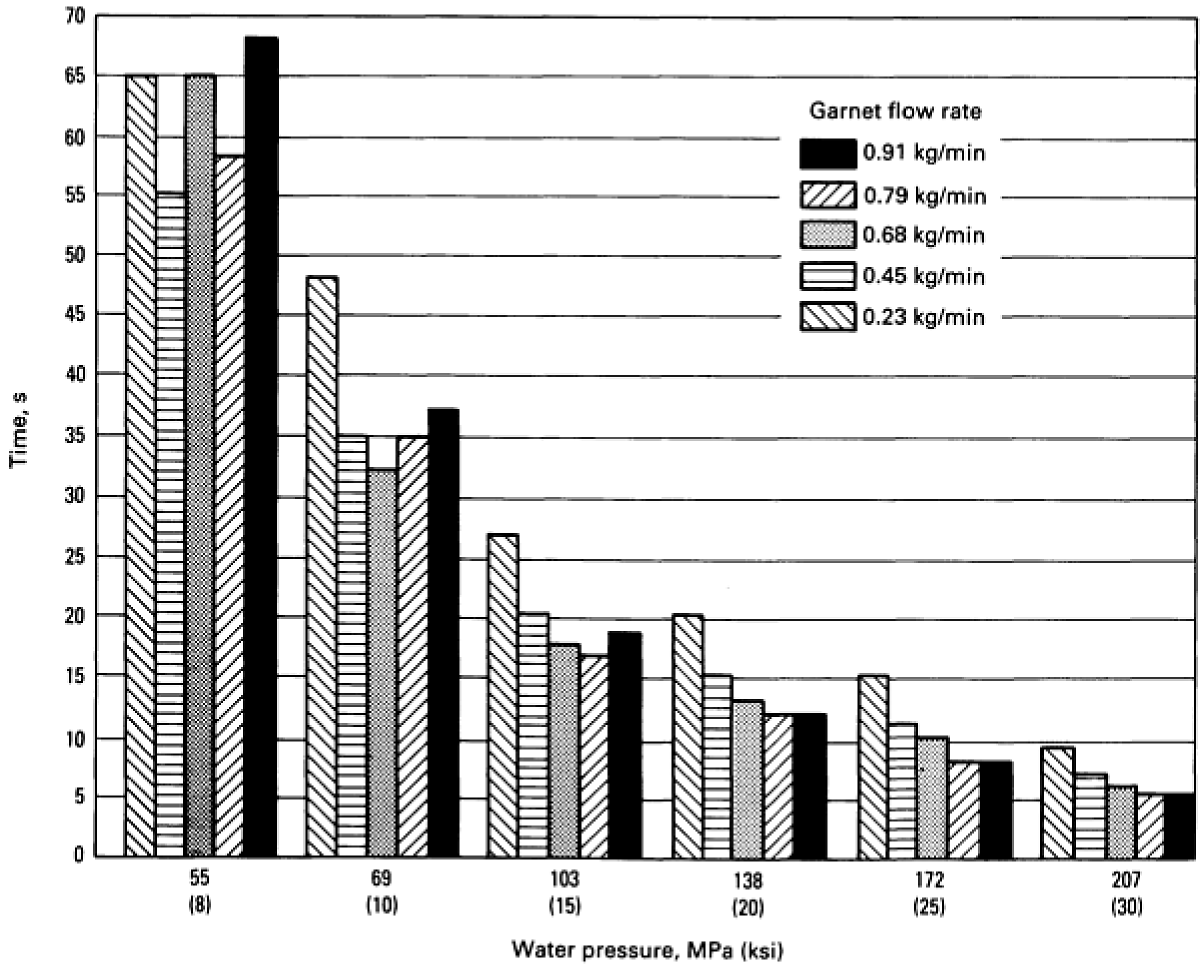

Fig. 8 Water pressures and garnet abrasive flow rates versus piercing times for 9.5 mm ($\frac{3}{8}$ in.) thick 6061 T6 aluminum. Source: Department of Industrial and Manufacturing Engineering, University of Rhode Island.

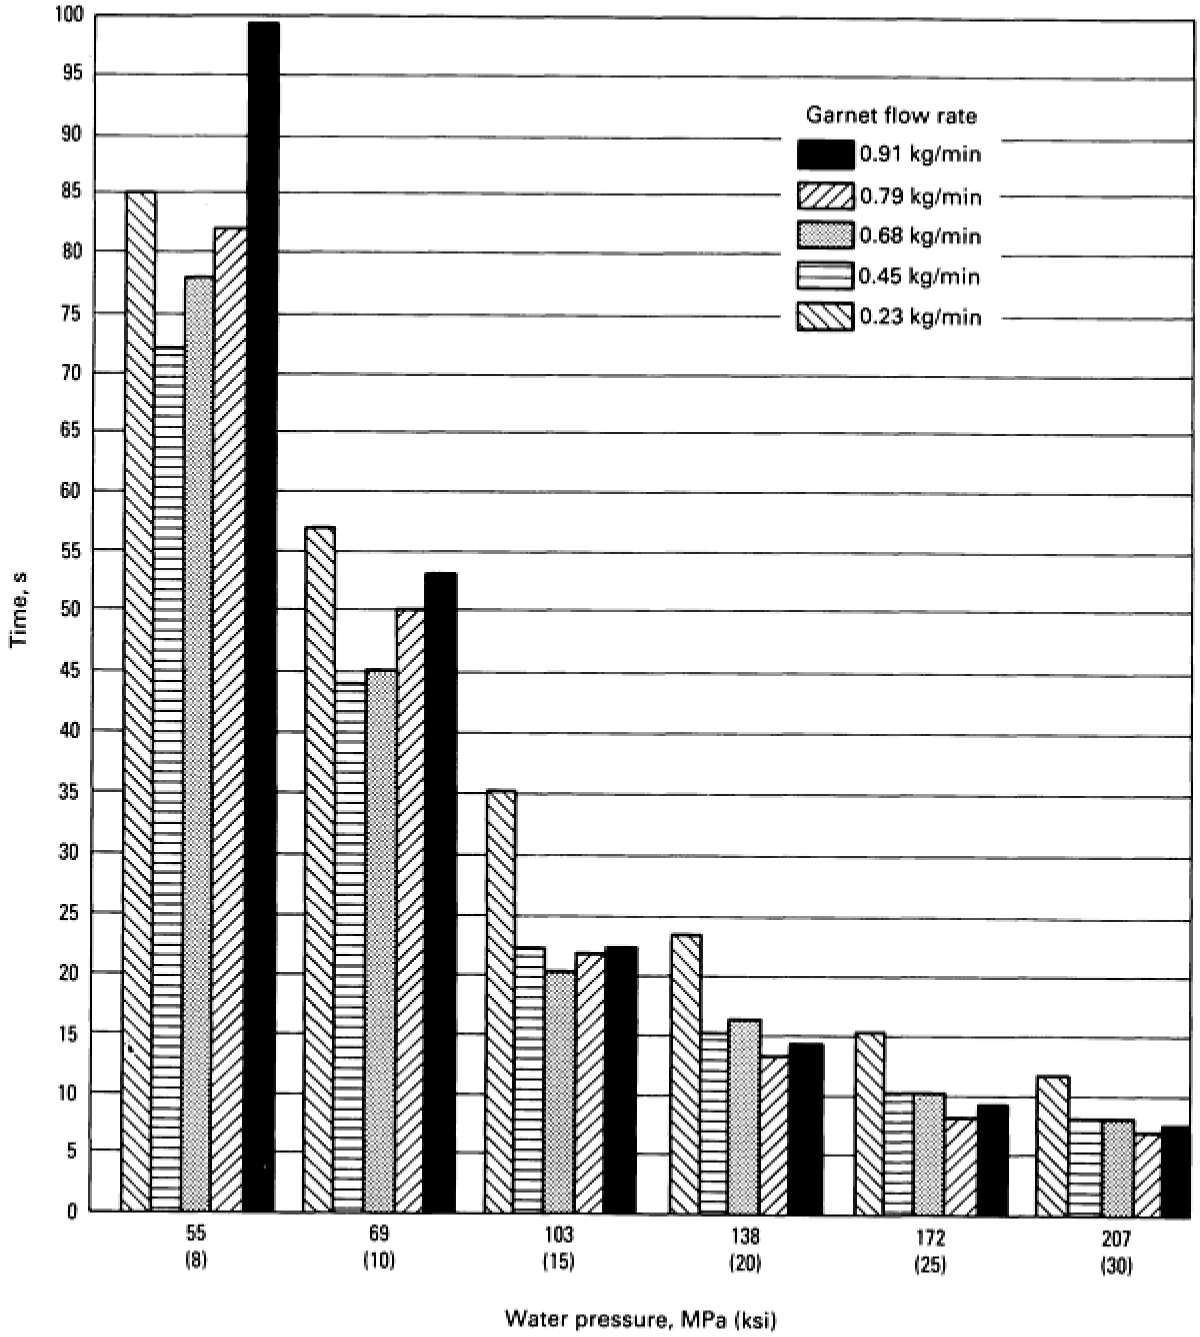

Fig. 9 Water pressure and garnet abrasive flow rates versus piercing times for 6.4 mm thick type 304 stainless steel. Source: Department of Industrial and Manufacturing Engineering, University of Rhode Island.

The garnet flow rate affects the piercing time. High garnet flow rate versus low garnet flow rate, with pressure being constant, requires a longer time for piercing.

Figure 10 shows that piercing time acts as an exponential function relating to thickness. The same trend can be seen with garnet flow rates of 0.45, 0.68, and 0.79 kg/min (1.0, 1.5, and 1.75 lb/min).

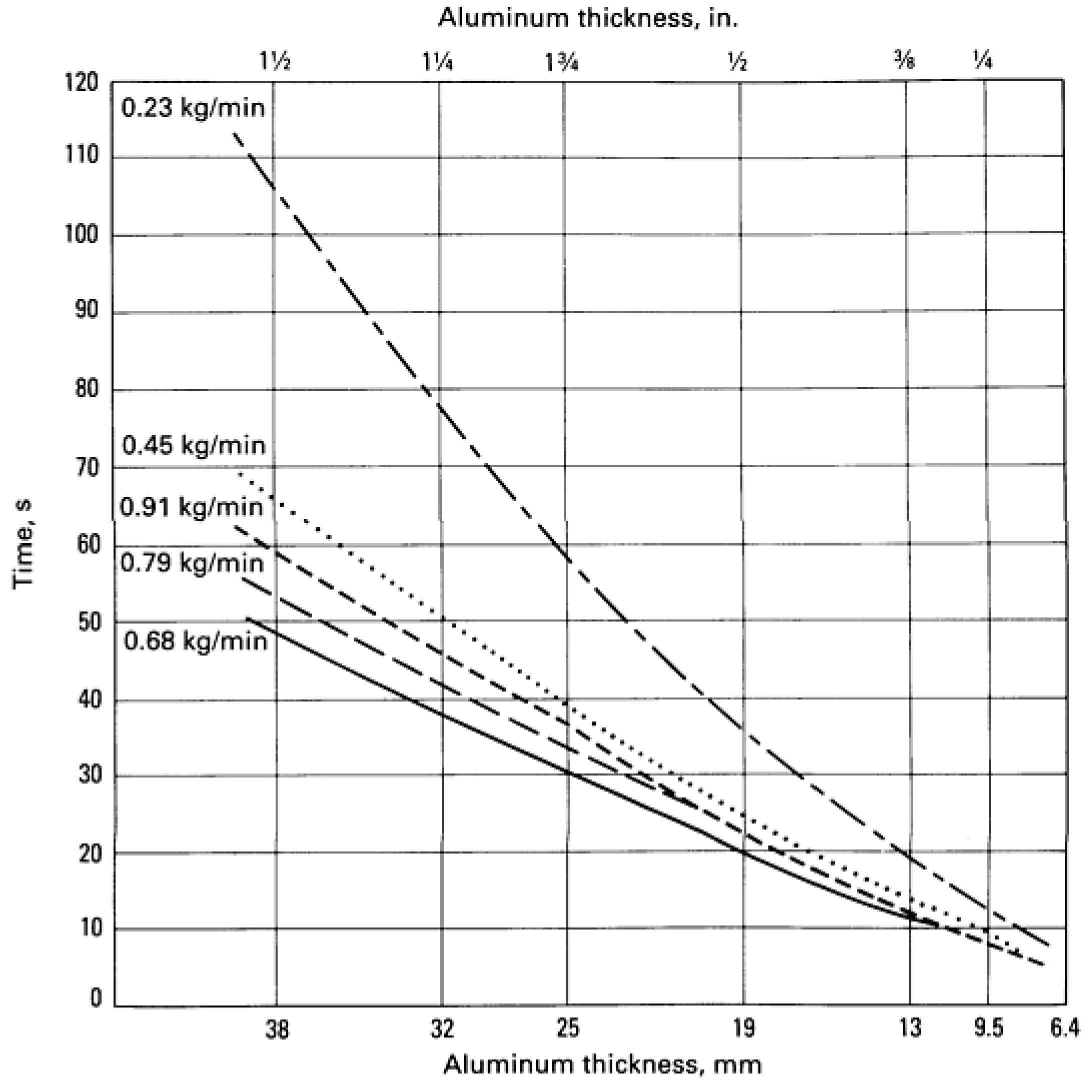

Fig. 10 Garnet abrasive flow rates and section thickness versus piercing times for 6061-T6 aluminum at a water pressure of 207 MPa (30 ksi). Source: Department of Industrial and Manufacturing Engineering, University of Rhode Island.

Figure 11 suggests that the fastest cutting rate was 134 mm/min (5.29 in./min) at garnet flow rates of 0.45 and 0.68 kg/min (1.0 and 1.5 lb/min). With a garnet flow rate of 0.68 kg/min (1.5 lb/min), the stainless steel was not cut completely through at 127 mm/min (5.0 in./min). This appears to reflect an unknown error.

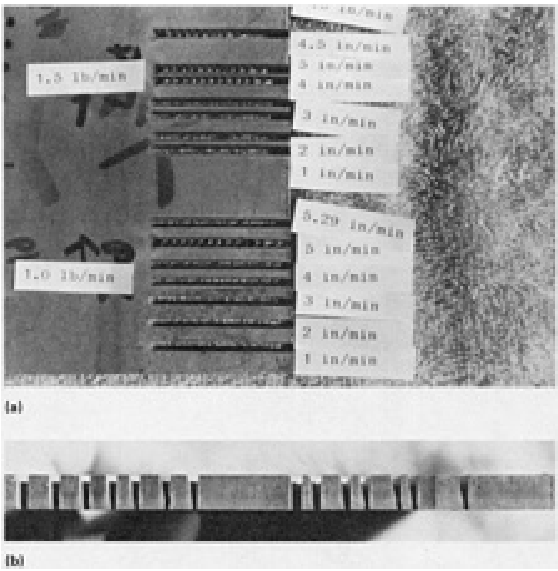

Fig. 11 Two views of 6.4 mm ($\frac{1}{4}$ in.) thick stainless steel cut at garnet flow rates of 0.45 and 0.68 kg/min (1.0 and 1.5 lb/min). (a) Top view. Top piece was cut at 250 mm/min (10 in./min). (b) Side view. Right section is 0.68 kg/min (1.5 lb/min). Left section is 0.45 kg/min (1.0 lb/min). Courtesy of Department of Industrial and Manufacturing Engineering, University of Rhode Island.

Pieces that were not cut completely through had small ridges in the half kerf of the cut. The number of ridges in the cut corresponded to an equal number of cycles of the intensifier pump.

At cutting speeds greater than 102 mm/min (4 in./min), a noticeable taper was evident in the kerf width. At cutting speeds less than 102 mm/min (4 in./min), no significant taper was evident. Varying the garnet flow rates had no significant effect on the width of the kerf.

The aluminum (Fig. 12) was cut at 305 mm/min (12 in./min) with garnet flow rates of 0.45 and 0.91 kg/min (1.0 and 2.0 lb/min). When using 0.45 kg/min (1.0 lb/min) and a cutting speed of 255 mm/min (10 in./min), there was difficulty in cutting completely through the piece.

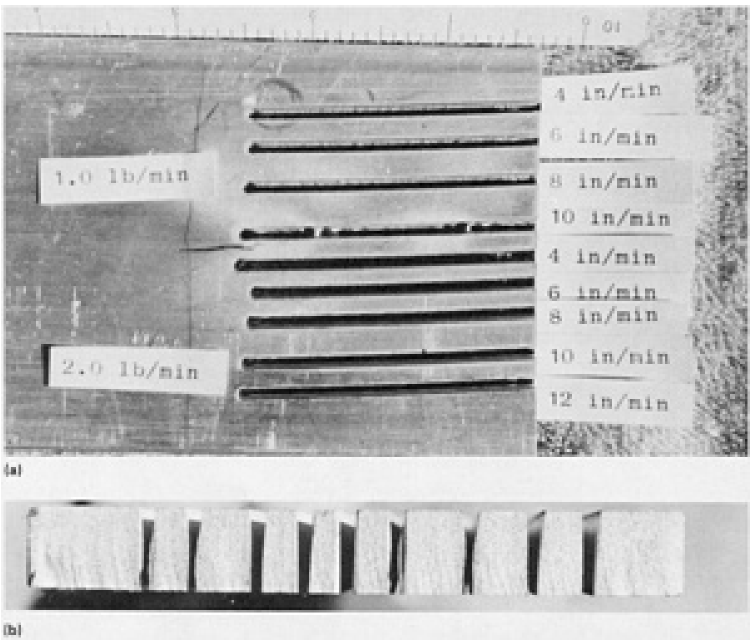

Fig. 12 Two views of 9.5 mm ($\frac{3}{8}$ in.) thick 6061 T6 aluminum cut at garnet flow rates of 0.45 and 0.91 kg/min (1.0 and 2.0 lb/min). (a) Top view. The top four cuts are at 0.45 kg/min (1.0 lb/min). The bottom five cuts are at 0.91 kg/min (2.0 lb/min). (b) Side view. Right four cuts are at 0.45 kg/min (1.0 lb/min); left five cuts are at 0.91 kg/min (2.0 lb/min). Courtesy of Department of Industrial and Manufacturing Engineering, University of Rhode Island.

Similar characteristics were found in the study of stainless steel and aluminum. There is a rounding effect, and the kerf is larger for cuts at the same speed but increasing garnet flow. As aluminum thickness increased to 38 mm (1$\frac{1}{2}$ in.), higher water pressure was needed with an increase in the garnet flow rate.

Example 2: Analysis of Varying Water Pressures and Garnet Flow Rates on Several Thicknesses of 6061 T6 Aluminum Bar Stock.

A piece of aluminum 6061 T6 bar stock 64 mm (2$\frac{1}{2}$ in.) wide by 38 mm (1$\frac{1}{2}$ in.) thick and 610 mm (2 ft) long was machined down to provide step thicknesses of 6.4, 9.5, 13, 19, 25, 32, and 38 mm ($\frac{1}{4}$, $\frac{3}{8}$, $\frac{1}{2}$, $\frac{3}{4}$, 1, 1$\frac{1}{4}$, and 1$\frac{1}{2}$ in.), as shown in Fig. 13(a).

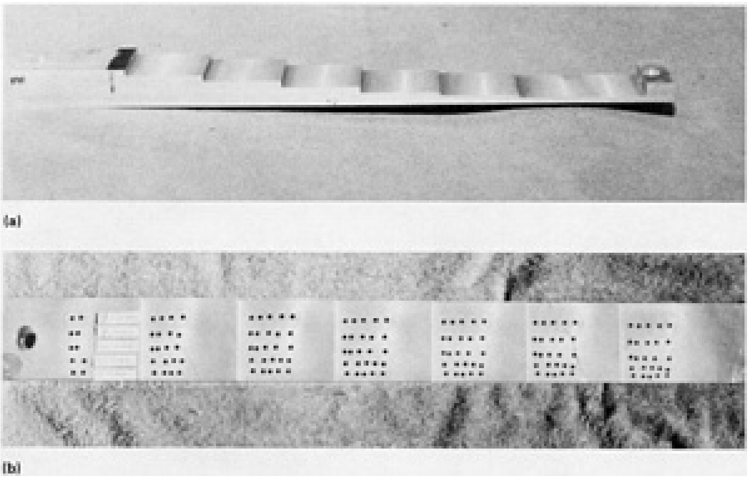

Fig. 13 Two views of various thicknesses of 6061 T6 aluminum used in piercing studies with varying water pressure and garnet flow rates used on each thickness. (a) Three-dimensional view of workpiece showing varying thickness of 640 mm (2 ft) long slab before piercing. From left to right, slab thicknesses are 38, 32, 25, 19, 13, 9.5, and 6.4 mm (1$\frac{1}{2}$, 1$\frac{1}{4}$, 1, $\frac{3}{4}$, $\frac{1}{2}$, $\frac{3}{8}$, and $\frac{1}{4}$ in.). (b) Top view of piece after piercing was performed. Left side is 38 mm (1$\frac{1}{2}$ in.) section. Courtesy of Department of Industrial and Manufacturing Engineering, University of Rhode Island.

Each section was pierced at several garnet flow rates with varying water pressures. The water pressures were 83, 103, 138, 172, and 207 MPa (12, 15, 20, 25, and 30 ksi). The garnet flow rates were 0.23, 0.45, 0.68, 0.79, and 0.91 kg/min (0.5, 1.0, 1.5, 1.75, and 2.0 lb/min).

The times were recorded using a digital timer connected to the robot controller. A new 1.6 mm (0.062 in.) nozzle was used with a 3.2 mm ($\frac{1}{8}$ in.) standoff.

An evaluation of the piercings illustrated that the entrance and exit hole sizes reflected the water pressure, sand flow, and section thickness (Fig. 13b). With the 0.23 kg/min (0.5 lb/min) garnet flow rate, there was a slight overall decrease in hole size as the section thicknesses were reduced.

Note cited in this section

* This flow rate is calculated by counting the number of times the intensifier pump cycled in 1 min. With this particular configuration, it cycled 50 times. The result obtained is (50 cycles/min) (0.076 L/cycle) = 3.8 L/min, or in English units: (50 cycles/min) (0.02 gal./cycle) = 1.0 gal./min.

Abrasive Waterjet Cutting

J. Gerin Sylvia, Department of Industrial and Manufacturing Engineering, University of Rhode Island

Factors Affecting Cut Quality

Bending of the kerf can be readily seen in the Plexiglass piece shown in Fig. 14. This bending motion occurs because the abrasive stream loses energy as it cuts and travels further down into the target piece and becomes progressively less efficient. Meanwhile, the nozzle is still moving and cutting the material at the top, and this forces the kerf to bend away from the direction of the motion of the nozzle. At high traverse speeds--especially in thick materials--this bending of the kerf will be most noticeable at the very end of the material.

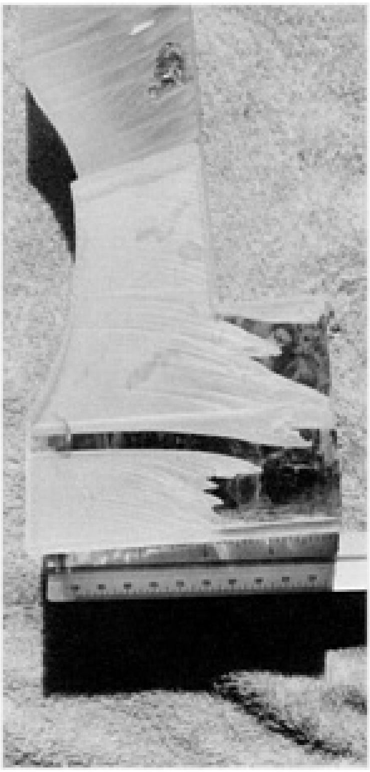

Fig. 14 Bending of kerf in a Plexiglass workpiece subjected to excessively high traverse cutting speeds. The portion at the bottom was pierced before cutting, and this caused a section of the hole to be eroded away as it was subsequently cut by abrasive waterjet nozzle. Courtesy of Department of Industrial and Manufacturing Engineering, University of Rhode Island.

This is the case with the 50 mm (2 in.) thick semihardened steel section shown in Fig. 15. Because the bend is a smooth one, the cutting action at the bottom depends on the continual cutting at the top. When the end of the material is reached, there is a sudden interruption in this bend, and the jet stream is no longer deflected onto the uncut bottom section. This leaves an uncut crescent-shaped piece at the very bottom of the end of the cut that must be cut again or broken apart by hand. This problem can be alleviated if the computer program of the robot includes provisions for either slowing the traverse rate at the very end of the cut so that the stream is barely bent and/or changing the approach angle of the nozzle at the very end of the cut.

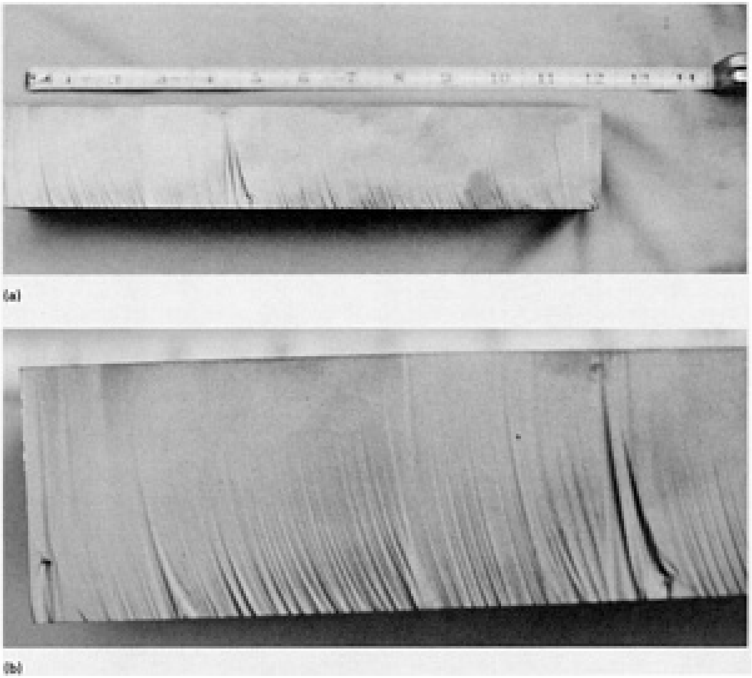

Fig. 15 Crescent-shaped striations in a 50 mm (2 in.) thick piece of semihardened steel cut at 22.3 mm/min (0.88 in./min). Direction of cut is from top of picture to bottom. (a) Waterjet failed to cut completely through the steel in two places (far left as well as at the 108 mm, or $4\frac{1}{4}$ in., mark). (b) Close-up of workpiece shows striations caused by bending of kerf, a result of the high traverse rate of the abrasive waterjet. Courtesy of Department of Industrial and Manufacturing Engineering, University of Rhode Island.

Incomplete Initial Cuts. The effects of an incomplete first cut can be seen in the Plexiglass shown in Fig. 14 and in the cut tantalum-silicon piece shown in Fig. 16. A very poor surface finish can be expected at the bottom of the cut if the abrasive waterjet stream does not cut completely through the material on the first attempt. At the bottom of the cut, where the cutting power of the garnet is expended, there are rough ridges, and the kerf width is greatly expanded because of the bouncing around of the excess garnet. This wider kerf and expanded area are especially noticeable on the cut surfaces of the tantalum-silicon piece (Fig. 16).

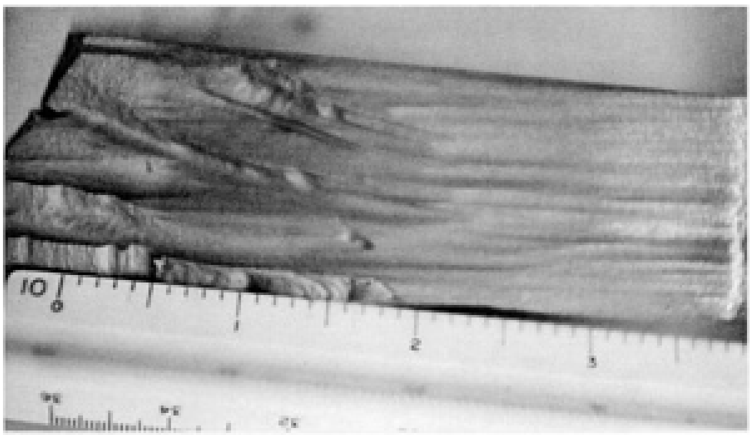

Fig. 16 Poor surface finish on a tantalum-silicon workpiece resulting from an incomplete initial cut by the abrasive waterjet stream. Left side is bottom of cut. Courtesy of Department of Industrial and Manufacturing

Engineering, University of Rhode Island.

Special Precautions for Thicknesses Over 6.4 mm ($\frac{1}{4}$ in.). Tantalum-silicon and Plexiglass samples up to 102 mm (4 in.) thick have been successfully cut with an abrasive waterjet. In cutting any material over approximately 6.4 mm ($\frac{1}{4}$ in.) thick, special precautions should be taken if a corner cut is to be made in the piece or if the material is to be pierced and then line cut.

When the Plexiglass piece shown in Fig. 14 was pierced, the hole itself was very smooth. However, when a traverse motion was initiated after piercing, the bending of the stream caused a section to the left of the hole to be cut away. This was not the desired effect. The same problem can occur when attempting a turn in the middle of the piece. The stream cannot simply bend around the turn. The nozzle must be stopped for a sufficient amount of time to allow the bend to straighten out, and then the nozzle can continue its motion.

Work Hardening. Abrasive waterjet machining alters the hardness of the cut surface of a number of metals. This slight work hardening is indicated in Table 3.

Table 3 Effect of abrasive waterjet cutting on surface hardening of metals

Metal	Hardness[a]	
	Base	Abrasive waterjet cut
Titanium	34 HRC	**34.3 HRC**
Aluminum 6061 T6	54.8 HRB	**58.7 HRB**
Magnesium	54.1 HRB	**58.4 HRB**
Carbon steel A-572	82.8 HRB	**84.5 HRB**
Tool steel	**91.5 HRB**	**93.3 HRB**

(a) Average of five measurements.

Abrasive Grit Size. Figure 17 shows how abrasive flow rates and grit number affect the depth of cut when machining cast iron. Figure 17 also indicates that neither coarse (36 and 16 grit) nor fine particles (100 and 150 grit) of garnet are the most effective abrasives. Medium abrasive of 60 and 80 grit has been found to be the most effective cutting media for a wide variety of metals.

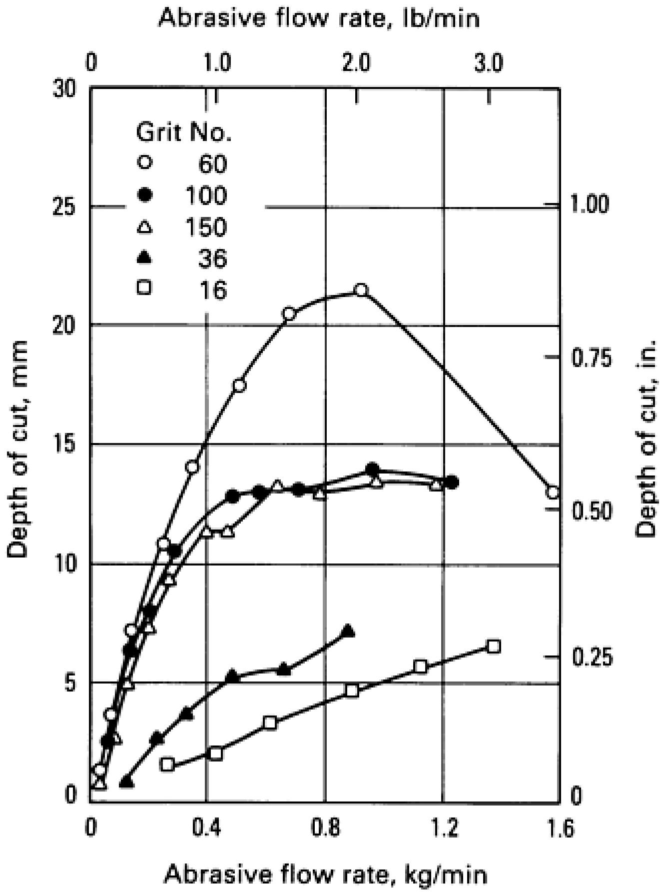

Fig. 17 Effect of abrasive flow rate and grit number on depth of cut (garnet abrasive; 220 MPa, or 32 ksi-water pressure; 0.46 mm, or 0.018 in., waterjet diameter; 152 mm/min, or 6 in./min, traverse speed; cast iron). Source: Department of Industrial and Manufacturing Engineering, University of Rhode Island.

Pressure is the most important parameter to be optimized in considering the depth of cut required in metals. Soft metals are insensitive to particle size but are very much affected by pressure. Figure 18 indicates the effect of increasing water pressure on 11 metals and a ceramic (Al_2O_3).

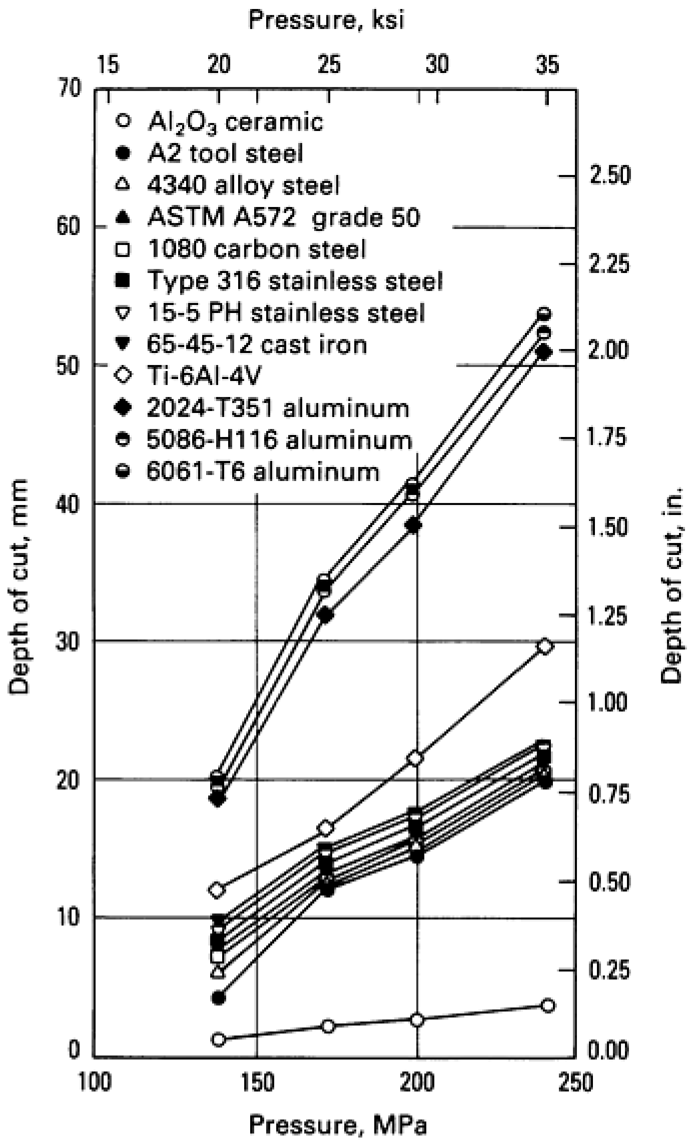

Fig. 18 Depth of cut results for different materials (60 grit garnet abrasive; 0.91 kg/min, or 2 lb/min, abrasive flow rate; 0.51 mm, or 0.020 in., waterjet diameter; 152 mm/min, or 6 in./min, traverse speed). Applications for Abrasive Waterjet Cutting

Machining of Metals and Metal-Matrix Composites. The following list summarizes the various applications for abrasive waterjet cutting:

- Foundries (removal of burned-in sand, cutting gates, and risers from cast parts)
- Naval and commercial shipyards (high-strength steel, lead, and so on)
- Railroad cars (manufacture and repair)
- Metal fabrication shops
- Aircraft manufacturers (titanium, Inconel, stacked metals)

- Heavy equipment manufacturers (tractors, hoists, cranes, industrial winches, derricks)
- Industrial vehicles (trucks, tankers, construction vehicles)
- Structural fabrications (bridges, sky-scrapers) and heavy aluminum works
- Specialty metal fabrication (titanium, nickel alloys, chromium alloys)
- Military vehicles (tanks, armored personnel carriers, landing craft)
- Oil and gas (oil well casings, pipeline repair, platform repair)
- Mining (metal structures)

The cutting speed of the abrasive waterjet has made it a valuable tool for high-volume applications. Table 4 indicates the effect of material thickness on cutting speed for eight widely used metals and an aluminum oxide ceramic.

Table 4 Effect of material thickness on abrasive waterjet cutting speed for various metals and a ceramic material

Abrasive used is garnet.

Cost savings of up to 50% have been obtained by one aerospace manufacturer using the abrasive waterjet to cut titanium and other metals for the B1-B bomber. The parts machined have included such labor-intensive components as wingsweep fairings, upper and lower panels, weapons bay doors, and miscellaneous bonded panels. These are large and complex parts--mostly 6.4 to 9.5 mm ($\frac{1}{4}$ to $\frac{3}{8}$ in.) thick and averaging 6400 to 7600 linear mm (250 to 300 in.) of periphery--that are ideally suited to a robot system capable of precision five-axis cutting over an extensive area. Data are unavailable for the 6.4 to 9.5 mm ($\frac{1}{4}$ to $\frac{3}{8}$ in.) thick material, but the firm is currently cutting 1.6 mm (0.063 in.) titanium using 0.68 kg/min (1.5 lb/min) of 60 grit red garnet abrasive at 305 mm/min (12 in./min).

Another aerospace manufacturer uses abrasive waterjet cutting to modify C-5 transport plane wing structures to upgrade C-5As to C-5Bs. Garnet is used as the abrasive to cut through aluminum and titanium up to 64 mm (2.5 in.) thick.

Where metallurgical contamination is a concern, as in the cutting of bimetallics, abrasive waterjet machining overcomes the problems of distortion, delamination, and contamination.

Abrasive waterjet cutting is also cost effective for composites. Metal-matrix composites that are cut mechanically at 25 mm/min (1 in./min) can be cut by an abrasive waterjet at 381 to 762 mm/min (15 to 30 in./min).

Figures 19, 20, 21, and 22 illustrate the wide variety of metals (including difficult-to-machine materials such as titanium and Alloy 100) and intricate shapes (specifically the bracket shown in Fig. 21 and the turbine rotor in Fig. 22) that can be easily cut with the abrasive waterjet. The stainless steel guide bracket shown in Fig. 21 illustrates profiling around corners that would be difficult to achieve with standard machining methods. This part would require 16 or more hours to complete using conventional methods; with the abrasive waterjet, such a part can be machined within a few hours.

mesh garnet abrasive at 207 MPa (30 ksi). Courtesy of Flow Systems, Inc.

Figure 23 summarizes the capabilities of the laser beam, oxyfuel, plasma arc, and the abrasive waterjet in cutting a variety of metals. Current technology limits the abrasive waterjet to cutting metals having a maximum thickness of 152 mm (6 in.). Detailed information on the other techniques is available in the articles "Thermal Cutting" and "Laser Cutting" in this Volume.

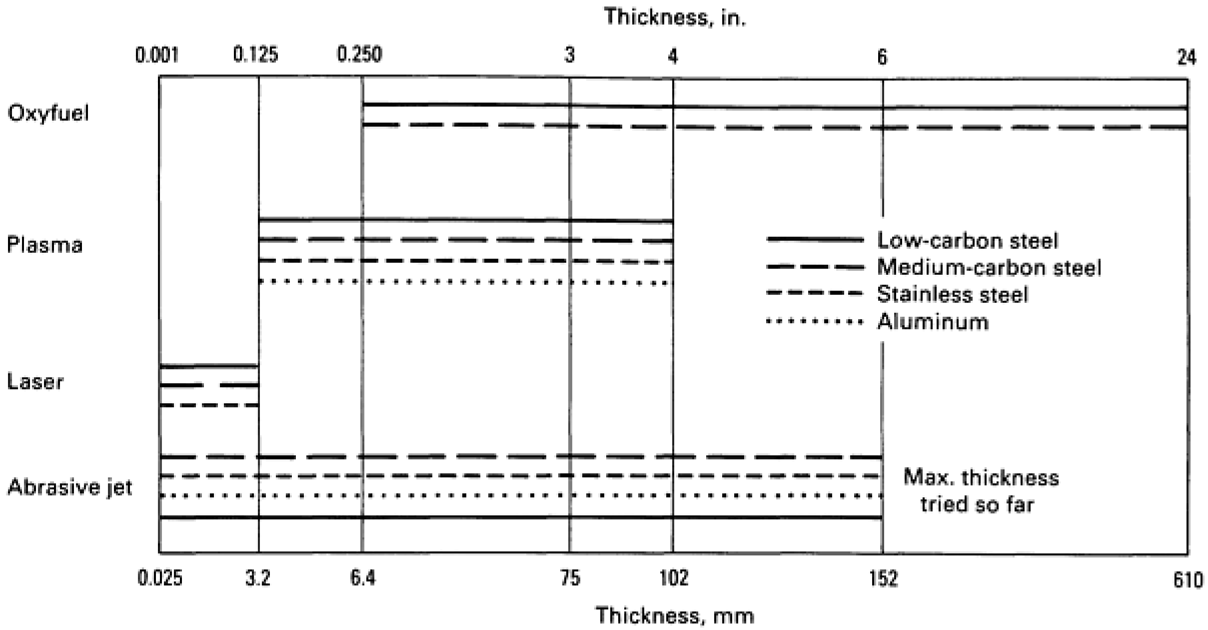

Fig. 23 Cutting thickness ranges for various cutting processes.

Machining of Nonmetallics. Figures 24 and 25 show some of the nonmetallic materials that are readily cut by the abrasive waterjet. Table 5 lists the cutting speeds obtainable for typical nonmetallic materials.

Table 5 Effect of material thickness on abrasive waterjet cutting speed for nonmetallic materials

Listed below are recent installations of representative abrasive waterjet technology used to cut nonmetallics for automotive applications:

- Trimming of thermoformed wood-fiber substrate interior door panels at speeds of 20 m/min (800 in./min)
- Elimination of an airborne asbestos dust problem encountered in the manufacture of 13 mm ($\frac{1}{2}$ in.) thick brake shoe linings; kerf loss was reduced to 0.25 mm (0.010 in.) while cutting efficiency was increased 30 to 50%
- Finish cutting to size of 3.9 kg ($8\frac{1}{2}$ lb) rear door panels after initial rough cutting with more conventional methods; the panels were made of two layers of sheet molding compound coated with continuous layers of polyester resin paste and then rolled to remove trapped air

Domestic and international electronics firms are using waterjet technology to cut the plastic laminates used in printed circuit boards. The hairlike size of the waterjet kerf and the omnidirectional, sharp cutting capabilities of the waterjet are ideally suited to the precision cutting and trimming of the boards even when they are loaded with their electronic components. The absence of any lateral forces or mechanical pressure, usually associated with mechanical cutters, eliminates the board flexure that could break solder joints.

J. Gerin Sylvia, Department of Industrial and Manufacturing Engineering, University of Rhode Island

Safety

Safety problems caused by such conditions as fire hazards and dust and noise pollution are minimized through the use of abrasive waterjet cutting, as follows:

- Safety is increased in an already hazardous atmosphere, particularly in comparison to flame and/or plasma cutting torches. Because there is no heat buildup with abrasive waterjet cutting, fire hazards are eliminated. There is no radiation emission or danger from flying slag particles
- Airborne dust is virtually eliminated, making operation less hazardous to personnel working in close proximity to the machine. Containment or other methods of airborne dust control are unnecessary
- Noise levels range from 85 to 95 dBA, which is consistent with OSHA regulations

Abrasive Waterjet Cutting

Introduction

STAINLESS STEELS are blanked, pierced, formed, and drawn in basically the same press tools and machines as those used for other metals. However, because stainless steels have higher strength and are more prone to galling than low-carbon steels and because they have a surface finish that often must be preserved, the techniques used in the fabrication of sheet metal parts from stainless steels are more exacting than those used for low-carbon steels. In general, stainless steels have the following characteristics, as compared with those of carbon steels:

- Greater strength
- Greater susceptibility to work hardening
- Higher propensity to weld or gall to tooling
- Lower heat conductivity

Forming of Stainless Steel

Revised by Joseph A. Douthett, Armco Inc.

Selection of Alloy

The properties and selection of stainless steels are discussed in the Section "Specialty Steels and Heat-Resistant Alloys" in *Properties and Selection: Irons, Steels, and High-Performance Alloys*, Volume 1 of the *ASM Handbook.*

General ratings of the relative suitability of the commonly used austenitic, martensitic, and ferritic types of stainless steels to various methods of forming are given in Table 1. These ratings are based on formability and on the power required for forming.

Table 1 Relative suitability of stainless steels for various methods of forming

Suitability ratings are based on comparison of the steels within any one class; therefore, it should not be inferred that a ferritic steel with an A rating is more formable than an austenitic steel with a C rating for a particular method. A, excellent; B, good; C, fair; D, not generally recommended

(a) Severe sharp bends should be avoided.

As Table 1 shows, the austenitic and ferritic steels are, almost without exception, well suited to all of the forming methods listed. Of the martensitic steels, however, only types 403, 410, and 414 are generally recommended for cold-forming applications. Because the higher carbon content of the remaining martensitic types severely limits their cold formability, these steels are sometimes formed warm. Warm forming can also be used to advantage with other stainless steels in difficult applications.

Formability. The characteristics of stainless steel that affect its formability include yield strength, tensile strength, ductility, (and the effect of work hardening on these properties), and the r value. The composition of stainless steel is also an important factor in formability. Figure 1 compares the effect of cold work on the tensile strength and yield strength of type 301 (an austenitic alloy), types 409 and 430 (both ferritic alloys), and 1008 low-carbon steel sheet.

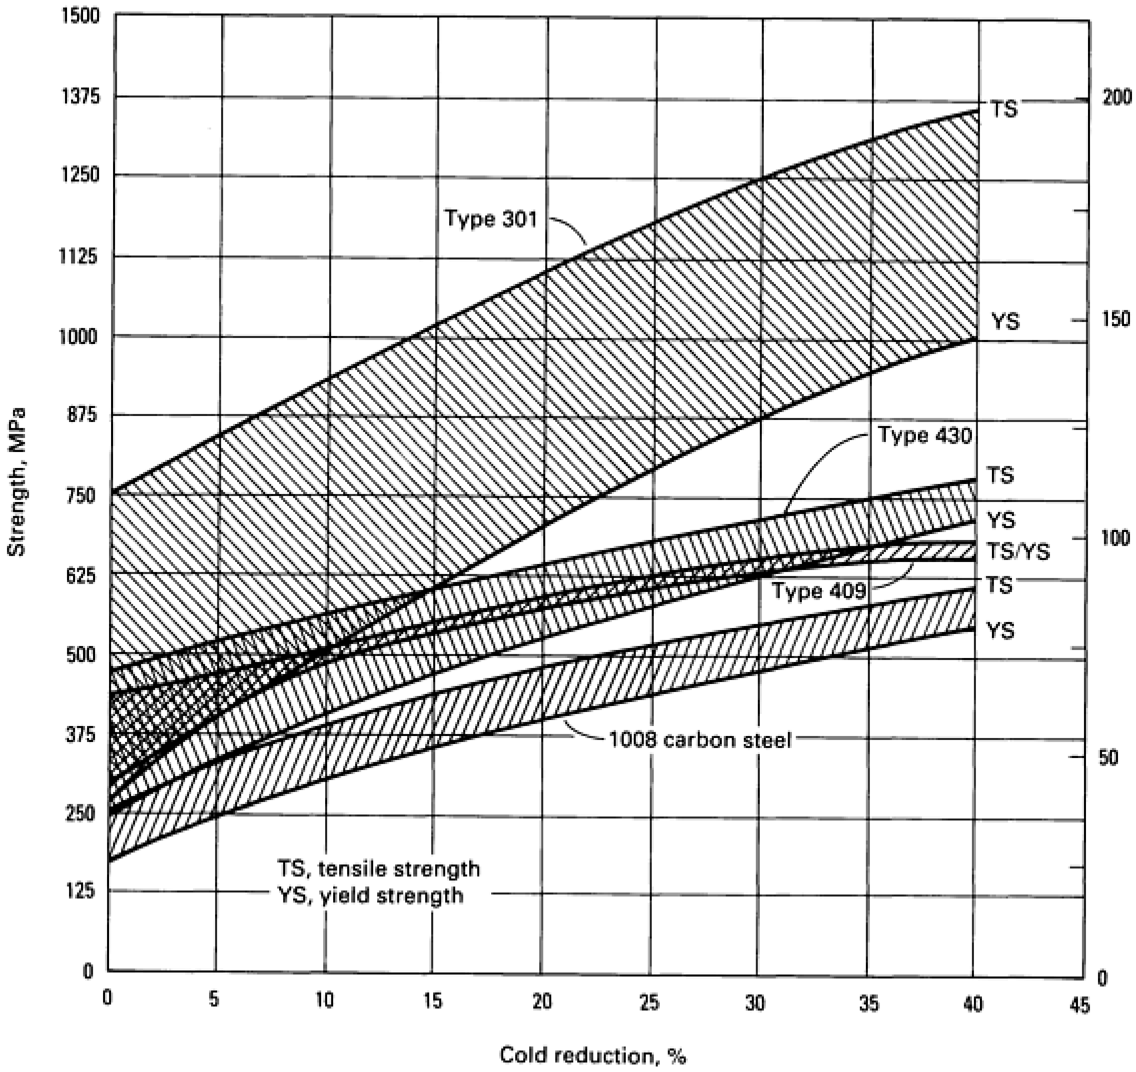

Fig. 1 Comparison of work-hardening qualities of type 301 austenitic stainless steel, types 409 and 430 ferritic stainless steels, and 1008 low-carbon steel.

Formability of Austenitic Types. Type 301 stainless steel has the lowest nickel and chromium contents of the standard austenitic types; it also has the highest tensile strength in the annealed condition. The extremely high rate of work hardening of type 301 results in appreciable increases in tensile strength and yield strength with each increase in the amount of cold working, as measured by cold reduction (Fig. 1). This response to work hardening is particularly important for structural parts, including angles and channel sections--which, after fabrication, are expected to have additional strength and stiffness. On the other hand, for deep-drawing applications, a lower rate of work hardening is usually preferable and can be obtained in the austenitic alloys that have higher nickel contents; notably, types 304, 304L, and 305.

In general, the austenitic alloys are more difficult to form as the nickel content or both the nickel and the chromium contents are lowered, as in type 301. Such alloys show increased work hardening rates and are less suitable for deep drawing or multiple forming operations. The presence of the stabilizing elements niobium, titanium, and tantalum, as well as higher carbon contents, also exerts an adverse effect on the forming characteristics of the austenitic stainless steels. Therefore, the forming properties of types 321 and 347 stainless steel are less favorable than those of types 302, 304, and 305.

Formability of Ferritic Types. The range between yield strength and tensile strength of types 409 and 430 narrows markedly as cold work increases, as shown in Fig. 1. This response is typical of the ferritic alloys and limits their formability (ductility) (in comparison with the austenitic alloys). Nevertheless, types 409 and 430, although lacking the formability of type 302, are widely used in applications that require forming by blanking, bending, drawing, or spinning.

One of the most important applications for type 430 stainless steel is in automotive trim or molding. Type 409 stainless steel has found wide acceptance as the material of choice in automotive exhaust systems.

Comparison With Carbon Steel. The curves for 1008 low-carbon steel are included in Fig. 1 as a reference for the evaluation of stainless steels. The decrease in formability of 1008 steel with cold work appears to fall between that of types 409/430 and that of the more formable type 301. Figure 1 also shows that cold work does not increase the strength of 1008 as rapidly as it does that of type 301 and the ferritic alloys.

Stress-Strain Relations. Figure 2 shows load-elongation curves for six types of stainless steel: four austenitic (202, 301, 302, and 304), one martensitic (410), and one ferritic (430). The figure also shows that the type of failure in cup drawing of the austenitic types was different from that of types 410 and 430, as shown in Fig. 2. The austenitic types broke in a fairly clean line near the punch nose radius, almost as if the bottom of the drawn cup were blanked out; types 410 and 430 broke in the sidewall in sharp jagged lines, showing extreme brittleness as a result of the severe cold work.

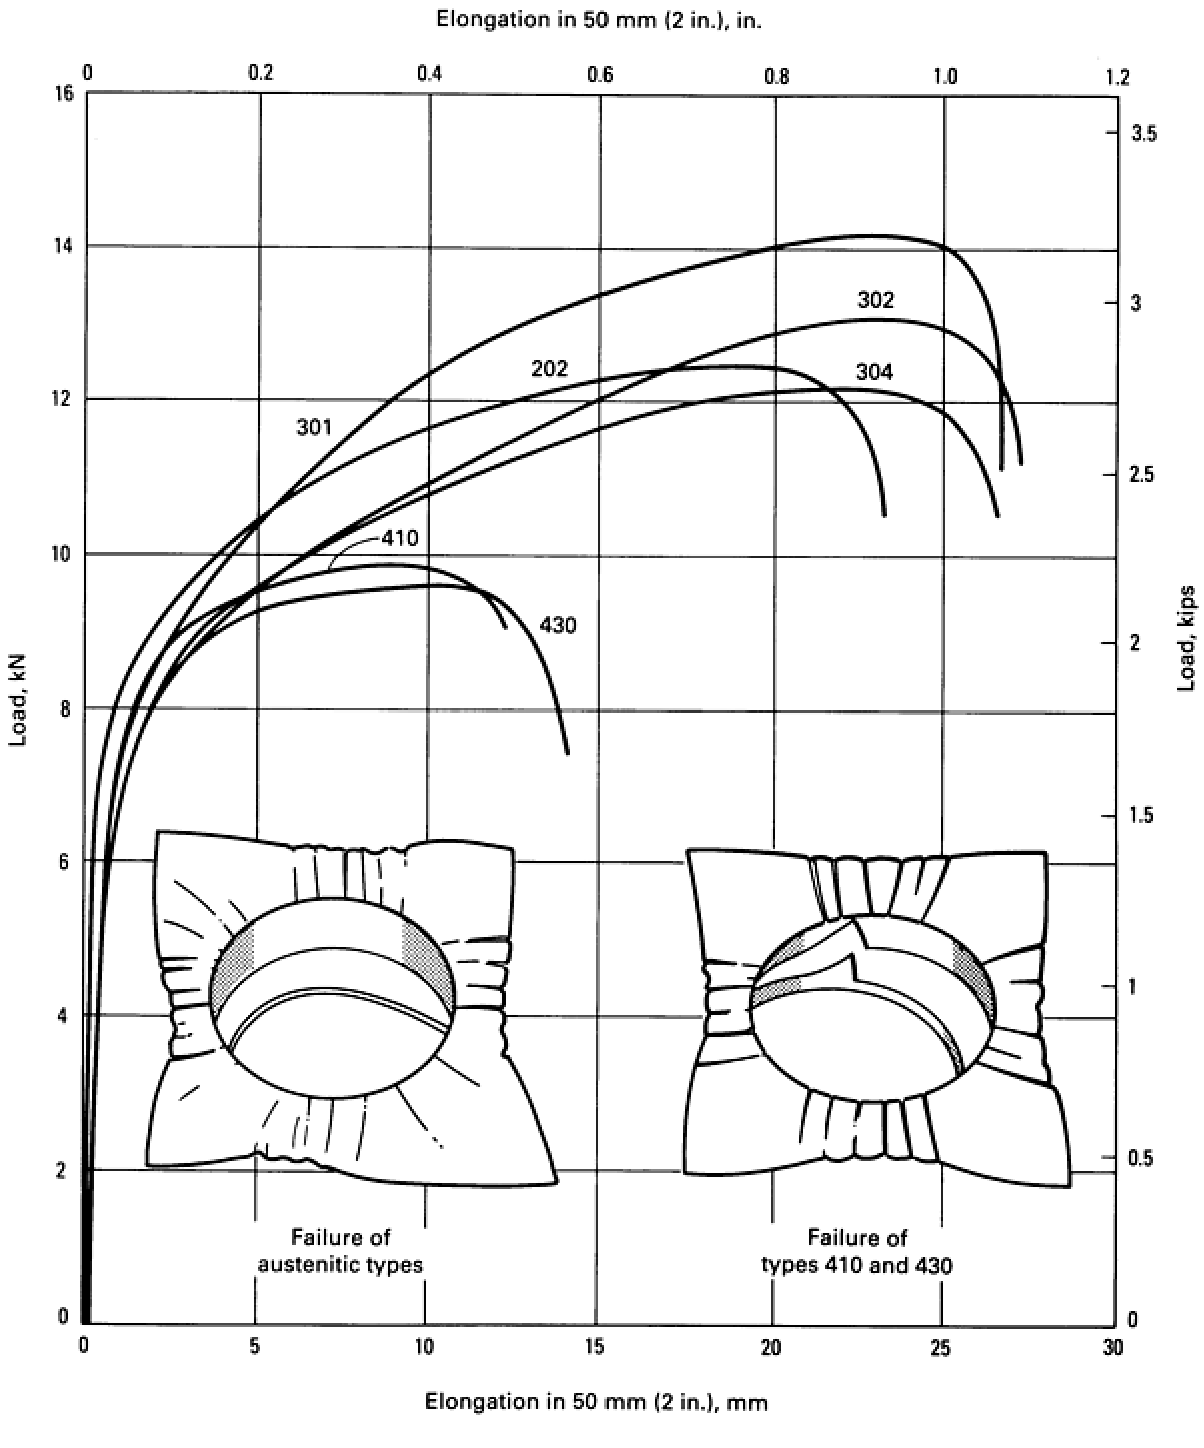

Fig. 2 Comparison of ductility of six stainless steels and of the types of failure resulting from deep drawing.

As suggested by the data in Fig. 2, the power required to form type 301 exceeds that required by the other austenitic alloys. In addition, type 301 will develop maximum elongation before failing. Types 410 and 430 require considerably less power to form, but fail at comparatively low elongation levels.

Power requirements for the forming of stainless steel, because of the high yield strength, are greater than those for low-carbon steel; generally, twice as much power is used in forming stainless steel. Because the austenitic steels work harden rapidly in cold-forming operations, the need for added power after the start of initial deformation is greater than that for the ferritic steels. The ferritic steels behave much like plain carbon steels once deformation begins, although higher power is also needed to start plastic deformation.

Forming of Stainless Steel

Revised by Joseph A. Douthett, Armco Inc.

Lubrication

Lubrication requirements are more critical in forming stainless steels than in forming carbon and alloy steels, because it usually is necessary to preserve the high-quality surface on stainless steels and because stainless steels have higher strength, greater hardness, lower thermal conductivity, and higher coefficient of friction. In forming stainless steels, galling and spalling occur more readily, and higher temperatures are reached in a larger volume of the workpiece. Local or general overheating can change the properties of the work metal and lubricant.

Table 2 lists the lubricants ordinarily used in forming stainless steel by various processes. Except for the special-purpose lubricants graphite and molybdenum disulfide, the lubricants are listed in the approximate order of increasing ability to reduce galling and friction. The ratings in Table 2 also consider other suitability factors, such as cleanliness and ease of removal. The desirable characteristics of a lubricant include the ability to reduce friction and wear, the dissipation of heat, durability, nonreactiveness with the base steel, and ease of removal. The higher temperatures generated when forming stainless alloys, particularly the austenitic varieties, frequently lead to breakdown of the polar lubricant molecules.

Table 2 Suitability of various lubricants for use in the forming of stainless steel

Ratings consider effectiveness, cleanliness, ease of removal, and other suitability factors. A, excellent; B, good; C, acceptable; NR, not recommended

Lubricant	**Blanking and piercing**	**Press-brake forming**	**Press forming**	**Multiple-slide forming**	**Deep drawing**	**Spinning**	**Drop-hammer forming**	**Contour roll forming**	Embossing

(a) Vegetable or animal types: mineral oil is used for blending.

(b) May be diluted with water.

(c) Water emulsions of soluble oils; contain a high concentration of extreme-pressure sulfur or chlorine compounds.

(d) Chalk (whiting) is commonest pigment: others sometimes used.

(e) Extreme-pressure types; may contain some mineral or fatty oil.

(f) Extreme-pressure chlorinated mineral oils or waxes; may contain emulsifiers for ease of removal in water-base cleaners.

(g) Viscosity of 4000 to 20,000 SUS (Saybolt Universal seconds, see ASTM D 2161 for more detailed information).

(h) For heavy plate.

(i) For cold forming only.

(j) Viscosity (200 to 1000 SUS) is influenced by base oil or wax, degree of chlorination, and additions of mineral oil.

(k) Solid lubricant applied from dispersions in oil, solvent, or water.

(l) For hot-forming applications only

Among stainless steel lubricants for severe drawing applications, the extreme-pressure (EP) additive types are the most desirable. Additives of chlorine or sulfur tend to react chemically with the steel surface at higher temperatures and form a readily shearable compound. Chlorine is the more popular EP additive, because sulfur tends to react with some steel tooling.

Mineral oils, soap solutions, and water emulsions of general-purpose soluble oils are omitted because they are ineffective in most forming of stainless. The recommended lubricants are discussed further in the sections that deal with the individual forming processes in the remainder of this article.

As a precaution, all lubricants should be removed, and the parts thoroughly dried, after completion of the sheet metalworking operation. Most lubricants must be removed before the formed parts are heat treated; this applies particularly to those containing insoluble solids, sulfur, or chlorine. In addition, certain metastable austenitic stainless alloys can react with their lubricant and cause delayed cracking in heavily strained areas. Rapid removal of the lubricant is therefore desirable.

Forming of Stainless Steel

Revised by Joseph A. Douthett, Armco Inc.

Blanking and Piercing

The shear strength of stainless steel is about twice that of low-carbon steel. Therefore, the available force for the blanking or piercing of stainless steel should be 50 to 100% higher than that for equivalent work on carbon steel.

Tools and power can be saved if the stock can be blanked at about 175 °C (350 °F). The finish will be better as well. Power requirements can also be reduced by using angular shear on the punch or the die. (Additional information is available in the Section "Blanking and Piercing of Steel Sheet, Strip, and Plate" in this Volume.)

Die Materials. Cutting edges must be of a hard, strong material. Recommended die materials, in order of suitability for increasing quantities, include O1, A2, D2, and D4 tool steels and carbide. Additional information is available in the article "Selection of Material for Blanking and Piercing Dies" in this Volume. The use of carbide for high-volume production in applications that do not require the impact resistance of tool steels is illustrated in the following example.

Example 1: Use of a Carbide Die to Form a Miniature Piece.

The cathode shown in Fig. 3 was produced in a three-stage progressive die made of carbide by piercing, blanking, and forming. The piece was trough-shaped, 6.4 mm ($\frac{1}{4}$ in.) long, of type 304 stainless steel, 0.08 mm (0.003 in.) thick. One end was rounded, and the other was V-shaped. The difference in contour of the two ends kept the pieces from stacking. Before forming, the blank was 9.5 mm ($\frac{3}{8}$ in.) wide. The piece was pierced with 68 holes, each 0.31 mm (0.012 in.) square. In this operation, the material was displaced by a pointed punch, rather than removed by a flat-nose punch. The pieces were cut from 152 mm (6 in.) wide strip, producing 16 pieces at a stroke. The press was a 130 kN (15 tonf) mechanical press that ran at 240 strokes per minute.

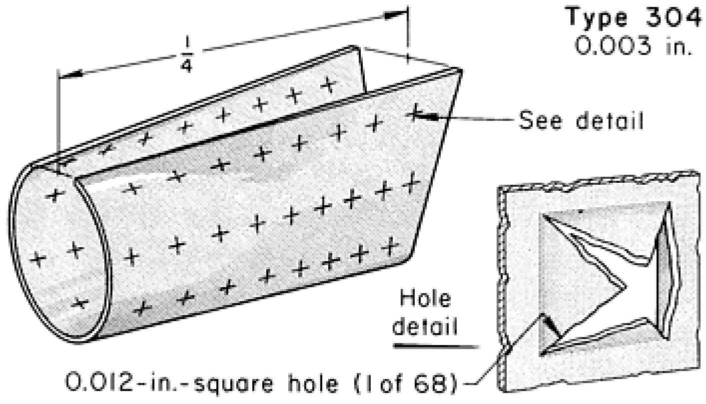

Fig. 3 Cathode produced in a progressive die with carbide tools. Dimensions given in inches.

Clearance between punch and die should be about the same as that for the blanking and piercing of cold-rolled low-carbon steel. Some manufacturers use less than 0.03 mm (0.001 in.) per side; others specify 5 to 10% of stock thickness per side for sheet and 10 to 15% of stock thickness for plates and bars. Studies have shown, however, that larger clearances--12.5 to 13.5%, and even up to 42%, of stock thickness--have resulted in increased die life (see the article "Piercing of Low-Carbon Steel" in this Volume).

Cutting edges should be carefully aligned, sharp, clean, and free of burrs. The importance of sharpness of cutting edges cannot be overemphasized.

Deburring. Generally, stainless steel does not shear clean, but leaves a rough work-hardened edge that is dangerous to handle and may adversely affect subsequent operations. Flat pieces can be rolled or pressed between dies adjusted exactly to the thickness of the stock, or the burrs can be removed by grinding, stoning, or filing.

Lubrication. The blanking and piercing of stainless is often done dry, but the lubricants indicated in Table 2 are sometimes used to prolong die life. Lubricants containing sulfur or chlorine are the most effective for this purpose. Emulsions are used for high-speed work.

Dimensions. Pierced holes should not be smaller than the thickness of the stock. Holes larger than 3.18 mm ($\frac{1}{8}$ in.) should be spaced so that the distance between centers is not less than $1\frac{1}{2}$ times the hole diameter. Small holes should have a distance between centers of at least $1\frac{3}{4}$ times the diameter of the holes. Holes should never be closer together than one stock thickness, nor should the edge of blanks be less than one stock thickness from the edge of the stock. For progressive-die operation, edge distances should be between $1\frac{1}{2}$ and 2 times stock thickness.

Nibbling. In some applications, an irregular contour is cut out by punching a series of overlapping holes along the contour. This process is called nibbling. A variety of unusual shapes can be cut at 300 to 900 strokes per minute by a press equipped with either a round or a rectangular punch.

Forming of Stainless Steel

Revised by Joseph A. Douthett, Armco Inc.

Press-Brake Forming

All of the austenitic stainless steels in the soft condition can be bent 180° over one stock thickness, but need up to 50% more power to form than that required by low-carbon steel. Springback is more severe with austenitic stainless steels than with low-carbon steel, and it must be allowed for. Work-hardened austenitic steel can be press-brake formed only to a very limited degree. If austenitic stainless steel is heated to about 65 °C (150 °F), it can be formed with appreciably less power than that required when it is cold and yet can be handled easily.

The straight-chromium grades of stainless steels vary in their response to press-brake forming. The low-carbon stainless steels containing 12 to 17% Cr bend readily but, like the austenitic steels, need more power for bending than that required for low-carbon steel. High-chromium low-carbon types, such as 446, bend better when heated to 175 to 205 °C (350 to 400 °F). The heating of these high-chromium low-carbon grades tends to lower the yield strength, but can simultaneously aid in allowing the forming to be done above the brittle-to-ductile transition temperature. For these alloys, that temperature can be at or above room temperature, depending on thickness. In room-temperature forming, the highly alloyed ferritic stainless steels have been known to benefit from slower bend speeds, which minimize the possibility of an impactlike load and resultant brittle fracture. High-carbon heat-treatable stainless steels are not recommended for press-brake forming, even if in the annealed condition.

Typical bending limits for the major stainless steels are shown in Table 3. A completely flat bend can generally be made in the 18-8 and similar alloys.

Table 3 Typical bending limits for six commonly formed stainless steels

Type	Minimum bend radius		
	Annealed to 4.75 mm (0.187 in.) thick (180° bend)	Quarter hard, cold rolled	
		To 1.27 mm (0.050 in.) thick (180° bend)	1.30-4.75 mm (0.051-0.187 in.) thick (90° bend)
301, 302, 304	$\frac{1}{2}t$	$\frac{1}{2}t$	**1*t***
316	$\frac{1}{2}t$	1*t*	**1*t***
410, 430	**1*t***	. . .	. . .

t, stock thickness

Dies. Press brakes can use dies with cross sections such as those shown in Fig. 4 for forming stainless steel in sheets up to 0.89 mm (0.035 in.) thick. Adjustable dies, such as that shown in Fig. 5, can be used for forming 180° bends in stainless steel sheet 0.30 to 0.46 mm (0.012 to 0.018 in.) thick.

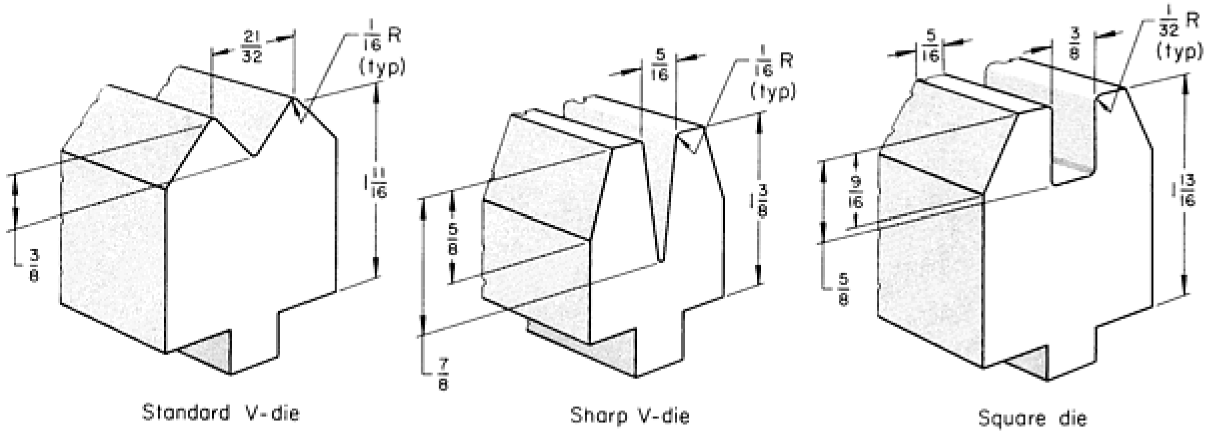

Fig. 4 Typical dies for the press-brake forming of stainless steel sheet up to 0.9 mm (0.035 in.) thick. Dimensions in figure given in inches.

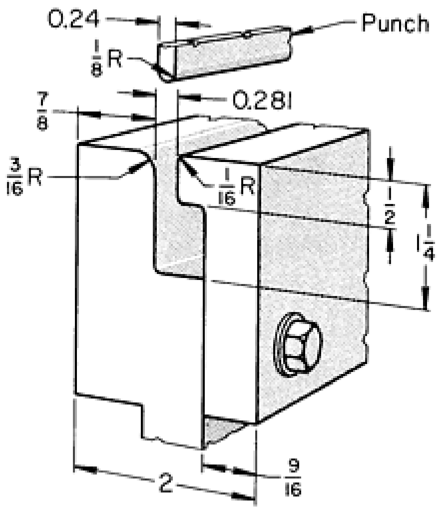

Fig. 5 Adjustable press-brake die for forming 180° bends in stainless steel sheet. Setup can be used for forming bends to 3.2 mm ($\frac{1}{8}$ in.) inside radius in sheet 0.30 to 0.46 mm (0.012 to 0.018 in.) thick, and it will produce 4.0 mm ($\frac{5}{32}$ in.) radius bends in half-hard stainless steel. Detachable side of die can be shimmed for bending thicker sheet or for bending with larger-radius punches. Dimensions in figure given in inches.

Springback is a function of the strength of the material, the radius and angle of bend, and the thickness of the stock; the thicker the stock, the less severe the problem. Table 4 shows the relationship between radius of bend and springback for three austenitic stainless steels. Ferritic steels usually exhibit less springback than austenitic steels, because the rate of work hardening of ferritic steels is lower. As a practical guide, the amount of springback is normally proportional to (0.2YS + UTS)/2.

Table 4 Springback of three austenitic stainless steels bent 90° to various radii

Steel and temper	Springback for bend radius of:		
	1*t*	**6*t***	20*t*
302 and 304, annealed	2°	4°	**15°**
301, half-hard	**4°**	**13°**	**43°**

Springback can be controlled by reducing the punch radius, by coining the line of bend (if the shape of the die is such that bottoming is feasible), and by overbending. For overbending, it is sometimes necessary only to make the punch angle smaller than the desired final angle of the workpiece, as in the following example.

Example 2: Setting a Flange Angle in a Press Brake.

The bracket shown in Fig. 6 was preformed in a U-die from a developed blank of type 302 stainless steel, half-hard, 1.0 mm (0.040 in.) thick. Only the punch angle needed to be reduced to set the angle on the flange.

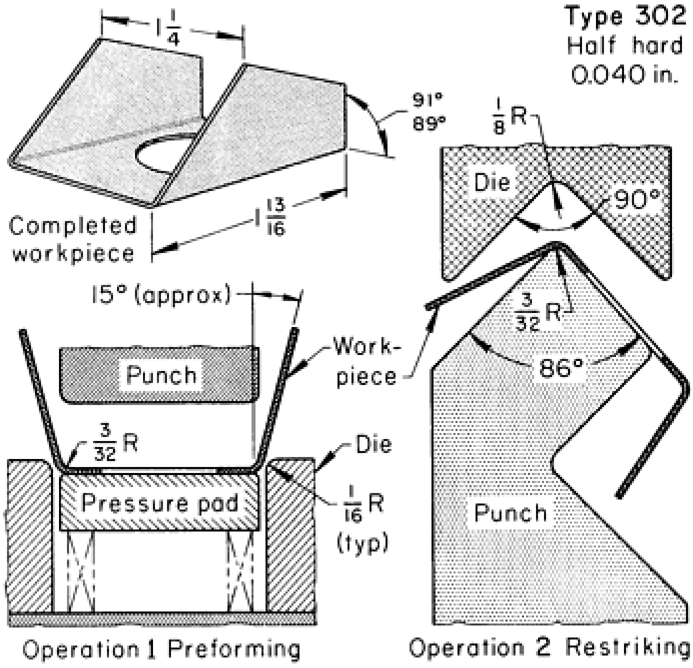

Fig. 6 Production of a U-shaped bracket from a developed blank by preforming, and restriking to set flange angles, in a press brake. Dimensions given in inches.

As the bracket came from the U-die, the springback in each flange was 15°. To correct this spread, the piece was put in a restrike die in a press brake, which set each angle separately. The restrike die angle was 90° with a 3.2 mm ($\frac{1}{8}$ in.) radius. The restrike punch was made to an angle of 86° with a 2.4 mm ($\frac{3}{32}$ in.) radius to coin the bend, so that the flanges would form to 90° ± 1°.

The lubricant was a water-soluble pigmented drawing compound. The workpiece was degreased after forming.

Lubricants. For ordinary press-brake operations (chiefly, bending and simple forming), lubricants are not used as frequently as with higher-speed press operations. Convenience of use is a major factor in selecting lubricants for this type of press-brake forming. Pigmented lubricants are not favored, and cooling effectiveness is of little significance at low production rates. For severe forming and for operations that would ordinarily be done in a press, if available, the recommendations in the "Press forming" column in Table 2 apply.

Applications of press-break forming are described in the following examples. Repetitive bends, as in corrugated stock, are frequently made one at a time in a press brake if the quantity of production is not sufficient to warrant a special die, as in the example below.

Example 3: Press-Brake Forming of Corrugations.

The corrugated sheet shown in Fig. 7 was formed from 0.41 mm (0.016 in.) thick full-hard type 302 stainless steel. The finished sheets, after bending, were 419 mm (16 $\frac{1}{2}$ in.) long, as shown, but the width, *w,* varied according to the use of the piece.

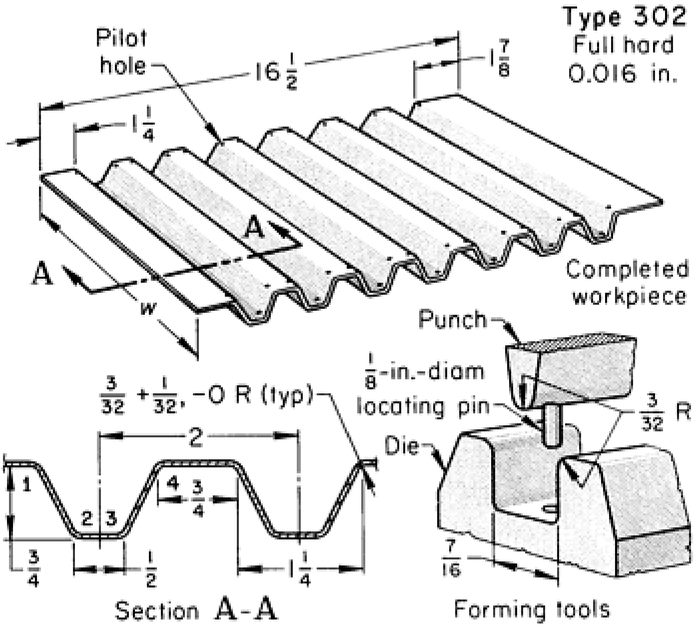

Fig. 7 Corrugated sheet in which corrugations were formed one at a time in a press brake, using tools shown. Dimensions given in inches.

The corrugations were made one at a time by air bending in the tooling shown at lower right in Fig. 7. Pilot holes in the workpiece and locating pins in the punch helped to keep the workpiece aligned. Deviation from flatness in the pieces was corrected by restriking some of the bends.

Irregular contours on long, narrow parts are conveniently produced by bending in a press brake. Because of the strength of stainless steels, the forming often must be divided among several successive operations, as in the example below.

Example 4: Forming of Stainless Steel Handrails in a Press Brake.

Figure 8 illustrates the shapes produced in five successive operations that were required for forming a handrail from 1.57 mm (0.062 in.) thick type 304 stainless steel. Because of flatness requirements and the resistance of the metal to bending, a 3600 kN (400 tonf) press brake was used.

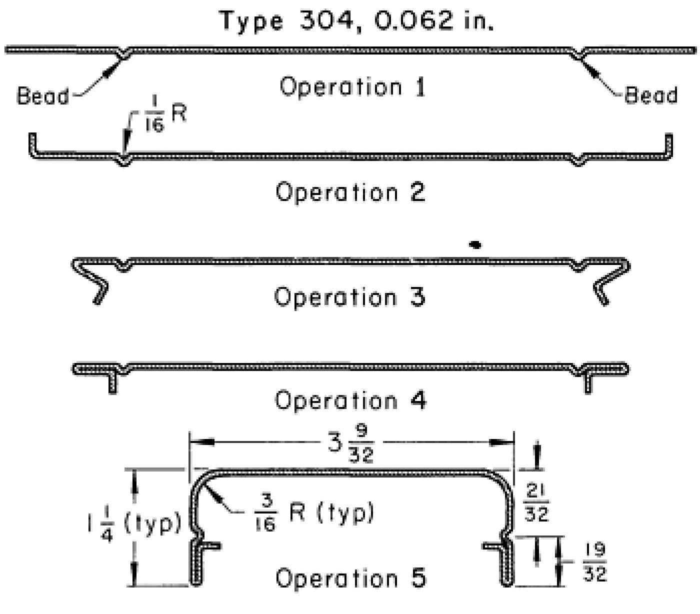

Fig. 8 Shapes progressively produced in the five-operation forming of a handrail in a 3600 kN (400 tonf) press brake. Dimensions given in inches.

Forming the 1.6 mm ($\frac{1}{16}$ in.) radius beads (operation 1, Fig. 8) was particularly troublesome because of the difficulty in retaining flatness. A force of 5300 kN (600 tonf), which exceeded the rating of the press brake, was used to form the beads.

The second and third operations presented no problems, but the fourth operation was difficult because the workpiece had to be held without marring the polished surface. Similar parts were produced from low-carbon steel without difficulty.

Forming of Stainless Steel

Revised by Joseph A. Douthett, Armco Inc.

Press Forming

Stainless steels are press formed with the same kind of equipment as that used in the forming of low-carbon steel. However, although all stainless steels are not the same in strength or ductility, they all need more power to form than carbon steels do. In general, presses should have the capacity for 100% more ram force than that needed for equivalent work in low-carbon steel, and frames should have the rigidity and bulk necessary to withstand this greater force.

Dies. In addition to wearing out faster, dies may fracture more readily when used with stainless steel than when used with low-carbon or medium-carbon steel. This is because of the greater forces needed for the working of stainless steel.

For the longest service in mass production, the wearing parts of the dies should be made of carbide, D2 tool steel, or high-strength aluminum bronze. Carbide can last ten times as long as most tool steels, but it is more expensive and does not have the shock resistance of tool steels and aluminum bronze. Tool steels such as D2 are preferred when resistance to both shock and wear is required.

Aluminum bronze offers the most protection against galling and scuffing of the workpiece. An oil-hardening tool steel such as O2 can be used for short production runs.

Austenitic Alloys. Workpieces can be stretched by applying high blankholder pressures to the flange areas to prevent metal from flowing into the die. This causes severe thinning, but work hardening may cause the thinned metal to be as strong as or stronger than the thicker unworked sections. Figure 9 shows a section of an automobile wheel cover made of type 301 stainless steel; the central portion was purposely thinned and work hardened by stretching. In the following example, one of the principal reasons for stressing the workpiece to the limits of formability was to work harden it for increased strength.

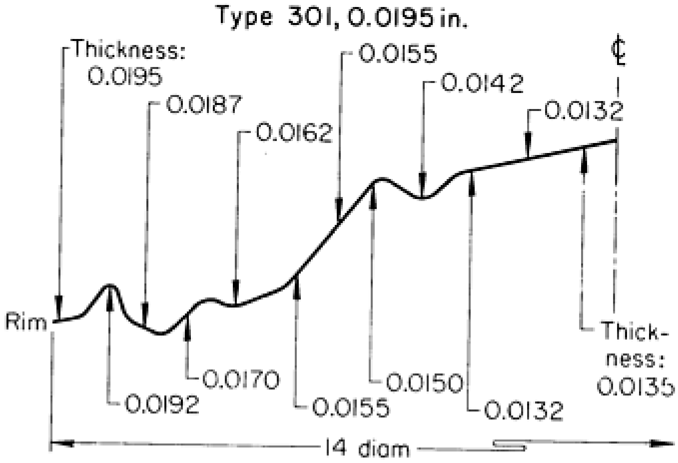

Fig. 9 Profile of a press-formed automobile wheel cover showing thinning purposely produced by severe stretching. Dimensions given in inches.

Example 5: Severe Forming for Intentional Work Hardening.

The material for a muffler header (Fig. 10) for a small aircraft engine was intentionally stressed nearly to the limits of formability to increase rigidity and to impart the necessary fatigue strength. The headers were made in two operations in a 530 kN (60 tonf) open-back-inclinable mechanical press having a 127 mm (5 in.) stroke. Each operation used a tool steel die hardened to 59 to 62 HRC. Production was 400 pieces per month.

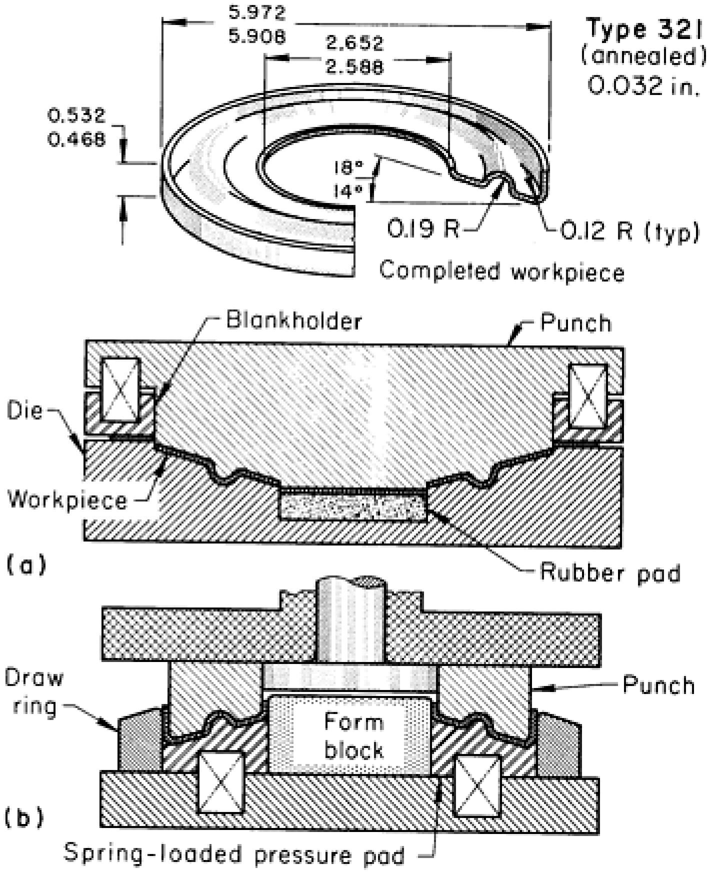

Fig. 10 Severe forming of an austenitic stainless steel aircraft muffler header to produce work hardening that would increase the rigidity and fatigue strength of the part. Dimensions given in inches.

The first die (Fig. 10a) was a compound die that formed the dish of the part, formed the bead in the dish, and blanked the inside and outside diameters. The blankholder at the outer edge of the workpiece was spring loaded, and a rubber pad supported the inner surface of the workpiece against the center blanking punch. The sequence was programmed so that the forming was completed before the outside and inside diameters were blanked, thus making the flange dimensions more accurate and concentric than would have otherwise been possible. Die life was approximately 20,000 pieces.

The second die (Fig. 10b) formed both the inner (stretch) flange and the outer (compression) flange. A spring-loaded pressure pad maintained the correct gripping pressure against the muffler-header body during this operation.

The blank was annealed type 321 stainless steel 0.81 mm (0.032 in.) thick, sheared to 216 mm (8 $\frac{1}{2}$ in.) square. The bead formed in the first die was used as a locating surface in the second die. The dies were brushed with oil between pieces.

The production rate for both operations was seven pieces per minute. Setup time for the first operation was 0.17 h; for the second operation, 0.31 h.

Stretching. Stainless steel has high ductility but wrinkles easily in compression. Therefore, if there is a choice in the direction of metal flow during forming, a better part is likely to be produced by stretching than by compression, as in the following example.

Example 6: Use of Clamping Plates and Bead to Control Metal Flow.

The dome section shown in Fig. 11 was formed from a tapered blank of annealed type 302 stainless steel in a 2200 kN (250 tonf) double-action hydraulic press. It was desirable to maximize metal flow from the narrow end of the blank in order to cause stretching rather than contraction in the metal and thus avoid wrinkles.

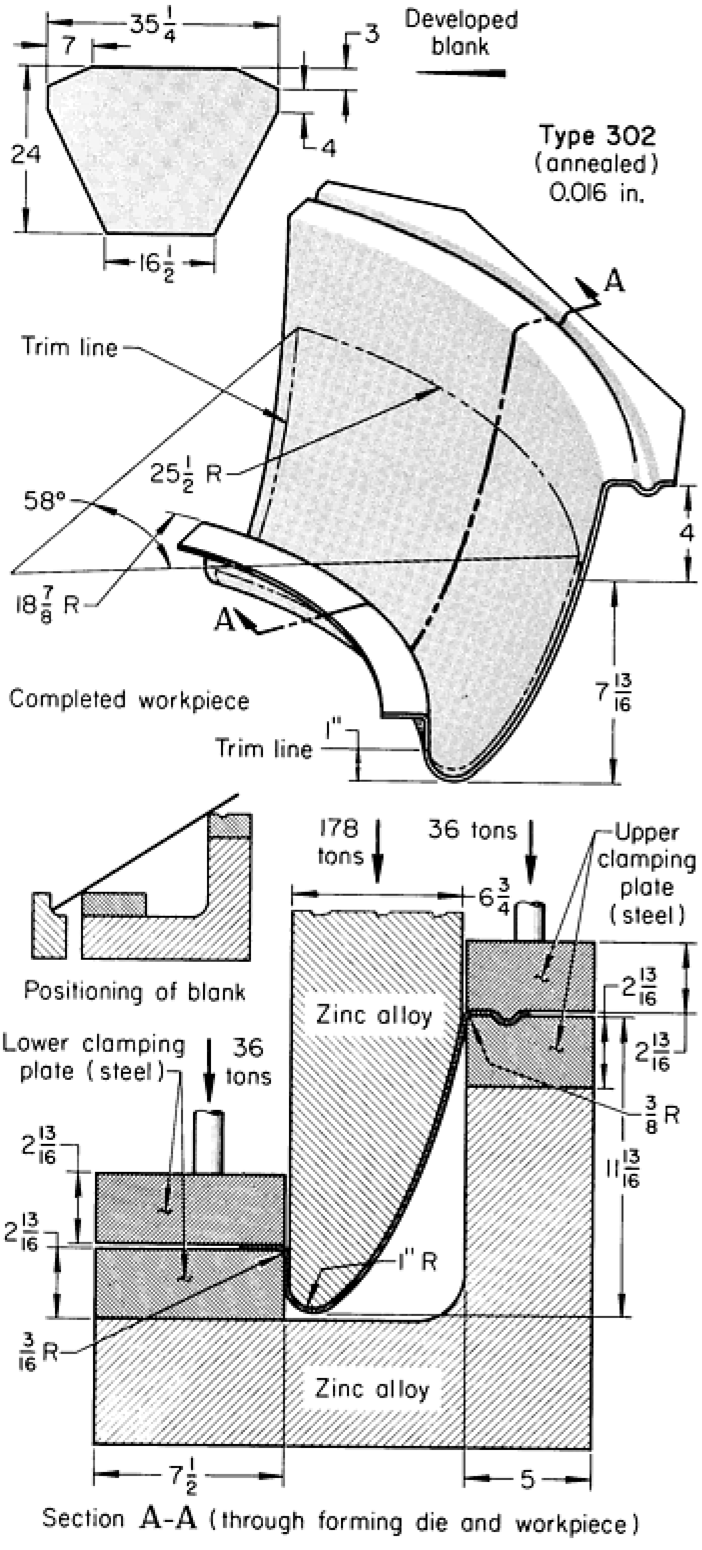

Fig. 11 Tools and clamping plates for controlling metal flow in press forming the part shown. Dimensions given in inches.

The dies could not be oriented to let the blank lie flat, because of the necessity for forming the reentrant angle next to the lower clamping plates. Both the upper and the lower edges of the blank were held between steel plates during forming. The clamping force on each pair of plates was 320 kN (36 tonf). Because the upper plates were twice as long as the lower and two-thirds as wide, the clamping force was distributed over a larger area and could have permitted most of the metal flow from the larger end, with attendant wrinkling of the work metal. The addition of a bead to the upper clamping plates improved holding at that end and caused most of the metal flow to occur at the small end of the blank. The application of a fatty acid type, nonpigmented drawing compound to the lower plates further encouraged metal flow from the small end of the blank. Scrap loss because of tearing over the relatively sharp lower die radius was 3%.

Ferritic Alloys. The formability of ferritic stainless steels, particularly the higher-chromium types, can be improved by warm forming at 120 to 200 °C (250 to 400 °F), rather than cold forming. The metal is more ductile at the higher temperatures, and less power is needed in forming. Some pieces that cannot be made by cold forming can be successfully made by warm forming.

Lubrication. The lubricant used most often in the press forming of stainless steel is the chlorinated type. It has unexcelled chemical EP activity, and the ability to adjust this activity and viscosity independently over an extremely wide range makes it the most versatile lubricant for this purpose. All chlorinated lubricants are readily removable in degreasers or solvents, and emulsifiers can be added to them for easy removal in water-base cleaners.

As shown in Table 2, pigmented pastes, sulfurized or sulfochlorinated oils, and dry wax or soap-borax films are also highly effective lubricants for press forming, but are less convenient to use. Heavy-duty emulsions, because of their superior characteristics as coolants, are preferred for high-speed operations. In the following example, high chlorine content and high viscosity were needed to produce acceptable parts (see also Example 15, in which a low-viscosity chlorine-base lubricant replaced a viscous mineral oil).

Example 7: Increase in Chlorine Content and Viscosity of Lubricant That Improved Results in Forming.

A wheel cover was made from a type 302 stainless steel blank, 457 mm (18 in.) in diameter by 0.71 mm (0.028 in.) thick, in two operations: draw, then trim and pierce. At first, a lightly chlorinated oil (10% Cl) of medium viscosity (1500 SUS, Saybolt Universal seconds, at 40 °C, or 100 °F) was used in drawing. Even though the draw was shallow, 12% of the wheel covers were rejected for splits and scratches.

A change was made to a highly chlorinated oil (36% Cl) of much higher viscosity (4000 SUS at 40 °C, or 100 °F). As a result, the rejection rate decreased to less than 1%. After forming, the wheel covers were vapor degreased.

Revised by Joseph A. Douthett, Armco Inc.

Combined Operations in Compound and Progressive Dies

The use of compound and progressive dies for the mass production of parts that require many operations or for an operation that is too severe to be done economically in a single-operation die is discussed in the article "Press Forming of Low-Carbon Steel" in this Volume. The same principles apply to their use on stainless steel for blanking, piercing, bending, forming, drawing, coining, embossing, or combinations of these operations.

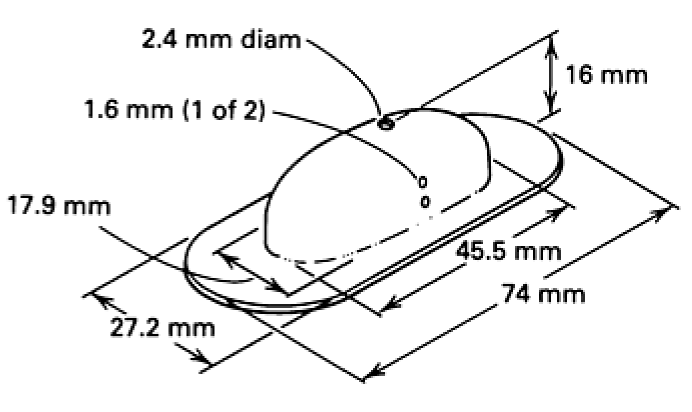
Both compound and progressive dies must be made of die materials that are hard enough to withstand the most severe demands of blanking and are tough enough for the most severe forming or coining operations. The lubricant must have enough body for the most severe draw, yet must be light enough not to interfere with the production of coined or embossed details or to gum up cutting edges. In a compound die in a double-action press, two draws can be made in stainless steel if the press capacity is not exceeded. The following example demonstrates the near-maximum severity of forming that can be achieved in a blank-and-draw compound die.

Example 8: Blanking and Severe Drawing in One Operation in a Compound Die.

The shell illustrated in Table 5 was blanked and drawn in a severe forming operation in a compound die at the rate of 16,000 pieces per year. The die was used in a 400 kN (45 tonf) mechanical press with an air cushion. The formed piece was restruck in the same die to sharpen the draw radius and to flatten the flange within 0.15 mm (0.006 in.). The die was made of A2 tool steel and had a life of 50,000 pieces per grind. An emulsified chlorinated concentrate was used as a lubricant.

Table 5 Production rates and labor time for making a severely drawn shell

Operation	**Production, pcs/h**	Labor per 100 pcs, h
Blank and draw[(a)]	922	**0.108**
Restrike[(a)]	1429	**0.070**
Pierce center hole; trim[(b)]	845	**0.118**
Pierce side holes[(c)]	786	**0.127**



(a) In a compound die, in a 400 kN (45 tonf) mechanical press with an air cushion.

(b) In a 200 kN (22 tonf) mechanical press.

(c) In a horn die in a 200 kN (22 tonf) mechanical press

After forming, the piece was then moved to a 200 kN (22 tonf) mechanical press, in which the 2.4 mm (0.093 in.) diam hole was pierced and the flange was trimmed to an oval shape. A second piercing operation, in a horn die in a 200 kN (22 tonf) mechanical press, pierced two 1.6 mm (0.062 in.) diam holes in the side of the shell. Air ejection was used in all operations except the final piercing, where the piece was picked off.

The material was type 302 stainless steel, 0.94 mm (0.037 in.) thick and 57 mm ($2\frac{1}{4}$ in.) wide, which had been annealed. Table 5 lists the production rate and labor time for each of the four operations.

Small, complex parts that must be made in large quantities are well suited to production in progressive or transfer dies. A transfer die uses a minimum of material and can accept coil stock, loose blanks, or partially formed parts. Scrap removal problems are lessened. A progressive die is preferred when the piece can remain attached to the strip.

In the following example, piercing, blanking, and forming were combined in a seven-stage progressive die. Although progressive, it was hand fed--a rather unusual combination.

Example 9: Producing a Small Bracket in a Progressive Die With Hand Feeding.

The small bracket shown in Fig. 12 was made in a seven-station progressive die from 9.5 mm ($\frac{3}{8}$ in.) wide stock that was hand fed into the 50 kN (6 tonf) press. Hand feeding was done because close operator attention was required to prevent jamming, which would have damaged the frail dies. The sequence of operations was as follows:

- Feed strip to finger stop; pierce
- Feed to notch-die opening; pierce
- Notch and trim lugs
- Form lugs
- Form and cut off
- Unload by blast of air

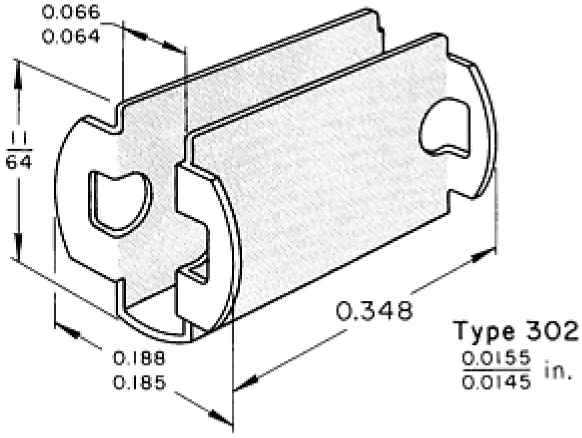


Fig. 12 Bracket that was made by hand feeding stock into a progressive die to avoid the jamming that would have been likely from automatic feeding. Dimensions given in inches.

The parts were barrel finished to remove burrs and to provide a smooth finish and high luster. The production rate was 2175 pieces per hour. Annual production was 2 million pieces. A chlorinated and inhibited oil was used as a lubricant.

Progressive Dies Versus Simple Dies. There is often a choice as to whether a stainless steel piece is to be made in a progressive die or in a series of single-operation (simple) dies. Deep forming usually presents difficulties in designing and constructing efficient and long-life progressive dies. The cost and delay involved in developing progressive tooling was justified for producing the frame described in the following example in quantities of 100,000 or more per year.

Example 10: Use of Progressive Dies for High-Quantity Production of Frames.

The frame shown in Fig. 13 was made of 0.56 mm (0.022 in.) thick type 430 stainless steel coil stock, 95.3 mm (3 $\frac{3}{4}$ in.) wide. The maximum hardness was 83 HRB.

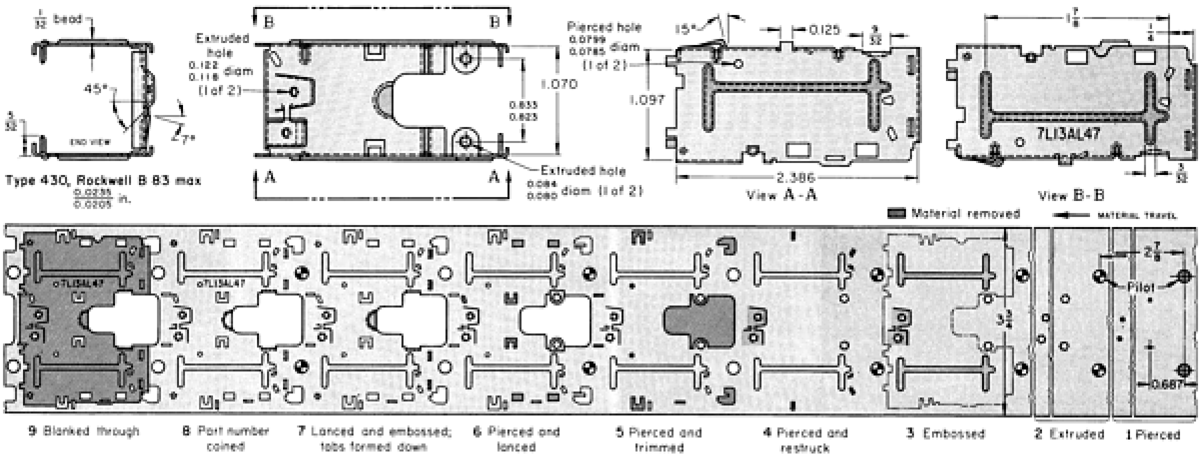

Fig. 13 Frame produced in a nine-station progressive die in the sequence of operations indicated on the strip development shown. Final forming was done in separate dies. Dimensions given in inches.

A nine-station progressive die was used to pierce and flange the holes, to emboss the stiffening beads on the two legs, to trim and form the tabs, to coin identification data, and to blank the part from the strip. Stops were then lanced and formed, and bottom flanges were formed in a forming die. A final forming die was used for the deep side flanges.

The progressive die was run in a 670 kN (75 tonf) mechanical press at a rate of 5000 pieces per hour. The first and second forming dies were run in a 270 kN (30 tonf) press at speeds of 984 and 936 pieces per hour, respectively.

Annual production was 90,000 frames, and demand was expected to increase. This, in addition to the short press time (0.2284 h per 100 pieces, as against an estimated 0.6665 h per 100 pieces if produced in eight separate dies) and the greater accuracy obtainable in the progressive die, justified the higher tooling cost for the progressive-die method (60% higher when compared to separate dies).

The dies were made of A2 tool steel and had a life of 50,000 to 75,000 pieces between regrinds. The lubricant was an emulsifiable chlorinated oil concentrate.

Revised by Joseph A. Douthett, Armco Inc.

Multiple-Slide Forming

Small high-production stainless steel parts can sometimes be formed in multiple-slide machines with the same kinds of tools as those used for the forming of low-carbon steel. Additional information is available in the article "Forming of Steel Strip in Multiple-Slide Machines" in this Volume. The following example describes the forming of a link for a flexible expanding wristband.

Example 11: Multiple-Slide Forming of a Wristband Link.

The workpiece shown in Fig. 14, a link for an expanding wristband, was formed in a multiple-slide machine from stainless steel strip 0.25 mm (0.010 in.) thick by 8.99 mm (0.354 in.) wide, and it was locked in shape by bent lugs. The production rate was 6000 pieces per hour.

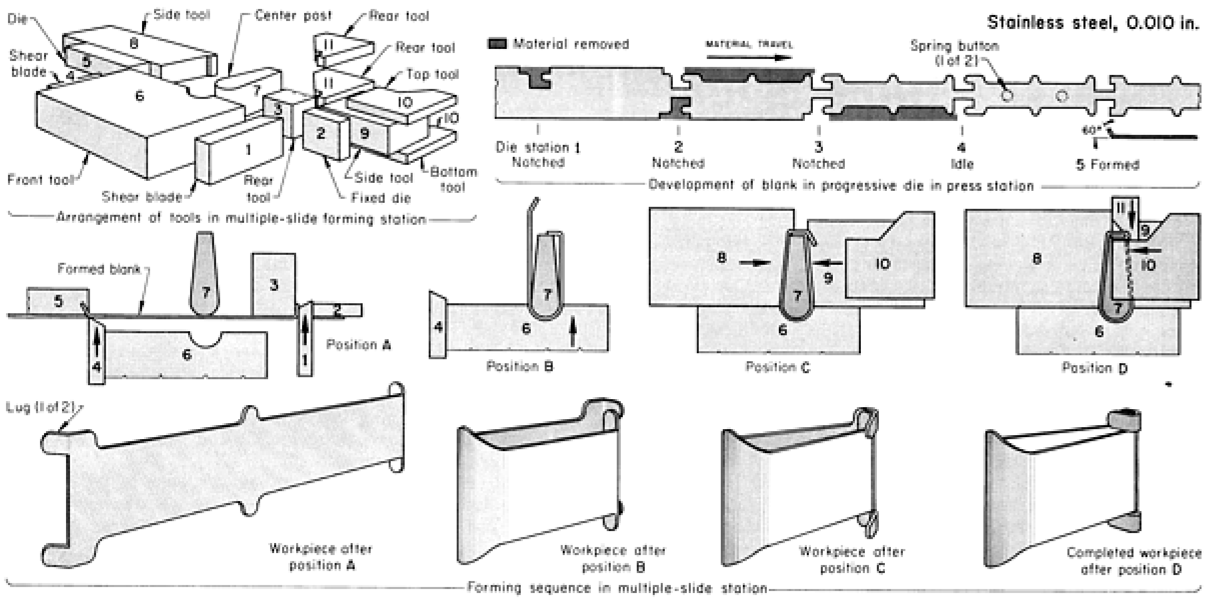

Fig. 14 Operations in the forming of a wristband link in a multiple-slide machine.

The blank for the link was made in a five-station progressive die mounted in the press station of the machine. As shown in the upper right corner of Fig. 14, the strip was notched in stations 1, 2, and 3 by four small heeled punches. For support against side thrust, the heels entered the die before engaging the stock. An air blast entering through holes in the punches removed the scrap in order to protect the die and the feed mechanisms. In the fifth die station, two lugs on the blank were bent 60°. Spring-actuated lifters stripped the blank from the bending section of the die after the lugs were bent. The workpieces were held together by a narrow strip of stock that was left to index the workpiece through the stations of the progressive die.

The blank was then fed to the forming station so that it was edge-up between the center post (7) and the front tool (6), as shown in position A in Fig. 14. As the blank entered the forming station, the center post moved upward into the forming position. The shear blade (1) then moved forward against the fixed die (2) to trim off the joining strip. The shear blade (1) also bent the end of the blank against the auxiliary rear tool (3), which then retracted. The other end of the blank was cut off by the shear blade (4) against the die (5).

After the blank was cut off by the shear blade (4), the front tool (6) bent the workpiece around the center post (7), as shown in position B in Fig. 14.

In position C, the workpiece was formed on the center post by the side tools (8 and 9) while still being held by the front tool (6). The front tool was wide enough to form the full width of the workpiece, including the lugs, but the side tools (8 and 9) were narrower, leaving exposed the top and bottom lugs that had been formed in the last press-die station.

In position D, the front and side tools (6, 8, and 9) held the part against the center post (7), while the rear tools (11) flattened the top and bottom lugs against the center post. The center post was then lowered from the workpiece. The side tool (9), which was spring loaded, slid between the top and bottom tools (10), permitting them to advance to form the top and bottom lugs into a U-shape. The side tool (9) held the workpiece against the front and side tools (6 and 8), while the top tools (10) tucked in the lugs.

With all the other tools holding the closed position against the workpiece, the rear tools (11) moved slightly to press the lugs closed against the top tools (10). As the tools opened, the completed link was then ejected by an air jet.

Deep Drawing

The percentages of reduction obtainable in deep drawing range from 40 to 60% for the chromium-nickel (austenitic) stainless steels of best drawability and from 40 to 55% for the straight-chromium (ferritic) grades (percentage of reduction = $[(D - d)/D] \times 100$, where D is the diameter of the blank and d is the inside diameter of the drawn piece). The amount of reduction obtainable varies greatly with the radius of the die and to a lesser extent with the radius of the punch nose. As the die radius decreases, the drawability decreases, as shown in Table 6 for austenitic stainless steel. Typically used punch and die radii are five to ten times metal thickness. With the ferritic grades, the drawability and ductility usually decrease with increasing chromium content. To offset this, steels with high chromium content are often warmed moderately before drawing.

Table 6 Effect of die radius on percentage of reduction obtainable in the deep drawing of austenitic stainless steel

Percentage of reduction = $[(D - d)/D] \times 100$, where D is the diameter of blank, and d is the inside diameter of the drawn piece

Die radius[(a)]	Reduction in drawing, %
15*t*	**50-60**
10*t*	**40-50**
5*t*	**30-40**
2*t*	**0-10**

(a) *t*, stock thickness

Presses used for the deep drawing of stainless steel differ only in power and rigidity from those used for low-carbon steel. Because of the higher work-hardening rate of stainless steel and its inherent higher strength, presses used for the deep drawing of stainless steel often need 100% more ram force and the necessary frame stiffness to support this greater force.

Dies for drawing stainless steel must be able to withstand the high force and resist galling. For ordinary service, D2 tool steel dies give a good combination of hardness and toughness. On long runs, carbide draw rings have exceptionally long life. Where friction and galling are the principal problems, draw rings are sometimes made of high-strength aluminum bronze. The following example describes an application in which the selection of tool material was critical in order to avoid scoring of the workpiece and to obtain acceptable die life in drawing.

Example 12: Use of a Carbide Blank-and-Draw Ring.

An orifice cup, 25 mm (1 in.) in diameter by 11 mm ($\frac{7}{16}$ in.) deep, was blanked and drawn in one operation. A 1.35 mm (0.053 in.) diam orifice was pierced in the cup in a second operation. The specifications called for the sides of the cup to be free of score marks from the die. The blank was 40.0 mm (1.575 in.) in diameter, cut from 0.97 mm (0.038 in.) thick type 302 stainless steel strip 50 mm (2 in.) wide.

The blank-and-draw tooling shown in Fig. 15 was originally made of tool steel of a grade no longer used. It produced fewer than 50 pieces without scoring the workpieces. The combination blanking punch and draw ring was chromium plated in an attempt to increase its durability. Adhesion of the plating was not satisfactory; the chromium started to peel after 180 pieces had been produced. A draw ring of graphitic tool steel was then tried, but this also scored the workpieces.

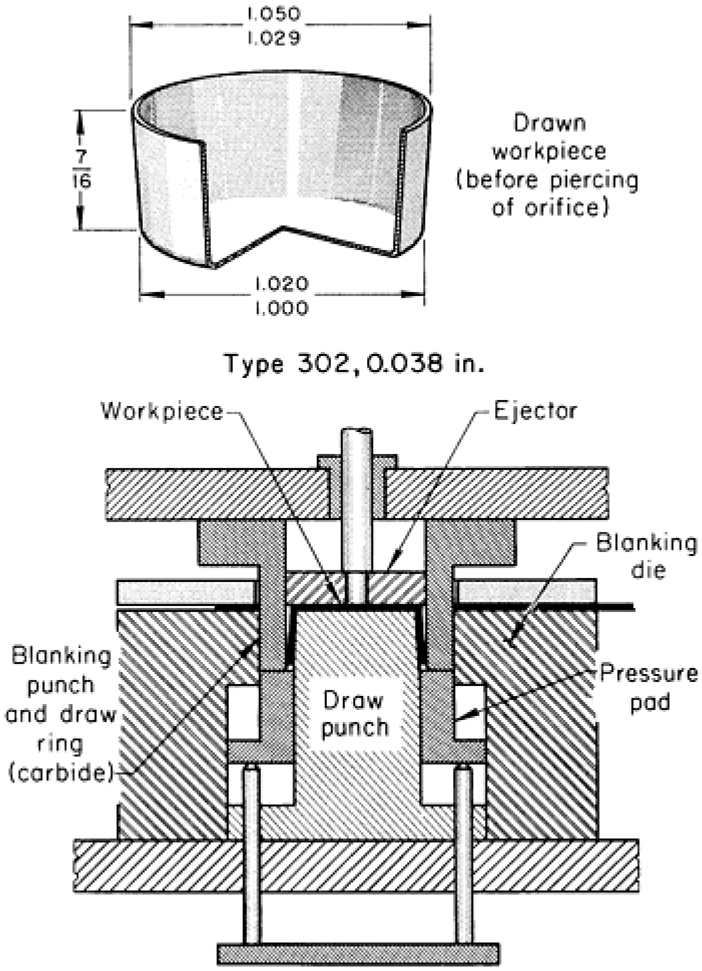

Fig. 15 Forming an orifice cup in a blank-and-draw die with a carbide punch and draw ring. Orifice was pierced in a second operation. Annual production was 60,000 pieces. Rate of blanking and drawing was 670 pieces per hour. Rate of piercing was 153 pieces per hour. Dimensions given in inches.

Finally, a new draw ring was made of sintered carbide consisting of 81% tungsten carbide, 15% Co and 4% Ta--a composition especially recommended for draw dies. The new ring, used with a chlorinated oil-base lubricant, withstood the heat and pressure generated by the severe blank-and-draw operation and produced mar-free parts. Maintenance was negligible, and after 3 years the carbide draw ring had produced 180,000 pieces, with little evidence of wear.

The blanking punch-to-die clearance was 0.05 mm (0.002 in.) per side. Drawing punch-to-die clearance was 0.851 mm (0.335 in.) plus 3° taper per side on the draw punch. The punch nose radius was 0.38 mm (0.015 in.), and the draw radius was 2.4 mm (0.093 in.).

Effect of Worn Draw Rings. The following example shows how the gradual wear of carbide draw rings in severe drawing affected the outside diameter of drawn shells.

Example 13: Effect of Wear of a Carbide Draw Ring on the Diameter of a Drawn Shell.

The carbide draw ring used in deep drawing a shell for pens and pencils made more than 225,000 pieces before it was replaced. Measurements of the pieces were made at production intervals, as shown in Fig. 16.

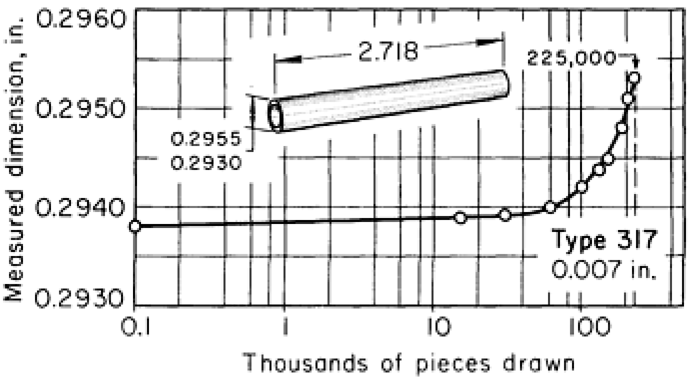

Fig. 16 Variation in diameter of a deep-drawn shell that resulted from wear of the carbide draw ring used. Dimensions given in inches.

Shortly after 225,000 pieces had been drawn, shells began to be produced that would no longer enter the "go" ring gage freely, because of wear on the draw ring. The worn draw ring, which permitted excessive springback, was replaced before the beginning of the next production run.

The shell was drawn from a blank of type 317 stainless steel 48.4 mm (1.906 in.) in diameter and 0.18 mm (0.007 in.) thick to a finished depth of 69.0 mm (2.718 in.) using chromium-plated punches. The shell was made in eight single-station dies, seven drawing and one end forming, at a rate of 600 per hour. The punches had a 2.29 mm (0.090 in.) nose radius, and the draw dies had a 90° conical entrance angle with a 1.52 mm (0.060 in.) radius blending the corners. A mixture of three parts inhibited hydraulic oil and one part chlorinated oil was used as lubricant.

Die clearance for heavy draws is 35 to 40% greater than the original metal thickness for austenitic alloys. For the ferritic alloys, which thicken less, 10 to 15% is generally adequate.

Figure 17 shows a profile of an austenitic stainless steel drawn part that illustrates the thickening pattern observed in drawing a cup from this material. If the process is one of stretching more than of drawing, the clearances do not have to compensate for natural thickening.

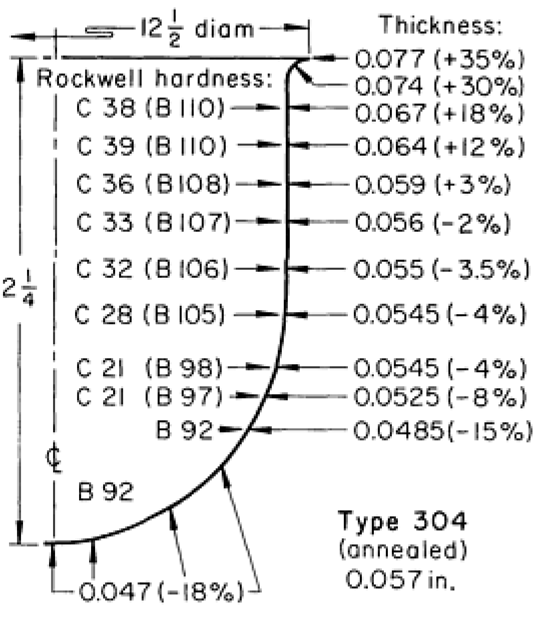

Fig. 17 Profile of a shell drawn from an austenitic stainless steel showing variations in hardness and thickness produced by drawing. Dimensions given in inches.

Clearances of less than the metal thickness are generally not used with stainless steel, because they result in ironing (squeezing of the metal between the punch and die). The austenitic stainless steels are not suited to ironing, because their high rate of work hardening promotes scoring and rapid wear of the dies. In addition, any substantial ironing in the drawing of austenitic stainless steels greatly increases the likelihood of fracturing the workpiece.

The example below describes an application in which the work metal was changed from galvanized carbon steel to a thinner ferritic stainless steel without a revision of die clearance. The resultant problems were solved by substituting an austenitic stainless steel that was better suited to the original clearance even though it had the same thickness as the ferritic steel.

Example 14: Matching Work Metal to Die Clearance.

Using the tooling shown in Fig. 18, basins were made at the rate of 10,000 to 15,000 pieces per year from galvanized carbon steel, 1.27 mm (0.050 in.) thick. The press was an 8900 kN (1000 tonf) hydraulic press with an air-over-oil pressure pad and a draw rate of 152 mm (6 in.) in 5 s. The punch, draw ring, and pressure pad for the drawing die (Fig. 18a) were hardened cast iron. Carbide inserts were used as cutting edges on the trimming punch and die (Fig. 18b). The locator on the trimming die was molded plastic, and the die plate was cast iron. Both dies were used side-by-side in the press at the same time because it had enough capacity to draw and trim in one stroke. Therefore, a finished piece was produced with each stroke of the press, using manual transfer.

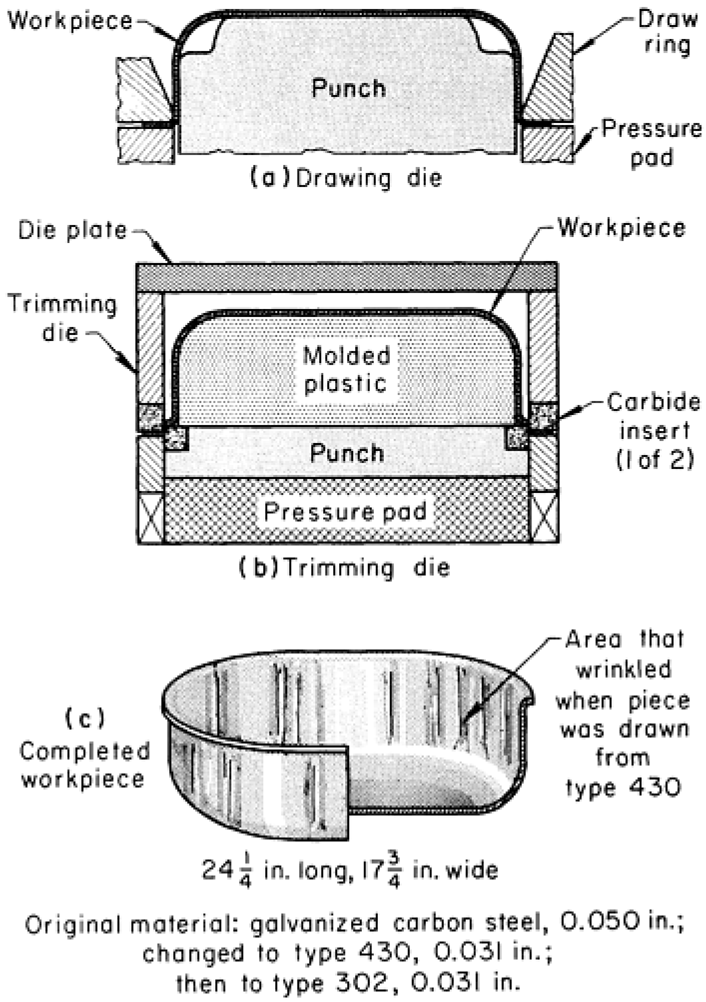

Fig. 18 Setups for drawing and trimming a basin. Die clearance (1.40 mm, or 0.055 in., per side) and drawing radius (6.4 mm, or $\frac{1}{4}$ in.) were not changed when 0.79 mm (0.031 in.) thick type 430 was substituted for 1.27 mm (0.050 in.) thick galvanized carbon steel as the work metal, and wrinkles resulted in drawing. Dimensions in figure given in inches.

To produce a more corrosion-resistant basin, type 430 stainless steel was substituted for the galvanized carbon steel. The type 430 was only 0.79 mm (0.031 in.) thick in order to minimize the increase in material costs; however, the same tooling was used because the relatively low annual quantity did not warrant the cost of retooling. Because the hold-down forces were not suitable for the ferritic stainless steel, several hundred pieces out of the first run were fractured in drawing.

When the hold-down pressure was adjusted to a level suitable for a ferritic stainless steel, contraction wrinkles formed where the material entered the throat of the die (Fig. 18c) because the die clearance was too great. The corners of the blank were cropped, the viscosity of the lubricant was changed, and the hold-down pressures were more closely adjusted in an effort to control wrinkling.

The data given in Table 7 for noncylindrical draws provide an explanation for the difficulties encountered in changing the work metal as well as guidance for the selection of a suitable stainless steel. According to these data, the thickness of type 430 stock that could best be formed by the die would be the same as that of the carbon steel previously formed. In addition, if the stock thickness were reduced, an austenitic steel such as type 302 could be used. The die clearance was 1.4 mm (0.055 in.) per side, and the draw ring radius was 6.4 mm ($\frac{1}{4}$ in.). Therefore, the die was suited for the 1.27 mm (0.050 in.) thick carbon steel, but not for the 0.79 mm (0.031 in.) thick type 430. However, 0.79 mm (0.031 in.) thick type 302 would be closely matched to the die capacity.

Table 7 Effect of die clearance and draw ring radius on noncylindrical draws of stainless steel

Stock thickness, *t*		Die clearance per side					
		Carbon steel		**Type 430**		Types 302 and 304	
mm	**in.**	**mm**	**in.**	**mm**	**in.**	**mm**	in.
1.27	0.050	1.40	0.055	1.40	0.055	2.29	**0.090**
0.76	**0.030**	**0.84**	**0.033**	**0.84**	**0.033**	**1.37**	**0.054**

Stock thickness, *t*		Draw ring radius				
		Carbon steel		**Type 430**		Types 302 and 304
mm	**in.**	**mm**	**in.**	**mm**	**in.**	
1.27	0.050	6.4-9.5	$\frac{1}{4}$ - $\frac{3}{8}$	6.4-9.5	$\frac{1}{4}$ - $\frac{3}{8}$	**4*t* min**

A change was made to type 302 stainless steel, 0.79 mm (0.031 in.) thick, with no further difficulty. A change to 1.27 mm (0.050 in.) thick stock of type 430 might have been successful.

Speed of drawing has an important bearing on the success of the draw. A rate of 6 to 7.5 m (20 to 25 ft) per minute is a good compromise between the rate of work hardening and the uniform distribution of stress. With proper forming techniques, the rate of fracture at this speed is often less than 2%.

Lubricants. Ordinarily, both sides of the workpiece need to be lubricated for each draw. If too little lubricant is used, tools may accumulate enough heat during a production run to cause the work metal to fracture because of galling. In tests with a minimum of lubricant, failures occurred after 25 draws.

The chemical type and the viscosity of the lubricant are both important. Either chemical or mechanical EP activity (see the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume) is needed for the severe deep drawing of stainless steel.

Viscosity or pigment loading must not be too high or too low. Too thick a lubricant can cause wrinkling of compressed metal; too thin, seizing or galling. The ability to remove a lubricant readily is also important. In general, the higher the viscosity, the more difficult the lubricant is to apply and remove.

The same characteristics that make chlorinated oils and waxes useful for the press forming of stainless steel (see the section "Press-Brake Forming" in this article) also make them useful for the deep drawing of these alloys. Table 2 lists other lubricants used in the deep drawing of stainless steel. Pigmented pastes and dry films are also effective (and in some cases superior) in deep drawing.

In Example 15, changing from a viscous mineral oil to a low-viscosity mineral oil blend of a chlorinated wax eliminated wrinkling and galling. Sometimes, however, there is no substitute for the physical separation and equalization of pressure provided by pigments, as in Example 16.

Example 15: Effect of Reducing Viscosity and Adding Chlorinated Wax to Mineral Oil Lubricant in Deep Drawing.

A coffeepot was deep drawn from a type 302 stainless steel blank, 355 mm (14 in.) in diameter by 0.81 mm (0.032 in.) thick, in two deep draws and one bulging operation. At first, the blanks were lubricated by brushing both sides with mineral oil having a viscosity of 6000 SUS at 40 °C (100 °F). The workpiece wrinkled in the first draw, and it galled in the second draw and in bulging.

The lubricant was replaced with a thinner mineral oil (viscosity: 500 SUS at 40 °C, or 100 °F) that was fortified with a chlorinated wax. The lubricant was brushed on, as before. Not only did the use of the modified lubricant eliminate the wrinkles in the first draw, but enough lubricant remained on the surface to prevent galling in the two other operations. Even though a fluid of much lower viscosity was used, the tenacity imparted by the chlorinated wax permitted the retention of sufficient lubricant for the subsequent bulging and deep-drawing operations.

Example 16: Pigmented Paste Versus Chlorinated Oil for Deep Drawing.

For easy cleaning in a vapor degreaser, highly fortified oils were specified for the deep drawing of a rectangular shell from 0.89 mm (0.035 in.) thick type 304 stainless steel. Chlorinated and sulfochlorinated oils with viscosities of 4000 to 20,000 SUS at 40 °C (100 °F) failed to eliminate welding to the dies and splitting of the workpiece at the corners. The shell, a well for a steam table, was deep drawn from a rectangular blank measuring 760 × 585 mm (30 × 23 in.) with corners trimmed at 45°. The shell was drawn in one operation, and the flange was then trimmed. Interior dimensions of the drawn shell were 510 × 305 × 150 mm (20 × 12 × 6 in.). Bottom corners had 16 mm ($\frac{5}{8}$ in.) radii; vertical corners, 29 mm ($1\frac{1}{8}$ in.) radii; and the flange, a 6.4 mm ($\frac{1}{4}$ in.) radius. The shell had approximately 3° taper on each side. The clearance between the punch and die was equal to the stock thickness.

The oil-type lubricant was replaced with a highly pigmented water-miscible fatty paste, diluted with two parts of water, which was applied to both sides of each blank by rollers. This lubricant eliminated the welding and allowed enough metal flow to prevent splitting. The drawn parts were cleaned with hot alkaline solution in a soak tank.

Lubricant Location. The location of the lubricant on the blank is also critical in the successful fabrication of a drawn part. Because all draws are made up of a combination of stretching and deep drawing, the lubricant location often depends on which type of forming is dominant. In a stretch condition, lubricant should especially be applied on the steel surface contacting the punch so that friction is minimized and the steel slips over the punch surface during stretching and thinning. Under deep-draw conditions, the steel surface contacting the die is definitely lubricated in order to allow ease of movement into the die cavity. However, whether stretch or deep drawing dominates, some lubricant is necessary on both steel surfaces to minimize the galling tendencies of stainless alloys.

Drawing Cylindrical Parts. When a part is made in several drawing operations, the amount of reduction in redrawing is related to the condition of the metal in the first drawing operation (cupping). If the material is highly stressed because of excessive blankholder pressure or because of small die radius, very little reduction can be made in the second operation.

General practice on the more formable grades of austenitic stainless steel is to allow 40 to 45% reduction in the first operation, followed by a maximum of 30% in the second operation, if the workpiece is not annealed between draws. With an anneal, the second reduction is usually 30 to 40%. On some parts, it may be preferable to spread the reduction over four draws before annealing--for example, successive reductions of 35, 30, 20, and 10%.

There is usually a decrease in drawability upon redrawing, and the greatest total reduction in a two-draw operation is most often produced by having the first-stage reduction as large as possible. During redrawing, it is advisable to use a tapered or rounded-end internal blankholder or sleeve to allow easy flow of metal into the die, as indicated in the article "Deep

Drawing" in this Volume. An internal blankholder with small-radius 90° corners causes the metal to be bent severely through two 90° bends before flowing into the die.

Optimal drawability is available at ram speeds of not more than 6 to 9 m (20 to 30 ft) per minute. Because of the strain-rate sensitivity of most stainless steels, work hardening of these alloys is minimized by slow forming.

The following example describes an application in which small shells were deep drawn in several steps to reduce the amount of work done in a single operation. Because production quantities were small, individual dies were more economical than a transfer die.

Example 17: Seven-Step Deep Drawing of a Fountain-Pen Cap.

Fountain-pen caps of various closely related designs were made on the same production line by one blanking and cupping operation and six redraws. A flat blank of type 302 stainless steel having a hardness of 83 to 88 HR15-T was used. The first five draws were usually the same for any of the caps made on the line; therefore, to set up for a different size of cap, only the compound blank-and-cup die and the last die (or, for some caps, the last two dies) needed to be changed. As a result, the changeover time was only about 45 min.

In the first operation, which was done in a 160 kN (18 tonf) mechanical press, a compound blank-and-cup die equipped with a rubber die cushion was used to cut circular blanks from 0.267 to 0.279 mm (0.0105 to 0.0110 in.) thick strip and to draw them into a cup. To make a typical cap 90 mm ($3\frac{1}{2}$ in.) long by 8.55 to 8.57 mm (0.3365 to 0.3375 in.) in outside diameter, a blank 55.9 mm (2.200 in.) in diameter was cut from stock 57 mm ($2\frac{1}{4}$ in.) wide and was drawn into a cup 19 mm ($\frac{3}{4}$ in.) deep by 31.8 mm (1.250 in.) in diameter--a 43% reduction in diameter. Reductions in the subsequent redraws were 27, 22, 18, 18, 16, and 15%, respectively. All except the last redraw were done in 35 kN (4 tonf) hydraulic presses with 152 mm (6 in.) strokes. The final redraw was made in a 55 kN (6 tonf) hydraulic press with a 305 mm (12 in.) stroke.

The draw dies were carbide inserts 13 to 16 mm ($\frac{1}{2}$ to $\frac{5}{8}$ in.) thick. The die openings had a 4.8 mm ($\frac{3}{16}$ in.) radius blending with a 1.6 mm ($\frac{1}{16}$ in.) wide land. There was a 2° relief per side below the land. The high-speed steel punches had a 2.4 mm ($\frac{3}{32}$ in.) nose radius and were chromium plated for smoothness and wear characteristics. The workpiece was pushed through the die and stripped from the punch by a split stripper plate under the draw die. The strippers were closed by cam action from the press stripper rod.

Because production quantities of any one part were small, this technique was preferable to making a transfer die for each of the several caps produced on this line. Operations were set up in machines in the line as they were needed and as the machines became available.

The final draw, which was the deepest, governed the final production rate of 575 pieces per hour. However, when there was a backlog of pieces, this operation was set up on two machines at the same time.

The blank-and-cup die made about 45,000 pieces before resharpening. The draw rings were used for 150,000 to 200,000 pieces before wear was too great. Dies in the first few draws were allowed to wear over a fairly wide range. As the die opening increased, clearance was maintained by increasing the thickness of the chromium plating on the punch. When the die openings were 0.10 to 0.13 mm (0.004 to 0.005 in.) oversize, the dies were replaced, and punches were returned to the original size by stripping, polishing, and replating.

The lubricant was a mixture of one part sulfur-free chlorinated oil with three parts inhibited hydraulic oil having a viscosity of 250 SUS at 40 °C (100 °F). This lubricant was furnished to all presses through a central pumping system.

Critical tolerances on these fountain-pen caps were ±0.02 mm (±0.001 in.) on outside diameter and ±0.01 mm (±0.0005 in.) on inside diameter. Holding the clearance between the draw die and punch to 10% greater than stock thickness helped to maintain these tolerances.

Steel Drawing Forces. Estimates of the maximum drawing forces necessary to form cups from an austenitic stainless steel, a ferritic stainless steel, and low-carbon steel are compared in Table 8. These drawing forces, in tons of force, are based on the formula $S\pi Dt$, where S is the tensile strength of the metal in tons of force per square inch, D is the cup diameter in inches, and t is the metal thickness in inches.

Table 8 Force required for drawing two stainless steels and low-carbon steel of 1.27 mm (0.050 in.) thickness to various diameters

Diameter of piece		Approximate drawing force required					
		Austenitic stainless steel, type 18-8		**Ferritic stainless steel, 17% Cr**		Low-carbon steel	
mm	**in.**	**kN**	**tonf**	**kN**	**tonf**	**kN**	tonf
125	5	350	39	180	20	160	**18**
255	10	700	78	520	59	350	**39**
510	**20**	**1400**	**157**	**1040**	**117**	**700**	**78**

Blankholding pressures for the austenitic alloys must be much higher than those for the ferritic types or low-carbon steels. For austenitic alloys, the pressure, P, on the metal under the blankholder is usually about 6.9 MPa (1.0 ksi); for the ferritic alloys, 1.4 to 3.4 MPa (0.2 to 0.5 ksi). Thinner material and larger flange areas generally require greater pressure.

Drawing Hemispherical Parts. The drawing of hemispherical, or dome-shaped, parts demands special attention to blankholder pressure to prevent wrinkling because so much of the metal surface is not in contact with any die surface for most of the draw. Only the very tip of the punch is in contact with the work at the start of the stroke, and the surface between the tip and the blankholder draws or stretches free until the punch descends far enough to contact it. An undersize punch can sometimes be used to draw or stretch the blank into a preform before the dome-shaped punch makes the final draw, as in the following example.

Example 18: Two-Stage Drawing of a Stepped-Diameter Hemisphere.

One of the critical points in the production of the vacuum-bottle top shown in Fig. 19 was the forming of the shoulder at the large end of the dome-shaped top. The stepped inside diameter of this shoulder had to be an exact fit with the body of the vacuum-bottle jacket. The pierced hole at the small end also had to be accurately formed to conform to the mouth of the inner container.

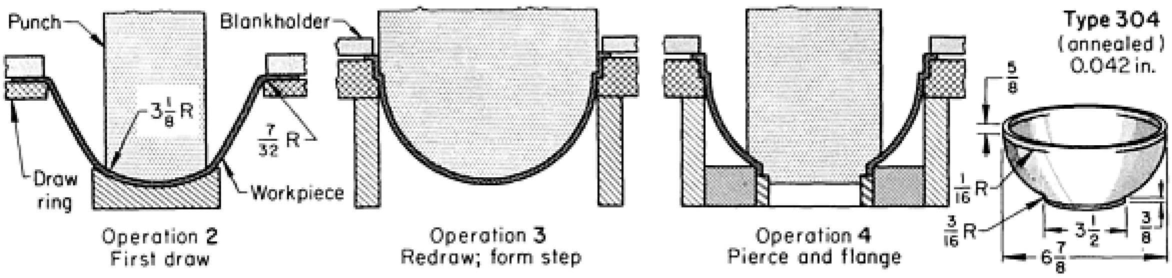

Fig. 19 Production of a stepped-diameter flanged hemisphere, in which a narrow punch was used in predrawing

the dome. The piece was drawn from a 280 mm (11 $\frac{1}{8}$ in.) diam blank produced in operation 1 (not shown). Dimensions in figure given in inches.

The stock was 289 mm (11.375 in.) wide annealed type 304 stainless steel strip, 1.1 mm (0.042 in.) thick. A single-action mechanical press with a spring-loaded pressure pad was used to cut 280 mm (11 $\frac{1}{8}$ in.) diam blanks from the strip, leaving 3.2 mm ($\frac{1}{8}$ in.) minimum scrap on each side of the strip.

The first draw was made in a 2200 kN (250 tonf) double-action mechanical press. The punch was 83 mm (3 $\frac{1}{4}$ in.) in diameter; therefore, much of the surface of the dome was drawn free (operation 2, Fig. 19). This required careful control of the blankholder pressure to prevent puckers and wrinkles. Blankholder pressure had to be adjusted for every lot of steel; it varied from 5.5 to 6.9 MPa (0.8 to 1.0 ksi). The die radius also had to be held closely (5.2 times the stock thickness). The first draw produced a cup 175 mm (6 $\frac{7}{8}$ in.) in diameter with a 235 mm (9 $\frac{1}{4}$ in.) diam flange.

The second draw was also made in the 2200 kN (250 tonf) double-action press. The punch for the second draw was shaped to the required inner contour of the part, including the step at the base of the dome, which was formed as the press bottomed at the end of the second draw stroke (operation 3, Fig. 19). This operation formed the dome shape of the bottle top by reshaping (mostly by stretching) the cup formed in the first draw. The metal for the cylindrical area above the step was drawn from the flange metal remaining after the first draw.

In the fourth operation, the hole in the top of the dome was pierced, and an internal stretch flange was formed around the hole. This was done with a spring-loaded piercing die, which gave sufficient resistance to let the piercing punch shear the material and then retreat under pressure from the flange-forming part of the punch. Both ends of the part were later trimmed in a lathe.

Drawing Rectangular Parts. During the deep drawing of a box-shaped part, the metal in the corners of the part and in the flange around the corner undergoes a change much like that which takes place when a round shell is drawn from a circular blank. Metal is compressed at the corners, and significant thickening occurs where the metal flows into the corners. The sides of the box undergo essentially no thickening, because there is no compression of the metal in the flange areas as it flows or bends over the die radius.

Clearances in the sides between the punch and die are ordinarily about 10% greater than the metal thickness to compensate for gage variations and to allow for metal flow. At the corners, punch-to-die clearances are similar to those used for cylindrical parts to allow for thickening.

Blankholding devices are almost always used in producing deeply recessed box-shaped parts in order to control the metal movement, particularly in the corners. The corners are under severe strain because of the intense compression of the flange metal, and most fracturing, if it does occur, takes place in the lower wall corner sections.

Punch and die radii are generally the same for rectangular draws as for circular draws. Some fabricators prefer to make the punch and die radii at the corners larger than along the sides in order to equalize the stress in the metal at the corners. The top surface of the draw die and the draw radii should be polished smooth (free of grind marks and well blended) to prevent localized retardation of metal flow with resultant uneven drawing of the metal. Burrs and bent edges on the blank often restrict metal flow or movement along the blankholder surface to such a degree that vertical wall fractures can occur.

Semideveloped blanks usually produce better results than rectangular ones. There are a number of patterns for trimming the corners, ranging from a simple 45° trim to patterns with a carefully developed area containing the optimal volume and area of metal.

The economic success of the run is related to tool wear and scrap rate. The following example describes a combination of tool materials that has given satisfactory performance in terms of parts or draws per regrind and redress. The same tooling can be used for both drawing operations, with the draw ring reversed to present a different radius for the second draw, as in the following example.

Example 19: Use of a Reversible Two-Radius Draw Ring for Drawing and Redrawing of a Flanged Rectangular Shell.

The flat-flanged single-sump kitchen sink shown in Fig. 20 was formed in four operations: blank, draw, redraw, and trim. Forming of the part was a combined draw-and-stretch operation. Because several different models, with drain holes in various locations, were made from the same drawn part, the drain hole was not pierced in the trimming operation but was made separately. The production rate was 50,000 to 100,000 pieces per year.

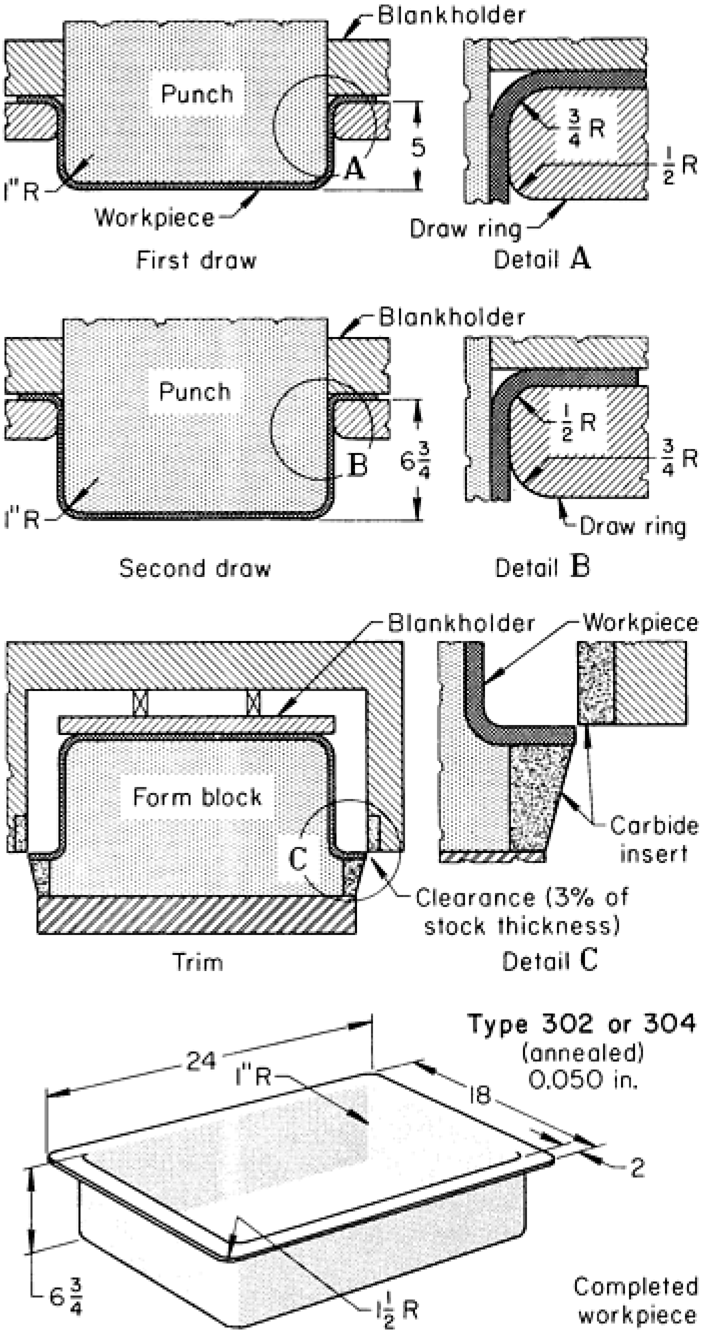

Fig. 20 Production of a flat-flanged sink basin by drawing and redrawing (using a two-radius reversible draw ring) and trimming. Dimensions given in inches.

The material was annealed type 302 or 304 stainless steel coil stock 735 mm (29 in.) wide and 1.27 mm (0.050 in.) thick, with a No. 2D sheet finish. Blanks 635 mm (25 in.) long were sheared from the coil at the rate of 40 per minute in a single-action mechanical press. Corners of the blanks were trimmed at 45°, removing 50 mm (2 in.) from each edge of the blank at each corner. Clearance for this trimming was kept at less than 5% of metal thickness to minimize edge distortion and burrs.

The draws were made in a 3600 kN (400 tonf) double-action mechanical press with 2200 kN (250 tonf) available for blank holding. The draw punch was made of alloy tool steel, and the blankholder was made of alloy cast iron. The reversible draw ring (Fig. 20) was made of hard aluminum bronze and had a 19 mm ($\frac{3}{4}$ in.) draw radius on one side for the first draw and a 13 mm ($\frac{1}{2}$ in.) draw radius on the other side for the redraw. The workpiece was annealed in an inert atmosphere at 1065 °C (1950 °F) between the first and second draws and then air cooled rapidly to room temperature.

The depth of the sink after the first draw was 127 mm (5 in.); after the second draw it was 170 mm (6 $\frac{3}{4}$ in.). Draws were made at a punch speed of approximately 6.4 m (21 ft) per minute, with less than 2% of the workpieces fracturing.

A similar 3600 kN (400 tonf) press was used to trim the piece. Carbide inserts provided shearing edges for the trimming operation. The sink was held on a form block of molded plastic or cast iron for trimming.

The second draw operation sharpened the bottom and flange corner radii and stretched the bottom surface and the side walls to remove any loose metal. Little or no metal was drawn into the part from the flange during the second draw.

Spinning

Stainless steel parts such as cups, cones, and dished heads can be readily formed by manual or power spinning, although more power is required than that needed for the spinning of low-carbon steel. Equipment and techniques for these processes are described in the article "Spinning" in this Volume.

Manual Spinning. The amount of thinning that occurs during manual spinning is related to the severity of the formed shape. A cross section is shown in Fig. 21 of a manually spun piece that thinned out to such a degree that it often fractured. This piece was excessively worked, and the mid-center area was work hardened beyond the capacity of the material, causing the workpiece to fracture. The piece was later made by press drawing the dome-shaped cup and spinning the broad flared flange.

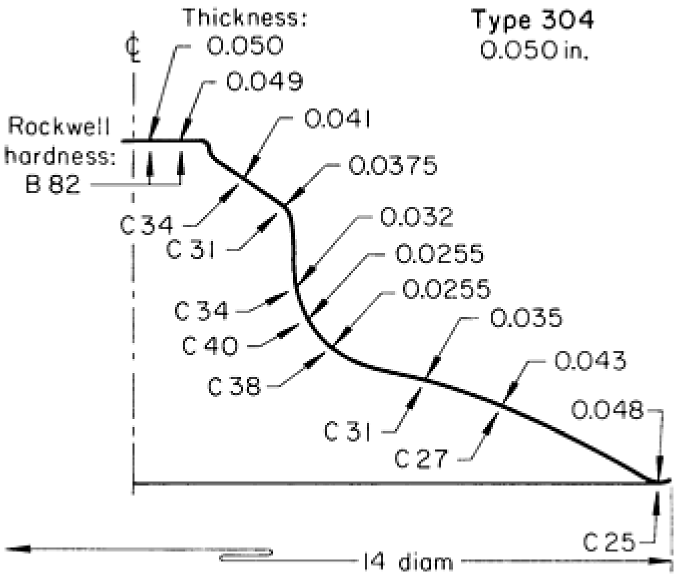

Fig. 21 Profile of shape, hardness, and thickness of a manually spun part that often fractured in its thinnest section. Dimensions given in inches.

The approximate limits of stretch in manual spinning are given in Table 9. These are for 1.57 mm (0.062 in.) thick fully annealed stock. The second stretch after annealing is about 8% less than the first. The amount of stretch is not necessarily uniform over the entire part; it varies with the severity of the form.

Table 9 Approximate limits of stretch in the manual spinning of stainless stools 1.57 mm (0.062 in.) thick

Type	Stretch (max), %
305	**45**
302	**40**
304	**40**
302B	**35**
316	**35**
316L	**35**
321	**35**
309	**30**
310	**30**

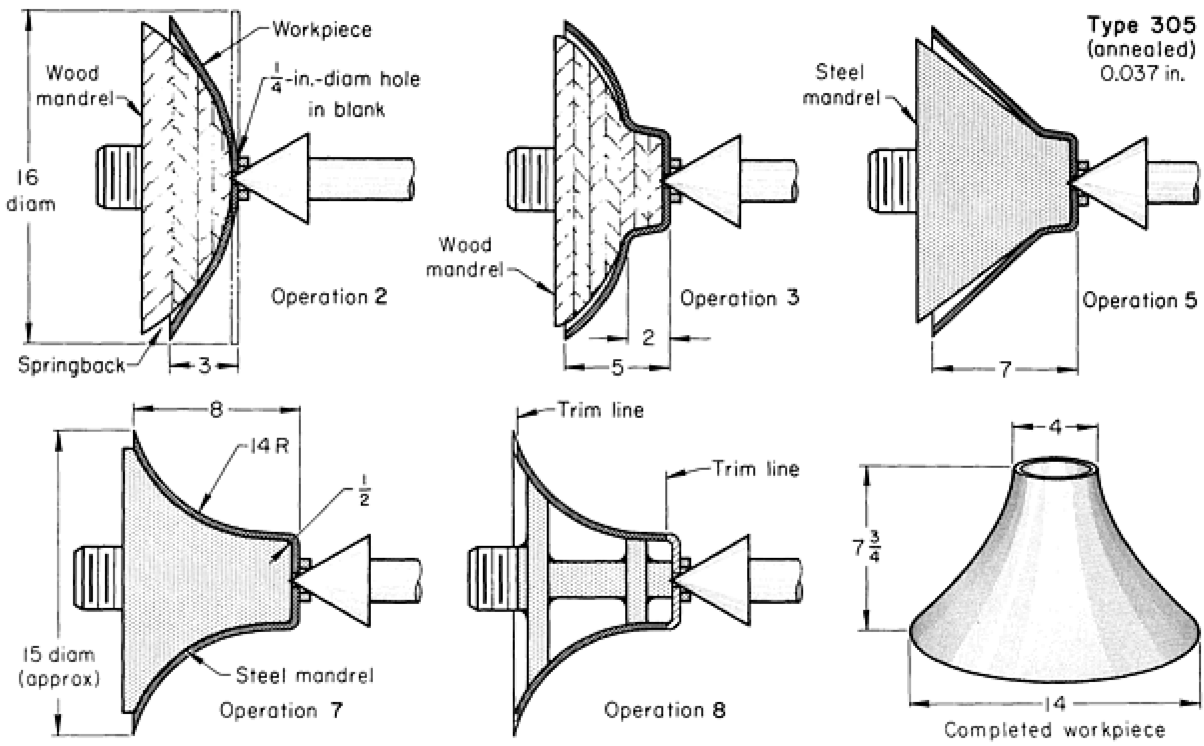
317	**30**
430	**30**
201	**25**
202	**25**
301	**25**
405	**25**
446	**25**
403	**20**
410	**20**

These limits are for stretching during one spinning pass; after being annealed, the metal can be respun to 8% less than the first stretch.

Although 300-series stainless steels can be formed by spinning, 302, 304, and 305 can be spun to greater reductions than other stainless steels before intermediate annealing becomes necessary. All anneals must be followed by pickling to remove oxides, thus restoring the clean, smooth surface. The No. 1 strip or 2D sheet finish is best for severe applications because the metal is in the softest stress-free condition and will take the greatest amount of working. The following example demonstrates the spinnability of type 305 stainless steel.

Example 20: Four-Pass Manual Spinning of a Cone From Type 305 Stainless Steel.

The 355 mm (14 in.) diam cone shown in Fig. 22 was produced in eight operations, including four manual spinning passes, from a 405 mm (16 in.) diam blank of 0.94 mm (0.037 in.) thick annealed type 305 stainless steel that had a No. 2D sheet finish or a No. 1 strip finish. Other types of austenitic stainless steel could have been used, but the reduction per pass would have been lower, in proportion to the increase in rate of work hardening.



Sequence of operations

Drill a 6.4 mm ($\frac{1}{4}$ in.) diam center hole in a 405 mm (16 in.) diam blank 0.94 mm (0.037 in.) thick.
Spin to 75 mm (3 in.) depth on a laminated hardwood mandrel at 300 rpm, applying manual pressure on lever and roller.
Spin to 125 mm (5 in.) depth on a second laminated hardwood mandrel to within 25 mm (1 in.) of edge.
Anneal in hydrogen atmosphere at 1040 °C (1900 °F); air cool.
Spin to 178 mm (7 in.) depth on a steel mandrel to within 25 mm (1 in.) of edge.
Anneal as in operation 4.
Spin to 205 mm (8 in.) depth and final shape on a steel mandrel.
Lathe-trim top and bottom ends to 195 mm (7 $\frac{3}{4}$ in.) final height of cone.

Fig. 22 Production of a stainless steel cone by four-pass manual spinning. Dimensions in figure given in inches.

As shown in Fig. 22, the mandrels for spinning were made of wood or steel. The spinning roller was made of hardened steel. Pressure was applied to the entire blank in the first spinning pass. In the three other passes, the outer 25 mm (1 in.) of the blank was not spun. This caused the edge to thicken to 1.78 mm (0.070 in.) and helped hold the outer shape. Thinning was greatest at the middle of the cone, to about 0.69 mm (0.027 in.) wall thickness (28% reduction). The surface area of the piece was increased 40%. The drastic working that accompanied the thinning and the increase in area made two anneals necessary (see sequence of operations, Fig. 22). Annual production quantity was 500 pieces.

The 400-series stainless steels, because of their relatively low ductility, do not adapt readily to manual spinning, especially when the deformation is severe. The high pressure of the forming tool causes wear of the work metal, resulting in early thinning and fracturing. Figure 23 shows forming speeds used for manual spinning of 400-series stainless steels.

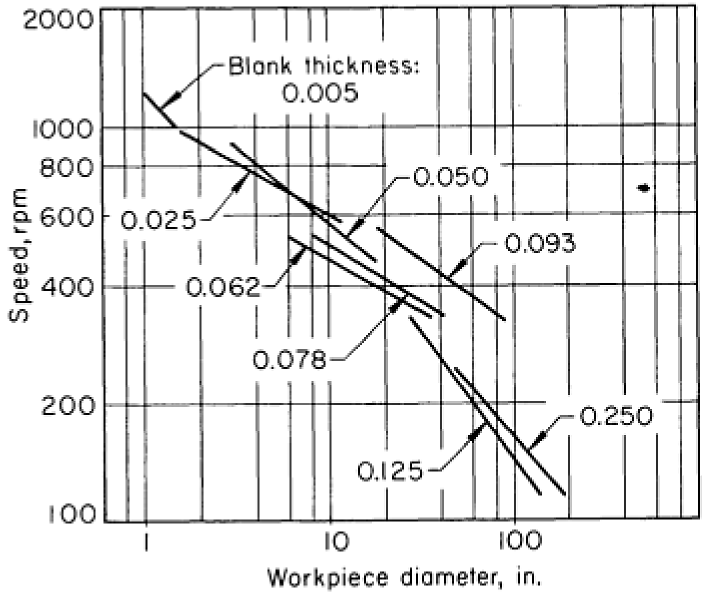


Fig. 23 Effect of workpiece diameter and blank thickness on rotational speed for the manual spinning of austenitic stainless steel. Dimensions given in inches.

The surface of severely spun parts is often very rough because of the action of the tools on the metal, and the production of a buffed or highly polished finish on a part spun from a 400-series stainless steel can be expensive. It is generally necessary to rough grind the material to smooth out the irregularities before polishing and buffing.

Typical stock thicknesses of stainless steel for manual spinning are 0.30 to 3.18 mm (0.012 to 0.125 in.), although stainless steels as thin as 0.13 mm (0.005 in.) and as thick as 6.35 mm (0.250 in.) have been spun by hand. The corner radius should be at least five times the thickness of the work metal. Allowance must be made in the size and shape of mandrels for springback and for heat-induced dimensional changes.

Power spinning is used for severe reductions and for work that cannot be done by hand. Stainless steels in both the 300 and 400 series are readily formed by power spinning, but the low-work-hardening types 302 and 305 are superior. Much larger reductions of type 430 can be made by power spinning than by manual spinning.

Spinning can be done hot or cold, although the severe reduction accompanying power spinning may cause so much heat that the spinning that began cold becomes warm spinning. Hot spinning, done only above 790 °C (1450 °F), is commonly used for work 4.8 to 13 mm ($\frac{3}{16}$ to $\frac{1}{2}$ in.) thick. The need for careful control of the temperature makes it difficult to hot spin metal that is less than 6.4 mm ($\frac{1}{4}$ in.) thick. Thicker stainless steel can be hot spun as easily as low-carbon steel.

Cracking at the edge is the main problem in the power spinning of austenitic stainless steels. The edge of the blank may need to be ground smooth to prevent cracking. A generous trim allowance is helpful so that the cracked edge can be cut off. Cracking and distortion can be prevented by keeping a narrow flange on the work. If the size of the spun piece is not correct after it cools (because of springback and heat expansion), the piece can be annealed and spun to size while it is still above 150 °C (300 °F).

Considerable thinning can be produced by power spinning, as indicated by the cross section of a deeply spun vessel shown in Fig. 24. The thickness of the vessel was reduced from 1.90 to 0.66 mm (0.075 to 0.026 in.) in one spinning operation. A preformed cup 152 mm (6 in.) in diameter and 75 mm (3 in.) deep, drawn on a conventional press, was used as the starting shape. The top of the vessel is much thicker than the wall. Thickening of the rim occurred during drawing, and it remained thick because there was essentially no deformation in this region during spinning.

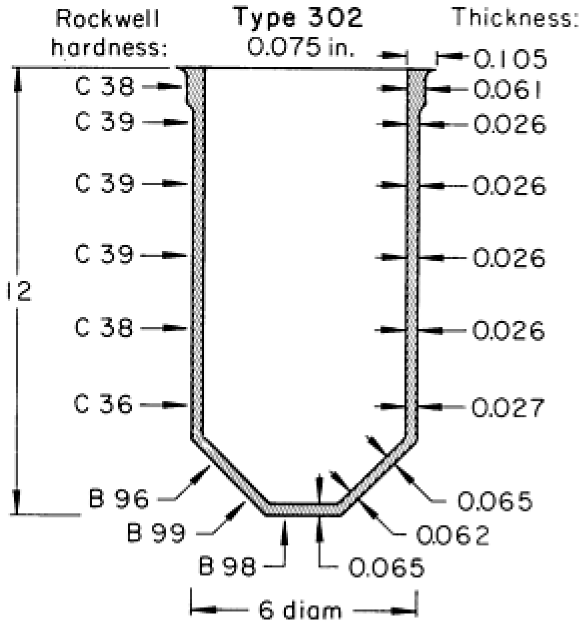

Fig. 24 Variations in hardness and thickness of a shell that was power spun from a preform drawn from stainless steel 1.9 mm (0.075 in.) thick. Dimensions in figure given in inches.

The surfaces of power-spun pieces are rough, and extensive finishing is required to make them smooth and bright. The spun surface is rough because the roller usually imparts a spiral or helical groove to the surface as the roller is fed into the metal while it rotates. Except for this disadvantage, power spinning is an excellent way of forming pieces from stainless steel.

Lubricants (see Table 2) are used to reduce friction, to minimize galling and tool drag, and to provide cooling. For manual spinning, firmly adherent lubricants are preferred; for power spinning, coolant action is more important. Lubricants containing sulfur or chlorine are usually avoided; they are difficult to remove completely and have harmful effects on heated stainless surfaces.

Forming of Stainless Steel

Revised by Joseph A. Douthett, Armco Inc.

Rubber-Pad Forming

Annealed austenitic stainless steels--types 301, 302, 304, 305, 321, and 347--are rubber-pad formed in thicknesses to 1.3 mm (0.050 in.). Most of the operations are straight flanging, especially in thicker workpieces. With auxiliary devices, such as wedges or rollers, pieces up to 2.0 mm (0.078 in.) thick can be formed. Flanges must be wide enough to develop adequate forming force from the unit pressure on their surface. For annealed stainless steels, the following minimum flange widths beyond the bend radius are recommended for successful forming:

Thickness	Flange width

mm	**in.**	**mm**	in.
0.41	0.016	6.35	**0.250**
0.51	0.020	6.86	**0.270**
0.64	0.025	7.37	**0.290**
0.81	0.032	8.38	**0.330**
1.02	0.040	9.14	**0.360**
1.30	0.051	10.0	**0.410**
1.63	0.064	12.2	**0.480**
1.83	**0.072**	**13.0**	**0.510**

In quarter-hard temper, types 301 and 302 up to 0.81 mm (0.032 in.) thick can be flanged if the flange is at least 16 mm ($\frac{5}{8}$ in.) wide.

The rubber-pad forming of contoured flanges in stainless steel requires more powerful equipment than that used for flat flanges. Most forming of contoured flanges is done on annealed stainless steel, but a limited amount is done on quarter-hard stock.

Stretch flanges are readily formed on annealed stainless steel up to 1.3 mm (0.050 in.) thick. Rubber-pad-formed stretch flanges of thin metal are generally smoother and more accurately formed than those formed by single-action dies. Die-formed flanges often curl outward, requiring considerable hand work for correction.

The hydraulic presses used in the Guerin process develop forming pressures to 34.5 MPa (5 ksi). Narrow stretch flanges that require pressures greater than 34.5 MPa (5 ksi) are formed with the aid of auxiliary devices, such as traps and wedge blocks, that raise the forming pressure locally (see the article "Rubber-Pad Forming" in this Volume).

Thin metal can be formed by means of a simple form block, but if the web is narrow, the workpiece should be protected by a cover plate to avoid distortion. The following example demonstrates the limits of rubber-pad forming of stretch flanges in stainless steel:

- The stock was quarter-hard type 302
- The workpiece had a narrow web and therefore required the use of a cover plate in forming
- The workpiece had external hole flanges
- The stretch flange was only 7.9 mm ($\frac{5}{16}$ in.) wide
- The curved workpiece was nearly 965 mm (38 in.) long

If a stainless steel part of this shape is more than 610 mm (24 in.) long, it is almost impossible to prevent the springback of the flange material from bowing the part unless curved dies are used.

Example 21: Use of a Curved Die With Cover Plates in Rubber-Pad Forming.

The strut shown in Fig. 25 had a 7.9 mm ($\frac{5}{16}$ in.) wide stretch flange and external 65° flanges on two lightening holes at the large end. It was rubber-pad formed from a quarter-hard type 302 stainless steel blank 0.41 mm (0.016 in.) thick.

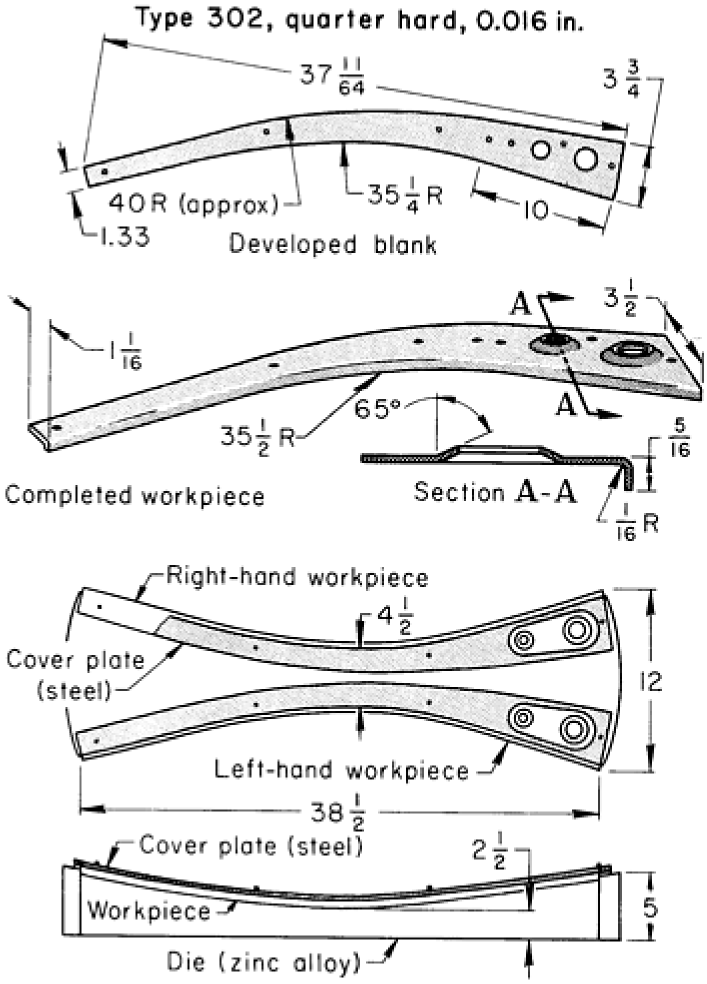

Fig. 25 Long narrow strut with a contoured stretch flange that was made by rubber-pad forming in a curved die with cover plates to prevent springback. Dimensions given in inches.

The zinc alloy die used was made with a curve to offset the springback of the flange (Fig. 25). Right-hand and left-hand pieces were flanged at the same time in the same die. A steel cover plate protected the thin web of each piece from distortion during forming. No lubricant was used. The pressure developed by the rubber was 10.3 MPa (1.5 ksi).

Deep Drawing. By the rubber-pad and rubber-diaphragm processes, stainless steels in both the 300 and the 400 series can be deep drawn to greater reductions than can be achieved with conventional methods. For extremely deep sections, the lower-work-hardening austenitic types 302 and 305 are recommended.

Two characteristics of rubber-pad methods make this great depth of draw possible. The first is controlled, continuously adjustable pressure on the blankholder or hold-down mechanism, and the second is the continuously variable draw ring radius. There is no draw ring as such, but the rubber that forms around the workpiece functions as a draw ring and conforms to the radius that will apply equal pressure to the entire surface of the workpiece. This minimizes both thinning at the punch radius and work hardening as the flange metal is drawn into the cup.

Figure 26 illustrates the relatively uniform wall thickness that can be produced by drawing using the rubber-pad method. For comparison, Fig. 17 shows the much greater variation in wall thickness produced by conventional deep drawing.

Additional information on deep drawing by rubber-pad techniques is available in the article "Rubber-Pad Forming" in this Volume.

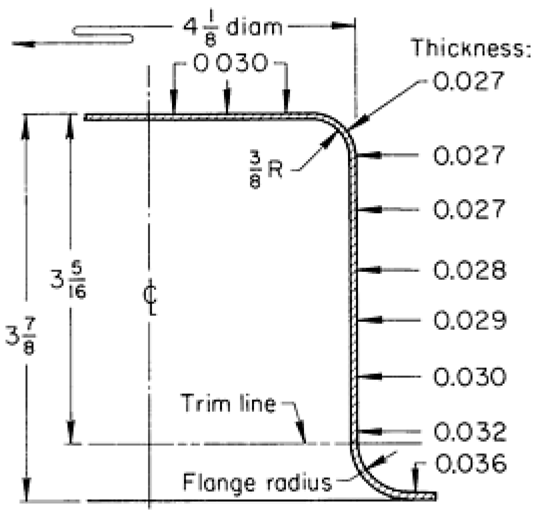

Fig. 26 Profile of a shell that was deep drawn from 0.76 mm (0.030 in.) thick stainless steel by the rubber-pad method showing the relatively uniform wall thickness obtained. Dimensions in figure given in inches.

Forming of Stainless Steel

Revised by Joseph A. Douthett, Armco Inc.

Drop Hammer Forming

A wide variety of sizes and shapes can be formed in thin stainless steel by drop hammer forming. The advantages of this method include high impact energy (which often means that a piece can be formed by one blow, as compared to four or five by other processes) and suitability to low-volume and experimental production.

Dies. Die material for drop hammer forming is less critical than for press forming. The dies are made of steel, plastic, zinc alloy, and lead. Zinc alloy is widely used.

Punches are often made of lead because it can be cast directly on the lower die and because its weight adds energy to the stroke of the drop hammer. Although the lead is reusable, the number of pieces that can be made from each cast punch is small--about 200. Plastic punches and dies impart a finish to formed parts that would otherwise be difficult to obtain. Steel dies are used for high production and for coining and sizing (see the article "Coining" in this Volume).

Die designs are generally similar to those for press forming, with the same punch and die radii to reduce stress on the work metal. Die design for the forming of beads and methods of relieving entrapment to ensure good metal flow in drop hammer forming are also similar to those used in press forming. A trapped-rubber technique somewhat similar to the Guerin process is described in the article "Rubber-Pad Forming" in this Volume.

Quality of Product. The dimensions of workpieces formed in a drop hammer are less consistent than those made by other processes, because the degree of impact is subject to operator skill and because the punch can shift under localized high loads. However, springback is less pronounced in drop hammer forming than in other forming methods because of the high impact and forming speed.

Lubrication. The lubricants that can be used in drop hammer forming are listed in Table 2. If working is severe enough to require annealing between stages, contaminants such as graphite or sulfur (from the lubricant) or zinc or lead (from the die) must be removed from the work surface. If these contaminants are left on the surface of the stainless steel when it is heated, they can cause serious surface deterioration.

Comparison With Press Forming. Press forming, although done rapidly, is inherently an operation in which ram speed and holding pressures can be closely controlled; however, in drop hammer forming, the only way to form a part is by sudden impact. In some applications, production difficulties are overcome by the high rate of energy release in a drop hammer. In others, especially those in which blankholder pressure is critical, press forming produces better parts more economically if the die is properly made, as in the following example.

Example 22: Change From Drop Hammer to Press Forming That Eliminated Wrinkling and Reduced Cost.

The tailpipe half shown at the top in Fig. 27 was originally produced in a drop hammer, using the tooling setup shown at the lower left in Fig. 27. The operation was unsatisfactory, however, because wrinkles occurred at the intersection of the 30° risers, and six operations totaling nearly 2 min per piece were required to complete each piece.

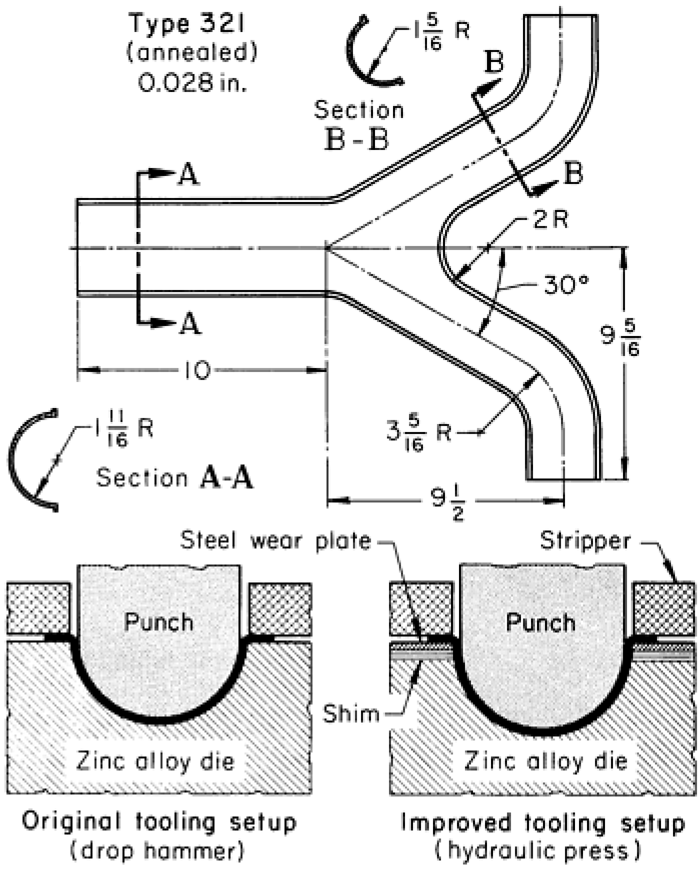

Fig. 27 Aircraft tailpipe half that was formed by the drop hammer and hydraulic press tooling setups shown. Dimensions given in inches.

The tools were redesigned for use in a 4400 kN (500 tonf) hydraulic press (lower right, Fig. 27). The zinc alloy die used in the drop hammer was reused in the press; to make it resistant to the abrasion of press forming with stainless steel, the die was faced off, and a low-carbon steel wear plate was installed. The 43 mm ($1\frac{11}{16}$ in.) radius had formed well in the drop hammer with very little springback, but springback in the press made it necessary to deepen the die. This was done by inserting shims between the die and the wear plate.

The press produced pieces that were completely free of wrinkles at the rate of two pieces per minute. This was a $1 \frac{1}{2}$ -min savings per piece.

The blank for both methods was annealed type 321 stainless steel measuring 510 × 610 mm (20 × 24 in.) and 0.71 mm (0.028 in.) thick. No lubricant was required for drop hammer forming; a wax emulsion was used for the press operation. Trimming after forming was done in a second press.

A drop hammer is ordinarily used for prototypes, and a press, using the prototype or improved dies, is used for mass production. If the quality of the prototype die is good, the drop hammer can be used for low production.

Forming of Stainless Steel

Revised by Joseph A. Douthett, Armco Inc.

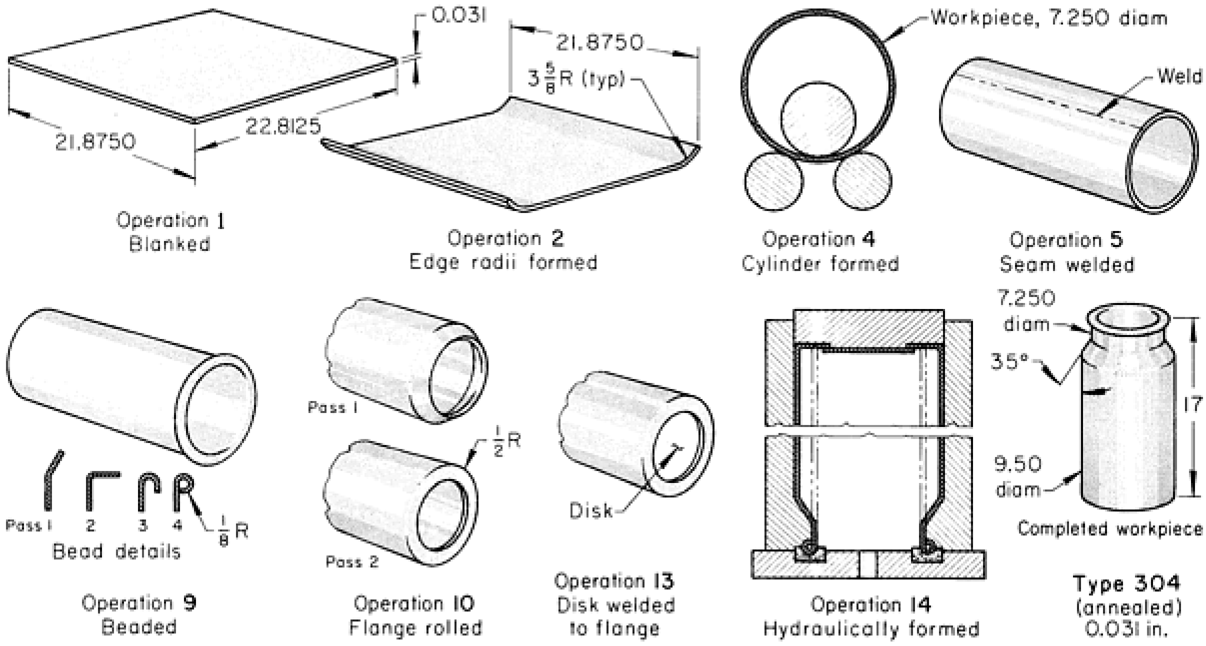
Three-Roll Forming

The three-roll forming of stainless steel is, in general, similar to the three-roll forming of other metals (see the article "Three-Roll Forming" in this Volume). Springback is a major problem with austenitic stainless steels, primarily because of the large radii involved and work hardening. It is important that the equipment be set up so that the desired curvature can be made in one pass. Because of the high rate of work hardening of austenitic stainless steels, subsequent passes are sometimes difficult to accomplish and control unless heavy equipment is used. The response of annealed ferritic stainless steel to three-roll forming is quite similar to that of hot-rolled low-carbon steel.

Three-roll and two-roll formers can be put in sequence with contour roll formers to make a cross-sectional shape and to bend or coil it, all in one production line. The following example describes an application in which three-roll forming was combined with press forming and hydraulic expansion forming.

Example 23: Use of Three-Roll Forming in the Production of a Container for Liquid.

Figure 28 shows eight of the 14 operations entailed in the production of a container for liquids by press forming and hydraulic expansion forming of a welded cylinder made from a radiused flat blank by three-roll forming in pyramid-type rolls. The six other operations are identified in the table that accompanies Fig. 28. These containers were produced in annual quantities of 10,000 to 100,000 pieces from annealed type 304 stainless steel coil stock 0.79 mm (0.031 in.) thick and 585.8 mm (23.0625 in.) wide.



Sequence of operations

Blank in die, in single-action press.
Form edge radii on blank, in a press brake.
Vapor degrease, to remove lubricant used in operations 1 and 2.
Roll cylinder, in three-roll former.
Weld cylinder seam, in automatic Heliarc setup using starting and stop-off tabs.
Trim tabs.
Hammer weld to induce compressive stress, using an air hammer at 310 kPa (45 psi).
Restore roundness of cylinder by rerolling several times in three-roll former.
Form bead on one end of cylinder, in four passes in an edger.
Roll flange on opposite end of cylinder, in two passes.
Trim flange.
Vapor degrease.
Weld (Heliarc) disk to inside of flange.
Expand and form to final shape (30% reduction in wall thickness), in a hydraulic expansion die (final pressure: 4800 kPa, or 700 psi).

Fig. 28 Use of three-roll forming in conjunction with press forming and hydraulic expansion forming, in the 14-operation production of a container for liquids. Dimensions given in inches.

Blanking the rectangular sheets for three-roll forming gave the workpiece the uniform square edges needed for maintaining the welded seam of the tube in axial alignment. The blanking tools were hardened high-carbon high-chromium tool steel; clearance was 0.08 mm (0.003 in.) per side. The stock was lubricated for blanking and edge radiusing, but the blanks were vapor degreased before three-roll forming.

Forming of Stainless Steel

Revised by Joseph A. Douthett, Armco Inc.

Contour Roll Forming

Stainless steel is ordinarily contour roll formed in the annealed condition. Types 410 and 430 are usually roll formed on equipment similar to that used for carbon steel, with a No. 2 finish generally specified. Speeds are usually in the range of

7.6 to 30 m (25 to 100 ft) per minute, with the heavier gages and more difficult sections being roll formed at the slower speeds.

Stainless steels in hard tempers, such as quarter-hard and half-hard type 301, are also frequently roll formed. Increased power over that used for forming the same steels in the annealed condition is necessary because of the higher initial strength of the strip. Springback must be compensated for by adequate overbending. Longitudinal cracking can be a problem with the hard tempers if adequate radii are not included in the design of the part.

Distortion or warpage of straight sections causes the greatest problem in roll forming the 300-series steels, particularly when the steel is thick. The distortion can be minimized by using more sets of rolls, or more passes, for greater control during each stage of bending. However, the skill of the operator is all-important in controlling distortion. Various straightening devices are usually attached or used on the last pass as the section emerges from the machine. In some applications, sections are deliberately curved.

With the chromium-nickel stainless steels, pickup on the rolls and galling of the strip sometimes occur. Highly polished rolls or bronze rolls are used with lubrication to minimize this problem when high pressure is needed. Heavy-duty emulsions containing chlorine offer the best combination of chemical EP and coolant activity (Table 2). Chlorinated oils or waxes are easy to use, but are less effective as coolants. For severe forming, the cushioning effect of pigments is sometimes needed (as in the next example), as well as efficient cooling.

Example 24: Nine-Station Contour Roll Forming of Annealed 304 Stainless Steel.

Figure 29 shows the sectional shapes progressively produced in the nine-station roll forming of a sheave track from annealed type 304 stainless steel strip 67.3 mm (2.648 in.) wide by 0.79 mm (0.031 in.) thick, with a No. 2 finish. In a tenth station, the formed track was straightened. As the track left the tenth station, it was clamped to a moving table that conveyed it to an abrasive wheel for cutoff into lengths of 3 to 6 m (10 to 20 ft). The material weighed 0.414 kg/m (0.278 lb/ft); annual production was 180 Mg (400,000 lb).

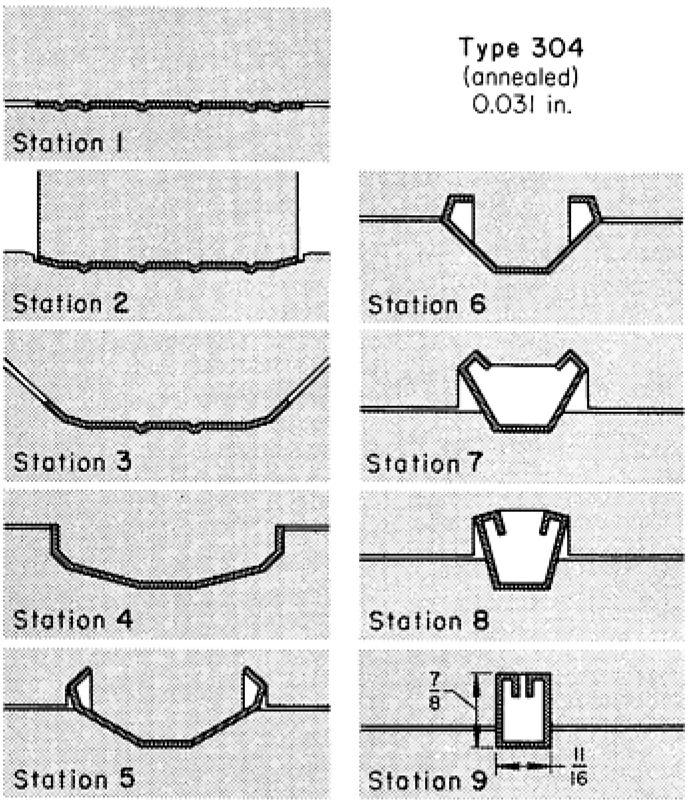


Fig. 29 Contour roll forming of a sheave track in nine stations. Dimensions given in inches.

During forming, the developed width of the section measured along the neutral axis increased only 1.02 mm (0.040 in.) to 68.2 mm (2.688 in.)--corresponding to only 1.5% stretch. The stretch was limited because the metal was restrained by the six pinch beads that were rolled into the strip before it was bent (stations 1, 2, and 3, Fig. 29). Each bead, 1.6 mm ($\frac{1}{16}$ in.) wide by 0.8 mm (0.030 in.) deep, permitted a sharp bend at that point without tearing or breaking the steel. The 50 to 55% elongation property of austenitic 304 stainless steel made it unlikely that the metal would break in bending. The strip was rolled with the slitting burr down so that the burr was flattened by the shoulders of the bottom roll of station 2.

The forming rolls were made of hardened steel, and the straightening rolls of hard bronze, for a good finish. Rolling speed was 17 m (55 ft) per minute. The lubricant was a pigmented water-soluble oil.

Plastic protective coatings are sometimes applied to the strip to minimize or prevent scratches and scuffing when high pressures are used and surface finish requirements are critical. On light-gage material (especially type 430), such protection is generally unnecessary if the fabricator is experienced in processing stainless steel. A detailed discussion of the equipment and techniques employed in contour roll forming is available in the article "Contour Roll Forming" in this Volume.

Revised by Joseph A. Douthett, Armco Inc.

Stretch Forming

The tools and techniques for stretch forming described in the article "Stretch Forming" in this Volume are applicable to stainless steel. Machines used for the stretch forming of stainless steel require 60 to 100% more power than that needed for similar operations on low-carbon steel of the same thickness.

Because of the abrasiveness of stainless steels, forming tools must be especially abrasion resistant. Wiping dies, wiping shoes, mandrels, and wear plates must be made of wear-resistant tool steel, carbide, or a bearing grade of bronze in order to avoid galling and welding.

Although the 300-series stainless steels are especially suitable for stretch forming because of their high work-hardening rate and ability to take large elongations, the 400-series steels are usable only for shallow stretched shapes. Type 301 is the austenitic steel that is best suited to stretch forming. Because of its high rate of work hardening, forming should be done slowly to derive maximum benefit from the ductility of type 301.

Maximum percentages of stretch for one-directional forming of various kinds of austenitic stainless steels are as follows:

- Annealed types 301, 302, 304, 305, 316, 321, and 347: 20% typical; possibly 30% on symmetrical and solid sections
- Quarter-hard types 301 and 302: 15% typical; possibly 20% on optimum sections
- Half-hard types 301 and 302: 5% typical; possibly 10% on optimum sections
- Full-hard type 301: possibly 2% on optimum sections

These figures should not be confused with permissible stretch in bending, nor are they the limits to which these stainless steels will stretch (which are considerably greater). Instead, these percentages, which determine the possible curvature of stretch-formed sectional shapes of stainless steel, are based on the distortion susceptibility of severely stretched stainless steel.

The upper limits can be extended by very slow stretching and forming, especially with hardened metal. In addition, to obtain maximum stretch from the harder tempers, workpieces should be carefully deburred. Automatic programming is valuable in applying continuously increasing tension to overcome the continuously increasing strength as work hardening takes place during stretch forming.

Lubricants. If there is little or no movement after contact between workpiece and form block, as in stretch wrapping or single-die draw forming, little or no lubricant need be used except when deformation is severe. A low-viscosity chlorinated oil or wax provides excellent chemical EP action and convenience of use. If there is considerable movement of the work metal against the dies (such as against the wiper shoe in radial-draw forming), pigmented lubricants are sometimes used. The following example describes an application in which no lubricant was used in the stretch forming of a sharply contoured part.

Example 25: Dry Stretch Forming of an Airfoil Leading Edge.

The leading edge of an airfoil was stretch formed dry from a type 302 stainless steel blank, 0.20 mm (0.008 in.) thick, 115 mm (4 $\frac{1}{2}$ in.) wide, and 5.5 to 6.7 m (18 to 22 ft) long, that had been roll formed to the airfoil contour shown in section A-A in Fig. 30. The blank had been annealed before roll forming, and it was stretch formed, without further annealing, to a 7.6 m (25 ft) radius with the heel of the contour pointing out (Fig. 30).

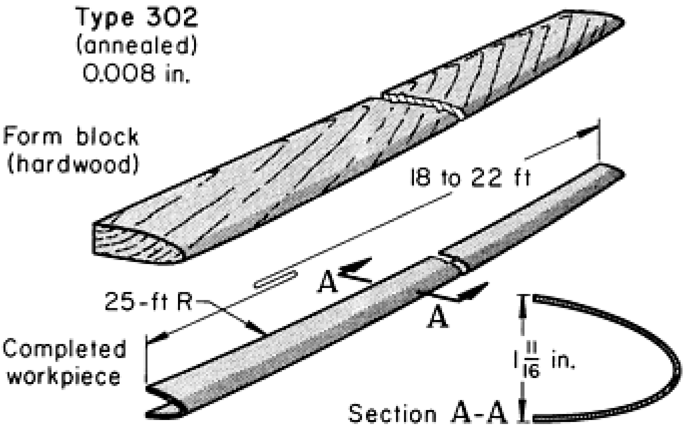

Fig. 30 Airfoil on which the leading edge was stretch formed to a long convex shape without lubricant in a radial-draw former.

The airfoil was stretch formed in a radial-draw former over a hard-maple form block with the airfoil contour carved into its surface (Fig. 30). Lubricant was not used, because it had previously caused local variations in friction. Time for forming was 10 min per piece with three men working. Setup time was 2 h. A typical production lot was 100 pieces.

The rolled contour had to be held within ±0.1 (±0.005 in.) after stretch forming. The envelope tolerance on the stretch-formed shape was 0.76 mm (0.030 in.).

Springback. In sharply contoured pieces that have a relatively deep, wide cross section, some springback cannot be avoided, even in annealed metal. During severe stretch forming, considerably higher strength, and therefore appreciably higher elastic recovery, is developed in the more highly stressed convex surface.

Springback in regular, symmetrical sections can usually be offset by overbending the piece. Dimensional variations in workpieces are primarily caused by variations in springback, which are in turn caused by variations in mechanical properties from sheet to sheet.

If the workpiece is irregular in cross section, if preformed flanges are to be held to a certain angular position, or if the curve of the form varies in severity, springback may cause twist or irregular distortion of the workpiece. Various methods of blocking, pretwisting, or overforming are used to prevent or correct this distortion. In the following example, an asymmetrical cross section was twisted during forming to offset the twist caused by springback.

Example 26: Use of Twisting to Compensate for Springback in Stretch Forming.

The curved channel section shown in Fig. 31 was stretch formed from quarter-hard type 302 stainless steel strip, 1.07 mm (0.042 in.) thick, that had been preformed in a press brake. Although the channel fit closely in the groove of the form block, springback caused considerable twist in the finished piece.

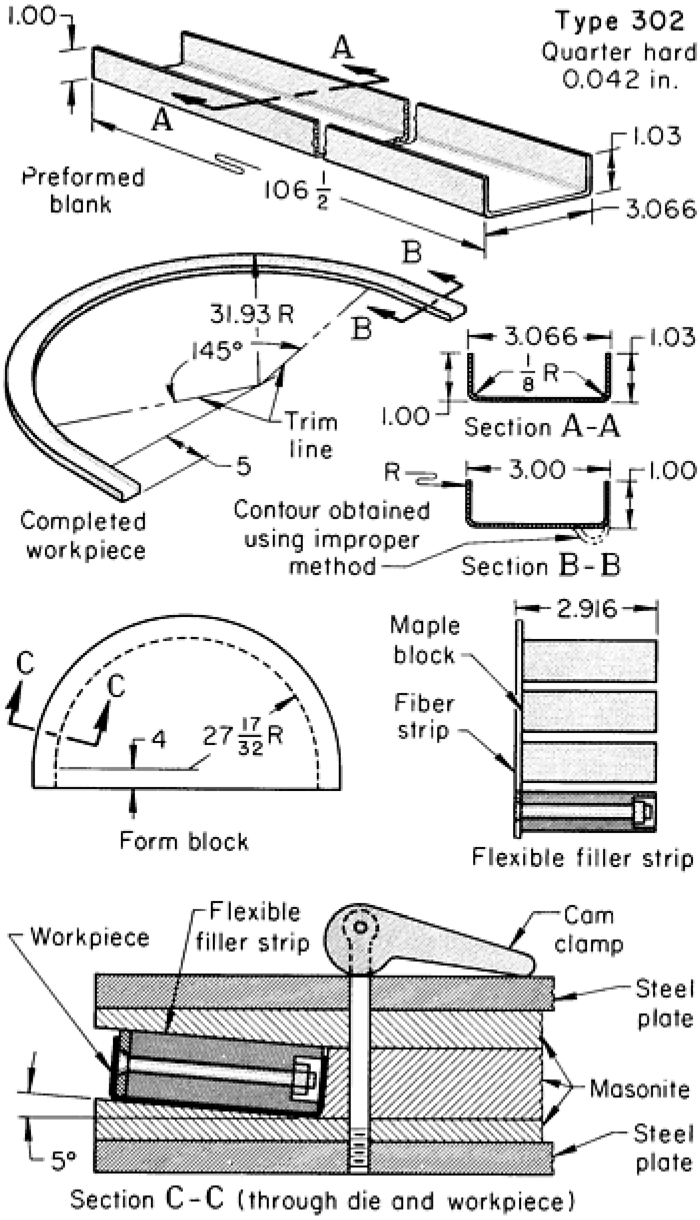

Fig. 31 Channel section that was stretch formed from a preform produced in a press brake, and details of tooling used in stretch forming, which provided reverse twist to compensate for springback. Dimensions given in inches.

Elastic recovery of the outer flange and the metal near the outer edge of the web caused buckling and twisting in the part as forming tension was released. To overcome this, the part was canted by the form block, and tension on the part was gradually increased during forming.

To establish a compensating initial reverse twist in the workpiece, spacers were added to the built-up form block to wedge the section to a 5° angle, as shown in Fig. 31. At the same time, a fiber filler strip with maple filler blocks was closely fitted into the channel to hold the cross-sectional contour. Details of the tooling are shown in Fig. 31.

The applied tension during stretch forming was 83.2 kN (18,700 lbf) at the start, 87.0 kN (19,550 lbf) at 45° bend, 90.7 kN (20,400 lbf) at 90°, 94.5 kN (21,250 lbf) at 135°, and 98.3 kN (22,100 lbf) upon completion of the bend. A nonpigmented fatty acid was used as the forming lubricant. After forming, the workpiece was trimmed to a 145° arc with a band saw.

Equalizing Stretch. In the stretch forming of sheets to a curvature in two directions (especially in stretching tempered material when the limits of stretch are very close), the quality of the product can be controlled much better if the stretch is uniform across the workpiece. One means of obtaining uniform stretch is to provide compensating contours (which are later trimmed off) at the end of the form block.

Forming of Stainless Steel

Revised by Joseph A. Douthett, Armco Inc.

Bending of Tubing

Austenitic stainless steel tubing can be bent to a centerline radius of 1 $\frac{1}{2}$ times tube diameter. As the ratio of tube diameter to wall thickness, *D*/*t*, increases, it becomes increasingly necessary to provide both internal and external support to keep the tube from collapsing as it is bent. When *D*/*t* is greater than 30, the tube is classed as a thin-wall tube. Interlocked tooling, as well as bending machines of a greater capacity than that required for thick-wall tubes, is strongly recommended for thin-wall tubing (see the article "Bending and Forming of Tubing" in this Volume).

For the bending of stainless steel tubing, wiper dies and mandrels are often made of aluminum bronze or a chromium-plated tool steel. Lubricants for the mandrel should be fairly heavy. Viscous or pigmented oil-base lubricants containing emulsifiers for ease of removal are used. Only the very lightest of lubricants should be used between the wiper die and the tube. A thin application of very light chlorinated mineral oil can be used in some bending operations without causing wrinkling. The following example describes techniques used in the bending of stainless steel tubing.

Example 27: Bending Difficult-to-Form Tubing Into an Aerospace Component.

The bent tube shown in Fig. 32, used in an aerospace assembly, was difficult to form within the specified tolerances (dimensions within 0.25 mm, or ±0.010 in.; angles within ± $\frac{1}{2}$ °; and flattening of the tube at bends not more than 0.05 mm, or 0.002 in.). The piece was produced from type 304 stainless steel tubing in nine operations in the following sequence (times shown are for the production of 100-piece lots):

- Cut tubing into lengths of 160 mm (6 $\frac{1}{4}$ in.) with an abrasive cutoff wheel; deburr roughly (3 h)
- Fill each workpiece with low-melting alloy (8 h)
- Make 160° bend in powered draw bender; gage the bend (5 h)
- Make 24° bend in hand bender; gage the bend (5 h)
- Trim ends to length in a cutoff fixture using an abrasive wheel (3 h)
- Melt out the filler (6 h)
- Deburr by hand, using a grinder and a drill (3 h)
- Passivate in a chemical dip (1 h)
- Inspect 100% with gage and by rolling an accurate ball through the completed part (2 h)

Springback in bending, about 5°, was corrected by overbending to a degree established in trial bends.

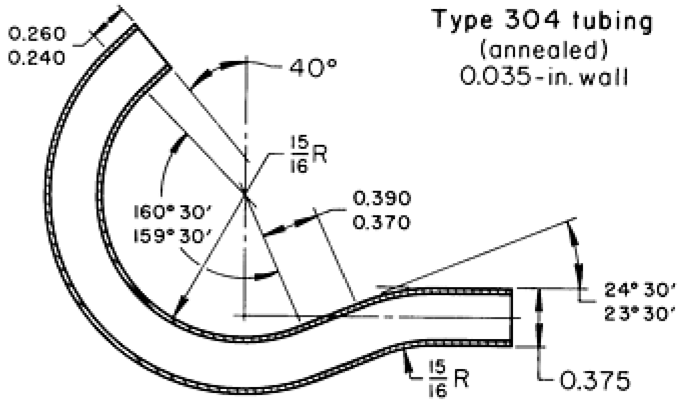

Fig. 32 Aerospace component that was bent from stainless steel tubing with the use of a low-melting alloy as a filler during bending. Dimensions given in inches.

Revised by Joseph A. Douthett, Armco Inc.

Other Forming Operations on Tubing

Stainless steel tubing can be easily flared to increase the diameter 25 to 30% if it is annealed. The diameter can be reduced by rotary swaging, or it can be increased by bulging or beading. Rubber punches are often used for this purpose, as described in the article "Rubber-Pad Forming" in this Volume.

Tubing of austenitic stainless steel can be hot formed by heating to 1175 to 1260 °C (2150 to 2300 °F). Work should be halted when the tube has cooled to 925 °C (1700 °F), and the tube should then be cooled rapidly to minimize the precipitation of carbides.

Because austenitic stainless steel tubing is stronger than carbon steel tubing and work hardens rapidly, warm forming (below the recrystallization temperature) is also used on this material. The temperature for warm forming should be kept below 425 °C (800 °F) to prevent the formation of carbides.

Tubing of ferritic stainless steels, such as types 430 and 446, is less easily formed than similar tubing of austenitic stainless steels. Ferritic tubing is hot formed at 1035 to 1095 °C (1900 to 2000 °F), and forming is stopped when the tubing cools to 815 °C (1500 °F). For best results, the range from 815 to 980 °C (1500 to 1800 °F) should be avoided, because ductility and notch toughness are progressively impaired as the tube cools through that range. Hot shortness may be encountered in the upper part of the range. Tubing of ferritic stainless steels is warm formed at 120 to 205 °C (250 to 400 °F).

Steel producers have studied the cold formability of 11% Cr (409) and 17% Cr (439 or 18% Cr-Nb) tubing materials, primarily because of requests from the automotive industry to use Ti or Ti + Nb stabilized ferritic alloys in exhaust systems. Such alloys are normally used in high-frequency welded or gas tungsten arc (GTA) welded (autogenous) and annealed tubing. Traditionally, the GTA welded and annealed tubes had more formability because of the elimination of the 8 to 15% cold work induced in forming the tube.

As these ferritic alloys were subjected to the demands of high-speed vector bending, particularly in making tubular exhaust manifolds, breakage rates increased to over 50%. In response, stainless steel producers borrowed technology from low-carbon steel production practices and developed a line of high-performance ferritic alloys with improved elongations and higher *r* values (>1.5). Additional information on the determination of *r* values is available in the article "Formability Testing of Sheet Metals" in this Volume.

Such alloys have permitted the greater use of high-frequency welded and unannealed tubes for thin-wall bends with a centerline bend radius less than twice the tube diameter. Furthermore, such bends can be made at room temperature, although care should be exercised in cold weather not to fabricate sub-room-temperature tubing. Finally, through tighter control of both melt chemistries and processing parameters, ferritic tube alloys with excellent welding and bending reproducibility from heat to heat have been developed.

Forming of Stainless Steel

Revised by Joseph A. Douthett, Armco Inc.

Forming Versus Machining

Although forming ordinarily requires expensive tooling and bulky equipment, it is a high-speed process, and for most parts that can be formed from sheet, it is more economical than machining for mass production. The following example shows how production techniques can vary with the size of the production lot to make the best use of each technique.

Example 28: Influence of Change in Quantity of Production Method and Product Design.

A threaded cap was made of type 347 stainless steel by three different methods. Each method involved a change in design, as illustrated in Fig. 33.

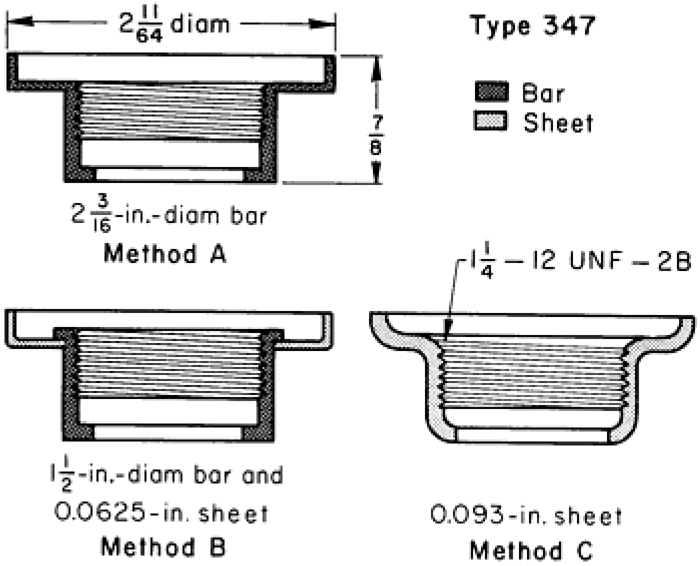

Fig. 33 Machining versus press forming for producing a cap. In method A, the cap (illustrated above) was completely machined from bar stock. In method B, the cap (redesigned) combined components that were press formed from sheet and machined from bar stock. In method C, the entire cap (again redesigned) was press formed from sheet and then partly machined. Dimensions given in inches.

The original order was for 100 caps, with an anticipated design change on future orders. The quickest and most economical production method was to machine the cap in one piece from bar stock (method A, Fig. 33).

The next order was for 1000 caps. The design and manufacturing methods were revised so that the cap was produced as an assembly of two components--one press formed from sheet and the other machined from bar stock (method B, Fig. 33).

When requirements increased to 5000 caps, a cost reduction was essential to obtain the order against a competitor's bid. The part was redesigned for production entirely from sheet by press forming and partial machining (method C, Fig. 33). Overall cost was reduced nearly 50% as compared to methods A and B.

The press-formed part of method B was made in a 400 kN (45 tonf) open-back-inclinable mechanical press at a rate of 200 to 250 pieces per hour. The die was made of oil-hardening tool steel. Method C used an air-hardening tool steel die and a 530 kN (60 tonf) open-back-inclinable mechanical press that made 300 to 350 pieces per hour. Mineral oil was used as a lubricant in both methods.

Forming of Heat-Resistant Alloys

Revised by S.K. Srivastava and E.W. Kelley, Haynes International

Introduction

WROUGHT HEAT-RESISTANT ALLOYS can be classified as iron-base, nickel-base, or cobalt-base alloys. Depending on the specific alloy, one or more of the following strengthening mechanisms can be used: solid-solution strengthening, precipitation hardening, and dispersion strengthening. The use of these various strengthening mechanisms leads to a wide range of microstructural and compositional variations. Despite this, heat-resistant alloys can be formed by techniques similar to those employed for the forming of AISI 300-series stainless steels, although the forming of heat-resistant alloys is more difficult. All heat-resistant alloys work harden rapidly. Figure 1 compares the degree of work hardening of several nickel-base alloys to that experienced in a cobalt-base alloy, an iron-base alloy, AISI type 304 stainless steel, and a low-carbon ferritic steel.

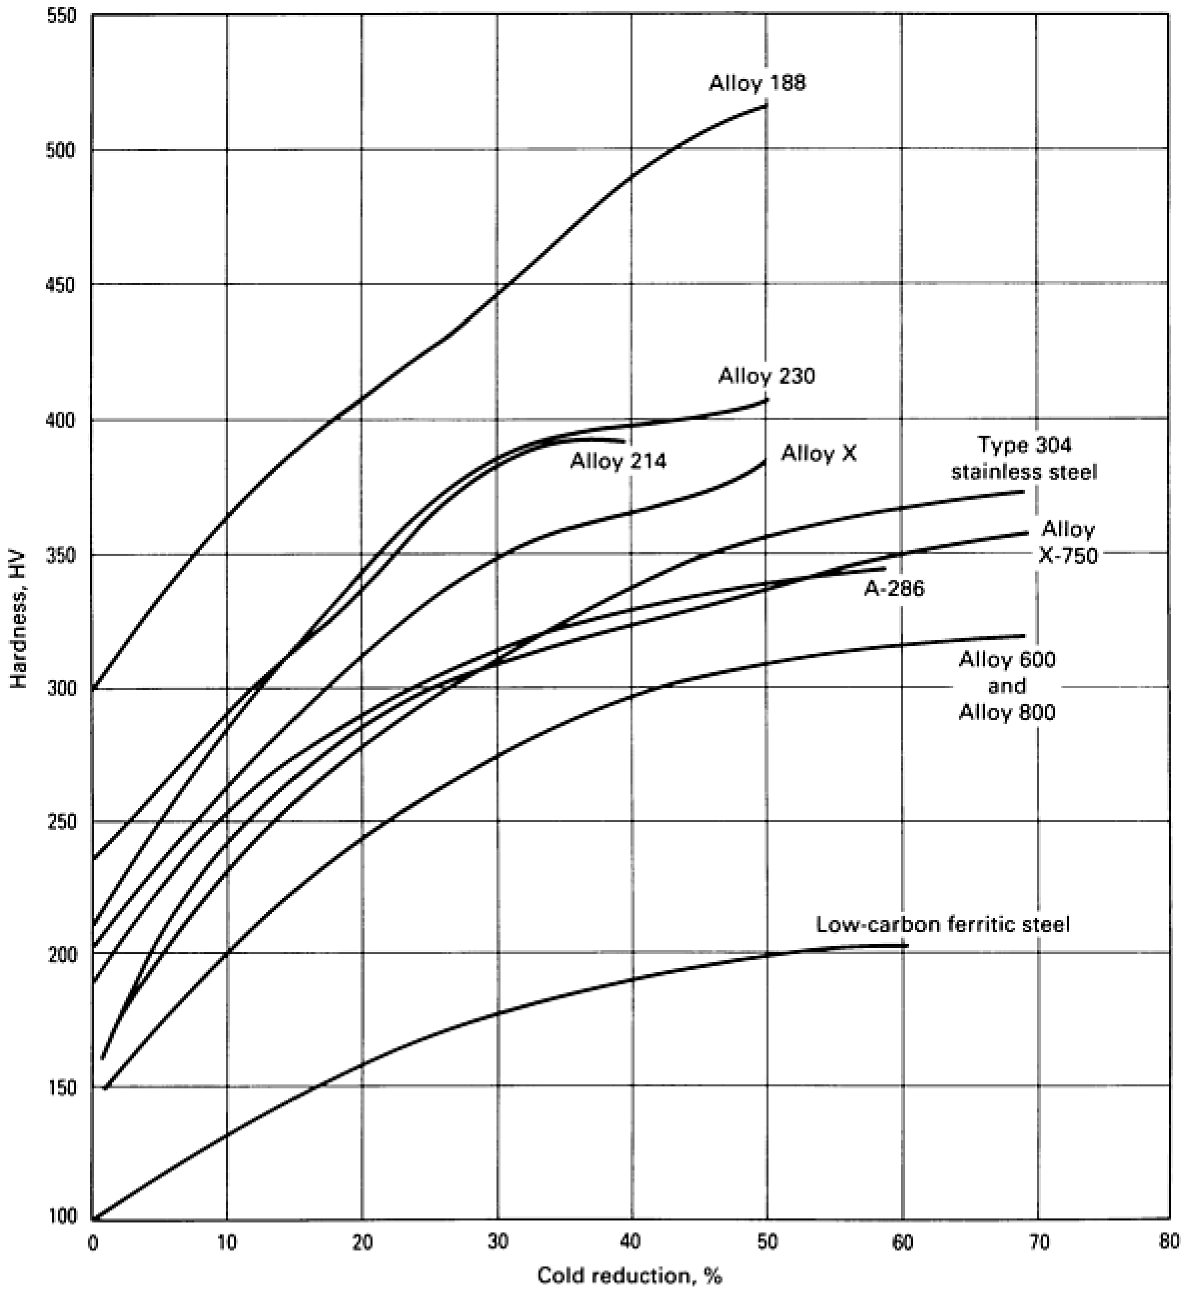

Fig. 1 Effect of cold reduction on the hardness of several heat-resistant alloys, type 304 stainless steel, and a low-carbon ferritic steel.

The differences in composition of the various heat-resistant alloys cause differences in their formability. Alloys that contain the greatest amount of cobalt, such as alloy 25 (Co-0.1C-20Cr-15W-10Ni) and alloy 188 (UNS R30188), require a greater magnitude of force to form than iron- or nickel-base alloys. Most alloys that contain substantial amounts of molybdenum or tungsten for strengthening, such as alloy 230 or alloy 41 (UNS N07041), are harder to form than alloys containing lesser amounts of these elements. Alloys that contain aluminum and titanium are strengthened by precipitation of the γ' phase. The volume fraction γ' depends strongly on the amounts of aluminum and titanium present and on overall composition. Examples of alloys that contain γ' include alloy 80A (UNS N07080), WASPALOY alloy (UNS N07011), and alloy 214. These typically contain 15, 20, and 33% γ', respectively. Many precipitation-hardened alloys require complex production steps to produce satisfactory components. Most of the iron- and nickel-base alloys contain less than 0.15% C; more carbon than this causes excessive carbide precipitation, which can severely reduce ductility. Small amounts of boron are used in some of the heat-treatable nickel-base alloys, such as alloy 41 and U-700 (Ni-18.5Co-15Cr-5.2Mo-3.5Ti-0.02B), to prevent carbide precipitation at grain boundaries; too much boron, however, can cause cracking during forming.

Sulfur causes hot shortness of nickel-base alloys. Silicon content should be below 0.60%, and preferably less than 0.30%. More than 0.60% Si causes cracking of cold-drawn alloys and may cause weld cracking in others. Silicon at levels of less than 0.30% usually does not contribute to difficulties in forming.

Cold forming is preferred for heat-resistant alloys, especially in thin sheets. Most of these alloys can be hot formed effectively only in a narrow temperature range (between about 925 and 1260 °C, or 1700 and 2300 °F). Intermediate annealing between cold-forming operations is usually preferred to hot forming.

Forming of Heat-Resistant Alloys

Revised by S.K. Srivastava and E.W. Kelley, Haynes International

---

Effect of Alloy Condition on Formability

For the fine grain structure that is best for cold forming, heat-resistant alloys must be cold worked (reduced) beyond a critical percentage reduction and then annealed. The critical amount of cold work varies with the alloy and with the annealing temperature, but is usually 8 to 10%. Reheating metal that is only slightly cold worked can result in abnormal grain growth, which can cause orange peel or alligator hide effects in subsequent forming.

For example, an alloy X (UNS N06002) workpiece, partly formed, stress relieved, and then given the final form, had severe orange peel on much of its surface. The partial forming resulted in about 5% cold working, and during stress relief, an abnormally coarse grain structure developed. The difficulty was corrected by making certain that the metal was stretched 10% or more before it was stress relieved. In addition, stress relieving was done at the lowest temperature and shortest time that could be used, because higher temperatures and longer times increased grain growth. Optimal time and temperature were determined by hardness testing.

Severely cold-formed parts should be fully annealed after final forming. If annealing causes distortion, the work can be formed within 10% of the intended shape, annealed, pickled, and then given the final forming.

Solution annealed products are usually soft enough to permit mild forming. If the solution annealed alloy is not soft enough for the forming operation, an annealing treatment must be used that will remove the effects of cold work and dissolve the age-hardening and other secondary phases. Some control of grain size is sacrificed, but if cooling from the annealing temperature is very rapid, the age-hardening elements will be retained in solution. Further annealing after forming can be done at a lower temperature to decrease the risk of abnormal grain growth. Several process anneals may be required in severe forming, but the high-temperature anneal need not be repeated. Annealing should be performed at a temperature that produces optimal ductility for the specific metal, as shown in the following example.

Example 1: Change in Heat Treatment to Eliminate Cracking.

A large manifold was made by welding together two drawn halves into a doughnut shape. Each half was drawn to a depth of 127 mm (5 in.) from 3.5 mm (0.25 in.) thick alloy 41 that had been solution treated at 1175 °C (2150 °F) and water quenched. Drawing of the plate stock on a 31,000 N (7000 lbf) drop hammer produced severe work hardening, and cracking occurred frequently. To eliminate the cracking, forming was done in three steps, and the parts were annealed at 1080 °C (1975 °F) before the second and the third step.

The forming characteristics of the alloy 41 plate were greatly improved by modifying the solution treatment. The revised treatment consisted of first soaking the alloy at 540 °C (1000 °F), transferring it to a gantry furnace, and holding it at 1080 °C (1975 °F) for 30 min. The work was then lowered rapidly through the bottom of the furnace into a salt bath at 205 to 260 °C (400 to 500 °F). Thus, the elapsed time between leaving the high-temperature zone and entering the quench was kept to 4 or 5 s, the alloy was in the precipitation range (595 to 1010 °C, or 1100 to 1850 °F) for a minimum time, and minimum hardness (16 to 21 HRC) was obtained. The salt bath provided a more uniform quench and a more ductile alloy than the original water quench. The better ductility of the alloy allowed forming of the manifold halves in two operations.

Forming of Heat-Resistant Alloys

Revised by S.K. Srivastava and E.W. Kelley, Haynes International

Formability Indicators

Formability refers to the ease with which sheet metal can be formed. Material formability is difficult to measure. There is no single index for predicting specific material formability for all processing conditions. The deformation modes in the forming of most sheet metal components are complex and consist of bending, unbending, stretching, and deep drawing. Materials, the process, and the final shape all interact in the forming and therefore should be considered simultaneously; this makes material formability an elusive factor to quantify. Forming technology depends a great deal on practical experience. Material characteristics such as tensile ductility, strain-hardening exponent, and anisotropy parameters can act as guides to the nature of formability and can be used for comparing materials.

In any forming operation, the useful ductility of material is that amount up to the point of necking. Greater ductility at peak load and a large separation between yield and tensile strengths are desirable. A measure of stretchability is provided by the strain-hardening exponent (*n* value). Plastic deformation in a tensile test can be related to true stress in the following manner:

$$\text{True stress} = K\,(\text{true strain})^{n} \quad \textbf{(Eq 1)}$$

where *K* is a strength constant. Most heat-resistant alloys possess *n* values in excess of 0.4; a high strain-hardening capacity results in spreading the strain away from any local region in the presence of a stress gradient.

The rolling and rerolling of a metal during its manufacture may cause alignment of individual grains. This imparts anisotropic plastic properties to the sheet. Recrystallization during annealing will tend to restore isotropy. The plastic strain ratio *R* (the ratio of the width strain to thickness strain in a uniaxial tensile test) is a measure of normal anisotropy, that is, the variation of properties in the plane of the sheet relative to those perpendicular to the sheet surface. The average *R* value is given by:

$$R = \frac{R_L + 2R_D + R_T}{4} \quad \textbf{(Eq 2)}$$

where the subscripts refer to tensile test measurements made in the longitudinal, diagonal, and transverse orientations of rolled sheet, respectively. The variation of the properties in the plane of the sheet is termed planar anisotropy and is given by:

$$\Delta R = \frac{R_L + R_T - 2R_D}{2} \quad \textbf{(Eq 3)}$$

For an isotropic material $R = 1$ and $\Delta R = 0$. A material with a high *R* value resists localized necking in the thickness direction; therefore, deep drawability is high. There are various correlations between deep drawability and *R* value. Planar anisotropy causes uneven flow of metal, resulting in earing of drawn cups. Some typical forming characteristics of several heat-resistant alloys are given in Table 1.

Table 1 Forming characteristics of some heat-resistant alloys

Source: Ref 1, 2

Forming limit curves are increasingly used to predict the formability of materials. The forming limit curve is experimentally constructed for combinations of strain paths to describe strain to necking (or fracture). More information on tests for formability is available in the article "Formability Testing of Sheet Metals" in this Volume.

Forming of Heat-Resistant Alloys

Revised by S.K. Srivastava and E.W. Kelley, Haynes International

Effect of Rolling Direction on Formability

Depending on the size, amount, and dispersion of secondary phases, the age-hardenable alloys show greater directional effects (Fig. 2) than alloys that are not age hardenable. However, vacuum melting and solution annealing serve to reduce directional effects (anisotropy). As shown by data for press-brake bending in Fig. 2, directional effects contribute erratically to cracking and surface defects. The following example shows how directionality seriously affected the forming characteristics of iron-base alloy A-286 (UNS S66286).

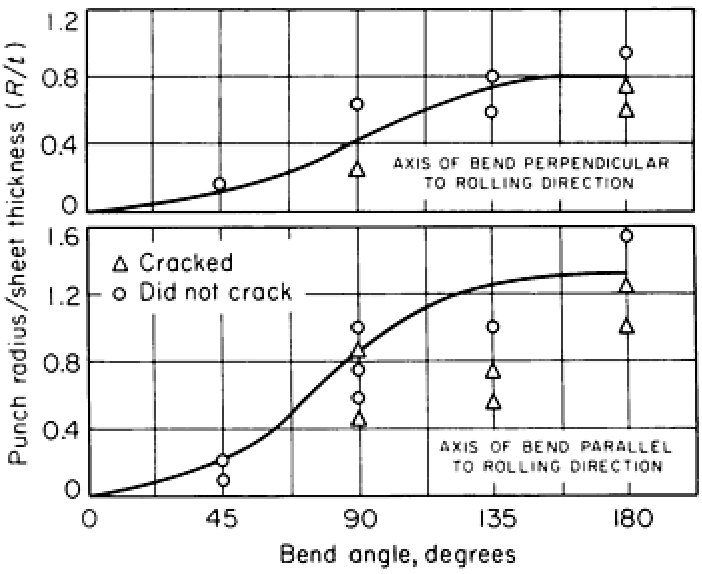

Fig. 2 Effect of forming direction relative to rolling direction on the formability of alloy 41 sheet 0.5 to 4.75 mm (0.02 to 0.187 in.) thick in press brake bending.

Example 2: Effect of Directionality in Bulging A-286.

A contoured exhaust cone (Fig. 3a) was made by cutting a flat blank from mill-annealed A-286 sheet, rolling and welding a cone from the blank, and then bulging the cone into final shape. Developed blanks for two cones were cut from one sheared rectangle (Fig. 3b) with little waste of stock.

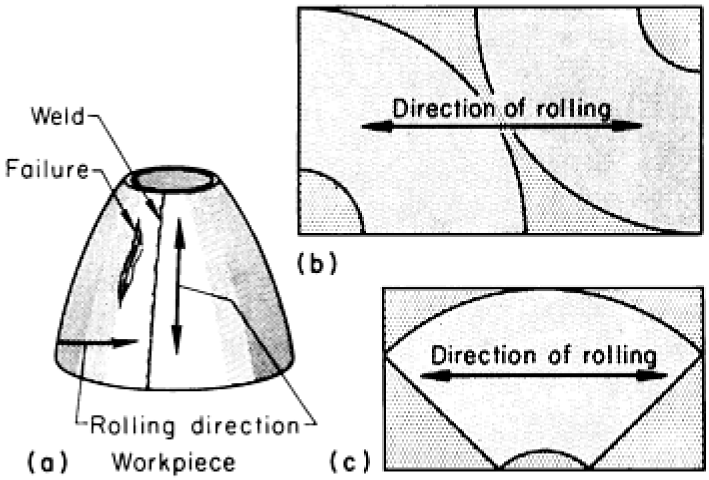

Fig. 3 A-286 exhaust cone that cracked in bulge forming, and the two layouts used in cutting the cone blanks from 1.0 to 1.3 mm (0.04 to 0.05 in.) thick sheet.

Several lots of A-286 produced good parts, but one lot of material cracked in bulging. As shown in Fig. 3(a), cracks occurred in the cone adjacent to the weld at the location where the forming stresses were perpendicular to the rolling direction (which was also the direction of minimum elongation). The good and inferior lots of A-286 were compared as to elongation with and across the rolling direction, and the inferior lot showed substantially greater difference in elongation between the two test directions.

	Good A-286	Inferior A-286
Elongation, %		
Perpendicular to rolling direction	41.0	**43.5**
Parallel to rolling direction	38.5	**37.2**
Difference	**2.5**	**6.3**

Annealing the welded cones before bulging reduced the number of cracked cones, but not by a satisfactory percentage. A higher percentage of acceptable cones resulted when the blanks were cut with their edges oriented to the rolling direction as shown in Fig. 3(c). Cones made from these blanks had less abrupt change in the forming direction relative to rolling direction on each side of the weld, and the forming stresses were never perpendicular to the rolling direction; however, there was more scrap material from cutting the blank. When a revision of production techniques at the mill reduced the elongation difference in the two directions of stress, it was possible to use the more economical blank layout shown in Fig. 3(b).

Forming of Heat-Resistant Alloys

Revised by S.K. Srivastava and E.W. Kelley, Haynes International

Effect of Speed on Formability

The speed at which a metal is deformed affects its formability. In general, each metal has a critical speed of forming. In some cases, the ductility increases until this critical speed is reached, after which it decreases sharply with increasing speed, as indicated by the curve in Fig. 4. This curve has a plateau of maximum strain where ductility is greatest. This plateau seems to be broad for most heat-resistant alloys. The breadth of the plateau depends on the use of biaxial or triaxial loading of the material during forming. Table 2 gives optimal speeds for three heat-resistant alloys and three forming operations.

Table 2 Recommended forming speeds for three heat-resistant alloys

Alloy	**UNS No.**	Forming speed for:					
		Tensile forming		**Bulge forming**		Draw forming

Forming of Heat-Resistant Alloys

Revised by S.K. Srivastava and E.W. Kelley, Haynes International

Methods and Tools

Few applications in forming heat-resistant alloys involve quantities that warrant the use of high-production methods and tools. Usually, only a few to a few hundred parts are needed. Therefore, methods that require a minimum of tooling, such as press-brake forming, drop hammer forming, spinning, and explosive forming, have been used more than other methods. Presses or other machines are the same as those used for forming steel, but more power is needed to form heat-resistant alloys because of their higher strength. The power required to form a given workpiece is from 50 to 100% more for heat-resistant alloys than for low-carbon steel.

Safety in Explosive Forming. Operations involving explosives and pressure vessels are governed by state, county, and municipal regulations. The requirements and restrictions of these regulations should be taken into account in tool design and operational setup for explosive forming (see the article "Explosive Forming" in this Volume).

Tools used for forming heat-resistant alloys are usually the same as those used for forming stainless steel in similar quantities (see the article "Forming of Stainless Steel" in this Volume). Clearance between punch and die is generally the same as that for stainless steel. Heat-resistant alloys also resemble stainless steels in that they are likely to adhere to dies or mandrels, resulting in galling or tearing of the dies and workpieces. Steel dies, punches, or mandrels can be plated with approximately 5 to 13 μm (0.2 to 0.5 mils) of chromium in order to minimize adherence. However, small production quantities seldom justify this practice. Cast iron has proved adequate and nongalling for many low-production forming tools. If a heat-treatable grade of iron is used, areas in which high wear is anticipated can be locally hardened.

Lubrication

Some lubrication is usually required for optimal results in drawing, stretch forming, or spinning. Lubrication is seldom needed for the press-brake forming of V-bends, but will greatly improve results if a square punch is used. Mild forming operations--for example, those no more severe than a 10% reduction--can usually be accomplished successfully with unpigmented mineral oils and greases. Polar lubricants, such as lard oil, castor oil, and sperm oil, are preferred for mild forming. They will usually produce acceptable results and are easily removed. For more severe forming, metallic soaps or extreme-pressure (EP) lubricants, such as chlorinated, sulfochlorinated, or sulfurized oils or waxes, are recommended. They can be pigmented with a material such as mica for extremely severe forming.

Lubricants that contain white lead, zinc compounds, or molybdenum disulfide are not recommended, because they are too difficult to remove before annealing or before high-temperature service. At high temperatures, any sulfur or lead on the surface of the alloys can be harmful. Sulfurized or sulfochlorinated oils can be used if the work is carefully cleaned afterward in a degreaser or an alkaline cleaner. Work that has been formed in zinc alloy dies should be flash pickled in nitric acid before heat treatment to prevent the possibility of zinc embrittlement.

Lubricants used for spinning operations must cling tenaciously; otherwise, they will be thrown off the workpiece by centrifugal force. Metallic soap or wax applied to the workpiece before spinning is usually satisfactory. In power spinning, a coolant should also be used during the process (see the article "Spinning" in this Volume).

Occasionally, it is advantageous to use two kinds of lubricant in the same operation. In one stretch-forming application, the strain at the middle of the work was 3 to 4%, but near the ends, where the metal pulled tangentially to the die, the strain was 10 to 12%. A light coat of thin oil was adequate for most of the work, but an EP lubricant was used at the ends. More information on lubricants for forming is available in the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume.

Forming Practice for Iron-Base Alloys

Alloy A-286 has work-hardening characteristics similar to those of type 304 stainless steel (Fig. 1) and has slightly lower formability. Most other iron-base heat-resistant alloys are somewhat less formable. Typical forming practice is described in the following examples.

Example 3: Forming A-286 Tube by Spinning.

The tube shown at the top of Fig. 5 was backward spun from a roll forging that had been solution annealed at 980 °C (1800 °F). A starting groove had been machined into the tube in a previous operation. Spinning was performed in three passes on a machine capable of spinning a part 1065 mm (42 in.) in diameter and 1270 mm (50 in.) in length. Backward spinning was used in preference to forward spinning because:

- The finished workpiece was longer than the mandrel
- Forward spinning would have required a change in workpiece design to permit hooking over the mandrel
- Backward spinning is faster than forward spinning

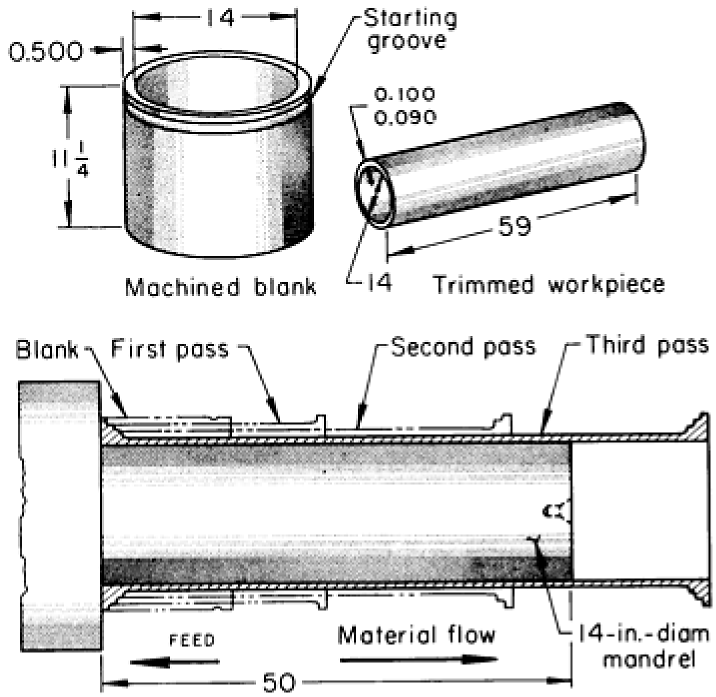

Fig. 5 Backward spinning of A-286 roll-forged tube (hardness: 200 HB max). Dimensions given in inches.

It was convenient to leave flanges at both ends and to trim these off later. The flanges prevented bell-mouthing and permitted trimming of the portions likely to have small radial cracks.

Example 4: Explosive Forming of A-286.

A tubular workpiece was explosively formed inside a die (Fig. 6) to produce a part having an internal flange. If this part had been produced by other methods, such a flange would have had to be welded on. A-286 sheet was rolled into a round cylinder 405 mm (16 in.) in diameter, welded, solution treated, and descaled. Tolerance on the diameter was ±0.75 mm (±0.03 in.).

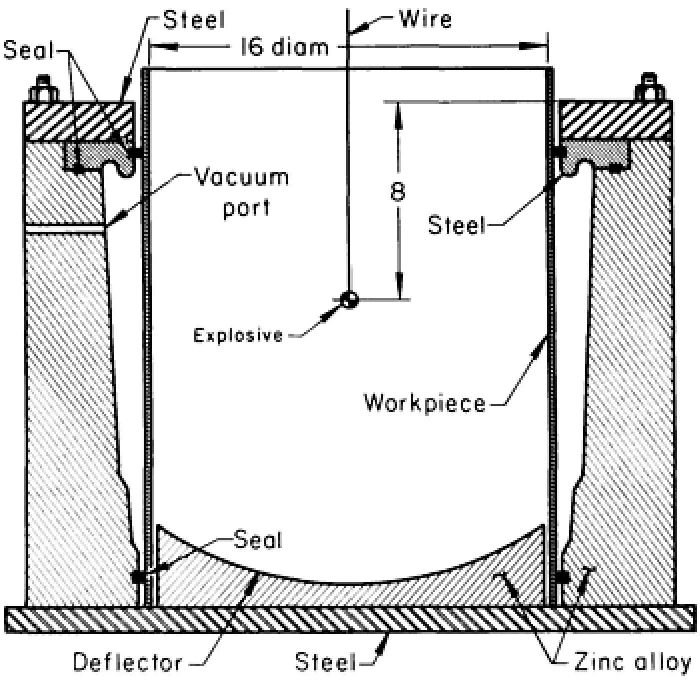

Fig. 6 Explosive forming a case from 1.5 mm (0.060 in.) thick A-286. Dimensions given in inches.

The explosive used was gel dynamite. Six shots were used to form the workpiece. For shots 1 and 2, 15 g of explosive was used; for shot 3, 18 g; for shot 4, 20 g; and for shots 5 and 6, 25 g. After three shots, the workpiece was solution annealed and descaled.

Forming Practice for Nickel-Base Alloys

Two types of annealing treatments are used to soften the age-hardenable nickel-base alloys for forming, based on the ductility needed for forming and, if subsequent welding is required, on the avoidance of adverse metallurgical effects during and after welding. A high-temperature anneal is used to obtain maximum ductility and when no welding will be done on the formed part. A lower-temperature anneal, resulting in some sacrifice in ductility, is used when the will be welded.

For example, solution annealing of alloy 41 at 1175 °C (2150 °F) followed by quenching in water gives maximum ductility. However, parts formed from sheet annealed in this way should not be welded; during welding or subsequent heat treatment, they are likely to crack at the brittle carbide network developed in the grain boundaries. A lower annealing temperature, preferably 1065 to 1080 °C (1950 to 1975 °F), results in less sensitization during welding and decreases the likelihood of grain-boundary cracking. Formability is reduced by 10 to 20%, but is adequate for most forming operations. Typical practice for forming nickel-base alloys is described in the following examples.

Example 5: Forming and Slotting Alloy X.

The 88 flutes in the workpiece shown in Fig. 7 were finish formed and slotted one at a time with hand indexing in a 450 kN (50 tonf) mechanical press at the rate of one piece every 14.6 min, including setup. Slots were required to be within 0.5 mm (0.02 in.) of true position.

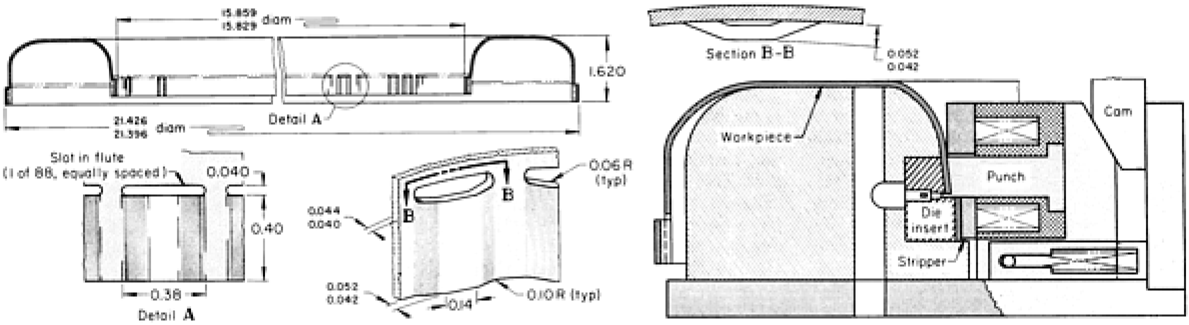

Fig. 7 Finish forming of flutes and piercing of slots one at a time in an alloy X workpiece using a mechanical press. Hardness of the workpiece was 74.5 to 81.5 HR30T. Dimensions given in inches.

The work metal was 1 to 1.1 mm (0.04 to 0.044 in.) alloy X sheet. Before the mechanical press operations, the sheet had been formed by a rubber-diaphragm process, electrolytically cleaned, annealed to 74.5 to 81.5 HR30T, pickled, restruck in the forming press, and trimmed. The flutes were partially formed in this series of operations.

In choosing a method of finish forming, it was decided that the only way to form the flutes to the required shape was to use a solid tool. The rubber-diaphragm forming process, however, was the best way to form the main contours of the part. The flutes could not be fully formed by a conventional die alone, because the percentage elongation exceeded the limits for alloy X (38 to 42% elongation in 50 mm, or 2 in.). By making use of the natural tendency of the blank to form wrinkles, the flutes were preformed during rubber-diaphragm forming, but pressures were only enough to form them 75% complete. However, the amount of elongation needed in the final die-forming operation was lowered, and definite locations for flutes were provided; therefore, each flute could be produced in one stroke of the mechanical press. The tooling (right side, Fig. 7) consisted of a die and a camactuated punch of high-carbon high-chromium tool steel hardened to 58 to 60 HRC, as well as die inserts, stripper, and cam sections of lower-alloy air-hardening tool steel. The punch pierced the slot and flattened the bulge above the flute. The stripper formed the flute when struck by the punch holder.

Example 6: Explosive Forming of Alloy 718.

Fully annealed alloy 718 (UNS N07718) sheet was used to make the flame deflector shown in Fig. 8. The sheet was rolled onto a cylinder, with the grain direction at right angles to the long axis. A 115 mm (4.5 in.) outside diameter by 815 mm (32 in.) long tube was gas tungsten arc welded from the cylinder using alloy 41 filler rod. The weld was made flush on the inside, and the outside was ground flush to +0.13 mm (+0.005 in.). The tube was spun to the dimensions shown in Fig. 8, fully annealed at 955 °C (1750 °F), and grit blasted. An outstanding characteristic of this alloy is its slow response to age hardening, which enables it to be welded and annealed with no spontaneous hardening unless cooled slowly. Explosive forming of the flame deflector was accomplished by three successive charges in a split die, and the workpiece was fully annealed after explosive forming.

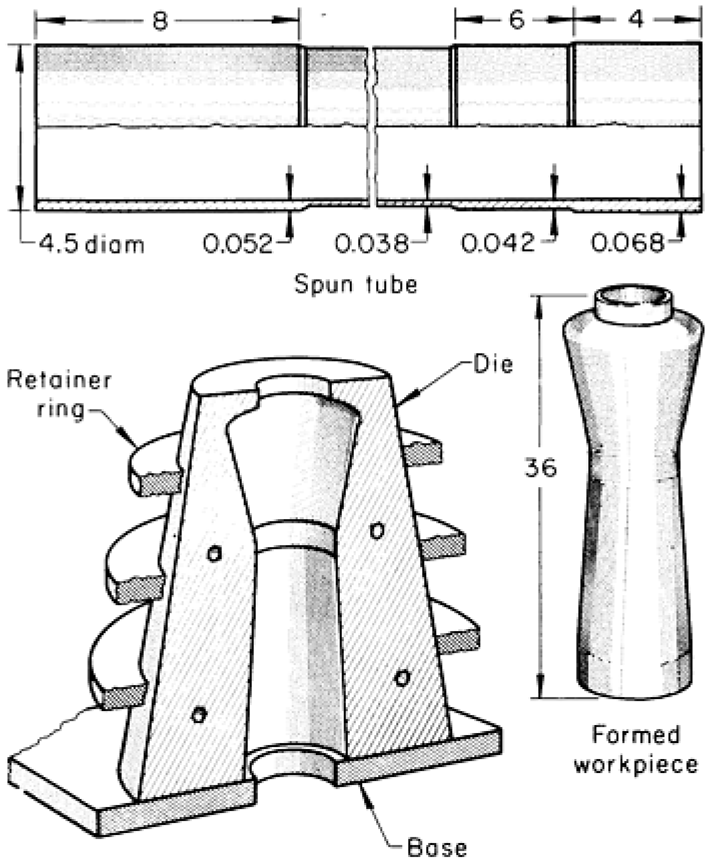

Fig. 8 Alloy 718 flame deflector (original sheet thickness: 1.8 mm, or 0.072 in.) produced by explosive forming in three successive charges. Dimensions given in inches.

Forming Practice for Cobalt-Base Alloys

Forming the cobalt-base alloys requires more force because they are usually stronger than the iron-base and nickel-base alloys. The cobalt-base alloys with less than 20% Ni, such as Elgiloy alloy (UNS R30003) and alloy 25, are more difficult to form. Alloy N-155 (UNS R30155), a more formable alloy, has a tensile strength of 828 MPa (120 ksi), a 0.2% yield strength of 414 MPa (60 ksi) and elongation of 40%. These alloys, like most of the nickel-base alloys, are age hardened for elevated-temperature service. The practice used in forming HS-25 and N-155 parts is described in the following examples.

Example 7: Explosive Forming of Alloy 25.

Figure 9 shows the setup used for the explosive forming of a tail-pipe ball from alloy 25 sheet. The sheet was gas tungsten arc welded (butt) into a cylinder, and the shape was formed by three explosive charges. No annealing was done between welding and the first two shots of explosive forming, but after the first two shots (50 g of dynamite for each), the workpiece was withdrawn from the die, annealed at 1175 °C (2150 °F), and descaled. The workpiece was returned to the die for further forming. The third explosive charge used 62 g of dynamite. Tolerance on diameters was maintained within ±0.25 mm (±0.01 in.).

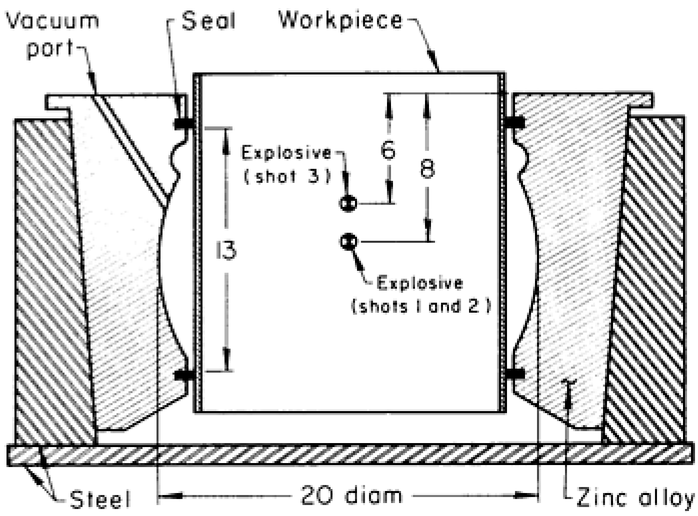

Fig. 9 Alloy 25 (sheet thickness: 1.7 mm, or 0.066 in.) welded cylinder in position for explosive forming. Dimensions given in inches.

Explosive forming was preferred over forming on an expanding mandrel. This is because the mandrel left flats on the wall of the workpiece and explosive forming did not.

Example 8: Alloy N-155 Exit Nozzle Produced by Tube Spinning and Explosive Forming.

The exit nozzle shown in Fig. 10 was produced from fully annealed 3.4 mm (0.135 in.) thick alloy N-155 sheet. The sheet was rolled into a cylinder, with grain direction at right angles to the long axis, and was gas tungsten arc welded. The weld was ground flush on both the inside and outside, after which the cylinder was tube spun to the various wall thicknesses shown in Fig. 10. The workpiece was then placed in a die and explosively formed to the shape shown at right in Fig. 10.

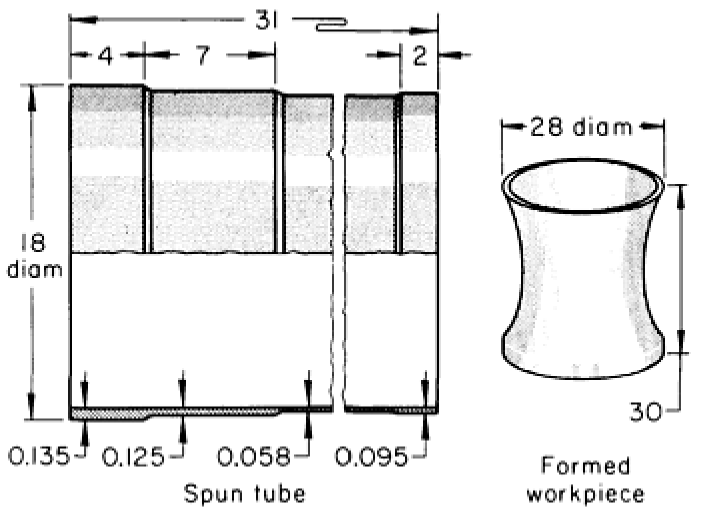

Fig. 10 Alloy N-155 exit nozzle produced by tube spinning and explosive forming. Dimensions given in inches.

The underwater explosive-forming technique was used, with a vacuum of 3 kPa (0.03 atm) between the workpiece and the die. The explosive charge was equal to 620 g of TNT and was placed at an average distance of 190 mm (7 $\frac{1}{2}$ in.) from the workpiece walls. The first shot produced approximately 90% of the final shape. A second shot, using the same size charge, completed the workpiece, after which it was fully annealed.

Forming of Refractory Metals

Revised by Louis E. Huber, Jr., Cabot Corporation

Introduction

REFRACTORY METALS are generally worked in small quantities. Production rates are low, each piece is handled separately, and the forming process is closely controlled.

Table 1 shows the composition of refractory alloys available as sheet. Typical conditions for bending 0.5 to 1.3 mm (0.020 to 0.050 in.) thick sheet are given in Table 2. Tensile-forming parameters for sheet materials are summarized in Table 3.

Table 1 Nominal compositions of refractory alloys available as sheet

Commercially pure niobium, tantalum, molybdenum, and tungsten sheets are also available.

Forming of Refractory Metals

Revised by Louis E. Huber, Jr., Cabot Corporation

Formability

Niobium and tantalum alloys are usually formed at room temperature in the annealed (recrystallized) condition, although the stress-relieved alloys are sufficiently ductile for most forming operations. Work hardening, especially of the stronger alloys, often necessitates annealing after severe forming.

Strong alloys of niobium and tantalum, which are made in limited quantity, are not listed in Table 1. These alloys have varying degrees of brittleness at low temperature, but can be formed by the same procedures used for molybdenum.

Molybdenum and tungsten are more difficult to form than niobium and tantalum, but if they are heated and certain precautions are taken, even complex parts can be formed. The greatest difficulty in forming these metals is their tendency toward brittle fracture (cracks and ruptures that occur with little or no plastic deformation) and delamination (a type of brittle behavior that produces cracks or ruptures parallel to the plane of the sheet). Tungsten can be hot formed only; it is brittle at room temperature.

At slow strain rates in tension and in bending, molybdenum and TZM alloys are ductile at room temperature, becoming brittle at lower temperatures. However, because of the high variable strain rates and triaxial stresses produced in the usual forming processes, these metals are usually hot formed in order to decrease the probability of brittle fracture. Molybdenum and tungsten blanks must have prepared edges to prevent cracking and splitting during forming.

Molybdenum and tungsten are generally supplied in stress relieved condition. Recrystallization increases the ductile-to-brittle transition temperature.

Effects of Composition on Embrittlement. Niobium and tantalum are severely embrittled by oxygen, nitrogen, and hydrogen, even in minute amounts. However, the usual melting and processing techniques keep the metals pure enough for good formability.

Some niobium alloys are more resistant to grain growth at high temperature than high-purity niobium. Alloys such as Nb-1Zr and C-103 are high-strength materials that resist grain growth at high temperature. These alloys have fine grain structure and elongate uniformly for forming and drawing operations.

Surface Contamination. The most common causes of surface contamination are failure to clean the surface properly and failure to provide the proper atmosphere in heat treatment. Niobium and tantalum are usually acid pickled, and they are heat treated in a vacuum or an inert gas atmosphere. Additional information on the heat treating of refractory metals is available in the article "Heat Treating of Refractory Metals and Alloys" in *Heat Treating*, Volume 4 of the *ASM Handbook.*

Generally, the high-strength alloys are more severely embrittled by surface contamination than the lower-strength alloys. Molybdenum and tungsten are much less susceptible to surface contamination by oxygen and nitrogen than niobium and tantalum.

Forming of Refractory Metals

Revised by Louis E. Huber, Jr., Cabot Corporation

Factors That Affect Mechanical Properties

The major variables that affect mechanical properties and formability are working temperature, temperature of anneals between operations, percentage of reduction after the final anneal, and temperature of final heat treatment.

Rolling. Refractory metal sheet is generally made by hot forging or extruding billets to make sheet bars, which are rolled to sheet at high temperature. The final rolling of niobium and tantalum alloys is done below 540 °C (1000 °F), often at room temperature. The cold-worked sheet is given a final recrystallization anneal to improve formability and ductility. The finish rolling of molybdenum and tungsten is done at high temperature, and final heat treatment is usually for stress relief only. Cross-rolled sheet is generally more formable, because cross rolling makes ductility almost equal in all directions.

Heat Treatment. In the annealed (recrystallized) condition and in the ductile range, refractory metals behave much like steel. For example, recrystallized tungsten, although brittle at low temperature, has 35% uniform elongation and 50% total elongation at 400 °C (750 °F). Cold working strengthens molybdenum and tungsten and makes them less formable. Although molybdenum and tungsten are given a final stress relief, they retain their cold-worked structure.

Figure 1 shows the effect of heat treatment and strain hardening on the ductility and the ductile-to-brittle transition temperature range of unalloyed molybdenum. The curves in Fig. 1 show that the ductile-to-brittle transition for unalloyed molybdenum is between -18 and -45 °C (0 and -50 °F) for the stress-relieved condition, between 25 and -25 °C (80 and -10 °F) for the stretch-strained condition, and at approximately 25 °C (80 °F) for the recrystallized condition.

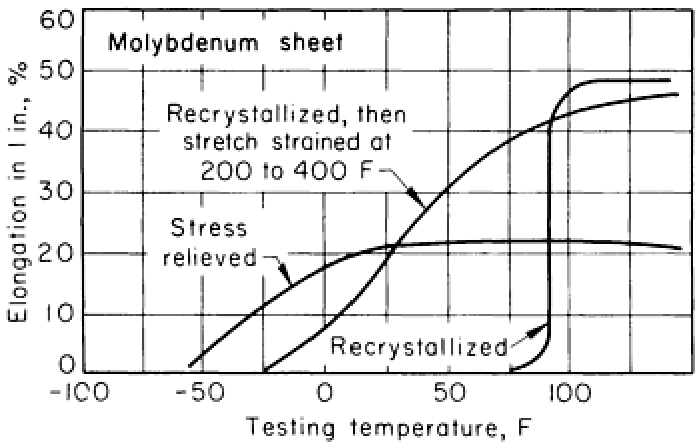

Fig. 1 Effect of heat treatment and strain hardening on the ductility and ductile-to-brittle transition temperature range of unalloyed molybdenum sheet as determined in tensile tests. The ductile-to-brittle transition occurs in the temperature range in the steep portion of the ductility curves.

Transition Temperature. Niobium, tantalum, and their most frequently used alloys are readily formable, and they are ductile at temperatures as low as -195 °C (-320 °F). Molybdenum and TZM, in the stress-relieved condition, have transition temperatures just below room temperature. Molybdenum may fracture or delaminate at room temperature under the high deformation rates and stresses generally encountered in forming practice. Therefore, molybdenum alloys are generally formed at moderate-to-high temperatures. Stress-relieved tungsten has a transition temperature of 150 to 315 °C (300 to 600 °F), so that all forming of tungsten must be done at high temperatures.

Figure 2 shows how temperature changes the strength and elongation of a typical high-strength niobium alloy with good formability. A slight increase in temperature reduces yield strength but also reduces ductility. The ductility is lowest at about 650 °C (1200 °F) and then increases with temperature. This reduced ductility is caused by strain aging, which is characteristic of body-centered cubic metals.

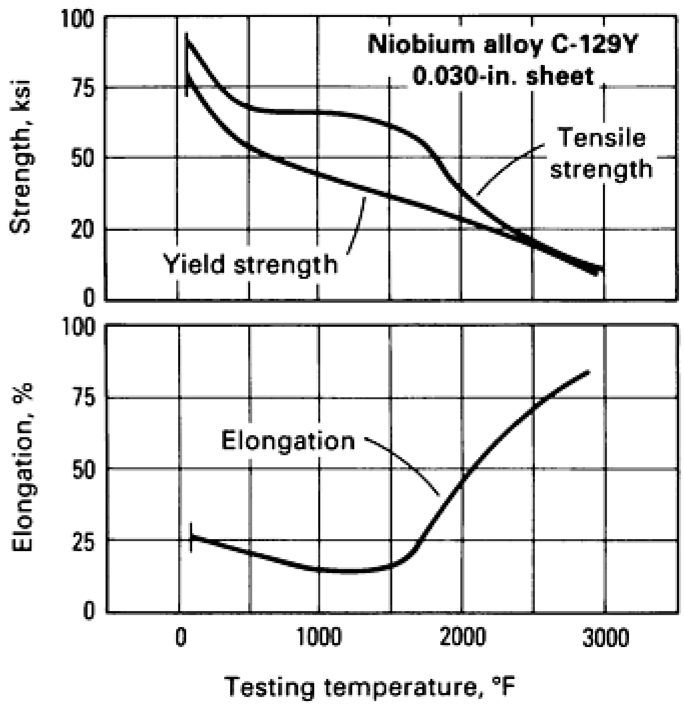

Fig. 2 Effect of temperature on strength and elongation of vacuum-annealed (recrystallized) niobium alloy sheet

Figure 3 shows how temperature changes the ductility of four typical refractory metals. The ductility minimums lie between 540 and 1095 °C (1000 and 2000 °F). The tantalum and niobium alloys in Fig. 3 were annealed (recrystallized), and the molybdenum alloy and tungsten were stress relieved. Tests above 260 °C (500 °F) were conducted in a vacuum.

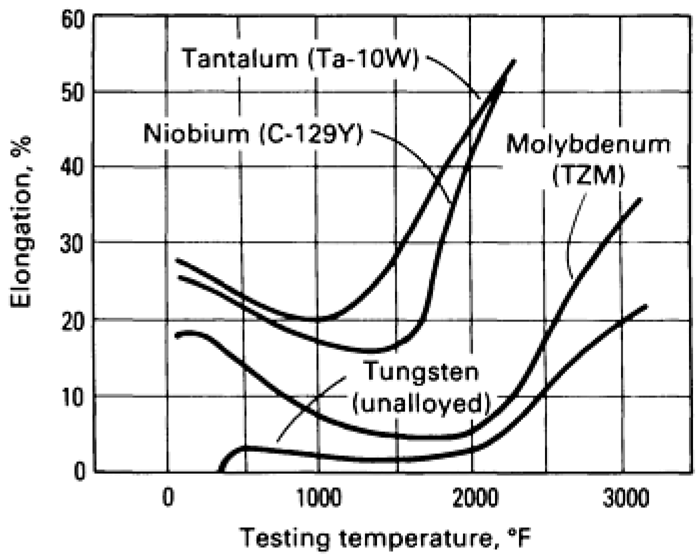

Fig. 3 Effect of temperature on the ductility of four refractory metals

Effect of Temperature on Formability

Annealed niobium and tantalum alloys are formed at room temperature. Heating these alloys would reduce their formability because of strain aging and would cause oxidation and possible surface contamination.

Tungsten is brittle at room temperature. Therefore, thin tungsten sheet is formed at 315 to 540 °C (600 to 1000 °F), and thicker sheet or complex shapes are formed at 540 to 815 °C (1000 to 1500 °F) after stress relief.

Molybdenum and molybdenum alloys, in thin sheets, can be cold formed to some extent, but heating helps to prevent fracture and delamination. As shown in Fig. 3, the TZM alloy is most ductile at 95 °C (200 °F). Further increases in temperature lessen ductility, because of strain aging. Most molybdenum is formed at 95 to 315 °C (200 to 600 °F), but thicker metal or complex shapes are formed at 315 to 650 °C (600 to 1200 °F).

Figure 4 shows the effect of heating on the bending of TZM sheet. This material is most formable at 95 to 205 °C (200 to 400 °F). Forming at lower temperatures may crack it.

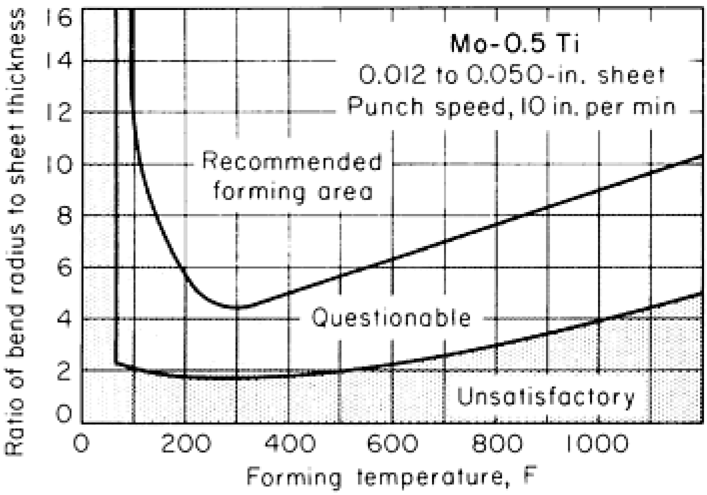

Fig. 4 Effect of temperature on the formability of Mo-0.5Ti sheet as indicated by the ratio of bend radius to sheet thickness

In one case, two sheets of TZM required bending. One sheet shattered when formed at room temperature, but the second sheet formed well in severe forming at 150 °C (300 °F). Erickson cup ductility tests indicated the two sheets to be of equal formability at room temperature.

Forming of Sheet

All of the common sheet-forming methods are used for refractory metals. However, the necessity of using elevated temperature in forming molybdenum and tungsten usually precludes the stretch forming and rubber-pad forming of these two metals.

Niobium and Tantalum. Almost all forming of niobium and tantalum is done at room temperature using conventional tools. A backup sheet is frequently used in a press brake to reduce galling or to provide support, so that the part will more closely follow the punch radius.

Niobium alloy C-103 is more ductile than type 310 stainless steel; it can be power spun to 60% reduction and deflects the rolls only half as much as 310 stainless. Tantalum can be spun in thicknesses as great as 15.75 mm (0.620 in.).

Tantalum, niobium, and Nb-1Zr sheet can be readily drawn into cups, tubes, or other shapes amenable to drawing methods. However, these materials exhibit a serious tendency toward galling to tool surfaces at contact pressures that are almost always exceeded in the drawing process. The tendency toward galling increases with each redraw, but can be significantly reduced or eliminated through careful attention to tool geometry, material surface condition, and workpiece lubrication.

The following rules should be observed when designing parts for deep drawing in these materials:

- Parts should have uniform wall thickness
- A 25% thinning allowance should be made on tight corners or extreme reductions in diameter; thinning can be effectively controlled through careful tool design
- The overall length should be less than nine times the smallest diameter in most cases, unless intermediate annealing is considered
- Bends of up to 90° can be made on inside radii of one-half the material thickness; bends over 90° should have an inside radius of at least one wall thickness
- Resultant surface finish is a function of grain size, severity of cold working, and original surface finish; it is difficult to "iron" to improve the surface finish because of galling

One method used to reduce galling consists of oxidizing the material surface by heating in an open furnace to temperatures as high as 650 °C (1200 °F) for tantalum or as high as 625 °C (1155 °F) for niobium or Nb-1Zr. The thickness of the oxide produced is related to the length of time at temperature and the surface condition of the material. A soak of 1 to 2 min produces a surface with greatly reduced tendency to gall. In most cases, this oxide must be removed from completed workpieces by acid etching or other means. The oxide is quite stable and is strongly abrasive to draw tooling. Serious reduction in tool life can be a problem when oxides are used.

Standard chlorinated drawing compounds are appropriate lubricants for the drawing of these materials. Spray or flood-type lubrication systems help to ensure adequate lubrication for parts requiring multiple redraws. Particular care must be taken to lubricate die surfaces, because dry spots will initiate galling.

Trimming or blanking operations should be conducted with a minimum punch-to-die clearance. This reduces metal pickup on tool surfaces. Burr-free or nearly burr-free results can be achieved.

Molybdenum and Tungsten. All of the common sheet-metal forming methods except rubber-pad forming and stretch forming are used for molybdenum and tungsten. These metals are formed at high temperature to prevent the cracking and delamination that occur when forming at room temperature. Stretch forming has not been successful, because of the difficulties in adapting high temperatures to the process.

Proper preparation of the edges of blanks is necessary in the forming of molybdenum and tungsten. All edges in tension during forming must be rounded or polished to prevent fracture. Shearing and sawing may cause edge cracking and delamination, which must be removed before forming.

Power and manual spinning are extensively used to work tungsten sheet. Tungsten can be power spun in machines that are capable of power spinning steel. Complex contoured or deeply recessed parts are often produced by drop hammer forming. All work is done with heated tools and with work metal temperatures ranging from 595 to 1095 °C (1100 to

2000 °F). Many failures in forming tungsten are caused by the stressing of edge defects in the starting blanks. These defects originate in sawing, shearing, or blanking and are difficult to detect visually.

Tools and workpiece blanks are heated by electrical-resistance elements, heat lamps, and gas torches. An allowance for the difference in thermal expansion between steel dies and a tungsten or molybdenum workpiece is required for all parts whose shape or dimensions will be out of tolerance because of forming at high temperature. Hot-work tool steels are satisfactory die materials. A bronze facing is recommended for steel dies if galling becomes a problem. Aluminum tooling is not recommended, because of its high thermal expansion.

Localized deformation and wrinkling of complex parts formed from molybdenum and tungsten generally result from poor die design and operation. These problems can be avoided by proper die clearance, staging and contours, and mechanical support. A steel backup sheet is sometimes used to ensure that the part more closely follows the punch or to reduce galling.

Forming of Preformed Blanks

Refractory metals that are preformed and welded into shaped blanks, cones, or cylinders can be formed by the same process used for unwelded blanks of common sheet metals. The welds must be of high quality to avoid defects or embrittlement. Chemical blanking, electrical discharge machining, abrasive cutting, and milling are preferred for making blanks. The following sequence of operations is generally used in preforming:

- Form intermediate shape
- Weld by the gas tungsten arc method
- Grind weld flush and inspect
- Stress relieve or anneal
- Form to final shape

Weldments of molybdenum and tungsten are generally formed at temperatures 95 to 150 °C (200 to 300 °F) higher than unwelded sheet of the same metals, and the weldments are usually stress relieved before forming. In some extreme applications, parts are stress relieved before and after welding, and after forming.

Forming of Refractory Metals

Revised by Louis E. Huber, Jr., Cabot Corporation

Lubricants

The types of lubricants used in the forming of refractory metals include oils, extreme-pressure lubricants, soaps, waxes, silicones, graphite, molybdenum disulfide, copper plating, and an acrylic enamel coating made by suspending powdered copper in acrylic resin.

Ordinary oils and greases are commonly used in the forming of niobium and tantalum, because these metals are generally formed at room temperature. Petrolatum is frequently used for severe forming operations. Solid lubricants and suspensions of suitable pigments, such as molybdenum disulfide with or without colloidal graphite, are used in the hot forming of molybdenum and tungsten. Chlorinated lubricants and others that decompose upon heating to form toxic or noxious fumes must not be used without proper safety precautions.

Introduction

ALUMINUM and its alloys are among the most readily formable of the commonly fabricated metals. There are, of course, differences between aluminum alloys and other metals in the amount of permissible deformation, in some aspects of tool design, and in details of procedure. These differences stem primarily from the lower tensile and yield strengths of aluminum alloys, and from their comparatively low rate of work hardening. The wide range of compositions and tempers of aluminum alloys also affects their formability. This article emphasizes those aspects of commercial forming processes and equipment that apply specifically to aluminum alloys. More general information on the forming of metals is given in other articles in this Volume.

General Formability Considerations

The formability of a material is the extent to which it can be deformed in a particular process before the onset of failure. Aluminum alloy sheet usually fails during forming either by localized necking or ductile fracture. Necking is governed largely by material properties such as work hardening and strain-rate hardening and depends critically on the strain path followed by the forming process. In dilute alloys, the extent of necking or limit strain is reduced by cold work, age hardening, gross defects, large grain size, and the presence of alloying elements in solid solution. Ductile fracture occurs as a result of the nucleation and linking of microscopic voids at particles and the concentration of strain in narrow shear bands. Fracture usually occurs at larger strains than does localized necking and therefore is usually important only when necking is suppressed. Common examples where fracture is encountered are at small radius bends and at severe drawing, ironing, and stretching near notches or sheared edges (Ref 1, 2).

Considerable advances have been made in the development of alloys with good formability, but, in general, an alloy cannot be optimized on this basis alone. The function of the formed part must also be considered, and improvements in functional characteristics, such as strength and ease of machining, often tend to reduce the formability of the alloy.

Effects of Alloying Elements. The principal alloys that are strengthened by alloying elements in solid solution (often coupled with cold work) are those in the aluminum-magnesium (5*xxx*) series, ranging from 0.5 to 6% Mg. These alloys often contain small additions of transition elements such as chromium or manganese, and less frequently zirconium to control the grain or subgrain structure and iron and silicon impurities that are usually present in the form of intermetallic particles. Figure 1 illustrates the effect of magnesium in solid solution on the yield strength and tensile elongation for most of the common aluminum-magnesium commercial alloys. Note the large initial reduction in tensile elongation with the addition of small amounts of magnesium.

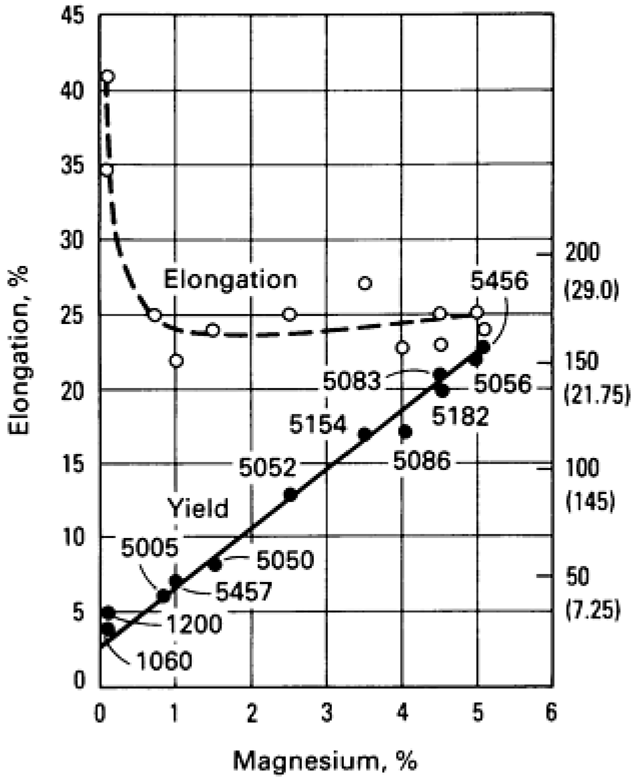

Fig. 1 Correlation between tensile yield strength, elongation, and magnesium content for some commercial aluminum alloys in the annealed temper. Source: Ref 3

The reductions in the forming limit produced by additions of magnesium and copper appear to be related to the tendency of the solute atoms to migrate to dislocations (strain age). This tends to increase work hardening at low strains, where dislocations are pinned by solute atoms, but it also decreases work hardening at large strains. Small amounts of magnesium or copper also reduce the strain-rate hardening, which in turn reduces the amount of useful diffuse necking that occurs after the uniform elongation. Zinc in dilute alloys has little effect on work hardening or necking and it does not cause strain aging.

Elements that have low solid solubilities at typical processing temperatures, such as iron, silicon, and manganese, are present in the form of second-phase particles and have little influence on either strain hardening or strain-rate hardening and thus a relatively minor influence on necking behavior. Second-phase particles do, however, have a large influence on fracture. The addition of magnesium promotes an additional reduction in fracture strain, because the higher flow stresses aid in the formation and growth of voids at the intermetallic particles. Magnesium in solid solution also promotes the localization of strain into shear bands, which concentrates the voids in a thin plane of highly localized strain.

Precipitation-strengthened alloys are usually formed in the naturally aged (T4) condition or in the annealed (O) condition, but rarely in the peak strength (T6) condition, where both the necking and fracture limits are low. Figure 2 shows the effect of a wide range of precipitate structures on some of the forming properties of alloy 2036 (Al-2.5Cu-0.5Mg). Curves similar in shape can be drawn for most of the precipitation-strengthened alloys in the 2*xxx* and 6*xxx* series.

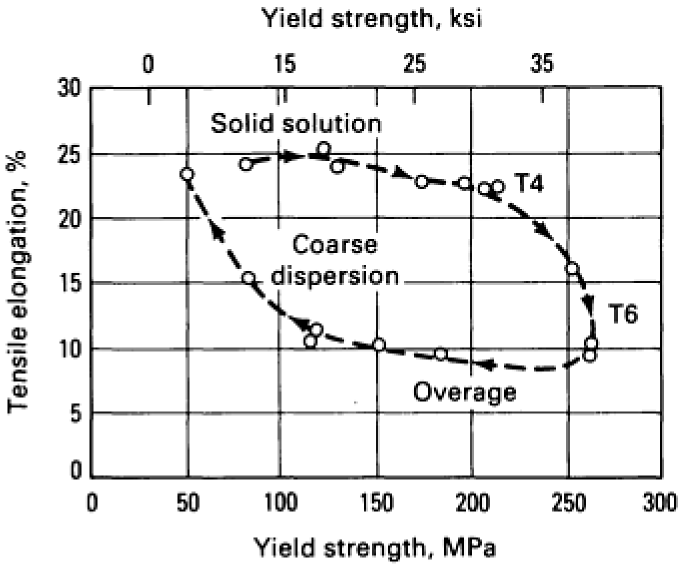

Fig. 2 Effect of precipitation on yield strength and elongation of aluminum alloy 2036. Source: Ref 3

The properties in Fig. 2 were obtained from sheet tensile specimens first solution heat treated, then aged at temperatures ranging from room temperature to 350 °C (660 °F). This produced a full range of structures from solid solution (as-quenched) through T4 and T6 tempers to various degrees of averaging and precipitate agglomeration.

Material Properties and Testing. To conduct a complete analysis of a formed part, the required mechanical properties, as determined by several standard tests, must be considered. These properties include those determined by tension testing and by other tests designed to simulate various production forming processes, including cup tests and bend tests. More information on the test methods briefly described here is available in the article "Formability Testing of Sheet Metals" in this Volume.

Tension testing is used to determine the commonly reported properties--(ultimate) tensile strength, (tensile) yield strength, and (total) elongation--as well as two properties especially important in forming (Ref 1), that is, the strain-hardening exponent n and the plastic-strain ratio r.

The strain-hardening exponent n of a material is determined from the true stress-true strain curve for that material using the formula:

$$\sigma = K\epsilon^n \quad \textbf{(Eq 1)}$$

where σ is true stress, ϵ is true strain, and K is a constant of proportionality.

The plastic-strain ratio r describes the resistance of the material to thinning during forming operations and is the ratio of the true strain in the width direction (ϵ_w) to the true strain in the thickness direction (ϵ_t) of plastically strained sheet:

$$r = \frac{\epsilon_w}{\epsilon_t} \quad \textbf{(Eq 2)}$$

A standard method for determining r using a tension specimen is given in ASTM E 517.

The tensile properties (as well as other mechanical properties) of many aluminum sheet alloys in medium and hard tempers exhibit directional sensitivity. The test direction should be reported along with test results. Directional sensitivity is important in analysis of forming operations that involve bending, flange stretching, or plane straining, all of which are encountered in the forming of ribs and troughs. Orientation of the rolling direction of the sheet relative to the direction of critical strain in the part often can mean the difference between producing a good art and producing scrap.

The Olsen cup test is a biaxial-stretch-forming test that has been used since the early 1900s (Ref 4). A specimen is stretched over a 22.2 mm ($\frac{7}{8}$ in.) diam ball lubricated by a small disk of oiled polyethylene. The flange of the specimen is tightly clamped. Maximum cup height is measured when necking occurs. The value reported is the ratio of cup height to cup diameter.

In the Swift cup test, a deep-drawn cup is used to determine the limiting draw ratio (LDR) of blank size to cup diameter. It is obtained with a 51 mm (2.0 in.) diam flat-bottom punch and a draw die appropriate for the thickness of the specimen. A circular blank is cut to a diameter smaller than the expected draw limit. Lubrication is provided by two oiled polyethylene disks, one on each side of the blank. The blank is drawn to maximum punch load, which occurs before the cup is fully formed. Successively larger blanks are drawn until one fractures before being drawn completely through the die. The diameter of the largest blank that can be drawn without fracturing, divided by cup diameter, determines the LDR.

In the bend test, strips of material are bent around mandrels having different tip radii. Often, mandrels are in the form of pins or rods. The mandrel is forced against one side of the specimen strip, and the other side is simply supported at the end points. The value reported is the minimum radius of mandrel, in multiples of the material thickness *t* around which the material can be bent 180° without cracking. The direction of the bend relative to the rolling (or extrusion) direction should be recorded with the test results.

Correlations Among Test Results. It has been found that results of simulative forming tests correlate quite well with results of tension tests. Specifically, the results of cup ductility tests, such as the Olsen and Swift tests, show good correlation with values of tensile elongation, strain-hardening exponent, and plastic-strain ratio. Olsen cup values correlate well with tensile elongation, and Swift cup values correlate with plastic-strain ratio.

Forming-limit diagrams, also known as forming-limit curves, are direct and useful representations of the formability of aluminum sheet. These diagrams illustrate the biaxial combinations of strain that can occur without failure.

To construct forming-limit diagrams, an array of circles, which often are 2.5 mm (0.1 in.) in diameter, is first imprinted by photoprinting, photoetching, or electroetching on the surface of the sheet metal before forming. The individual circles become ellipses wherever deformation occurs, except in areas where pure biaxial stretching occurs. The major and minor axes of the ellipses are compared with the circles of the original grid to determine the major and minor strains at each location. The areas immediately adjacent to failures are of particular concern in evaluating the forming capabilities of the metal. Failure can be defined by several criteria, but the onset of visible necking is the most widely used. The loci of strain combinations that produce failures define the forming-limit curve. The area below this curve encompasses all the combinations of strain that the metal can withstand.

Forming-limit diagrams for a variety of aluminum alloys and tempers are shown in Fig. 3, 4, and 5. More information on the construction and use of forming limit diagrams is available in the article "Process Modeling and Simulation for Sheet Forming" in this Volume.

Equipment and Tools

Most of the equipment used in the forming of steels and other metals is suitable for use with aluminum alloys. Because of the generally lower yield strengths of aluminum alloys, however, required press capacities are usually lower than for comparable operations on steel, and higher press speeds can be used. Similarly, equipment for roll forming, spinning, stretch forming, and other forming operations on aluminum need not be as massive or rated for such heavy loading as for comparable operations on steel.

Tools. Total wear on tools used in forming aluminum is somewhat less than when forming steel. This results in part from the lower force levels involved and in part from the smoother surface condition that is characteristic of aluminum alloys. Accordingly, tools can sometimes be made from less expensive materials, even for relatively long runs.

However, a higher-quality surface finish is generally required on tools used with aluminum alloys, to avoid marking. The oxide film on the surface of aluminum alloys is highly abrasive, and for this reason many forming tools are made of hardened tool steels. As a rule, these tools, even if otherwise suitable, should not be used interchangeably to form steel parts, because this could destroy the high-quality finish on the tools.

Most aluminum alloys require smaller clearances between punches and dies in blanking and piercing than do steels. On drawing tools, they require larger clearances but about the same radii, to allow the free flow of metal and avoid excessive stretching.

The amount of springback in forming aluminum alloys is generally less than it is in forming low-carbon steel, and this must be considered in tool design. The amount of springback is roughly proportional to the yield strength of the metal. Additionally, the lower rate of work hardening of aluminum alloys permits a greater number of successive draws than is usually possible with steel. More information on equipment for sheet forming is available in the article "Presses and Auxiliary Equipment for Forming of Sheet Metal" in this Volume.

Lubricants

Lubricants must be specifically selected for their compatibility with aluminum alloys and their suitability for the particular forming operation in question. A lubricant suitable for use on a steel part will not necessarily be suitable for use in the forming of a similar aluminum alloy part.

The proper formulation of lubricants for the forming of aluminum alloys must take into account the special requirements of regulation of moisture content in nonaqueous systems, corrosion inhibitors, and pH control, in order to prevent staining or corrosion and to make duration of contact with the workpiece less critical.

The lubricants most widely used in the forming of aluminum alloys are listed below in approximate order of increasing effectiveness:

- Kerosene
- Mineral oil (viscosity of 40 to 300 SUS a 40 °C, or 100 °F)
- Petroleum jelly
- Mineral oil plus 10 to 20% fatty oil
- Tallow plus 50% paraffin
- Tallow plus 70% paraffin
- Mineral oil plus 10 to 15% sulfurized fatty oil and 10% fatty oil
- Dried soap films or wax films
- Fat emulsions in aqueous soap solutions with finely divided fillers
- Mineral oil with sulfurized fatty oil, fatty oil, and finely divided fillers

The use of various special-purpose lubricants is discussed in sections of this article that deal with individual forming processes. The article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume contains more information on lubricants for sheet forming.

Blanking and Piercing

Blanking and piercing of aluminum alloy flat stock are ordinarily done in punch presses because of their high production rates and ability to maintain close tolerances. Press brakes are sometimes used, particularly for experimental or short-run production.

The generally lower shear strength of aluminum alloys usually dictates the use of presses or press brakes of lower capacity than those used for comparable operations with steel. Total required shearing force can be calculated as the product of shear strength, total length of cut, and metal thickness, but allowance must be made for different alloys, for dulling of the cutting edges of punches and dies, and for variation in clearance between punch and die. The shear strengths of the commonly used aluminum alloys range from 62 to 338 MPa (9 to 49 ksi), whereas the shear strength of a typical low-carbon steel is 241 to 462 MPa (35 to 67 ksi).

Tool Materials. A discussion of materials for blanking and piercing dies is given in the article "Selection of Material for Press-Forming Dies" in this Volume. Aluminum alloys are classed with other soft materials, such as copper and magnesium alloys. In general, for a given tool material, tool life is longer for blanking and piercing aluminum alloys than for blanking and piercing steel.

In some applications, a less expensive die can be used than is true for steel parts, particularly for relatively short runs. Cast zinc dies, which cost only about one-fifth as much as tool steel dies, are used for runs of up to about 2000 parts. Steel-rule dies and template dies also reduce tooling costs for short runs or moderate-length runs. For example, an aluminum alloy blank 495 by 305 mm (19.5 by 12 in.) by 1 mm (0.040 in.) in thickness was made in a steel-rule die having an expected life of 150 pieces. For the production quantity, burr height did not exceed 0.127 mm (0.005 in.). Punches and die buttons for seven pierced holes of 3.9, 4.8, and 6.4 mm ($\frac{5}{32}$, $\frac{3}{16}$, and $\frac{1}{4}$ in.) diameter were incorporated in the die.

Low-carbon steel or cast iron dies sometimes replace hardened tool steel dies, even for long runs. Punches are usually made from annealed or hardened tool steel, depending on the size and complexity of the part and the length of the run. Cemented carbide tools are seldom required, even for extremely long runs.

Tolerances. A tolerance of ±0.127 mm (0.005 in.) is normal in the blanking and piercing of aluminum alloy parts in a punch press. Using a press brake, it is possible to blank and pierce to a location tolerance of ±0.25 mm (0.010 in.) or less, although tolerances for general press brake operations usually range from ±0.51 to ±0.76 mm (0.020 to 0.030 in.).

For economy in tool cost, specified tolerance should be no less than is actually necessary for the particular part. A tolerance of ±0.127 mm (0.005 in.) would probably require that the punch and die be jig ground, adding 30 to 40% to their cost. A tolerance of ±0.05 mm (0.002 in.) may require the addition of a shaving operation. In addition to the cost of an extra die, labor costs would be increased by the added operation.

For extremely accurate work, an allowance must be made for the shrinkage of holes and expansion of blanks resulting from the elasticity of the stock. This allowance, made to both punch and die, does not change the clearance between them, and is primarily a function of stock thickness. For large sizes and normal tolerances, this correction is not very important.

Clearance between punch and die must be controlled in blanking and piercing in order to obtain a uniform shearing action. Clearance is usually expressed as the distance between mating surfaces of punch and die (per side) in percentage of work thickness.

Correct clearance between punch and die depends on the alloy as well as the sheet thickness. Suggested punch-to-die clearances in terms of percentage of sheet thickness *t* for blanking and piercing aluminum alloys in various tempers are listed in Table 1.

The character of the shearing action also depends on the sharpness of the tools. Dull cutting edges on punch and die have effects similar to those of excessive clearance, with the effect on burr size being particularly pronounced.

With proper clearance, the fractures proceeding from the punch surface and from the die surface of the work meet cleanly without secondary shearing and excessive plastic deformation. Secondary shearing indicates that the clearance is too small; a large radius or dished contour at the sheared edge and a stringy burr indicate that the clearance is too large.

For additional information on punch-to-die clearances, see the article "Piercing of Low-Carbon Steel" in this Volume.

Die Taper. The walls of die openings in blanking or piercing dies are often tapered $\frac{1}{2}$° from the vertical, to minimize sticking of the blank or slug in the die. A straight, vertical section of at least 3.2 mm ($\frac{1}{8}$ in.) or equal to the metal thickness for stock thicker than 3.2 mm ($\frac{1}{8}$ in.) is usually left at the upper end of the die opening, to provide for sharpening without changing the clearance. Tapered die relief is usually more suitable for piercing aluminum than is counterbore design relief.

Stripping force of 3 to 20% of the total capacity needed for blanking and piercing is used for aluminum alloys. The force needed depends on the alloy, temper, and stock thickness. Sharpness of cutting edges on punch and die, lubrication, and uniformity of application of stripper-plate pressure also affect stripping force.

Lubricants are normally used in blanking or piercing aluminum alloy parts to reduce sticking of slugs or blanks in the die opening and to facilitate clean stripping from the punch without buckling. Lower tool maintenance costs and smoother edges on blanks or holes can be obtained with suitable lubrication.

Forming of Aluminum Alloys

Press-Brake Forming

The press-brake forming techniques used with aluminum alloys are similar to those used with steel and other metals, differing only in some details of tool design (see the article "Press-Brake Forming" in this Volume).

Tolerances in press-brake forming are larger than those in punch press operations. For simple shapes that are relatively long and narrow, a tolerance of ±0.8 mm ($\frac{1}{32}$ in.) can usually be maintained. On larger parts of more complex cross section, the tolerance may be as much as ±1.6 mm ($\frac{1}{16}$ in.).

Springback, or partial return to the original shape upon removal of the bending forces, occurs in most bending operations. The amount of springback depends on the yield strength and thickness of the material and on the bend radius. Table 2 shows the effects of these variables, giving springback allowances in degrees of overbending that have been used for high-strength aluminum alloys 2024 and 7075.

Table 2 Springback allowances for 90° bends in 2024 and 7075 aluminum alloy sheet

The springback allowance, or number of degrees of overbending required, ranges from 1 to 12° for 2024-O and 7075-O (yield strength of 76 MPa, or 11 ksi, min), and from $7\frac{1}{4}$ to $33\frac{1}{2}$° for 2024-T3 (yield strength of 345 MPa, or 50 ksi). The allowance increases with increasing yield strength and bend radius, but varies inversely with stock thickness. The allowance for bends of other than 90° can be estimated on a proportional basis. For bend angles of less than 90°, the springback may be greater unless the bend radius is decreased, because the metal in the bend area may not have been stressed beyond its yield point.

Radii to which bends can be made depend on the properties of the metal and the design, dimensions, and condition of the tools. For most metals, the ratio of minimum bend radius to sheet thickness is approximately constant, because ductility is the primary limiting factor on minimum bend radius. This is not true for aluminum alloys, for which the ratio of bend radius to sheet thickness increases with the thickness.

With special tooling, aluminum alloys can be bent to smaller radii than those indicated in standard tables. Bottoming dies and dies that combine bottoming with air bending are used for this purpose. Hydraulic forming, forming with rubber-pad dies, and high-energy-rate forming also produce good small-radius bends.

Sometimes it is possible to take advantage of the grain direction in the work metal: The most severe bends can be made across the direction of rolling. If similar bends are made in two or more directions, it is recommended that, if possible, all bends be made at an angle to the direction of rolling. Local heating along the bend lines can sometimes be used to produce small bend radii without fracture; this is particularly useful in bending plate.

The maximum temperature that can be used without serious loss in mechanical properties is 150 to 205 °C (300 to 400 °F) for cold-worked material. Reheating of naturally aged aluminum alloys 2014 and 2024 is not recommended unless the part is to be artificially aged. Generally, any reheating sufficient to improve formability will lower the resistance to corrosion to an undesirable degree, except with alclad sheet.

Blank Development. For relatively simple parts, particularly those for which close tolerances are not required, the blank layout can be developed directly by using bend-allowance tables or equations. As a rule, the initial calculated blank layout and die design are developed into final form by successive trial and modification.

Lubricants are needed for nearly all press-brake forming of aluminum alloys. The light protective film of oil sometimes present on mill stock is often adequate for mild bending operations, but when this is not sufficient, a lubricant is usually applied to the working surfaces of the tools and the bend area of the workpiece to prevent scoring and metal pickup.

Tools. The bending, forming, piercing, and notching dies used in press brakes for aluminum alloys are much the same as those used for low-carbon steel. To prevent marring or scratching of the workpiece, tools used for bending steel should be carefully cleaned and polished before being used for aluminum alloys. Rubber pads used in press-brake dies, when clean, will not scratch the surface of an aluminum sheet.

Because of the differences in tensile strength and springback, shut height settings for aluminum alloys may be different from those for low-carbon steel.

Contour Roll Forming

Aluminum alloys are readily shaped by contour roll forming, using equipment and techniques similar to those used for steel (see the article "Contour Roll Forming" in this Volume). Operating speeds can be higher for the more ductile aluminum alloys than for most other metals. Speeds as high as 245 m/min (800 ft/min) have been used in mild roll forming of 0.8 mm ($\frac{1}{32}$ in.) thick alloy 1100-O sections 15 to 30 m (50 to 100 ft) long. Power requirements for roll forming of aluminum alloys are generally lower than is the case for comparable operations on steel, because of the lower yield strength of most aluminum alloys.

Tooling. The design of rolls and related equipment, as well as the selection of tool materials, is discussed in the article "Contour Roll Forming" in this Volume. The most commonly used material is L6 tool steel, a low-alloy nickel-chromium grade with excellent toughness, wear resistance, and hardenability. For extremely severe forming operations or exceptionally long runs, a high-carbon high-chromium grade such as D2 is preferred because it has superior resistance to galling and wear. These tool steels are hardened to 60 to 63 HRC. The tools are highly polished and are sometimes chromium plated to prevent scratching and to minimize the pickup of chips when surface finish of the work is critical.

For short runs and mild forming operations, rolls can be made of turned and polished gray cast iron (class 30 or better) or low-carbon steel. For light-gage metals, tools made of plastics reinforced with metal powder, or of specially treated hardwood, have occasionally been used. For some applications in the roll forming of light-gage alloys when quality of surface finish is the primary concern, use has been made of cast zinc tools, at the cost of shorter tool life.

Extremely close tolerances are required on tool dimensions. Allowance for springback must be varied with alloy and temper, as well as with material thickness and radius of forming, as indicated in Table 2. Final adjustments must be made on the basis of production trials.

Tolerances of ±0.127 mm (0.005 in.) are common in contour roll forming, and ±0.05 mm (0.002 in.) can be maintained on small, simple shapes formed from light-gage metals. One or two final sizing stations may be required for intricate contours or when springback effects are great.

Lubricants are required in nearly all contour roll forming of aluminum alloys. For high-speed or severe forming operations, the rolls and workpiece may be flooded with a liquid that functions as both a lubricant and a coolant. A soluble oil in water is preferred for this type of operation. When a more effective lubricant is required, a 10% soap solution or an extreme-pressure (EP) compound may be used. These are better suited for minimizing tool wear and producing a high-quality finish, but are more difficult to remove.

Applications. Roll-formed aluminum alloy parts made from sheet or coiled strip include furniture parts, architectural moldings, window and door frames, gutters and downspouts, automotive trim, roofing and siding panels, and shelving.

Tubing in sizes ranging from 19 to 203 mm ($\frac{3}{4}$ to 8 in.) in outside diameter and from 0.64 to 3.9 mm (0.025 to 0.156 in.) in wall thickness is made in a combined roll-forming and welding operation (see the article "Contour Roll Forming" in this Volume). Linear speeds of 9 to 60 m/min (30 to 200 ft/min) are used in this process. Applications include irrigation pipe, condenser tubing, and furniture parts.

Other applications of contour roll forming include the forming of patterned, anodized, or pre-enameled material. Such applications impose stringent requirements on tool design and maintenance, and lubrication sometimes cannot be used because of the nature of the coating or because of end-use requirements.

Deep Drawing

Equipment, tools, and techniques used for deep-drawing aluminum and aluminum alloys are similar to those used for other metals, and are described in more detail in the article "Deep Drawing" in this Volume. This section deals with those aspects of deep drawing that are specific to aluminum alloys, and is restricted to procedures using a rigid punch and die. Other procedures are described in subsequent sections of this article.

Equipment. Punch presses are used for nearly all deep drawing; press brakes are sometimes used for experimental or very short runs. Presses used for steel are also suitable for aluminum.

Capacity requirements, determined by the same method used for steel, are generally lower for comparable operations because of the lower tensile strength of aluminum alloys.

Press speeds are ordinarily higher than they are for steel. For mild draws, single-action presses are usually operated at 27 to 43 m/min (90 to 140 ft/min). Double-action presses are operated at 12 to 30 m/min (40 to 100 ft/min) for mild draws, and at less than 15 m/min (50 ft/min) for deeper draws with low and medium-strength alloys. Drawing speeds on double-action presses are about 6 to 12 m/min (20 to 40 ft/min) with high-strength alloys.

Tool Design. Tools for deep drawing have the same general construction as those used with steel, but there are some significant differences. Aluminum alloy stock must be allowed to flow without undue restraint or excessive stretching. The original thickness of the metal is changed very little. This differs from the deep drawing of stainless steel and brass sheet; each of which may be reduced by as much as 25% in thickness in a single draw.

Clearances between punch and die are usually equal to the metal thickness plus about 10% per side for drawing alloys of low or intermediate strength. An additional 5 to 10% clearance may be needed for the higher-strength alloys and harder tempers.

With circular shells, metal thickening occurs with each draw, therefore clearance is usually increased with each successive draw. The restrictions imposed on the drawing of rectangular shells by metal flow at the corners make equal clearances for each draw satisfactory. The final operation with tapered or rectangular shells serves primarily to straighten walls, sharpen radii, and size the part accurately. Therefore, the clearance for these operations is equal to the thickness of the stock.

Excessive clearance may result in wrinkling of the sidewalls of the drawn shell. Insufficient clearance burnishes the sidewalls and increases the force required for drawing.

Radii on Tools. Tools used for drawing aluminum alloys are ordinarily provided with draw radii equal to four to eight times the stock thickness. A punch nose radius is sometimes as large as ten times the stock thickness.

A die radius that is too large may lead to wrinkling. A punch nose radius that is too sharp increases the probability of fracture or of residual circular shock lines that can be removed only by polishing.

Nonetheless, failure by fracture can sometimes be eliminated by increasing the die radius, or by making the drawing edge an elliptic form instead of a circular arc.

Surface Finish on Tools. Draw dies and punches should have a surface finish of 0.4 μm (16 μin.) or less for most applications. A finish of 0.08 to 0.1 μm (3 to 4 μin.) is often specified on high-production tooling for drawing light-gage or precoated stock. Chromium plating may also be specified to minimize friction and prevent pickup of dirt or other particles that could damage the finish on the part.

Tool Materials. The selection of materials for deep drawing tools is discussed in the article "Selection of Material for Deep-Drawing Dies" in this Volume. Materials for small dies are chosen almost entirely on the basis of performance, but cost becomes a significant factor for large dies. Local variation in wear on tools is an important factor in tool life. A twentyfold variation in rate of wear can be observed on the die radius.

Lubricants for deep drawing of aluminum alloys must allow the blank to slip readily and uniformly between the blankholder and the die, and must prevent stretching and galling while this movement takes place.

The drawing compounds can be applied only to the areas that will be subjected to a significant amount of cold working, unless local application interferes with the requirements of high-speed operation. Uniformity of application is critical, especially to enable the maintenance of correct blankholder pressure around the periphery of the die.

Drawing Limits. The reduction in diameter that is possible in a single operation with aluminum alloys is about the same as that obtainable with drawing-quality steel. For deep-drawn cylindrical shells, reductions in diameter of about 40% for the first draw, 20% for the second draw, and 15% for the third and subsequent draws can be obtained with good practice. The part can usually be completely formed without intermediate annealing. Four or more successive draws without annealing can be performed, with proper die design and effective lubrication, on such alloys as 1100, 3003, and 5005. The amount of reduction decreases in successive draws because of the loss in workability due to strain hardening. The total depth of draw thus obtainable without intermediate annealing exceeds that obtainable from steel, copper, brass, or other common materials.

For high-strength aluminum alloys, the approximate amount of permissible reduction is 30% for the first draw, 15% for the second draw, and 10% for the third draw.

Local or complete annealing is usually necessary after the third draw on alloys such as 2014 and 2024. Alloys 3004, 5052, and 6061 are intermediate in behavior.

The rate of strain hardening is greatest for the high-strength alloys and least for the low-strength alloys. Table 3 shows the changes in mechanical properties that result from successive draws with alloys 3003 and 5052. The major portion of the change is accomplished in the first draw. The rate of strain hardening is more rapid with high-strength heat-treatable alloys such as 2014 and 2024.

Table 3 Effect of drawing on mechanical properties of aluminum alloys 3003 and 5052

Number of draws	**Tensile strength**		**Yield strength**		Elongation in 50 mm (2 in.), %
	MPa	**ksi**	**MPa**	**ksi**	
Alloy 3003					
0	110	16	41	6	**30**
1	131	19	117	17	**11**
2	152	22	145	21	**9**
3	162	23.5	152	22	**8**
4	169	24.5	155	22.5	**8**
[a]	(200)	(29)	(186)	(27)	**(4)**
Alloy 5052					
0	193	28	90	13	**25**
1	238	34.5	221	32	**6**
2	272	39.5	248	36	**6**

(a)	**(290)**	**(42)**	**(255)**	**(37)**	**(7)**

(a) Values in parentheses are typical values for these alloys in the full hard condition.

Practical limits for single-operation deep drawing of cylindrical cups and rectangular boxes have been expressed in terms of dimensional ratios, as shown in Fig. 6. (Reverse redrawing can be used to obtain a deeper shell than indicated by the limits in Fig. 6 for conventional drawing methods.)

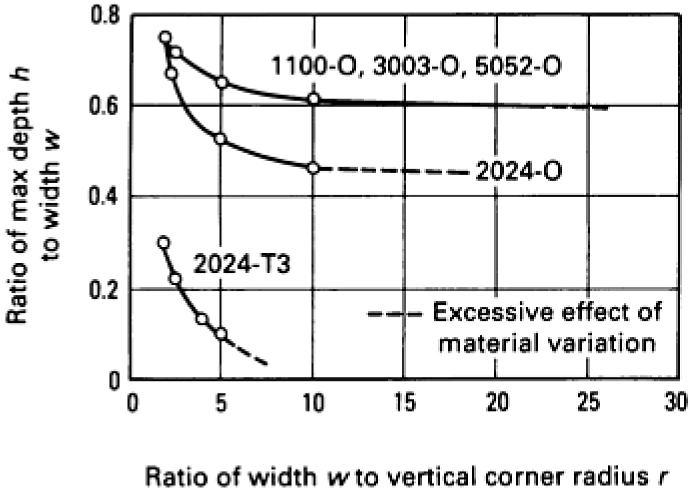

Fig. 6 Drawing limits for single-operation drawing of cylindrical cups or rectangular boxes from aluminum alloy sheet 0.66 to 1.63 mm (0.026 to 0.064 in.) thick. For cylindrical cups, width *w* equals diameter and vertical corner radius *r* equals half the diameter. For rectangular boxes, width *w* equals the square root of the projected bottom area. If length is more than three times width, drawing limits will be more severe than those shown above. For flanged boxes, the flange width must be included in depth *h*.

The relation of the metal thickness t to the blank diameter D is an important factor in determining the percentage reduction for each drawing operation. As this ratio decreases, the probability of wrinkling increases, requiring more blankholding pressure to control metal flow and prevent wrinkles from starting. Figure 7 shows the effect of this ratio on percentage reduction of successive draws, without intermediate annealing, for low-strength alloys such as 3003-O.

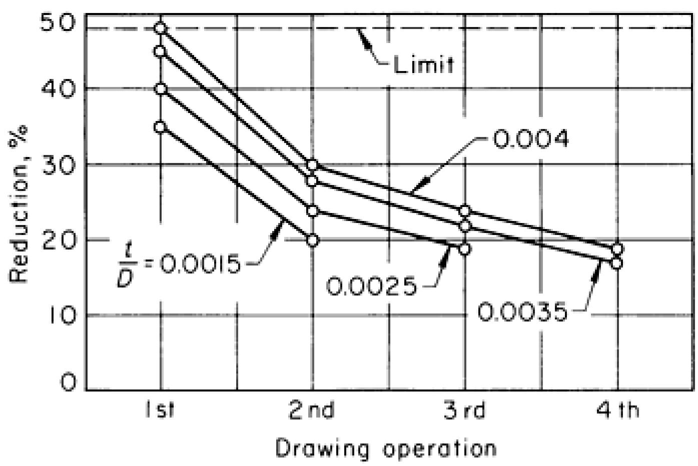

Fig. 7 Effect of thickness-to-diameter ratio on percentage of reduction for successive drawing operations without intermediate annealing for low-strength aluminum alloys such as 3003-O. *t*, metal thickness. *D*, blank

diameter

Blank development is of particular importance in the deep drawing of large rectangular and irregular shapes. Excessive stock at the corners must be avoided, because it hinders the uniform flow of metal under the blankholder and thus leads to wrinkles or fractures.

With suitable tooling and careful blank development, large rectangular and irregular shapes can often be produced economically in large quantities by deep drawing. Smaller quantities are made in sections with inexpensive tooling and then assembled by welding. Both the welding operation and the subsequent grinding and polishing of the weld areas are time consuming and costly.

Warping. The nonuniformity of stress distribution in the drawing of rectangular or irregular shapes increases the tendency toward warping. Bowing or oilcan effects on the major surfaces become more pronounced with increasing size of the part. Changes can sometimes be made in dimensional details of the drawing tools to eliminate these defects without the need for extra forming operations.

Miscellaneous Shapes. Other shapes often produced by deep drawing (besides cylindrical and rectangular shells) include hemispherical shells, flat-bottom hemispherical shells, and tapered shells.

Hemispherical shells with a final inside diameter of less than about 150 times the original metal thickness can be drawn in one operation. For inside diameters of more than 150 times thickness, two draws are usually required, to avoid wrinkles. Local thinning in the first draw must be avoided if the second draw is to be successful.

Flat-bottom hemispherical shells, unless very shallow, require at least two draws. The first draw produces a rounded shape, with a larger radius in the bottom area than on the side areas. The final draw flattens the bottom and gives the sides a uniform curvature of the radius required.

Tapered shells require more drawing operations for a given depth of draw than do most other symmetrical shapes. The number of steps required increases with the taper angle.

The bottom edges, except for the final operation, do not have the contour of a circular arc. The profile consists of essentially flat sections at an angle of about 40 to 50° from the horizontal. Stepwise reductions are made along the line of final contour, as shown in Fig. 8, and the final draw straightens out the sidewalls to the desired shape.

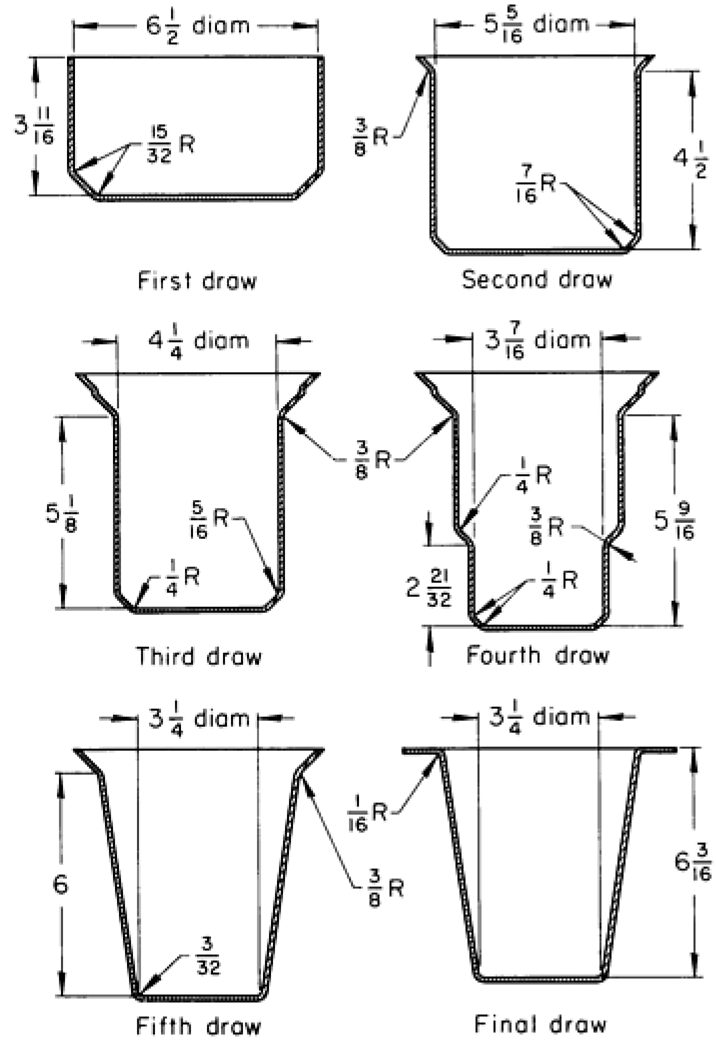

Fig. 8 Typical progression of shapes in multiple-draw forming of a tapered shell from an aluminum alloy blank 1.63 mm (0.064 in.) thick and 292 mm ($11\frac{1}{2}$ in.) in diameter. Dimensions given in inches

Each operation after the first is restricted to a shallow draw to minimize strain hardening. With alloys of low and intermediate strength, this procedure makes it possible to complete the series of draws without annealing. Contrary to normal practice, the amount of reduction per draw need not be lowered after the second draw. However, polishing or burnishing is often required on the completed shell to obtain a good-quality finish on the sidewalls.

Ironing is avoided in some deep drawing applications with aluminum alloys, but can be used to produce a shell with a heavy bottom and thin sidewalls. The shell is first drawn to approximately the final diameter. The drawing lubricant is then removed, and the shell is annealed, bringing it to temperature rapidly to minimize the formation of coarse grains in areas that have been only slightly cold worked.

The sidewalls can then be reduced in thickness by 30 to 40% in an ironing operation. By repeating the cleaning, annealing, and ironing steps, an additional reduction of 20 to 25% can be obtained, with good control over wall thickness.

A typical use of ironing is shown in Fig. 9. Here a cylindrical shell is produced with a thick bottom and thin sidewalls by a single deep draw and two successive ironing operations. The approximate final diameter and about half the final depth are obtained in the drawing operation. Wall thickness is reduced 33% in the first ironing step and 19% in the second.

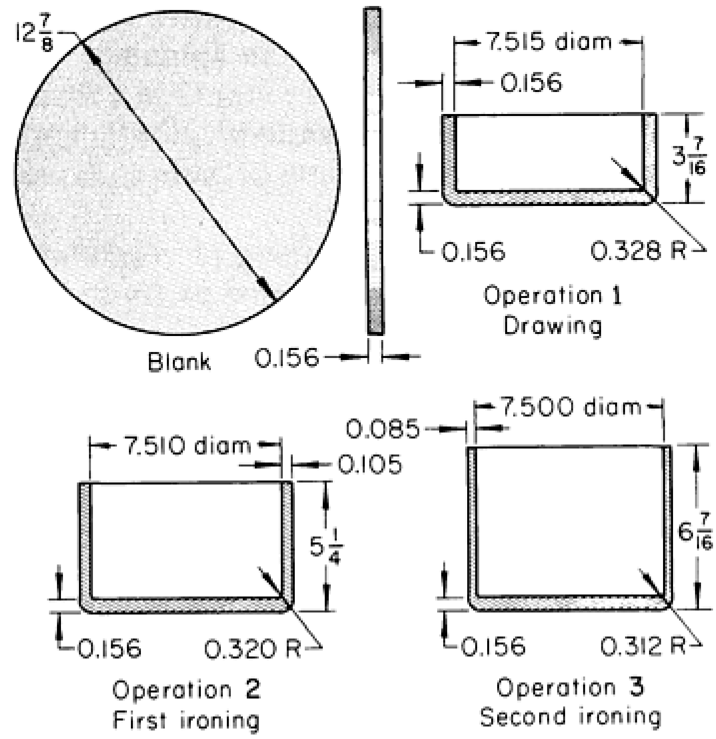

Fig. 9 Progression of shapes in production of a shell with a thick bottom and thin sides in one draw and two ironing operations. Dimensions given in inches

Hot Drawing. Severe drawing operations are often impossible to perform at room temperature on large and relatively thick shapes made from high-strength aluminum alloys. However, the lower strength and increased ductility at temperatures above the recrystallization point of the alloy make it possible to produce large and relatively thick shapes by hot drawing. There is little or no advantage when stock is less than 3.2 mm (0.125 in.) thick. Alloys frequently used in applications of this type include nonheat-treatable alloys 5083, 5086, and 5456, and heat-treatable alloys 2024, 2219, 6061, 7075, and 7178.

Heavy-duty presses and related equipment are required. Drawing temperatures range from 175 to 315 °C (350 to 600 °F). The length of time the workpiece is held at temperature is controlled to avoid excessive grain growth in areas with little strain hardening. Ordinary drawing compounds break down or burn at elevated temperature, and are not suitable for hot-drawing operations.

Graphite-containing tallow and hard yellow naphtha soap have sometimes been used as lubricants at intermediate elevated temperature. Lubricants that remain stable above 260 °C (500 °F) include graphite and molybdenum disulfide. These materials can be used in the colloidal form with a volatile vehicle, mixed with other lubricants, or applied to the die as powders.

Spinning

Spinning is often used for the forming of aluminum alloy shapes that are surfaces of revolutions. The manual lathes, automatic spinning machines, chucks, and tools used for aluminum alloys are essentially the same as those used for steel and the other metals commonly formed by spinning (see the article "Spinning" in this Volume).

Hand-spinning lathes and simple tools are suitable for forming aluminum alloy blanks 0.51 to 2.05 mm (0.020 to 0.081 in.) thick; with proper care, stock as thin as 0.10 mm (0.004 in.) can be spun. For thicker and larger blanks, auxiliary equipment is used to apply pressure to the workpiece. This equipment varies from a simple scissors arrangement to feed screws for controlling tool advance; pressure against the work is provided by air or hydraulic cylinders.

Blanks up to 6.4 mm ($\frac{1}{4}$ in.) thick can usually be spun at room temperature. For greater thicknesses, semimechanical to fully mechanical equipment is used, and the work metal is heated. Work metal 25 mm (1 in.) or more in thickness requires special heavy-duty machines and hot spinning.

Aluminum alloy parts 76 mm (3 in.) thick have been spun experimentally. Equipment is available for the spinning of parts as large as 5 m (16 ft) in diameter.

Tolerances for the spinning of aluminum alloys are essentially the same as those for other common metals.

Alloys. A number of aluminum alloys are widely used in spinning applications. Desirable properties are ductility, relatively low ratio of yield strength to ultimate strength, low rate of work hardening, and small grain size.

The alloys of low and intermediate strength that are spun most frequently include 1100, 2219, 3003, 3004, 5052, 5086, and 5154. Annealed blanks are generally used for severe forming; however, a harder temper is sometimes preferred, if it is sufficiently formable, to avoid a tendency to ball up ahead of the tool. A harder temper also may be used when forming is not severe enough to give the product its necessary strength by work hardening.

Heat-treatable alloys used for high strength in the finished part are 2014, 2024, and 6061. If the forming is extensive, these alloys often must be annealed several times during spinning, or they may be spun hot.

One method used frequently for spinning heat-treatable alloys is:

- Spin annealed blank to approximate form
- Solution heat treat and quench
- Spin to final form at once, before appreciable age hardening

If spinning to the final form cannot be done after solution heat treating and quenching, the quenched parts should be placed in a refrigerator, or packed in dry ice, and held as close to -20 °C (0 °F) as possible until they can be spun. The parts are aged to the T6 temper after spinning has been completed.

Typical spindle speeds for spinning flat blanks and drawn shells of various diameters are listed in Table 4. Rotational speed is decreased as blank diameter increases, so that peripheral speed is maintained in the same range regardless of the size of the workpiece. Peripheral speed ordinarily averages about 915 m/min (3000 ft/min) for aluminum alloys. This is somewhat faster than the speeds normally used in spinning copper, brass, stainless steel, and low-carbon steel.

Table 4 Typical spindle speeds for the spinning of aluminum alloy flat blanks

Blank diameter		Spindle speed, rpm
m	**in.**	
Flat blanks		
Up to 0.3	Up to 12	**600-1100**
0.3-0.6	12-24	**400-700**
0.6-0.9	24-36	**250-550**
0.9-1.8	36-72	**50-250**
1.8-3.0	72-120	**25-50**
3.0-4.5	120-180	**12-25**
4.5-5.3	180-210	**12**
Drawn shells		
0.25-0.35	10-14	**1000-1200**
0.35-0.50	14-20	**650-800**
0.50-0.75	20-30	**475-550**
0.75-1.0	30-40	**325-375**

1.0-1.3	40-50	**250-300**
1.3-1.8	50-70	**200-210**
1.8-2.3	**70-90**	**150-175**

Lubricants are needed in nearly all spinning operations. Beeswax, tallow, and petroleum jelly are suitable for most small parts. Hard yellow naphtha soap is an effective lubricant for larger workpieces. Colloidal graphite in kerosene, or compounds containing molybdenum disulfide, are used in hot spinning. Lubricating compounds used must be easily removable from the finished part without costly treatments.

Applications. Parts produced from aluminum alloys by spinning include tumblers, pitchers, bowls, cooking utensils, ring molds, milk cans, processing kettles, reflectors, aircraft and aerospace parts, architectural sections, tank heads, and streetlight standards.

Spinning is often selected in preference to drawing when quick delivery of small quantities is important, because the spun parts can usually be delivered before drawing tools have been made. Cones, hemispheres, tapered shapes, and parts with complex or reentrant contours (if surfaces of revolution) are often more readily formed by spinning than by other methods. Spinning is also used for very large parts when suitable press equipment and tools are not readily available or are too costly.

Spinning is not usually economical for quantities of more than 5000 to 10,000 pieces because of comparatively low production rates and resulting high unit labor costs. There are exceptions, especially in the power spinning of truncated cone-shape parts having included angles of 40° or more. Spinning is capable of producing such parts at lower cost than deep drawing, it gives a uniform wall thickness and a surface free from wrinkles, and it increases the tensile strength of the work metal by as much as 100%.

Stretch Forming

Almost all of the aluminum alloys can be shaped by stretch forming. In this process, the work metal is stretched over a form and stressed beyond its yield point to produce the desired contour (for a detailed description, see the article "Stretch Forming" in this Volume).

Typical shapes produced by stretch forming are shown in Fig. 10. These include large shapes with compound curvature formed by longitudinal and transverse stretching of sheet, and compound bends or long, sweeping bends formed from extrusions.

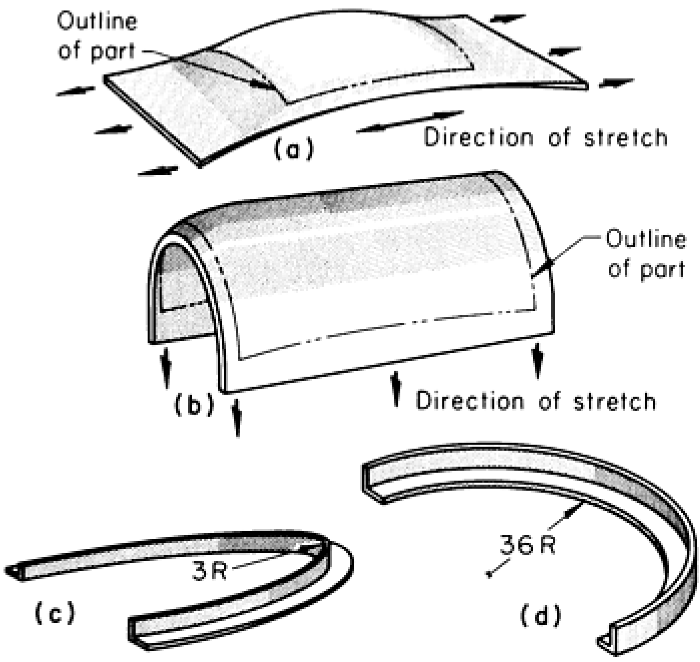

Fig. 10 Typical stretch-formed shapes. (a) Longitudinal stretching. (b) Transverse stretching. (c) Compound bend from extrusion. (d) Long, sweeping bend from extrusion. Dimensions given in inches

Alloys. Properties desirable for stretch forming are high elongation, wide forming range (spread between yield strength and tensile strength), toughness, and fine grain structure. Table 5 shows the effect of elongation and forming range on stretchability ratings for the alloys most commonly used in stretch forming. The stretchability rating varies directly with the forming range, except for 6061-W (which has somewhat higher elongation than adjacent alloys) and 7075-T6 (which has by far the lowest elongation listed). Alloys 1100-O and 3003-O, with the highest elongation shown, nevertheless are less desirable for stretch forming than are the alloys above them in the list. Their low strength and the narrow spread between yield strength and tensile strength make them particularly susceptible to local necking and premature failure in stretch forming.

Table 5 Mechanical properties and stretchability ratings for aluminum alloys most commonly used in stretch forming

Alloy	**Tensile strength**		**Yield strength**		**Forming range**[(a)]		**Elongation in 50 mm (2 in.), %**	Stretchability rating[(b)]
	MPa	**ksi**	**MPa**	**ksi**	**MPa**	**ksi**		
7075-W[(c)]	331	48	138	20	193	28	19	**100**
2024-W[(c)]	317	46	124	18	193	28	20	**98**
2024-T3	441	64	303	44	138	20	18	**95**
6061-W[(c)]	241	35	145	21	97	14	22	**90**
7075-O	221	32	97	14	124	18	17	**80**
2024-O	186	27	76	11	110	16	19	**80**
6061-O	124	18	55	8	69	10	22	**75**
3003-O	110	16	41	6	69	10	30	**75**
1100-O	90	13	35	5	55	8	35	**70**
7075-T6	**524**	**76**	**462**	**67**	**62**	**9**	**11**	**10**

(a) Tensile strength minus yield strength.

(b) Relative amount of stretch permissible in stretch forming, based on 7075-W as 100.

(c) Freshly quenched after solution heat treatment

Tools. The materials used for the form block or die depend on the production quantities required, the severity of local stress and wear on the die, and the thickness and wear properties of the alloy to be formed. Materials include wood, plastics, faced concrete, cast zinc alloys, aluminum tool and jig plate, cast iron, and (rarely) steel or chromium-plated steel.

Lubricants are recommended in the stretch forming of aluminum alloys. Water-soluble oils are commonly used, with viscosity dependent on the severity of forming. Calcium-base greases, paraffin, beeswax, and commercial waxes also are used. The application of too much lubricant can result in buckling of the workpiece.

Sometimes a layer of sheet rubber, glass cloth, or plastic between die and workpiece serves as a lubricant. Because of their inherent lubricity, zinc alloy dies require only a minimum of lubrication. Smooth-surface plastic dies may require no lubrication, because of their low coefficient of friction against aluminum.

Applications. The various stretch-forming techniques (including stretch drawing, stretch wrapping, and compression and radial drawing) are used extensively in the aerospace industry. Typical parts produced include wing-skin and fuselage panels, engine cowlings, window and door frames, and trim panels used in aerospace, automotive, architectural, and appliance industries.

Stretch draw forming of aluminum is done using both the matched-die and form block techniques. The matched-die method uses a single-action hydraulic press equipped with a means of closing and moving the jaws that grip each end of the blank. The punch is attached to the bed of the press, and the die is attached to the ram.

The alternate method uses a form block that is attached to a stationary bed or a hydraulic cylinder. With this method, the blank is gripped with jaws that hold it in tension or draw it over the form block.

Stretch wrapping uses a form block that is bolted to a rotary table. One end of the blank is clamped to the form block or to a table-mounted gripper. A hydraulic cylinder or a gripper applies tension to the other end of the blank while the form block revolves into it with the turning of the table.

Shaped form blocks that match the contour of extruded or rolled sections are used for support during forming. Filler strips, either segmented or made of low-melting alloys or strips of aluminum, are used to prevent the collapse of sections.

Radial-draw forming is a combination of stretch wrapping and compression forming. The workpiece is pressed against the form block by a roller or shoe while being wrapped around the turning form block. This method can be used, for example, to form a flange to a compound curvature while forming a leg, as in the part shown in Fig. 11.

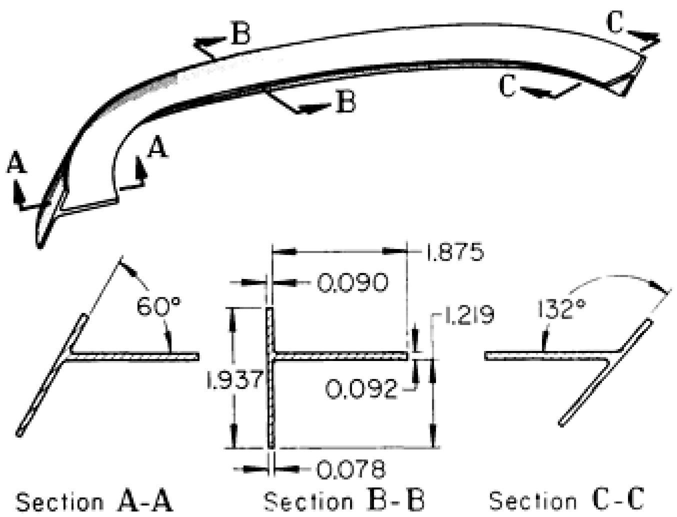

Fig. 11 Aluminum alloy 7075-O radial draw formed T-section with radical changes in angle between leg and flange. Dimensions given in inches

Rubber-Pad Forming

Aluminum alloys are formed by several techniques that can be classified as rubber-pad forming. A general description of processes, equipment, tools, and applications is given in the article "Rubber-Pad Forming" in this Volume.

Alloys for rubber-pad forming are selected on the same basis as they are selected for similar bending or deep-drawing operations. With nonheat-treatable aluminum alloys, the temper that will meet the forming requirements and give the maximum strength in unworked areas is usually chosen.

Heat-treatable aluminum alloys ordinarily are either formed in the annealed temper and then solution heat treated or formed in the freshly quenched W temper.

Tool materials are usually masonite for short runs and aluminum alloy, zinc alloy, or steel for longer runs. Several types of rubber have been used as the pad material. Certain grades of rubber have particularly good resistance to oils and forming lubricants and are available in a range of hardness, tensile strength, and deflection characteristics to meet different forming requirements.

Capabilities. A given alloy and temper can sometimes be formed more severely by rubber-pad forming than with conventional tools because of the multidirectional nature of the force exerted against the workpiece. Also, the variable radius of the forming pad assists in producing a more uniform elongation of the workpiece than in conventional forming operations.

Forming the shallow part shown in Fig. 12 with a rubber pad and a rigid female die used the variable radius to advantage. The development of wrinkles was almost eliminated, because the rubber acted as a blankholder and kept the work in contact with the flat and contoured die surfaces as the drawing progressed. A drawing compound was used on the blank.

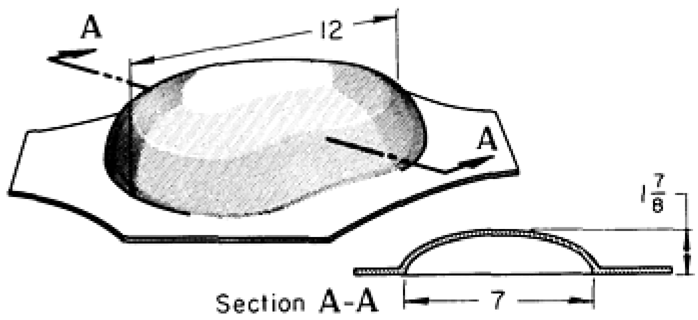

Fig. 12 Shallow part that was drawn from aluminum alloy 6061-O with a rubber pad and a rigid female steel die, in one operation. Dimensions given in inches

Limitations. The simpler types of rubber-pad forming have relatively low production rates and correspondingly high unit labor costs compared with punch-press operations. However, the hydroforming (fluid-forming) process is adaptable to automatic loading equipment and thus has fairly high production rates.

Applications. Rubber-pad forming is widely used in the aerospace industry, especially for structural parts and skin components. Products made in other industries include appliance parts, license plates, numerals, lighting reflectors, skin panels for buildings, moldings, utensils, and parts drawn from prefinished sheet.

Most rubber-pad forming is done on material 1.6 mm ($\frac{1}{16}$ in.) or less in thickness, with only a small percentage being thicker than 6.4 mm ($\frac{1}{4}$ in.). However, aluminum alloy parts 15.8 mm ($\frac{5}{8}$ in.) thick have been formed in special heavy-duty equipment of the rubber-diaphragm type.

Some bulkheads and brackets have both straight and curved flanges with joggles at both ends. The form blocks for such parts are sometimes interchangeable between the Guerin and Verson-Wheelon rubber-pad processes (see the article "Rubber-Pad Forming" in this Volume). Handwork is usually necessary to set the joggles and to smooth minor buckling in the shrink flanges.

The simultaneous blanking and piercing of flat stock can also be done with rubber-pad tooling. This type of operation is limited to aluminum alloy sheet no thicker than about 1.63 mm (0.064 in.).

The control of metal movement that can be obtained with rubber-pad forming not only permits more severe forming than do conventional tools, but also is applicable to beading operations. Beads are frequently used to obtain rigidity on large surfaces without increasing the metal thickness.

With a conventional steel punch, die, and blankholder, metal is moved from the edges of the workpiece toward the bead, making the edges somewhat concave, and sometimes producing warpage or oilcan effects. Some movement of metal toward the formed area is usually desirable, in order to prevent excessive thinning or cracking of the beads. In the forming of some parts, however, it may be necessary to restrict metal movement to the immediate vicinity of the beads.

The deep-drawing capabilities of rubber-pad processes vary with the different types of equipment. The severity of drawing possible with heavy-duty rubber-pad drawing by the Marform process (see the article "Rubber-Pad Forming" in this Volume) is compared below with that possible in conventional drawing. The comparison is based on the drawing of alloys 1100-O and 3003-O.

Drawing severity	**Reduction in diameter, %**	Ratio of depth to diameter
Rubber-pad drawing		
Typical	57	**1.1**
Maximum	72	**3.0**
Conventional drawing		
Maximum	**40**	**0.45**

Forming of Aluminum Alloys

Superplastic Forming (Ref 6)

Superplastic behavior has been demonstrated in several aluminum alloys, including the high-strength alloy 7475. The prime material requirement for superplasticity--a fine, stable grain size--can be achieved in aluminum alloys by either static or dynamic recrystallization. In static recrystallization, a deformed microstructure is allowed to undergo discontinuous recrystallization during static annealing, leading to a fine-grain microstructure at the start of superplastic forming. In dynamic recrystallization, a deformed microstructure undergoes gradual, continuous recrystallization and grain refinement in the course of superplastic forming.

The microstructures of superplastic aluminum alloys can be either dual-phase or essentially a single phase with very small amounts of second phase present. Some amount of second phase is always necessary to develop and stabilize a fine-grain structure.

Table 6 lists the nominal compositions of several superplastic aluminum alloys, their typical grain sizes, and selected mechanical properties. For comparison, the elongations and yield strengths of aluminum alloys 1100-O and 2024-T3 are also shown.

Table 6 Nominal compositions, typical grain sizes, and selected mechanical properties of several superplastic aluminum alloys

Elongation and yield strength of aluminum alloys 2024-T3 and 1100-O are shown for comparison.

(b) In aged condition whenever applicable.

(c) In dynamically recrystallized condition.

Superplasticity in Aluminum Alloy 7475. The high strength and high fracture toughness of alloy 7475 are the main reasons for examining superplasticity in this material. A number of grain refinement methods have been developed for 7*xxx* series aluminum alloys; of these, the Rockwell method (Ref 15) has been relatively easy to implement. A schematic of the Rockwell grain refinement process is shown in Fig. 13. A critical aspect of the process is the heating rate in recrystallization, which must be extremely rapid in order to activate simultaneously as many nuclei as possible.

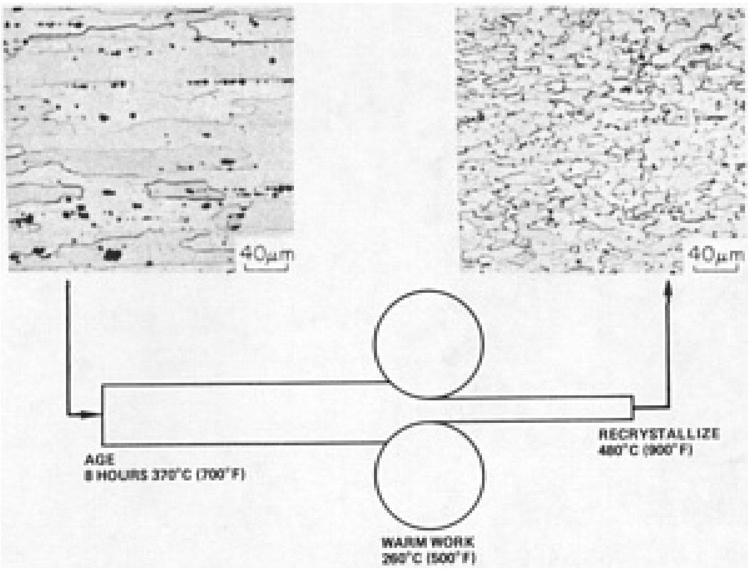

Fig. 13 Steps involved in thermal and mechanical processing to produce superplastic aluminum alloy 7475. Source: Ref 15

Stress versus strain rate plots and corresponding values of strain rate sensitivity index *m* for alloy 7475 are shown in Fig. 14. The effect of grain size on flow stress and *m* value is apparent: Flow stress increases with grain size, while *m* decreases. At a grain size of 10 to 14 μm (400 to 560 μin.) and a strain rate of 2×10^{-4} s^{-1}, flow stresses are very low (~ 690 kPa, or 100 psi). Peak *m* values are very high (~0.8). Flow stress at the same strain rate but a grain size of 40 μm (1600 μin.) is more than doubled to about 1380 kPa (200 psi); peak *m* value has decreased to approximately 0.7.

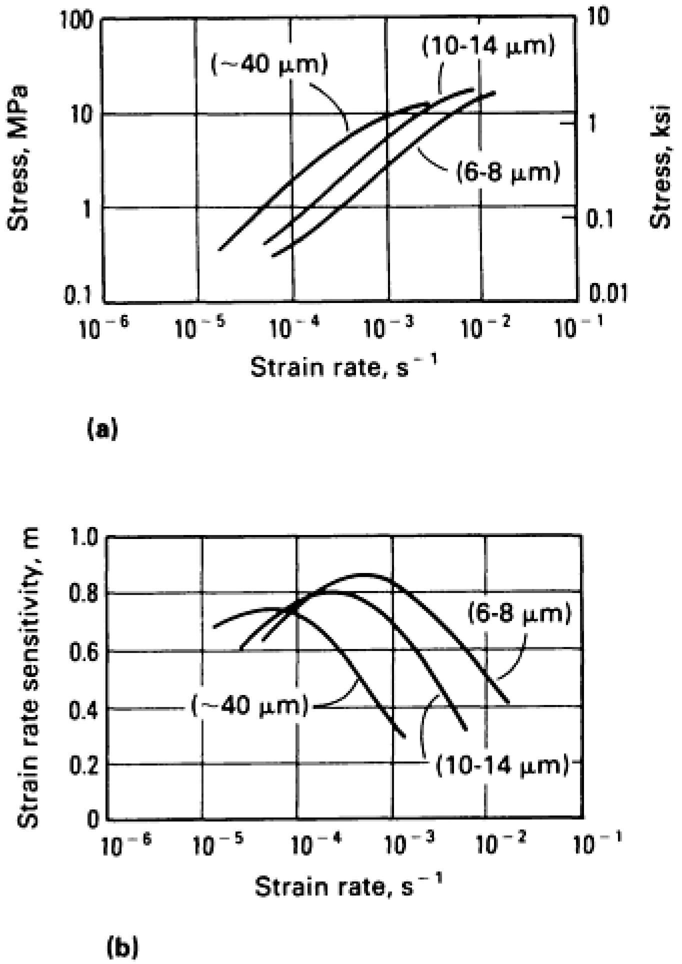

Fig. 14 Stress versus strain (a) and corresponding strain rate sensitivity *m* (b) for superplastic aluminum alloy 7475 in three different grain sizes. Tests were performed at 516 °C (960 °F), the optimal forming temperature for alloy 7475. Source: Ref 6

Superplastic Forming Processes. A number of processes are used for superplastic forming, including blow forming, vacuum forming, thermoforming, deep drawing, and dieless drawing. All of these processes are discussed in detail in the article "Superplastic Sheet Forming" in this Volume. Information on superplastic forming of titanium alloys also is discussed in the article "Forming of Titanium and Titanium Alloys" in this Volume.

Cavitation (formation of internal microvoids during superplastic forming) is a problem in most superplastic aluminum alloys. Many factors, including alloy cleanliness, grain size, flow stress, strain rate, forming temperature, and hydrostatic pressure, influence cavitation in aluminum alloys. Factors that increase the flow stress of the alloy--including large grain size (or excessive grain growth), high applied strain rate, and low forming temperature--increase the tendency toward cavitation.

Cavitation can be reduced by imposing a pressure on the back side of the sheet during forming (Fig. 15). The forming pressure must be higher than this back pressure. The same forming rates can be achieved with or without back pressure. Back pressures of 690 to 3450 kPa (100 to 500 psi) are generally suitable for suppressing cavitation. A die apparatus used to provide back pressure during forming is illustrated in Fig. 15.

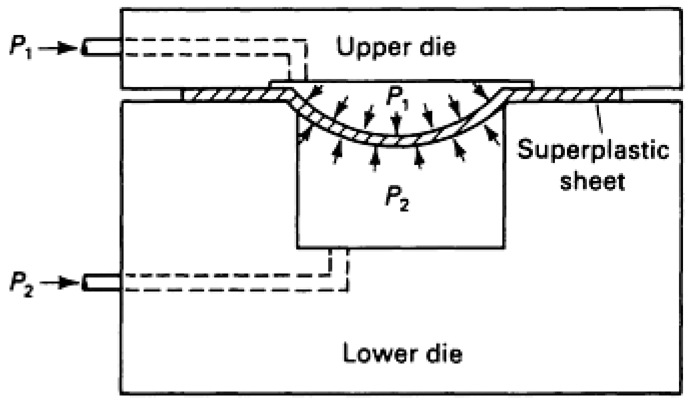

Fig. 15 Die apparatus for providing back pressure during superplastic forming to suppress cavitation. P_1, forming pressure; P_2, back pressure. Source: Ref 6

Applications. The use of superplastically formed aluminum components in the aircraft industry is increasing. Figure 16 illustrates the cost and weight savings possible when conventionally fabricated components (in this case, an airframe member) are replaced by superplastically formed parts.

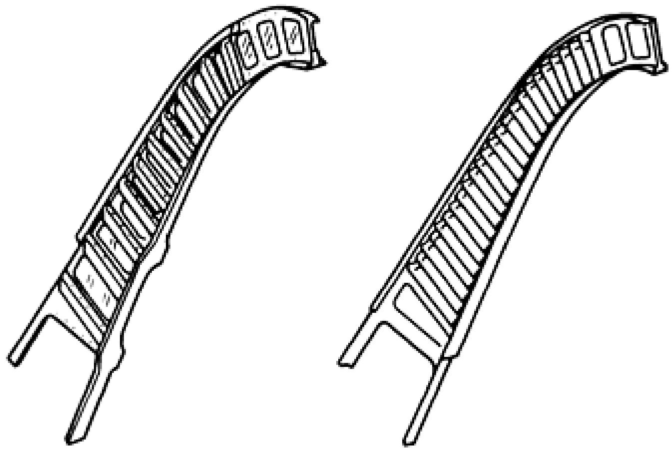

Fig. 16 Example of cost and weight savings obtainable using superplastic forming in the aircraft industry. Conventionally fabricated part (a) had 15 pieces and required 212 fasteners; the superplastically formed part (b) consists of 3 parts and requires 45 fasteners. This results in a 56% cost savings and a 13% weight savings.

Explosive Forming

Explosive forming is one of the high-energy-rate forming (HERF) methods that are employed in the production of aluminum alloy parts, mainly in the aerospace industries. It is often used to produce parts whose size exceeds the limits of conventional equipment or whose thickness requires pressures not obtainable with conventional equipment. It is also used to form small quantities of complex parts that would be more costly to produce by conventional techniques.

Deformation velocities are several hundred feet per second, compared with 0.15 to about 6 m/s (0.5 to about 20 ft/s) for conventional forming processes. The time required for the workpiece to deform to its final shape is a few milliseconds, with working pressures of several thousand to several hundred thousand pounds per square inch. Water usually serves as the pressure medium.

Details of equipment, tools, and procedures used in explosive forming are available in the article "Explosive Forming" in this Volume.

Capabilities. Types of operations possible in explosive forming include panel forming (bending), piercing, flanging, shallow dishing, deep drawing, and cylindrical bulging. Part dimensions range from 25 mm (1 in.) to about 15 m (50 ft); work metal thicknesses range from several thousandths of an inch to about 152 mm (6 in.).

Alloys. The explosive forming process can be used with any aluminum alloy. Formability is a direct function of the ordinary tensile elongation values, but the function is different for each alloy, because of different strain-rate behavior. Alloy 1100-O is rated the most formable of all common metals by explosive forming.

Effect on Mechanical Properties. Changes in mechanical properties as a result of explosive free-forming operations are essentially the same as those observed with conventional forming techniques to produce the same part. Explosive forming in a die, however, often causes the metal to strike the die at extremely high velocity. The resulting high interface pressures can increase the yield and tensile strengths substantially. Forming capability is increased when critical forming velocities are exceeded.

Dies. Only a forming die or cavity is needed for explosive forming, because the shock wave acts as a punch. Some direction and concentration of the shock wave is obtained with suitably shaped and positioned reflectors.

Cast iron and cast steel are the most frequently used die materials. A variety of other materials and combinations of materials are used, depending on the impact of the shock wave workpiece against the die, the size of the die, dimensional tolerances on the part, and quantity of parts. These materials include low-melting cast alloys and plastics, reinforced concrete, concrete faced with plastic-glass composites, and high-impact steel.

The air between the workpiece and die cavity must be evacuated before forming, because the forming speed is so great that the air will be trapped between the workpiece and die rather than displaced, as in conventional press forming. Trapped air and excessive lubrication cause malformed areas. The vent holes for evacuating the air must be placed in noncritical areas; otherwise, marks will appear on the formed parts. In thinner parts, the forming force will pierce holes in the parts, with the vent hole acting as a piercing die. The surface finish of the die cavity is also important because it is reproduced in mirror image on the workpiece.

Lubricants, if used, are usually extreme-pressure (EP) types. Because of the high velocity and the extreme pressures of forming, excessive lubrication must be avoided. Dies of low-melting alloys or those with smooth surfaces require little or no lubrication.

Springback is of importance in die design. Increasing the explosive charge or reducing the standoff distance reduces springback. However, die wear is thereby increased and the more brittle die materials may fracture. A compromise is often required. Compensation is sometimes made for die wear by reducing charge size or increasing standoff distance to produce a controlled amount of springback and maintain dimensional tolerances.

Studies on alloy 2219 have shown springback to increase when sheet thickness decreases between 6.35 mm (0.250 in.) and 0.81 mm (0.032 in.), and also to increase substantially when a lubricant is applied. Incremental forming, on the other hand, has been observed to reduce the extent of springback. Draw radius, draw depth, and die material have shown no significant effect on springback behavior.

Examples of Applications. The forming of flat and moderately curved shapes has been one of the most useful applications of explosive forming. These have included parts ranging from small, detailed items a few square inches in area to large panels with areas in excess of 2.8 m^2 (30 ft^2).

The curved, corrugated panel shown in Fig. 17 was formed from alloy 2014 in the O, T4, and T6 tempers in a laminated epoxy-fiberglass die. The panel was formed in a single shot, using a detonating fuse as a source of energy.

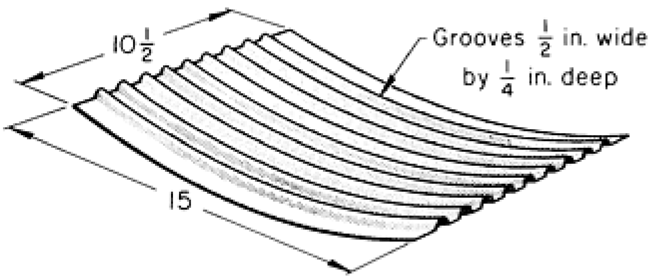

Fig. 17 Curved corrugated panel produced by explosive forming from aluminum alloy 2014 0.51 mm (0.020 in.) thick. Dimensions given in inches

Another example of an explosively formed aluminum part is the alloy 6061 instrument container shown in Fig. 18. The part was produced in a closed die using a hydraulic clamping system; tolerances were ±0.076 mm (0.003 in.).

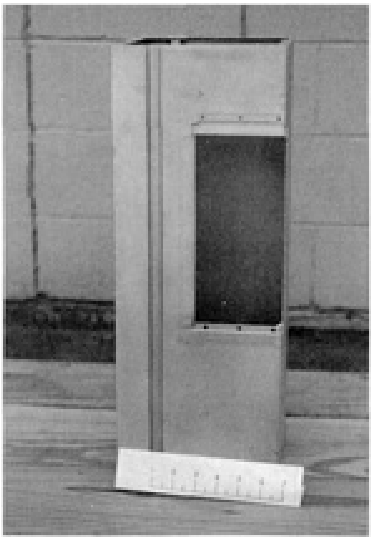

Fig. 18 Aluminum alloy 6061 instrument container fabricated from a blank by explosive forming. Courtesy of Explosive Fabricators, Inc.

Tubular parts also are readily shaped by explosive forming, using a length of detonating cord suspended along the axis of the tube.

Electrohydraulic Forming

Another high-energy-rate forming (HERF) method used in the fabrication of aluminum alloy parts is electrohydraulic forming (EHF). In this process, either a spark gap or an exploding bridgewire is employed to discharge electrical energy in water or another liquid. This generates an extremely high pressure and a shock wave similar to those produced in explosive forming. Once the energy is released in the transfer medium, the remainder of the operation is essentially the same as it is for explosive forming.

Capabilities of electrohydraulic forming differ somewhat from those of explosive forming. The spark gap method can apply programmed repetitive shock waves of varying magnitude without removal of the workpiece from the die.

The exploding-bridgewire method is less readily automated, but the shock wave can be localized and directed by the shape and placement of the wire.

Dimensional tolerances can be held to lower limits than with explosive forming, because the discharge of energy is more closely controlled. For this reason, electrohydraulic forming is sometimes used for a restrike or sizing operation after preliminary explosive forming to an approximate contour.

Commercial equipment is available that can produce about 3000 small- or medium-size pieces per week.

Examples of Applications. Electrohydraulic forming is well suited to the production of parts such as those shown in Fig. 19 and to the production of other transitional shapes in tubing. Both of the parts shown in Fig. 19 were originally fabricated by welding two drawn pieces, but the use of EHF resulted in considerable cost savings as well as in parts with closer tolerances and better surface finish.

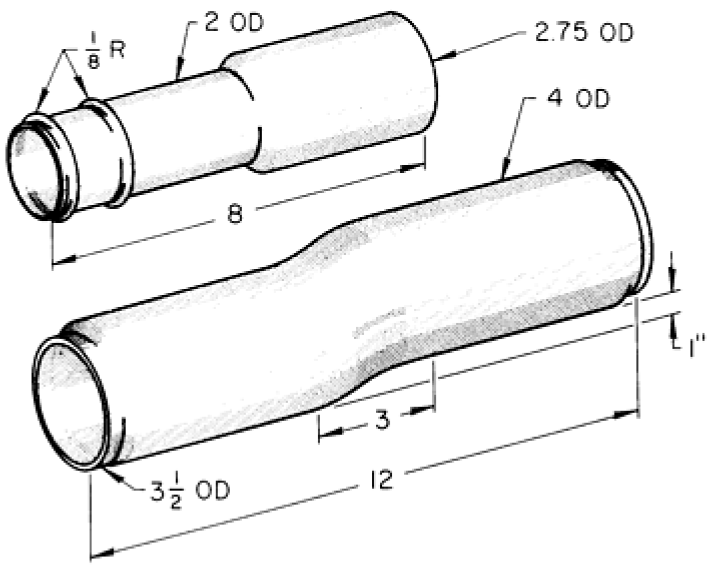

Fig. 19 Alloy 5052-O stepped tube and offset tube produced as one-piece units by electrohydraulic forming.

Electromagnetic Forming

Operations generally similar to those described for the preceding two HERF methods also can be carried out by electromagnetic forming. In this process, the discharge of a capacitor through a coil generates an intense magnetic field. This field interacts with the electric currents induced in a conductive workpiece to produce a force perpendicular to the workpiece surface.

Details of the process and of equipment, tools, and procedures are described in the article "Electromagnetic Forming" in this Volume. The method is suitable for aluminum alloys because of their formability and high electrical conductivity. Pressure-tight joints, electrically or thermally conductive joints, torque joints, and structural joints between metals can be produced by EMF techniques in a variety of shapes.

Examples of Applications. Electromagnetic forming is being used to attach an aluminum skirt to a machined bulkhead as part of an engine inlet mounting assembly for an aircraft (Fig. 20). The skirt is positioned over the bulkhead, and EMF is used to compress the skirt locally into a premachined configuration in the bulkhead.

Fig. 20 Aluminum alloy engine inlet mounting assembly for an aircraft before (right) and after (left) assembly by electromagnetic forming. Courtesy of Grumman Aircraft Systems

Welding and mechanical fasteners also were considered for this application. Welding was eliminated because of the large difference in section thicknesses being joined and the distortion that would accompany the welding operation. Mechanical fasteners were eliminated because of the increased stresses that would be caused by adding holes to the bulkhead. Joint integrity is of paramount importance because the completed assembly is used in the very front of an aircraft engine and any failure could result in ingestion of debris into the engine itself. The EMF joint meets all design requirements for the application. Another example of the use of EMF is in the joining of both ends to a tubular aluminum alloy 6063-T832 drive shaft (Fig. 21).

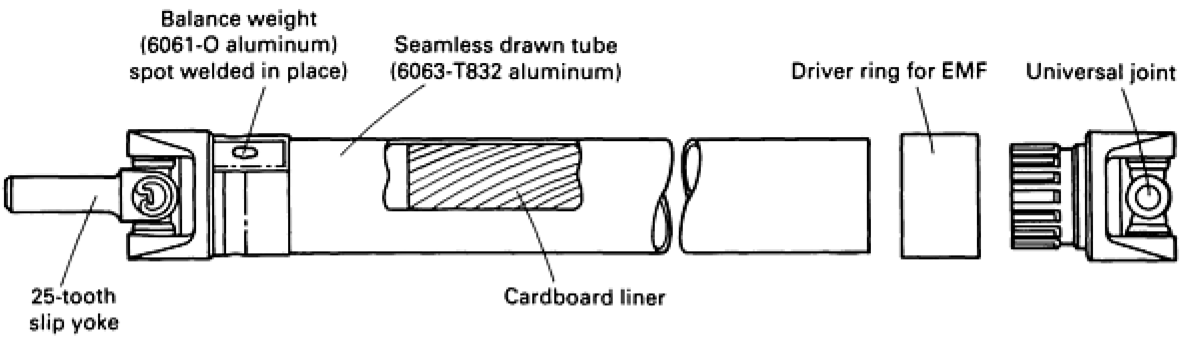

Fig. 21 Schematic of aluminum alloy 6063-T832 drive shaft with ends attached to drawn aluminum shaft by electromagnetic forming. Source: Ref 17

Hydraulic Forming

True hydraulic forming by direct oil pressure against the surface of the workpiece has been applied to aluminum alloy flat stock. The process has been used mainly for the drawing of multiple beads on small quantities of large, flat sheets of thin material for aerospace applications. As shown in Fig. 22, a form block attached to the ram of the press holds the workpiece tightly against a selector plate, through which oil is introduced into channels at the bead locations.

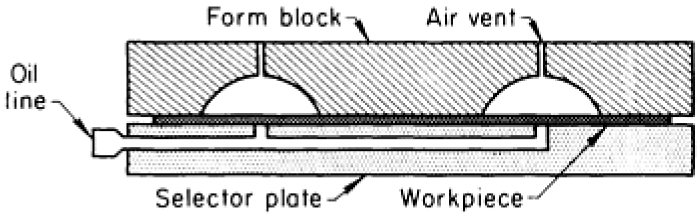

Fig. 22 Typical tooling setup for hydraulic forming of multiple beads in flat stoc.

In typical applications, up to 20 beads have been drawn in parts 510 to 760 mm (20 to 30 in.) wide by 1525 to 2030 mm (60 to 80 in.) long and about 0.30 mm (0.012 in.) thick, made from alloy 2024. Clamping force required is about 2.7 MN (300 tonf), and necessary forming oil pressure is about 6.9 MPa (1 ksi). Vents are provided in the form block to allow the escape of air from each bead cavity. The oil film left on the form block after each operation provides sufficient lubrication to draw the next part.

Forming by Shot Peening

The major application of shot peening is to increase the fatigue life of metal parts by producing a uniform compressive stress in the surface layers. Shot peening is sometimes used as a metal-forming process, and is especially useful in the forming of large, irregularly shaped parts from aluminum alloy sheet stock.

Shot. When steel shot is used to peen form aluminum alloy parts, the parts are usually treated chemically after forming to remove particles of iron or iron oxides that may be embedded in the surface.

Slugs cut from stainless steel or aluminum alloy wire are sometimes used. When peening with aluminum alloy slugs, no subsequent chemical treatment is needed, and the danger of overpeening and high localized residual stress (which sometimes occurs with steel or iron shot) is also eliminated.

Automatic or semiautomatic devices are available for the separation and removal of fines and undersize shot, and for the addition of new shot. Manual handling of shot and batch replacement may be more feasible for small-scale operations. The proportion of full-size shot in the system is usually maintained at a minimum of 85%.

Control. The effectiveness of shot peening depends on the size, shape, material, and velocity of the shot, and on the quantity of shot striking a unit area per unit time. The combined effect of these variables is known as peening intensity.

The angle at which the shot strikes the work also affects the peening intensity, which is proportional to the sine of the angle of impingement. The amount of breakdown of the shot will, of course, also affect peening intensity. The extent of surface coverage as measured by visual or instrumental techniques is often used, together with Almen test strips, to control peening operations.

Applications. One of the earliest forming applications of shot peening was the contour forming of integrally stiffened aircraft wing panels. Because of their extreme length and variable thickness, these parts are ill suited for forming by mechanical processes. Other parts formed by shot peening include honeycomb panels and large tubular shapes. Large, irregularly shaped parts are conveniently formed by this method.

If a part is deformed beyond the specified amount, the contour can be corrected by peening the reverse side. Also, peening can be used as a salvage procedure to correct the contours of bent or distorted parts.

The process is usually carried out as a free-forming technique, without dies or form blocks. Contour is checked against a template. The peening intensities and the number of passes are varied depending on the material and the severity forming required. Local areas can be subjected to the required treatment.

Drop Hammer Forming

Drop hammer forming is of value for limited production runs that do not warrant expensive tooling. For example, it is often used in experimental work to make trial parts and parts that are expected to undergo frequent design changes.

Tooling costs are low, and finished parts can be produced quickly. However, only relatively shallow parts with liberal radii can be drop hammer formed, and material thickness must be in the range of about 0.61 to 1.63 mm (0.024 to 0.064 in.). Also, wrinkling occurs frequently, and a high degree of operator skill is required.

Equipment and Tools. Air-operated hammers with sensitive and accurate control are usually preferred to hammers operated by gravity or steam.

The material is formed in a sequence of small steps. In a typical setup, several plywood or rubber spacers are stacked on the die face, and one or more are removed after each stroke to form the workpiece progressively.

In a variation of this procedure, a series of dies can be used to accomplish the progressive forming. Only the last of these dies requires close tolerances. A rubber pad several inches thick is sometimes used between workpiece and punch in all but the final step.

Dies are simple and inexpensive. Bottom dies are cast from zinc alloy. Punches can also be made from zinc alloy, but if requirements on sharpness of radii and accuracy of contour are not stringent, punches cast from lead are used for short runs. These need not be cast accurately because they deform to the shape of the bottom die in a few strokes. For longer runs, tools can be made of cast iron or cast steel. Lubrication requirements are similar to those for drawing operations.

Alloys used most frequently are 1100, 3003, 2024, 5052, 6061, and 7075. Annealed tempers permit the greatest severity of forming. Intermediate tempers of the nonheat-treatable alloys are often used for channel shapes and shallow, embossed panels. Heat-treatable alloys can be partly formed in the annealed condition and given a restrike operation after heat treatment, or they can be formed in the fresh W temper.

All processing conditions being equal, aluminum alloy stock will wrinkle more readily than the same thickness of steel sheet. For comparable results in forming, aluminum alloys must be about 40% thicker than steel. More information on this process is available in the article "Drop Hammer Forming" in this Volume.

Other Forming Methods

A number of additional conventional forming processes are applied to aluminum alloy sheet, including embossing, coining, stamping, curling, expanding or bulging, contracting or necking, hole flanging, and beading or ribbing.

Embossing, Coining, and Stamping. These three closely related methods for making shallow impressions and patterns by compression between a punch and a die are frequently combined with drawing. In these operations, the material must yield under impact and compression, and it must be ductile to avoid fracture in tension.

Uniform thickness in all areas of the workpiece generally is maintained in embossing; however, some stretching occurs. Simple designs are produced with light pressure, using a punch of the desired shape and an open female die. Complex patterns require high pressure and a closed matching female die or a rubber female die.

Coining differs from embossing in that the metal is made to flow, thus producing local differences in metal thickness. The design on the top and bottom surfaces may be different. Very high pressure is required.

Stamping produces cut lines of lettering or patterns in one side of the workpiece, to a depth of 0.51 to 1.0 mm (0.020 to 0.040 in.). The depth of penetration must be carefully controlled to minimize distortion and to prevent the design from appearing on the opposite side. Outline or open-face stamps are preferred.

Curling or false wiring can be done in a variety of machines, such as press brakes, single-action punch presses, lathes, roll-forming machines, or special beading machines. The selection of machine depends on the shape and the number of parts required. Circular parts are usually curled on spinning lathes, and rectangular parts are curled in presses. Long, relatively narrow parts can be curled in press brakes or roll-forming machines. Various types of machines have been built specifically for curling in high production quantities.

The edge to be curled should be of uniform height and free from roughness on the outside of the curl. Preferably it should be rounded slightly before beginning the operation. The minimum radius for curling should be $1\frac{1}{2}$ to 4 times the metal thickness, depending on alloy and temper.

Expanding or bulging of aluminum alloy parts can be carried out by several means including segmented mechanical dies, rubber punches, or hydraulic pressure.

Segmented mechanical expanding dies are relatively inexpensive and are capable of high production rates, but are limited to certain shapes and may produce marks on thin stock or low-strength alloys.

Rubber punches are widely used and are applicable to extremely difficult operations or those impossible to do by other means. Rubber is selected at a hardness, tensile strength, and deflection most suitable for the workpiece shape. The rubber punch or pad must be correctly shaped and located to apply pressure to the shell wall at the required points; it must be kept free from oil; and it should be lubricated with talc, pumice, or other powder-type lubricant.

Water and oil can also be used to exert pressure directly against the workpiece, but this technique requires expensive tooling and controls, and is often messy.

Contracting or necking operations reduce the diameter of a shell, usually at the open end. This entails reductions ranging in severity from the forming of a shallow circumferential groove to the forming of a bottleneck shape.

Reduction in diameter in a single operation should not exceed 8 to 15%, depending on alloy, temper, and extent of prior work hardening. The angle from the body to the necked diameter should be less than 45°, to prevent collapse of the shell. It may be necessary to anneal the workpiece locally.

Hole flanging, the forming of a flange or collar around a hole in sheet stock, can be a critical operation. The hole should be punched from the side opposite the intended flange. This prevents splitting of the severely stretched outer edge of the flange. Splitting could be initiated by the burred edge of the hole.

Shallow-flanged holes can be produced in a single pierce-and-flange operation with a stepped punch. The edges of the pierced hole should also be as smooth as possible. Low-strength ductile alloys in the annealed temper will permit forming the deepest flanges and the sharpest bend radii. More information on hole flanging is available in the article "Press Bending of Low-Carbon Steel" in this Volume.

Beading or ribbing is usually the most economical way to provide stiffness and avoid oilcan or buckling effects in large panels. Beads that extend from edge to edge of the workpiece are conveniently formed either by bending in a press brake or with corrugating rolls.

Beads that do not extend all the way across the part require a stretching or forming operation either with a rubber-pad die or in a punch press with a rigid punch and a rigid die. A double-acting die and a blank-holder can be used to prevent wrinkling at the ends of the beads, and deep, parallel beads are often made one at a time. Rubber-pad forming can also be used, as can drop hammer forming for small quantities.

Introduction

BERYLLIUM has been successfully formed by most common sheet metal forming operations. The following are required:

- Equipment that can be controlled at slow speeds and that can withstand the use of heated dies
- Dies that can withstand the temperatures at which beryllium is commonly formed
- Facilities for preheating and controlling the temperature of dies and workpieces
- In some applications, facilities for stress relieving the work at 705 to 790 °C (1300 to 1450 °F)
- Special lubrication
- Safety precautions when grit blasting is required for cleaning after forming

Almost all beryllium currently used is produced by consolidating beryllium powder into a block by vacuum hot pressing. The powder is obtained by chipping and then mechanically or pneumatically pulverizing a vacuum-cast ingot. The hot pressed block can be warm rolled to the desired sheet thickness.

Unalloyed beryllium is available in two grades, I (instrument grade) and S (structural grade). Typical applications for instrument-grade beryllium include gyroscopes, components in inertial guidance systems, and precision satellite and airborne optical components. Structural grades find application as satellite superstructures, antenna booms, and optical support structures. Table 1 lists the compositions of four grades of vacuum hot pressed beryllium.

Table 1 Compositions of four grades of vacuum hot pressed beryllium

Grade	Composition[(a)]							
	Be, %	**BeO, %**	**Al, ppm**	**C, ppm**	**Fe, ppm**	**Mg, ppm**	**Si, ppm**	Other, ppm
S-65B	99.0 min	1.0	600	1000	800	600	600	**400**
S-200F	98.5 min	1.5	1000	1500	1300	800	600	**400**
I-220A	98.0 min	2.2	1000	1500	1500	800	800	**400**
I-400	**94.0 min**	**4.2 min**	**1600**	**2500**	**2500**	**800**	**800**	**1000**

(a) Maximum, unless otherwise indicated

Information on the production and consolidation of beryllium powder is available in the articles "Production of Beryllium Powders" and "Forging and Hot Pressing" in *Powder Metal Technologies and Applications*, Volume 7 of the *ASM Handbook;* the metallography and microstructures of unalloyed beryllium are discussed in the article "Beryllium" in *Metallography and Microstructures*, Volume 9 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

Forming of Beryllium

Revised by Larry A. Grant, Electrofusion Corporation

Formability

The formability of beryllium is low compared with that of most other metals. Beryllium has a hexagonal close-packed (hcp) crystal structure; thus, there are relatively few slip planes, and plastic deformation is limited. For this reason, all beryllium products should be formed at elevated temperature (generally 540 to 815 °C, or 1000 to 1500 °F) and at slow speeds.

Temperature, composition, strain rate, and previous fabrication history have marked effects on the results obtained in the forming of beryllium.

Effect of temperature on formability (in terms of bend angle at fracture) of two grades of powder sheet is shown in Fig. 1. Although these data show the effect of temperature on bendability, maximum strain on a 2*t* bend radius is not achieved at less than 90°. Therefore, it should not be assumed that the quantitative results shown in Fig. 1 can always be applied directly in practice.

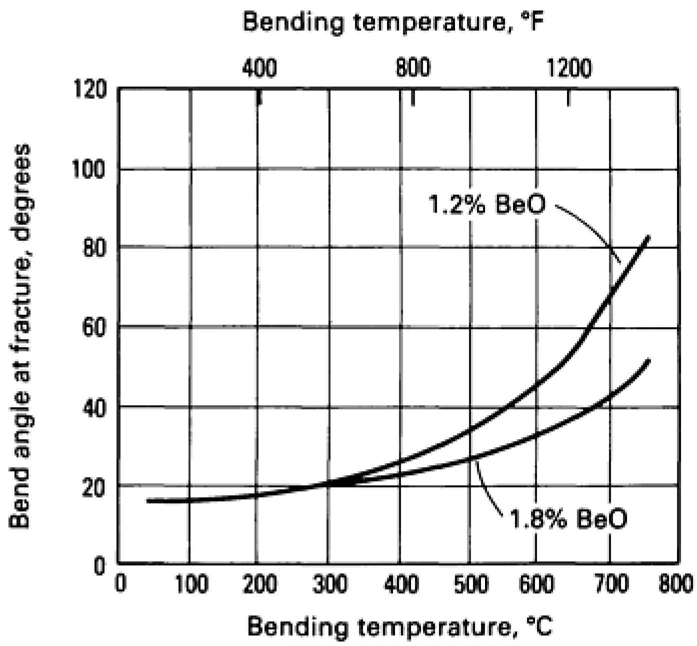

Fig. 1 Bend angle to fracture versus temperature of beryllium sheet using a 2*t* bend radius

It should be noted that Fig. 1 was generated using beryllium sheet with a guaranteed elongation of only 5%. Current beryllium sheet products have guaranteed room-temperature elongations of 10%; typical values of 15 to 20% indicate that, if the test illustrated in Fig. 1 were repeated today, improvement in results would be significant. In one case, a 90° bend with a 2*t* radius was achieved in 0.5 mm (0.020 in.) thick beryllium sheet.

Effect of Composition. The oxide content of ingot and powder sheet has a significant effect on formability, as shown by the curves in Fig. 1. As the oxide content increases, yield strength increases and ductility decreases.

Effect of Strain Rate. Strain rate greatly influences the formability of beryllium. For instance, the stroke of a press brake is too fast for making sharp bends in hot beryllium. Slow bending, by means of equipment such as a hydraulic or air-operated press, is usually used. Minimum bend limits for the press-brake method and the slower-press method are compared in Fig. 2 for bending of cross-rolled powder sheet.

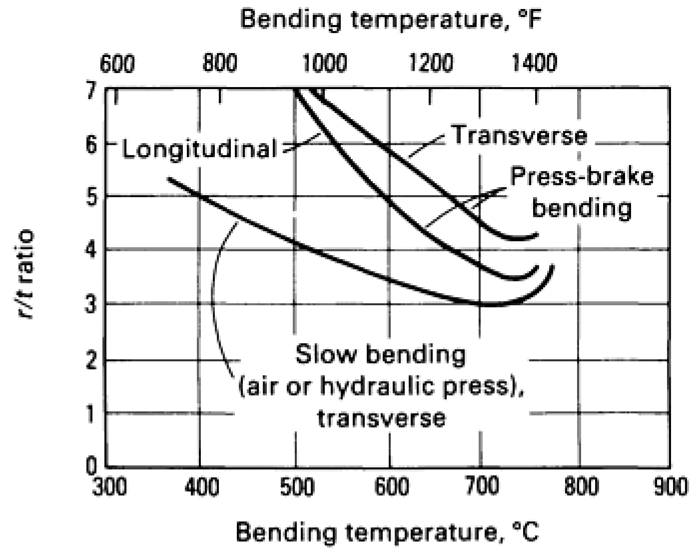

Fig. 2 Minimum bending limits for press-brake versus slower (hydraulic) bending of beryllium sheet in transverse and longitudinal directions. ***r*****, bend radius;** ***t*****, sheet thickness**

In a laboratory, a radius of $2\frac{1}{2}t$ was bent in beryllium sheet at the rate of 50 mm/min (2 in./min), and a radius of $5\frac{1}{2}t$ at 305 mm/min (12 in./min). Forming temperature in both cases was 745 °C (1375 °F).

Effect of Fabrication History. Beryllium products consolidated by vacuum hot pressing have low ductility, even at a theoretical density of 100%. The ductility of hot pressed beryllium can be increased by hot mechanical working.

Equipment and Tooling

Presses operated by air or hydraulic systems are usually used for forming beryllium, because of the slow speeds required. Standard mechanical presses or other fast forming presses are not suitable.

Critical components of the equipment must be protected against damage by the heat of forming. This protection usually is achieved by means of simple insulation.

Tooling. Because the tools used for forming beryllium will be heated, allowances must be made for thermal expansion, high-temperature strength, and oxidation when selecting tool material and designing tools. Tooling requirements for forming beryllium are similar to those for hot forming titanium (see the article "Forming of Titanium and Titanium Alloys" in this Volume). When only a few pieces are required, mild steel is usually used for dies. However, mild steel oxidizes rapidly at elevated temperatures, and when more than a few identical pieces are to be formed, the best practice is to make dies from hot work die steels, stainless steel, or one of the nickel-base or cobalt-base heat-resistant alloys.

Heating Dies and Workpieces

In most forming applications, both the die and the workpiece must be preheated. Dies are specially constructed to permit heating; heat may be supplied by either electrical elements or gas burners. Although sometimes torches are satisfactory for heating the work (as when heating sheet for spinning), usually a furnace is preferred. No specially prepared atmosphere is needed.

At the maximum temperature used for forming beryllium, surface oxidation is usually negligible. However, if desired, to prevent surface discoloration (hard oxide layer), the workpiece can be coated with a film of commercial heat-resistant oil. After forming, the film of oil can be removed by wet blasting, or by degreasing with an agent such as trichloroethylene.

In the forming of thin sheet (less than ~1 mm, or 0.040 in., thick), cooling of the work between the furnace and the forming equipment is often a problem. Overheating to compensate for this heat loss is not recommended. One satisfactory solution is to "sandwich" thin sheets of beryllium between two sheets of low-carbon steel. This sandwich is retained throughout heating and forming.

Stress Relieving

Stress relieving between stages of forming, or after forming is completed, is needed only in the forming of relatively thick sheet or in severe forming. For some finish-formed parts, stress relieving has proved an effective means of counteracting "oil canning" or excessive warpage. When stress relieving is used, regardless of whether it is an intermediate step or a final operation, holding at 705 to 760 °C (1300 to 1400 °F) for 30 min is recommended. No specially prepared atmosphere is needed.

Forming of Beryllium

Revised by Larry A. Grant, Electrofusion Corporation

Lubrication

Lubrication or coating of some type is needed in most beryllium forming operations. For less severe operations, such as bending, powdered mica has been used.

For operations such as joggling, forming in matched dies, or deep drawing, colloidal graphite in oil is commonly used. The role of lubrication is especially critical in deep drawing, and is discussed in more detail in the section "Deep Drawing" in this article.

Forming of Beryllium

Revised by Larry A. Grant, Electrofusion Corporation

Safety Practice

No special precautions or safety measures are required in forming of beryllium because no fines or oxide dust is created in forming; and the maximum temperature (815 °C, or 1500 °F) used for preheating causes the formation of only a thin film of hard oxide, which under normal operating conditions will not harm personnel. Extreme caution should be used, however, and safety equipment should be available in the event of a furnace overrun.

However, if parts require cleaning after forming and if grit blasting is used, the wet method is recommended. Wet blasting minimizes the possibility that beryllium oxide dust will contaminate the surrounding atmosphere. Adequate ventilation must be provided if parts are processed by chemical etching after forming.

The usual precautions observed in working with beryllium must be taken. Details on protection can be obtained from the publication "Health Protection in Beryllium Facilities," which is available from the U.S. Atomic Energy Commission. Also, a video tape, "Beryllium: Safe Handling," is available through Brush Wellman Inc.

Forming of Beryllium

Revised by Larry A. Grant, Electrofusion Corporation

Deep Drawing (Ref 1)

Deep drawing is the forming of deeply recessed (cuplike) parts by means of plastic flow of the material (see the article "Deep Drawing" in this Volume). Tooling consists of a punch and a suitable die or draw ring. Normally, the deformation in deep drawing is actually a combination of deep drawing and stretching.

There are two parameters that must be under control during any successful deep-drawing operation: friction and hold-down pressure. Both can be controlled by proper die design and lubricant selection, as discussed below.

Lubrication is required to prevent galling between the beryllium workpiece and the die. A lubricant film must be maintained over that portion of the blank surface making contact with the drawing surfaces of the die throughout the entire draw. Because elevated temperatures (595 to 675 °C, or 1100 to 1250 °F, for the workpiece; 400 to 500 °C, or 750 to 930 °F, for the dies) are required to deep draw beryllium, conventional lubricants applied directly to the blank and die will burn off, causing galling between workpiece and die at high-pressure areas such as the draw ring. The solution to this problem is best achieved by using die materials that are self-lubricating, such as graphite or an overlay of colloidal suspension of graphite on an asbestos paper carrier.

The technique of using consolidated graphite as a self-lubricating die material was initially developed for forming small, thin-walled parts to finished size. This technique has evolved to the point that very deep drawing of 6.35 mm (0.25 in.) thick blanks over a graphite draw ring is routine. The disadvantage is that such draw rings have short service life.

Organic emulsified suspensions of powdered graphite, aluminum, and copper have all been used successfully to lubricate punches to facilitate part stripping. These materials can also be applied to the draw ring to improve lubricity of the drawing surface under the graphite-impregnated paper.

Blank development for deep drawing of beryllium generally follows the same rules as for other metals. Blanks too thin to support themselves during the early stages of drawing will buckle or wrinkle. A restraining force is required to prevent this.

There are numerous factors involved in determining whether blank restraint is required during any drawing operation. The two most important are the ratio of blank diameter d to blank thickness t and the percentage of reduction from one draw to the next.

The relationship between reduction R and d/t is shown in Fig. 3 for cylindrical parts, whether they are flat bottomed or hemispherical cups. The areas under the curves were determined experimentally, with the curves themselves being the normal limit of formability for a given reduction at a given d/t ratio.

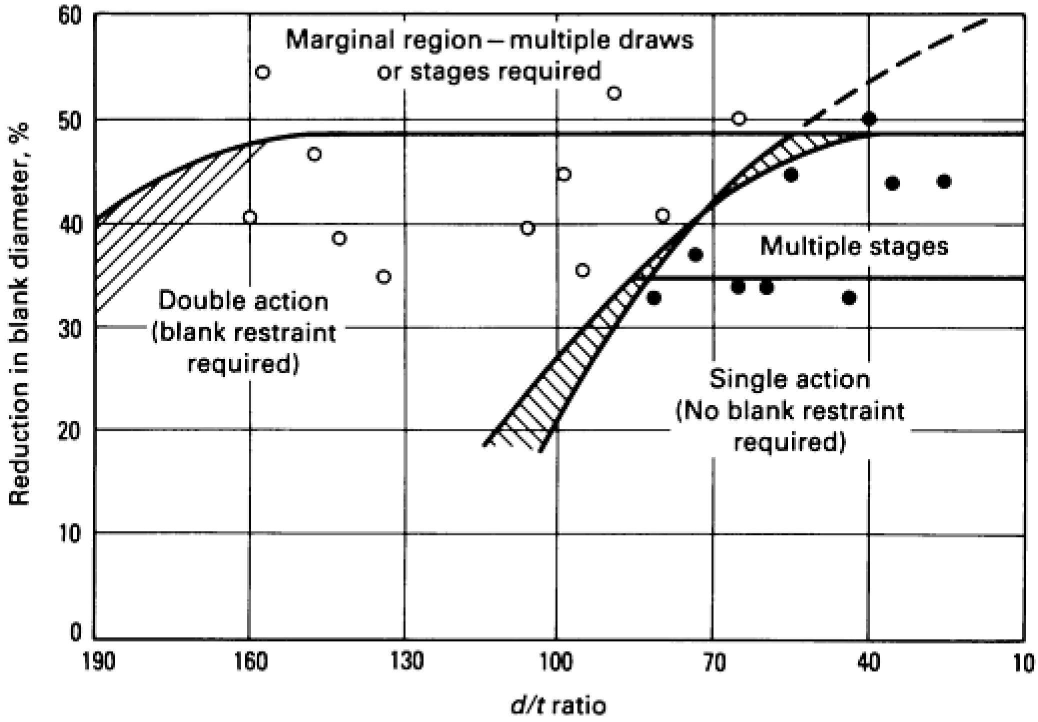

Fig. 3 Percent reduction in deep-drawing versus diameter-to-thickness (*d*/*t*) ratio for deep drawing of cylindrical beryllium shells. X and O, experimental observations used to derive the curve limits; *d,* blank diameter; *t,* blank thickness; shaded areas, marginal. Source: Ref 1.

The curves in Fig. 3 describe formability limits; therefore, some consideration should be given during design to avoid borderline cases. Reductions of more than 50% are possible but will require partial drawing followed by several anneals, usually with a high failure rate. Several stages of tooling requiring smaller reductions is a more practical approach.

Tool Design. There are many different tool designs for deep drawing sheet metal parts. Two general types will be described here. One type does not apply blank restraint to prevent wrinkling and is referred to as single action. The other type does apply blank restraint and is referred to as double action.

Single-action tooling should be used to form parts that fall in the no-restraint section of Fig. 3. Double-action tooling, or tooling which applies blank restraint to avoid wrinkling, was developed in two forms. In one system, the lower cushion ram in a hydraulic press is used as the second action for blank restraint (Fig. 4). The other type of double-action tooling used to deep draw beryllium are described in detail in Ref 1.

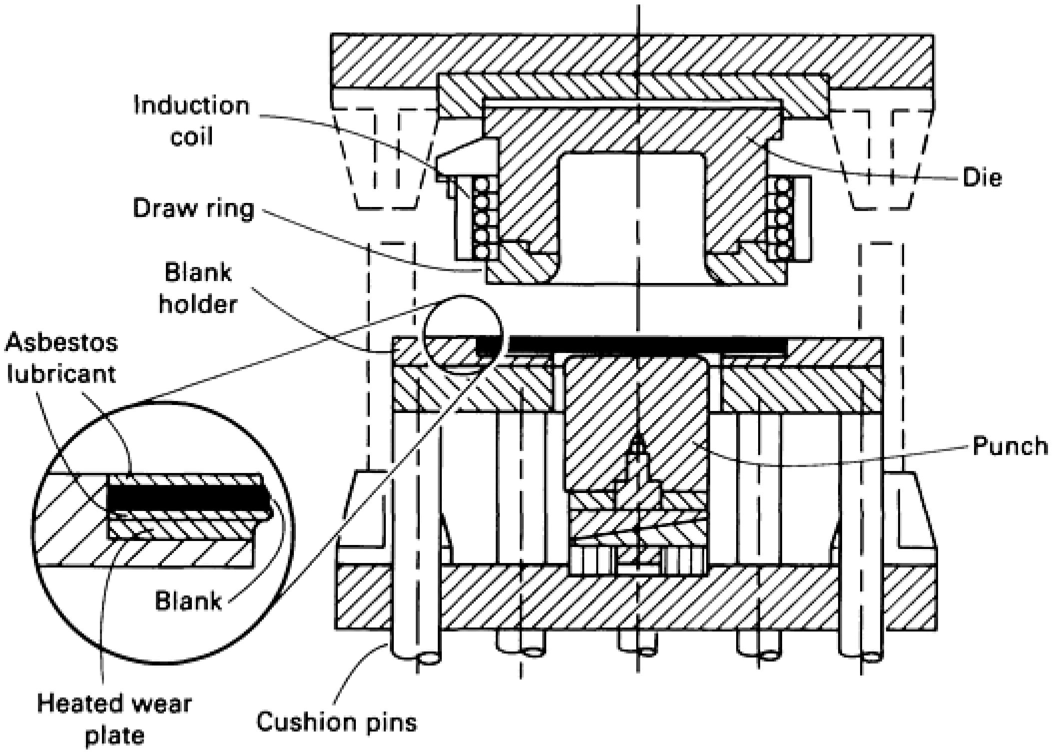

Fig. 4 A double-action tool for deep drawing of beryllium that uses the action of the lower press action for blank restraint. Lubrication with this type of tooling is best achieved using asbestos paper impregnated with colloidal graphite (see inset). Source: Ref 2.

Materials used for beryllium deep-drawing tooling need not be exotic. Gray cast iron is satisfactory for most punch and die applications. Drawing surfaces are usually made from a free-machining tool steel or, in the case of very large dies, low-carbon steel that has been carburized after machining.

Strain rates during deep drawing of beryllium may vary widely, depending on the severity of the draw. For deep drawing simple hemispherical shells, punch speeds of 760 to 1270 mm/min (30 to 50 in./min) are commonly used. With optimal die clearance and lubrication, strain rates in excess of 2500 mm/min (100 in./min) have been observed in successful deep draws.

Applications. Numerous shapes have been deep drawn from beryllium. Considerable material savings may be achieved by deep drawing rather than machining thin-walled parts. The process lends itself to cup-shaped parts that have a slightly thicker wall at the equator than at the pole because of thickening in this area during forming.

Three-Roll Bending (Ref 1)

Three-roll bending is a process for shaping smoothly contoured, large-radius parts by applying three-point bending forces progressively along the part surface (see the article "Three-Roll Forming" in this Volume). Usually one or more of the forming rolls is driven. The process has been used to form curved panel sections and full cylinders from beryllium. As in all forming operations for beryllium, it is necessary to heat the blank to achieve the necessary ductility to avoid cracking.

Applications. Three-roll bending has been used to form precision beryllium cylinders. The cylinders were joined by an electron beam fusion weld and are round within 0.5 mm (0.02 in.) total indicator reading on the diameter.

Panels for the Agena spacecraft also have been formed to a 762 mm (30 in.) radius of curvature. There were two sizes of panels formed, 635 × 635 mm (25 × 25 in.) and 559 × 355 mm (22 × 14 in.), at thicknesses of 1.4 and 1.88 mm (0.055 and 0.074 in.), respectively, from cross-rolled beryllium powder sheet. The flat beryllium sheet was heated to about 427 °C (800 °F), placed on a stainless steel sheet somewhat longer than the beryllium, and manually rolled to contour. The stainless steel sheet was used to "lead-in" the beryllium and reduce the flat end inherent to roll forming. The rolled panels were stress-relieved at 732 °C (1350 °F) for 20 min.

Revised by Larry A. Grant, Electrofusion Corporation

Stretch Forming (Ref 1)

Stretch forming is the shaping of a sheet or part, usually of uniform cross section, by first applying suitable tension or stretch, then wrapping it around a die of desired shape (see the article "Stretch Forming" in this Volume). When applying this technique to beryllium, the wrapping operation usually takes place quite slowly.

Tooling. Two commonly used types of tooling used to stretch form beryllium are generally described as open-die and closed-die tooling. Open die, the most common, consists of a male die with the desired contour and some means of forcing the blank to assume that contour. Tension is not normally required for beryllium because the high modulus resists buckling and wrinkling.

Closed die tooling has male and female counterparts. The male die is used to force the blank into the female die, thereby causing the blank to assume the contour of the male die. This type of tooling lends itself well to beryllium forming because both portions of the die may be heated to facilitate maintenance of the heat necessary in the blank to avoid cracking. Friction forces on the female die can help to restrain the part and cause stretching.

Floyd and J.N. Lowe, Ed., Plenum Press, 1979, p 107-124

Spinning

Beryllium sheets up to 5.1 mm (0.200 in.) thick have been successfully formed by spinning. For sheets less than about 1 mm (0.040 in.) thick, a common practice is to sandwich the beryllium between two 1.5 mm (0.060 in.) sheets of low-carbon steel and heat the sandwich to 620 °C (1150 °F) for spinning. The steel sheets not only help to maintain temperature, but also help to prevent buckling. Beryllium sheets more than about 1 mm (0.040 in.) thick usually are not sandwiched between steel sheets for spinning, and are heated to 730 to 815 °C (1350 to 1500 °F).

Hemispherical shapes have been spun in as many as nine stages with no adverse effect on the properties of the beryllium. The part and mandrel often are torch-heated during spinning.

Lubrication is especially important in spinning. Colloidal graphite or glass is usually used. Wet blasting is the recommended means of cleaning the workpiece after spinning.

Figure 5 plots combinations of conditions under which parts of a variety of shapes have been successfully produced by spinning cross-rolled beryllium powder sheet. The points plotted, however, represent only limited data, and many more points would have to be established before it would be safe to designate dimensional limitations for spinning specific shapes. More information on the spinning process is available in the article "Spinning" in this Volume.

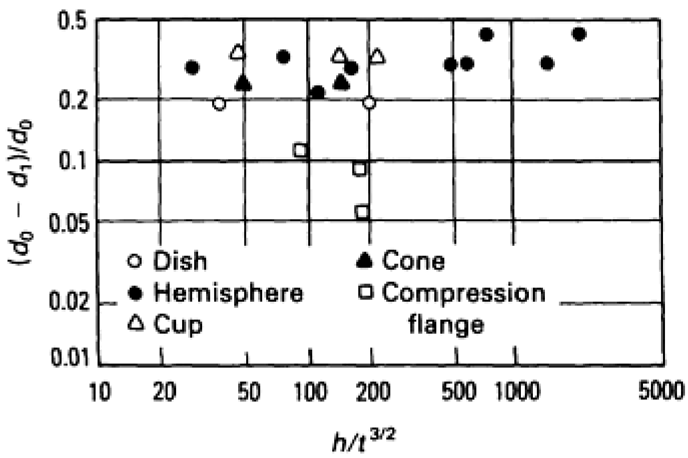

Fig. 5 Dimensional combinations for the successful spinning of beryllium sheet. d_0, blank diameter; d_1, diameter of spun part; *t*, blank thickness; *h*, height of spun part

Forming of Copper and Copper Alloys

Frank Mandigo and Jack Crane, Olin Corporation

Introduction

COPPER AND MOST COPPER ALLOYS are readily formed at all sheet gages. The copper alloys commonly formed are characterized by strength and work-hardening rates between those of steel and aluminum alloys. This article will review the general characteristics of copper and copper alloys and how these characteristics affect the behavior of strip in different types of forming operations. The attempt is to provide an understanding of copper alloy formability coupled with illustrative data rather than to offer a complete single-source alloy data reference.

Acknowledgements

The authors would like to acknowledge the significant contributions to this article from John Breedis, Olin Corporation, and John Turn, Brush Wellman Inc. Without their assistance, completion of this document would not have been possible.

Forming of Copper and Copper Alloys

Frank Mandigo and Jack Crane, Olin Corporation

General Considerations

The combination of moderate-to-high strength, high electrical and thermal conductivity, modest cost, good corrosion and stress-corrosion resistance, and ease of joining, coupled with good formability, accounts for the use of copper and copper alloys in a wide range of applications. The list of typical applications given below reveals the diversity of forming operations used:

Application	Forming operations
Electrical terminals and connectors	**Bending, stretch forming, blanking, coining, drawing**
Electronic lead frames	**Bending, coining, blanking**
Hollow ware, flatware	**Roll forming, blanking**
Builder's hardware	**Shallow and deep drawing, and stretch forming operations**
Heat exchangers	**Roll forming, bending, sinking, blanking**
Coinage	**Blanking, coining, embossing**
Bellows, flexible hose	**Cupping, deep drawing, bending**
Musical instruments	**Blanking, drawing, coining, bending, spinning**
Ammunition	**Blanking, deep drawing**

These applications are illustrated in Fig. 1, 2, 3, 4, 5, 6, 7, and 8.

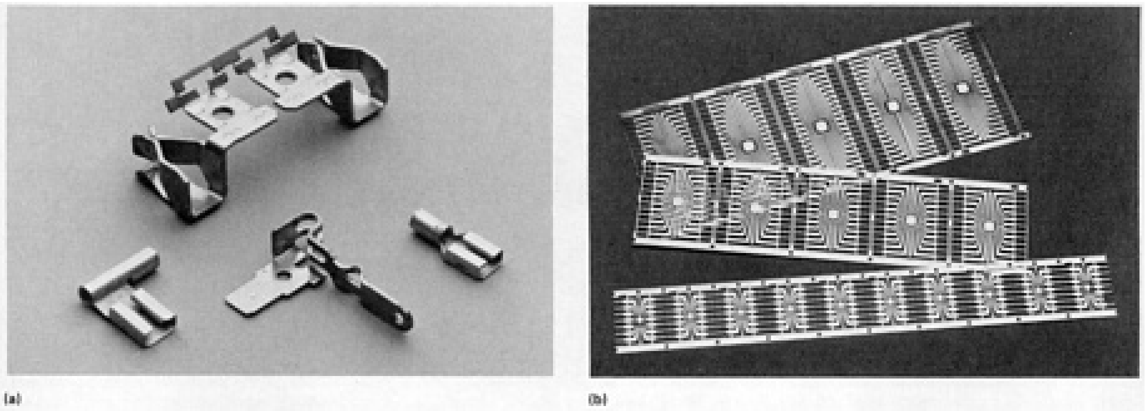

Fig. 1 Electrical and electronic applications for formed copper alloy parts. (a) Connectors used in home appliances and automotive electrical systems. (b) Copper alloy leadframe for a semiconductor device.

The forming of any part involves the interaction of material, tooling, and lubrication. Tooling and lubrication are discussed in the article "Presses and Auxiliary Equipment for Forming of Sheet Metal" and "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume and are noted in this article only where there are unique or specific requirements for a copper alloy or a given forming operation. The forming characteristics of copper and copper alloys will be discussed at length. All of the various major forming operations considered in this article--blanking, bending, stretch forming, drawing, and coining--depend on some optimal combination of strength, ductility, and work-hardening behavior of the sheet metal to provide the most cost-effective part. Therefore, much of this article is devoted to understanding the trade-offs in strength, work-hardening, and ductility available by selection of material composition and temper. Strain rate sensitivity m is also a factor in some forming operations. However, m is of practical significance only at elevated temperature. A more comprehensive treatment of the relationships between these materials characteristics and formability is available in the article "Formability Testing of Sheet Metal" in this Volume and in the article "Sheet Formability Testing" in *Mechanical Testing*, Volume 8 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

Other materials characteristics that reflect formability and can be determined using simple test specimens include the plastic-strain ratio r, which is a measure of sheet anisotropy; the limiting draw ratio (LDR); bulge height; and minimum bend-forming radius. These measurements are primarily used to assess drawing and stretching capacity specific to a given alloy composition, cold-work level, and texture development.

Effects of Composition, Cold Work, and Heat Treatment on Formability

Copper alloys are primarily strengthened by cold work or by alloying additions that solid solution strengthen and enhance strain hardening. A finely dispersed second phase is sometimes used as a grain refiner to maximize strength/ductility combinations and/or as a means of ensuring good surface finish after forming.

Precipitation hardening is important to a small but important class of alloys, most notably, the beryllium copper alloys. Copper-nickel-aluminum and copper-nickel-silicon alloys are also commercially important precipitation-hardenable alloys. Spinodal and/or precipitation hardening is available in the copper-nickel-tin and copper-nickel-chromium systems. Hardening by martensite transformation is available in the copper-aluminum system, but is rarely used commercially.

Copper alloys are classified using the Unified Numbering System (UNS). The designations of the Copper Development Association (CDA) are also used and correspond closely to UNS designations. Wrought copper alloys are divided in the UNS system into the following groups:

Copper and high-copper alloys	**C1*xxxx***
Zinc brasses	**C2*xxxx***
Zinc-palladium brasses	**C3*xxxx***
Zinc-tin brasses	**C4*xxxx***
Tin bronzes	**C5*xxxx***
Aluminum, manganese, and silicon	**C6*xxxx***
Copper-nickel and copper-nickel-zinc alloys	**C7*xxxx***

Copper alloys are supplied in annealed (soft) and cold-worked (hard) tempers, as defined in Table 1. These designations are only guidelines; the supplier should be consulted for specific property/temper characteristics. Temper designations for precipitation-hardened alloys are covered in the section "Precipitation Hardening and Cold Working" in this article.

Table 1 ASTM B 601 temper designations for copper and copper alloys

Temper designation	Temper name or material condition
Annealed tempers	
025	**Hot rolled and annealed**
050	**Light annealed**
060	**Soft annealed**
061	**Annealed**
065	**Drawing annealed**
068	**Deep-drawing annealed**
070	**Dead soft annealed**
080	**Annealed to temper--** $\frac{1}{8}$ **hard**
081	**Annealed to temper--** $\frac{1}{4}$ **hard**

HT08	**H08 and order heat treated**

Solid-Solution Strengthening and Cold Working. Solute elements provide a major means of strengthening copper, and the magnitude of strengthening depends on the type and level of addition. Table 2 lists mechanical properties resulting from various alloying additions to copper in the annealed condition. Neither tensile elongation (Table 2) nor reduction in area fully defines usable formability and should not be used to correlate formability; they can, however, offer some insight into formability. It is clear from Table 2 that strength higher than that of pure copper (Alloy C11000) can be acquired with limited or no loss of ductility by solid-solution alloying.

Table 2 Mechanical properties of selected solid-solution copper alloys

Grain sizes of all materials listed ranged from 0.010 to 0.025 mm (0.0004 to 0.001 in.).

Alloy designation and common name	**Nominal composition, %**	**0.2% offset yield strength**		**Tensile strength**		Elongation, %
		MPa	**ksi**	**MPa**	**ksi**	
C11000 (Electrolytic tough-pitch)	99.90 min Cu	83	12	241	35	**48**
C21000 (Gilding, 95%)	Cu-5Zn	97	14	262	38	**45**
C23000 (Red brass, 85%)	Cu-15Zn	110	16	290	42	**45**
C26000 (Cartridge brass, 70%)	Cu-30Zn	179	26	379	55	**48**
C50500 (Phosphor bronze, 1.25% E)	Cu-1.4Sn	124	18	290	42	**47**
C51000 (Phosphor bronze, 5% A)	Cu-5Sn	165	24	345	50	**50**
C61000[(a)] (. . .)	Cu-8Al	207	30	483	70	**65**
C70600 (Copper nickel, 10%)	Cu-10Ni	124	18	317	46	**38**
C71500 (Copper nickel, 30%)	Cu-30Ni	172	25	400	58	**32**
C75200 (Nickel silver, 65-18)	**Cu-18Ni-18Zn**	**179**	**26**	**414**	**60**	**37**

(a) Available only as tube, but properties are illustrative of copper-aluminum alloy strip properties.

Figure 9 shows the work-hardening behavior of copper (C11000) and several copper alloys in terms of strength and ductility versus cold reduction. The relative work-hardening effects of various alloying elements are evident; the strong effect of aluminum is contrasted with the weak effect of nickel, with zinc and tin being intermediate. Ductility, as indicated by tensile elongation, decreases with cold reduction. Again, however, the combination of strength and ductility is enhanced by solid-solution additives even after cold working.

elongation.

Precipitation Hardening and Cold Working. Precipitation-hardenable alloys offer the opportunity to form parts in the maximum-ductility (solution-annealed) condition and then harden the formed part to maximum strength with a precipitation heat treatment. However, fabrication requirements may preclude this option. Alloys containing 0.15 to 2.0% Be can be strengthened by solid-state precipitation. For alloys with high beryllium content (1.8 to 2.0%), combinations of cold work and elevated-temperature aging produce material with tensile strength above 1380 MPa (200 ksi). Lower beryllium contents are used to sacrifice some strength for better thermal and electrical conductivities. Forming can precede aging or follow it; the choice is based on property and formability requirements, as well as practicality.

In many cases, volume changes that accompany aging, or other fabricating constraints, preclude aging treatment of the formed part, and the precipitation-hardened alloys are therefore provided in mill-hardened tempers. Mill-hardened alloys are either solution annealed or cold rolled before being given an aging treatment at the mill to produce a specific set of final properties.

Mill-hardened tempers are designed to balance the requirements of strength and formability. They are of particular importance for intricate parts such as electronic connectors, where elimination of customer heat treatment and cleaning steps are important to the economics and/or fabrication of the part. Parts that require sharp bends or maximum formability should be formed from the annealed or rolled tempers before final aging to reach the desired peak strength.

Mill-hardened tempers are much stronger than unaged rolled tempers, but compromise some formability compared to the rolled tempers in favor of avoiding customer aging and cleaning. The grain size of these alloys is less than 0.03 mm (0.001 in.) for gages from 0.1 to 1.27 mm (0.004 to 0.050 in.) thick. Temper designations for precipitation-hardening systems are given in Table 3; mill-hardened temper designations correspond to supplier designations.

Table 3 ASTM B 601 temper designations for precipitation-hardened copper alloys

Temper designation	Temper name or material condition
Solution-treated temper	
TB00	**Solution heat treated**
Solution-treated and cold-worked tempers	
TD00	**TB00 cold worked to $\frac{1}{8}$ hard**
TD01	**TB00 cold worked to $\frac{1}{4}$ hard**
TD02	**TB00 cold worked to $\frac{1}{2}$ hard**
TD03	**TB00 cold worked to $\frac{3}{4}$ hard**
TD04	**TB00 cold worked to full hard**
Precipitation-hardened temper	
TF00	**TB00 and precipitation hardened**
Cold-worked and precipitation-hardened tempers	
TH01	**TD01 and precipitation hardened**
TH02	**TD02 and precipitation hardened**
TH03	**TD03 and precipitation hardened**
TH04	**TD04 and precipitation hardened**
Precipitation-hardened and cold-worked tempers	
TL00	**TF00 cold worked to $\frac{1}{8}$ hard**
TL01	**TF00 cold worked to $\frac{1}{4}$ hard**
TL02	**TF00 cold worked to $\frac{1}{2}$ hard**
TL04	**TF00 cold worked to full hard**
TL08	**TF00 cold worked to spring**
TL10	**TF00 cold worked to extra spring**
TR01	**TL01 and stress relieved**
TR02	**TL02 and stress relieved**
TR04	**TL04 and stress relieved**

Mill-hardened tempers	
TM00	**AM**
TM01	$\frac{1}{4}$ **HM**
TM02	$\frac{1}{2}$ **HM**
TM04	**HM**
TM06	**XHM**
TM08	**XHMS**

The mechanical properties of four precipitation-hardenable alloys in the solution-annealed condition are given in Table 4. The work-hardening behavior of several precipitation-hardening systems in the solution-annealed condition is shown in Fig. 10. The strong effect of beryllium content on solid-solution strengthening and work hardening is evident in Fig. 10 for Alloy C17200. Table 5 lists the mechanical properties of selected tempers of mill-hardened alloys.

Table 4 Mechanical properties of precipitation-hardenable copper alloys in the annealed condition

Postforming Heat Treatment. Heat treatments, aside from those employed to precipitation harden, are used after forming to reduce susceptibility to stress corrosion (primarily the brasses) or to increase the stiffness or stress relaxation resistance of electrical or electronic springs (mainly the brasses, aluminum bronzes, and copper-silicon alloys). These postforming treatments are performed at low temperatures.

Formability of Copper Alloys Versus Other Metals

In forming a given part, no single materials property completely defines formability. As previously noted, formability can best be rationalized in terms of the strength, work hardening, and ductility of a copper alloy, but these parameters do not allow direct correlation with formability. The problem becomes even more difficult when comparing different alloy systems--for example, ferrous and nonferrous.

Figure 11 shows the annealed ultimate tensile and yield strengths and response to cold rolling for AISI type 304 stainless steel, 1045 steel, aluminum Alloy 1100, copper Alloy C11000, and some selected copper alloys. The high work-hardening rate and strength of the austenitic stainless steel are evident. The copper alloys range from above aluminum to above low-carbon steel in strength and work-hardening rate. A comparison of limiting draw ratio with the plastic-strain ratio *r* for ferrous and nonferrous alloys is shown in Fig. 12. Increasing values of *r* and LDR reflect increasing drawability (see the section "Drawing and Stretch Forming" in this article).

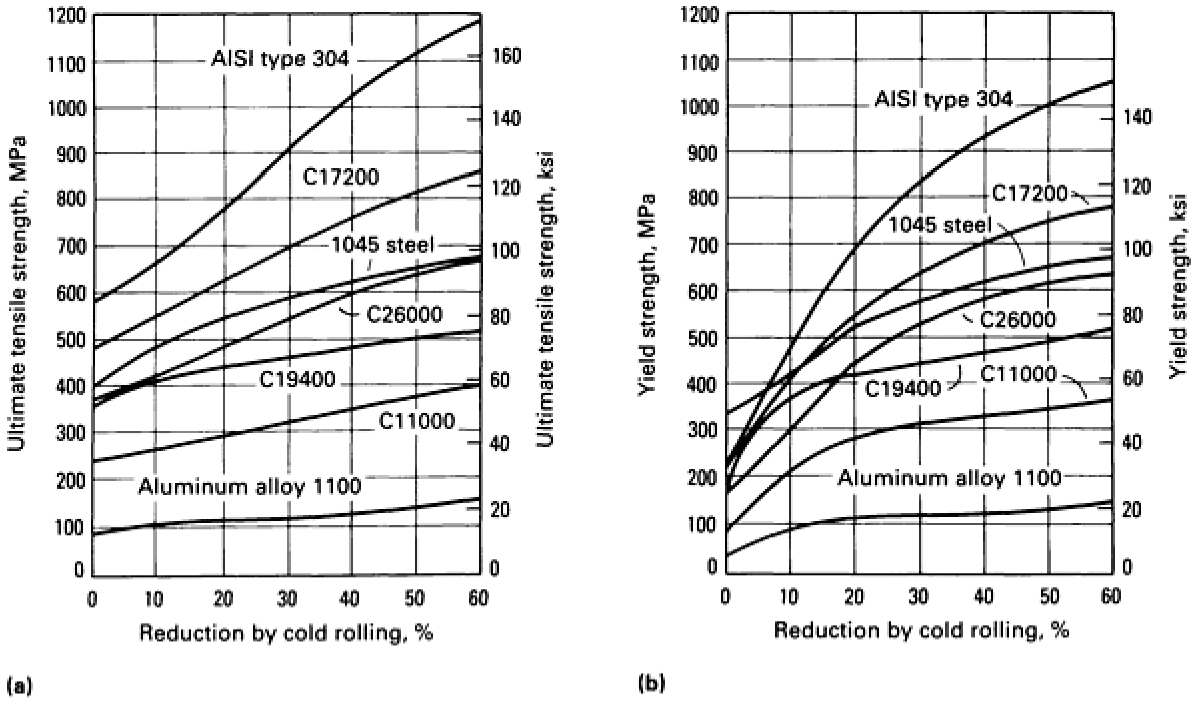

Fig. 11 Work-hardening behavior of copper alloys versus that of low-carbon steel, austenitic stainless steel, and aluminum. (a) Effect of cold work by rolling reduction on ultimate tensile strength. (b) Effect of cold work on yield strength.

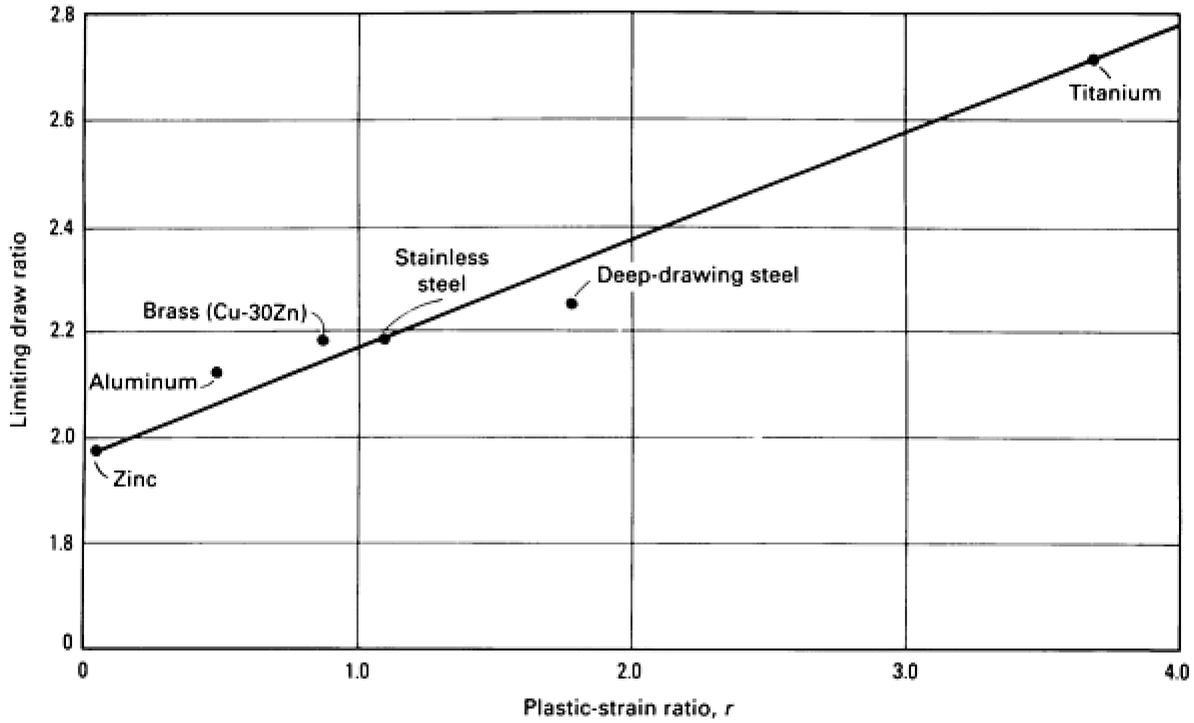

Fig. 12 Plastic-strain ratio *r* versus limiting draw ratio for different metals. Source: Ref 1

In general, copper alloys offer better strength/formability combinations than most other alloy systems. The choice of material system is usually based on economics, including material and other fabrication costs as well as properties.

Forming of Copper and Copper Alloys

Frank Mandigo and Jack Crane, Olin Corporation

Blanking and Piercing

Nature of the Operation. Blanking, piercing, and related cutting operations (trimming, notching, parting, and so on) are often used to provide parts that are subsequently formed to final shape by such operations as bending, drawing, coining, and spinning. Cutting operations are frequently conducted in the same press tooling used to form and shape the final part geometry. The principal objective of any cutting operation is to produce a workpiece that has the correct geometric shape, is free of distortion, and possesses sheared edges that are of sufficient quality to allow subsequent forming, finishing, and/or handling operations.

Materials Considerations. Copper and copper alloys can be readily blanked and pierced. The strip characteristics that directly affect the quality of the workpiece and/or final part produced by cutting operations are flatness, dimensional tolerances, (width, thickness, and so on), and shear-to-break ratio. The flatness and dimensional tolerances of copper alloy strip depend on the equipment and manufacturing expertise. The shear-to-break characteristics of strip depend on strip composition and temper.

Effects of Alloy Composition and Temper. The quality of blanked edges--shear to break, rollover, breakout angle, burr height, and so on--is determined by both die clearance and material characteristics. Burr-free and distortion-free parts can be cut from annealed copper alloy strip at die clearances to about 5% of strip thickness. Unalloyed coppers, such as C10100 and C10200, require smaller clearances (usually <5%) and less latitude in actual values to produce burr-free edges, even in rolled tempers. Copper alloys that contain second-phase particles (for example, C19400), that have high solute additions (such as C26000 or C51000), and/or that are cold rolled more than 50% generally exhibit high-quality blanked edges at die clearances in the range of 3 to 12%. Low-lead additions to brass and other copper alloys will decrease burrs and the shear-to-break ratio in blanking operations--but at some cost to formability in almost all types of forming.

Forming of Copper and Copper Alloys

Bending

Nature of the Operation. Many connectors, terminals, and spring-like components are fabricated by simple bending operations. Bending is an operation in which a blanked coupon is wrapped, wiped, or formed over a die to a specified radius and bend angle. Bend formability is usually expressed as minimum bend radius *R* in terms of strip thickness *t* (***R***/*t*). Minimum bend radius is defined as the smallest radius around which a specimen can be bent without cracks being observed on the outer fiber (tension) surface. Bend deformation is highly localized and is confined to the region of the workpiece in contact with the bending die. Workpiece thickness is not substantially reduced unless the bend radius is less than 1.0*t* or the part is coined during bending. A detailed review of bend testing is provided in the Section "Bend Testing" in *Mechanical Testing*, Volume 8 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

Materials Characteristics. Ductility is the principal materials factor that determines bend formability. The ductility factor of first order importance is the ability of a material to distribute strain in a highly localized region, that is, necking strain. The necking strain available depends on alloy composition and temper. As strength is increased by cold work, the ability of an alloy to distribute necking strain decreases. The extent to which bend formability is decreased with increasing strength is dependent on the alloy composition and the strengthening mechanism. Conventional tensile elongation cannot be used to predict bend formability, because it does not adequately account for the contribution of necking strain. However, if the tensile specimen gage length were decreased to define an area of deformation equal to that deformed during bending, comparable ductility values would be obtained.

Effect of Alloy Composition, Temper, and Orientation. Bend data for a wide range of copper alloys are summarized in Table 6. Strength-to-bend formability characteristics are dependent on alloy composition, temper, and orientation. The principal strengthening mechanism is through solute additions to increase the work-hardening rate. For example, additions of 15 and 30% Zn to copper increase the tensile-strength-to-bend properties by 220 and 290 MPa (32 and 42 ksi), respectively, for 0.25 mm (0.010 in.) thick good-way bends at a bend radius of 0.4 mm ($\frac{1}{64}$ in.). Precipitation strengthening is also an important mechanism employed to improve the strength-to-bend performance of copper alloy strip, particularly if the part is bent in a softer temper and subsequently aged to a higher strength.

"Good way" and "Bad way" refer to the orientation of the bend with respect to the sheet or strip rolling direction (see Fig. 13). Note: Tensile strengths of 965 and 1103 MPa (140 and 160 ksi) are available in 0.25 and 0.5 mm (0.010 and 0.020 in.) thicknesses with specially supplied mill tempers.

Source: Ref 2

(a) Sheet thickness, mm (in.).

(b) Bend radius, mm (in.).

(c) Mill hardened to strength shown, then formed.

The practice of cold rolling to increase strip temper degrades bend formability. However, it is often used because most alloys still exhibit useful bend formability at modest cold-rolling reductions. Product applications that require both high strength and good bend performance are usually satisfied by selecting copper alloys that are precipitation and/or solute strengthened with additions that greatly increase the work-hardening rate and thus minimize cold-rolling requirements to achieve the desired strength.

Bend formability is typically dependent on bend direction with respect to strip-rolling direction (Fig. 13 and Table 6). All cold-rolled materials exhibit directionality. The extent of bend directionality varies from alloy to alloy, but always increases with increasing cold reduction. Bend directionality results from the development of strong textures during rolling. Copper alloys with low stacking fault energy, such as Alloy C26000 (cartridge brass), develop strong {110} <112> textures during rolling and can exhibit bend directionality even at approximately 30% cold-rolling reduction. Dilute copper alloys and copper-nickel alloys do not develop well-defined rolling textures, and they show less bend directionality even at high (70%) cold-rolling reductions. In general, sharper bends can be made in the good-way than in the bad-way orientations for alloys that are cold rolled and/or solute strengthened. Bend anisotropy in precipitation-hardening systems is strongly process dependent.

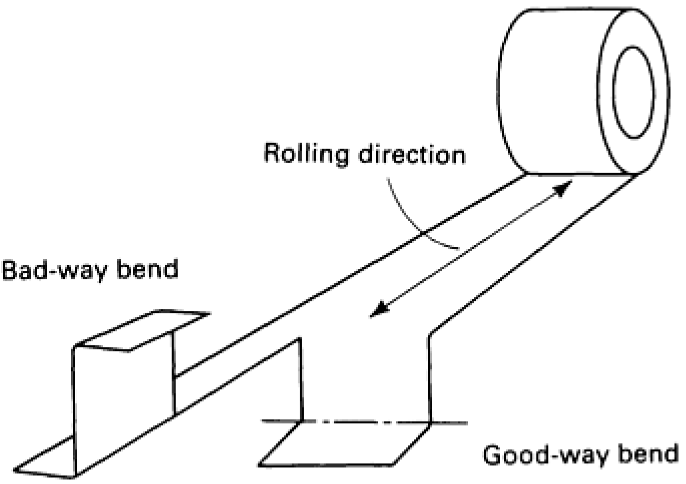

Fig. 13 Bend formability of copper alloys as a function of rolling direction. Bends with the axis transverse to the rolling direction are termed good-way bends; bends with the axis parallel to the rolling direction are bad-way bends. See also Table 6. Source: Ref 3

Figure 14 shows the effects of bend directionality on part layout. This part includes both good-way and bad-way bends. If the part were fabricated from an alloy with strong bend directionality--for example, phosphor bronze (Alloy C51000) in spring temper--the part layout would be restricted to avoid failure at bad-way bends. With alloys such as C68800 or C72500, which exhibit significantly less bend directionality, the part layout is not as restricted. It is not always possible to orient parts to minimize web scrap, regardless of the alloy selected, because tool design and part-handling and transfer costs may override the cost penalty of poor strip utilization.

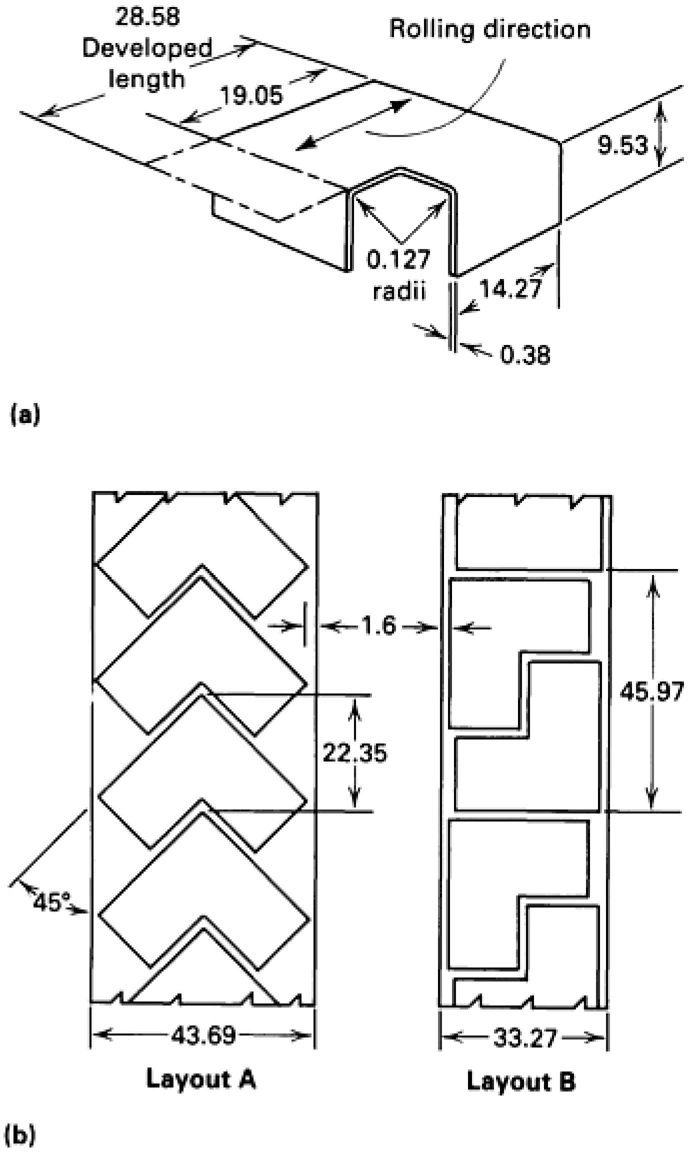

Fig. 14 Impact of bend anisotropy on part layout. (a) Hypothetical part, which has equal-radius bends at 90° orientations in the plane of the strip. Selection of the appropriate copper strip alloy for this application depends on the material strength and the bend properties in the relevant orientations. (b) Potential nesting of blanks for the part shown in (a). Layout A is required for directional alloys such as C51000 and results in 38% scrap; a nondirectional alloy such as C68800 would allow the more efficient layout B, with 23% scrap. Dimensions given in millimeters (1 in. = 25.4 mm). Source: Ref 3.

Special Considerations. The values listed in Table 6 for the minimum bend radii of various alloys as a function of temper are approximate; actual results can deviate because of tool condition and shop practice. The bend performance required also depends on the part application. For example, orange peel (surface roughening) is unacceptable if the part is to be plated or subjected to other finishing operations and if appearance is important. Often, more than one alloy is available that will meet product requirements. In the absence of other limitations, bend formability may be the deciding factor in alloy selection.

The bend performance of copper alloy strip degrades as bend angle increases; that is, a 180° bend is more severe than a 90° bend angle. The effect of bend angle on bend formability is more severe as gage increases and/or bend radius decreases. Bend performance improves as the width-to-thickness ratio of the bend region is reduced to values of less than 8 to 1. Reducing the width-to-thickness ratio can enhance bend performance by as much as three times.

Forming of Copper and Copper Alloys

Frank Mandigo and Jack Crane, Olin Corporation

Drawing and Stretch Forming

In drawing and stretch forming, a suitably shaped blank of sheet metal is drawn or formed into a die cavity to produce a part. A clamping ring, draw beads, and/or other restraints are usually applied at the periphery of the blank to prevent wrinkling and/or tearing of the blank as it is drawn or formed into the die cavity. The complexity of the edge restraint required is usually directly proportional to the complexity of the final part.

A deep-drawn part is characterized by having a depth greater than the minimum part width. A deep-drawn part can be fabricated in a single drawing step or in multiple steps by redrawing preforms developed by deep-draw, shallow-draw, and/or stretch-forming methods. Ironing can be used during redrawing to control the wall thickness of the final part. Additional anneals may be required between redrawing steps.

A shallow-drawn part has a depth less than the minimum part width and is usually formed in one process step. It can be a final part or the preform for deep drawing.

A stretch-formed part is fabricated by pressing a punch into a blank that is fully or partially restrained at its periphery to develop positive biaxial strain on the part surface. A stretch-formed part can be a final part or the preform for drawing operations. Additional information on drawing and stretch forming is available in the articles "Deep Drawing" and "Stretch Forming" in this Volume.

Materials Characteristics and Effects of Alloy Composition and Temper

Single-Step Drawing. Copper alloys that have high *r* values will provide the largest limiting draw ratio in a single deep-draw step. The *r* value is defined as the ratio of true width strain to true thickness strain in the region of uniform uniaxial elongation during a tensile test. It measures the resistance of a material to thinning. The *r* value correlates with deep-drawing performance because it reflects the difference between the load-carrying capability of the cup sidewall and the compression load required to draw in the flange of the cup or blank during a deep-drawing operation.

The deepest single-step draws (highest LDR) can be made with Alloy C52100, followed by the brasses (in order of decreasing zinc level) and by copper. The LDR of cartridge brass (Alloy C26000) increases as its grain size increases.

Multiple-Step Deep Drawing. The number of redrawing steps and the frequency of intermediate annealing treatments required depend on the initial preform geometry, the extent of ironing required, and the work-hardening rate of the particular alloy. Fewer redrawing steps are required if the preform geometry closely matches that of the final part. The trade-offs involved in selecting a fabrication procedure for the initial preform (for example, deep drawing, shallow drawing, or stretch forming) are complex.

In contrast to single-step deep drawing, in which alloys with high work-hardening rates give the highest LDR, copper alloys with lower work-hardening rates can be redrawn and ironed more times without intermediate annealing. The curves shown in Fig. 15 suggest that Alloy C11000 (electrolytic tough-pitch, ETP, copper) will possess better redrawing and ironing characteristics and will require lower press forces than copper alloys with solute additions of zinc, tin, and/or silicon.

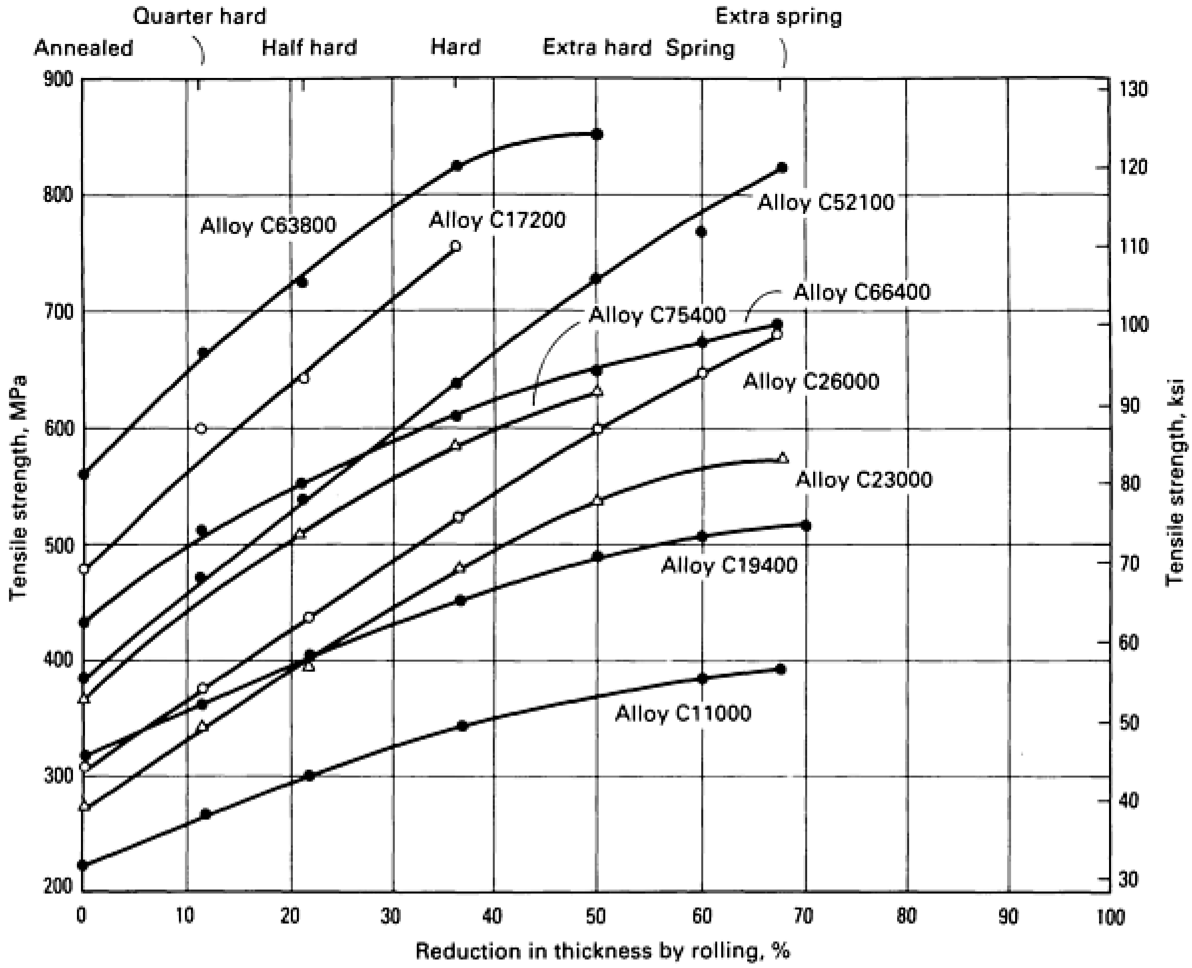

Fig. 15 Redrawing characteristics of 1.0 mm (0.040 in.) thick sheets of several copper alloys. Curves of lower slope indicate a lower rate of work hardening and therefore a higher capacity for redrawing. Source: Ref 3.

In general, successively smaller reductions are selected at each redrawing step to ensure that the punch forces required to decrease the flange circumference do not exceed the load-carrying capability of the part sidewall. The magnitude of the incremental steps of redrawing is decreased if the part sidewall is to be ironed. Ironing increases the strength of the sidewall and flange proportionally to the distance from the cup bottom. In some applications, redrawing capacity can be improved by increasing the temper of the initial strip to enhance the load-carrying capability at the junction of the part sidewall and the cup bottom. The alternative is to use a stronger alloy.

Stretch Forming. The stretch formability of copper alloys correlates with the total elongation measured in a tension test. Annealed alloys that show high work-hardening rates offer the best stretch-forming characteristics. Improved combinations of strength and stretch formability are achieved by solute elements that greatly increase the work-hardening rate. Cold rolling to increase strip temper (strength) significantly reduces stretch formability.

The variation of tensile elongation with cold-rolling reduction for copper alloys is shown in Fig. 16. These data indicate that high-tin and high-zinc alloys offer the best combinations of strength and stretch formability.

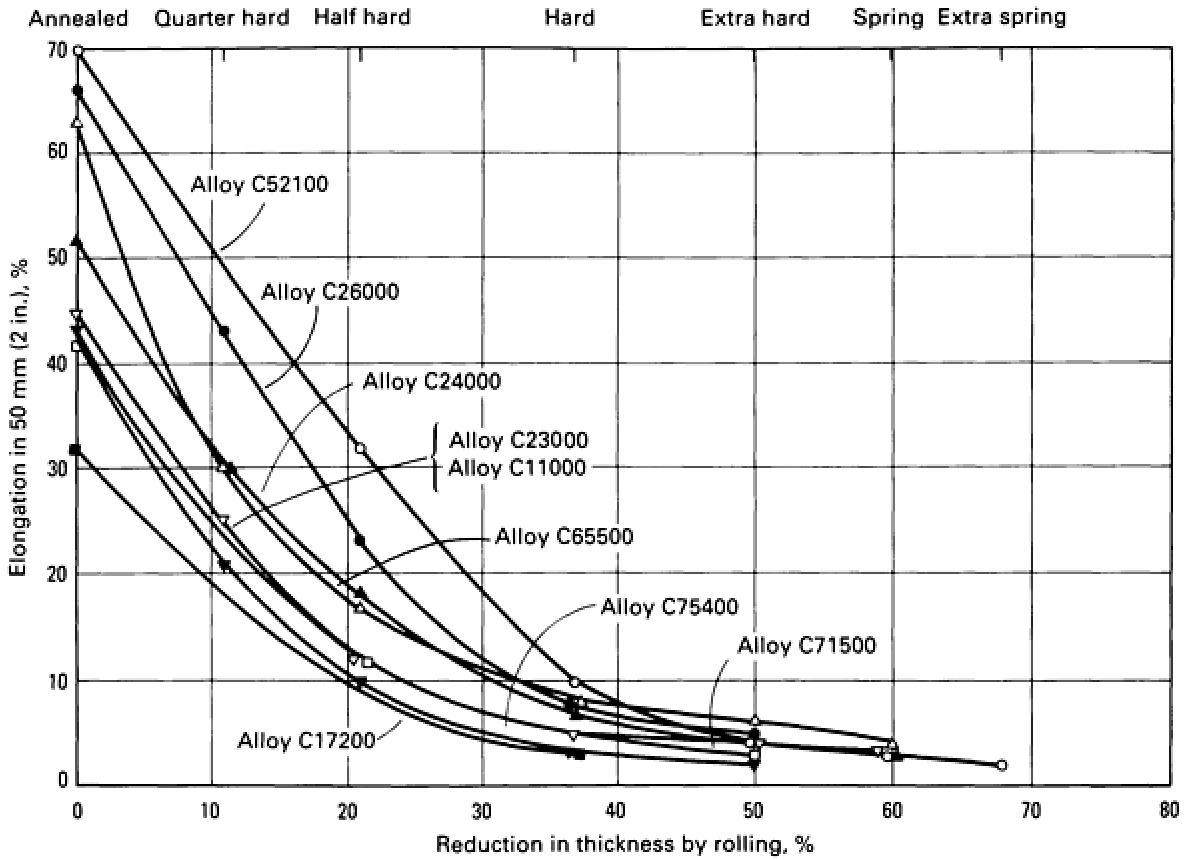

Fig. 16 Stretch-forming characteristics of 1.0 mm (0.040 in.) thick copper alloys. Elongation values for a given percentage of cold reduction indicate the remaining capacity for stretch forming in a single operation. Source: Ref 3.

Specific Characteristics of Copper Alloys. The higher-zinc brasses, such as Alloy C24000 (low brass), Alloy C26000 (cartridge brass), and Alloy C26200 (high brass), have strengths comparable to those of low-carbon steels and high ductilities. They are outstanding materials for deep drawing and stretch forming.

Many other families of copper alloys also have good deep-drawing and stretch-forming properties. Phosphor bronze A (Alloy C51000) has an excellent combination of high strength and high ductility and is used to form deep-drawn thin-wall shells that are then annealed and corrugated to produce bellows with high fatigue strength, corrosion resistance, and excellent flexibility.

The nickel silvers (copper-nickel-zinc) are white copper alloys that also have excellent deep-drawing characteristics similar to those of the high-zinc brasses. However, they have somewhat higher work-hardening rates and require more intermediate annealing for redrawing than cartridge brass. In the fully annealed condition, Alloy C63800 (Cu-3Al-2Si-0.4Co) also exhibits good deep drawability (similar to that of the nickel silvers). Annealed high-zinc leaded brasses are suitable for shallow-drawn parts, such as garden-hose coupling nuts.

Copper-zinc-tin alloys such as C40500, C41100, C42200, and C425000 respond well to drawing and redrawing operations. With regard to deep-drawing properties, C40500 and C41100 are similar to the high-copper brasses, and C42200 and C42500 are similar to C24000.

Beryllium coppers can be drawn in the solution-annealed temper and then age hardened. For example, annealed Alloy C17200 has been deep drawn to 80% reduction before annealing. Parts drawn from beryllium-copper alloys can subsequently be heat treated to produce tensile strengths to 1275 to 1380 MPa (185 to 200 ksi).

There are many other special-purpose coppers and copper alloys. By examining their compositions and mechanical properties carefully and by comparing them with standard alloys, the user can estimate how they will respond in deep-drawing applications.

Grain Size Effects. For the coppers and single-phase alloys, grain size is the basic criterion by which deep drawability and stretch forming are measured. In general, for a given alloy and sheet thickness, ductility increases with grain size, and strength decreases. However, when grain size is so large that there are only a few grains through the thickness of the sheet or strip, both ductility and strength, as measured by tensile testing, decrease. Figure 17 illustrates how elongation changes with grain size for three different thicknesses of Alloy C26000 (cartridge brass). General recommendations for the grain size of annealed strip for drawing and stretch-forming operations are provided in Table 7, along with the expected surface characteristics.

Table 7 Available grain size ranges and recommended applications

Average grain size		Type of operation and surface characteristics
mm	**in.**	
0.005-0.015	0.0002-0.0006	**Shallow forming or stamping. Parts will have good strength and very smooth surface. Also used for very thin metal**
0.010-0.025	0.0004-0.001	**Stampings and shallow-drawn parts. Parts will have high strength and smooth surface. General use for metal thinner than 0.25 mm (0.010 in.)**
0.015-0.030	0.0006-0.0012	**Shallow-drawn parts, stampings, and deep-drawn parts that require buffable surfaces. General use for thicknesses under 0.3 mm (0.012 in.)**
0.020-0.035	0.0008-0.0014	**This grain size range includes the largest average grain that will produce parts essentially free of orange peel. Therefore, it is used for all types of drawn parts produced from brass up to 0.8 mm (0.032 in.) thick**
0.010-0.040	0.0004-0.0016	**Begins to show some roughening of the surface when severely stretched. Good deep-drawing quality in 0.4-0.5 mm (0.015-0.020 in.) thickness range**
0.030-0.050	0.0012-0.002	**Drawn parts from 0.4-0.64 mm (0.015-0.025 in.) thick brass requiring relatively good surface, or stamped parts requiring no polishing or buffing**
0.040-0.060	0.0016-0.0024	**Commonly used for general applications for the deep and shallow drawing of parts from brass in 0.5-1.0 mm (0.020-0.040 in.) thicknesses. Moderate orange peel may develop on drawn surfaces**
0.050-0.119	**0.002-0.0047**	**Large average grain sizes are used for the deep drawing of difficult shapes or deep-drawing parts for gages 1.0 mm (0.040 in.) and thicker. Drawn parts will have rough surfaces with orange peel except where**

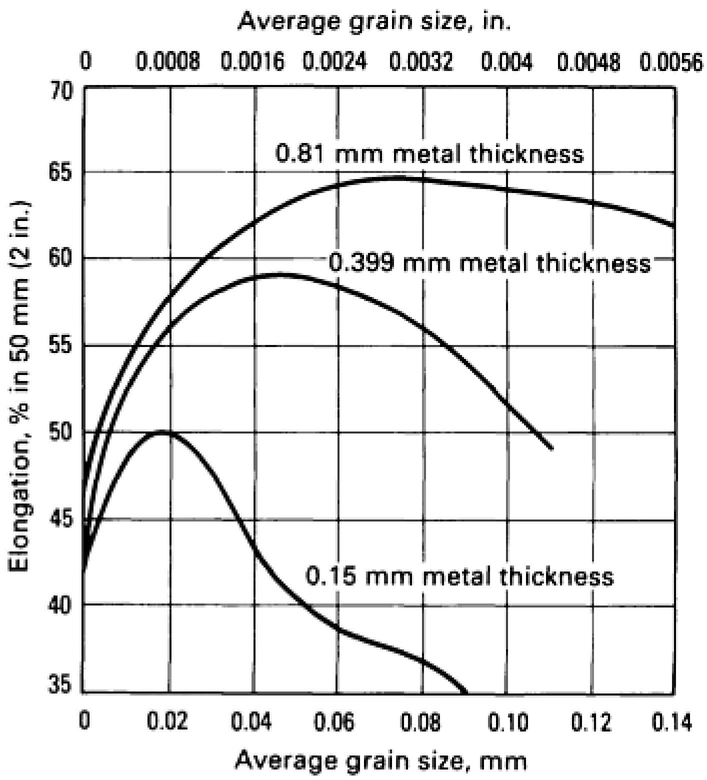

Fig. 17 Elongation versus grain size for Alloy C26000 sheets of various thicknesses. Source: Ref 3.

For optimal deep-drawing and stretch-forming properties, the grain size chosen should provide maximum elongation. With reference to Fig. 17, peak elongation for 0.15 mm (0.006 in.) thick strip occurs at an average grain size of 0.020 mm (0.008 in.). For 0.40 mm (0.0157 in.) thick brass, a range of 0.038 to 0.061 mm (0.0015 to 0.0024 in.) average grain size would provide maximum drawability. For 0.81 mm (0.032 in.) thick material, a range of 0.060 to 0.090 mm (0.0024 to 0.0035 in.) average grain size would give optimal performance.

The surface finish required on the final part is an important consideration when selecting the grain size to be used. When metal with a coarse grain size is drawn or stretch formed, the surface roughens and develops an appearance resembling orange peel. Such a surface is more difficult and costly to polish and buff. Therefore, when a part requiring a buffed surface is to be produced, much effort is expended in designing the tools and process to use brass with a fine grain size.

A classic example of this situation is the one-piece brass or bronze doorknob (Fig. 3a). Such useful and decorative articles are made by the millions, and these types of shapes are difficult to produce on draw presses. These parts are usually produced in transfer presses, and the process can include 15 to 20 operations with one intermediate anneal or partial anneal. The Alloy C26000 or C22000 strip from which these parts are made is usually about 0.76 mm (0.030 in.) thick, and the grain size is usually 0.020 to 0.035 mm (0.008 to 0.0014 in.) or 0.015 to 0.030 mm (0.0006 to 0.0012 in.) to provide sufficient ductility for the part to be drawn without surface roughening.

Special Considerations (Ref 4). A common concern in all drawing operations is the formation of ears at the top of the cup sidewall. Ears occur in preferred directions (usually 45 or 0 to 90°) relative to the strip-rolling direction. Earing reflects the crystallographic texture of the strip. In part manufacture, ears must be trimmed; therefore, nonearing grades of copper and copper alloy strip are preferred for drawn parts.

A common concern in all drawing operations is the formation of ears at the top of the cup sidewall. Ears occur in preferred directions (usually 45 or 0 to 90°) relative to the strip-rolling direction. Earing reflects the crystallographic texture of the strip. In part manufacture, ears must be trimmed; therefore, nonearing grades of copper and copper alloy strip are preferred for drawn parts.

For copper alloys, the reduction in diameter in a single draw (cupping) usually ranges from 35 to 50%, with a 50% reduction corresponding to ideal conditions. Drawing procedures vary widely in commercial practice. Reductions for successive draws of the commonly formed brasses, under favorable operating conditions and without intermediate annealing, are usually 45% for cupping; 25% for the first redraw; and 20, 16, 13, and 10% for subsequent redraws. Greater reductions are usually obtained with blank thicknesses larger than about 1.62 mm (0.064 in.); for blank thicknesses less than about 0.38 mm (0.015 in.), reductions are usually about 80% of the percentages given above. With an annealing operation before each redraw, a reduction of 35 to 45% in each successive redraw can be obtained under favorable operating conditions, assuming that the accompanying reduction in wall thickness is acceptable.

Die radius usually varies from about twenty times the metal thickness for material 0.127 mm (0.005 in.) thick to about five times the metal thickness for material 3.18 mm (0.125 in.) thick. Radii of this size prevent high stress concentrations at the die opening, which can lead to tearing in subsequent draws. Sharper radii are needed for flanged shells and for meeting special design requirements.

The punch radius, except for the final stages of drawing, is usually less than one-third of the punch diameter, or four to ten times the metal thickness. Clearance between punch and die is maintained at values that produce at least a slight amount of ironing of the sidewalls.

Coining

Nature of the Operation. Coining is a cold-forming process in which the work metal is compressed between two dies so as to fill the depression of both dies in relief or to reduce the strip thickness. The most familiar coining operation is the minting of coins. However, one of the most common uses of coining is in reducing the thickness or width of electrical and electronic connectors and leadframe leads.

Materials Characteristics. The ability of a material to be coined is determined by its strength and work-hardening rate. In general, copper, the lower-zinc brasses, the lower-alloy nickel silvers, and the copper nickels, which all exhibit low work-hardening rates, exhibit good coinability (Fig. 15).

Forming of Copper and Copper Alloys

Frank Mandigo and Jack Crane, Olin Corporation

Spinning

Nature of the Operation. Spinning is a method of forming sheet metal or tubing into seamless hollow cylinders, cones, hemispheres, or other circular shapes by a combination of rotation and force. Manual and power-automated equipment is used for spinning copper alloys. More information is available in the article "Spinning" in this Volume.

Materials Characteristics. The principal materials factors that determine the spinnability of copper alloys are plastic-strain ratio *r*, total available elongation, and work-hardening rate. In general, alloys with high *r* values, high tensile elongation, and low work-hardening rates exhibit the highest spinnability.

Effects of Alloy Composition and Temper. Tough-pitch copper (Alloy C11000) is the easiest copper material to spin and usually does not require intermediate annealing. Brasses, except for the multiphase alloy Muntz metal (C28000), are readily spun, although the higher-zinc brasses sometimes require intermediate annealing. Tin brasses containing at least 87% Cu require higher spinning pressure and more frequent annealing than brasses. Nickel silvers that contain at least 65% Cu, as well as the copper nickels, are also well suited for spinning. Phosphor bronzes, aluminum bronzes, and silicon bronzes are difficult to spin, but can be spun into shallow shapes under favorable conditions. Copper alloys that are difficult to spin include Muntz metal, nickel silvers containing 55% Cu or less, beryllium coppers, alloys containing more than about 0.5% Pb, naval brass (C46400), and other multiphase alloys.

The single-phase high-strength copper alloys can be heated for spinning to reduce the force required to permit the spinning of thicker material or to permit more severe deformation, provided the increased cost for heating is justified. The forming characteristics of Muntz metal, extra-high-leaded brass, and naval brass are also improved at elevated temperature, but special precautions must be taken to avoid even the unintentional heating of the workpiece in spinning brasses that contain 0.5% Pb or more and more than 64% Cu.

Annealed tempers are almost always used in spinning copper alloys. Larger grain sizes (lower hardnesses) are easier to spin; finer grain sizes may be needed to meet surface finish requirements.

Although stock as thin as 0.1 mm (0.004 in.) can be manually spun under special conditions, manual spinning is usually restricted to thicknesses of 0.51 to 6.35 mm (0.020 to 0.250 in.). Powered equipment is used in the upper part of this range, and stock thicknesses in excess of 25.4 mm (1 in.) can be shaped by hot power spinning.

Applications. Typical products that are spun from copper alloys include bell-mouth shapes for musical instruments, lighting fixture components, vases, tumblers, decorative articles, pressure vessel parts, and other circular parts with bulged or recessed contours.

Frank Mandigo and Jack Crane, Olin Corporation

Contour Roll Forming

Nature of the Operation. Contour roll forming is an automated high-speed production process that is capable of producing tubular, box, angular, and folded parts of varied and complex shapes (see the article "Contour Roll Forming" in this Volume). Auxiliary operations such as notching, slotting, punching, and embossing can be combined with contour roll forming.

The materials characteristics that determine the roll-forming capability of copper alloy strip are the same as those that govern bend and stretch formability (see the sections "Bending" and "Drawing and Stretch Forming" in this article).

Alloy and Temper Effects. The bend properties given in Table 6 provide an indication of the relative suitability of copper alloys for contour roll forming. Annealed tempers are needed for complicated shapes and parts with extremely sharp bends or for severe stretch forming.

Applications. Contour roll forming is used less extensively with copper alloys than with steel and aluminum alloys because there are fewer copper alloy parts that are made in sufficient volume to be produced economically by this type of forming operation. Applications are primarily in the automotive and architectural industries.

Rubber-Pad Forming

Nature of the Operation. In this process, the rubber pad usually serves as the female die, in conjunction with an inexpensive male punch. The pad is practically incompressible, and it transmits pressure in all directions in the same manner as hydraulic fluid. Rubber-diaphragm forming uses hydraulic fluid behind the rubber pad. The most important reasons for using rubber-pad forming in preference to conventional press techniques or other production methods are improved formability, low tooling costs, and freedom from marking of workpiece surfaces. This is the most cost-effective method of fabricating one-piece doorknobs.

Deep drawing by rubber-diaphragm or Marforming techniques often permits a 65% reduction of diameter in a single draw, without producing wrinkles or surface defects that could require expensive finishing operations. More information on the Marform process and other rubber-pad forming techniques is available in the article "Rubber-Pad Forming" in this Volume.

Materials Characteristics. The materials properties of greatest importance in rubber-pad forming are the same as those that control strip performance in metal dies; that is, deep drawing is dependent on the plastic-strain ratio r, stretch forming is dependent on tensile elongation, bending is determined by strip ductility, and so on.

Effects of Alloy Composition and Temper. The same principles can be used to select the appropriate alloy composition and temper for rubber-pad die forming that are used for parts formed with conventional metal dies.

Forming of Copper and Copper Alloys

Frank Mandigo and Jack Crane, Olin Corporation

Specialized Forming Operations

Hydraulic Forming. Copper alloys are sometimes formed by applying direct hydraulic pressure to the surface of the workpiece in order to shape the workpiece against a rigid die. This procedure can be used to form grooves on large, thin, flat sheets and to shape small parts to irregular contours. Tool cost is low, but the method is ordinarily applicable only to small-lot production because of comparatively low production rates.

Embossing and swaging, which are closely related to coining (being compressive or deformation operations), are also frequently used in the cold forming of copper alloys. The principles of alloy selection described for coining apply equally to embossing and swaging. However, embossing (impressing letters, numerals, or designs into a surface by displacing metal to either side) can be done on any copper alloy, with special attention to tooling and selection of temper on the less formable alloys. Swaging is often used for the production of complicated electrical contacts from copper or brass.

Electromagnetic forming, also known as magnetic pulse forming, is a process for forming metal by the direct application of an intense, transient magnetic field. The workpiece is formed without mechanical contact by the passage of a pulse of electric current through a forming coil (see the article "Electromagnetic Forming" in this Volume).

Electromagnetic forming can be used on copper and some brasses because of their high electrical conductivity and excellent formability. Metals with a resistivity greater than about 16 $\mu\Omega\cdot$ cm are formed by the use of a copper or aluminum electromagnetic driver that is one to three times the thickness of the work metal. Thermally or electrically conductive joints and structural joints are produced in a single forming operation. Field shapers are frequently used to concentrate the forming force.

Electrical connections are made by electromagnetically swaging a copper band onto the end of stranded electrical conductor wire before insertion into a brass terminal. Optimal conductivity with 100% mechanical strength and long life under severe service conditions are obtained by using swaging forces great enough to compact the strands of the conductor so that a cross section of the joint appears to be essentially solid copper.

Special Forming Considerations for Conductive Spring Materials. Increasingly, contact designers are developing parts that rely on stepped or tapered beam thickness for optimal deflection or normal force characteristics. Some designs involve complex geometries requiring high formability in some regions (as for crimp connections) coupled with high strength in other regions (to resist permanent set in spring connections). Stepped or tapered contact beam thicknesses can be achieved by coining heavier-gage strip in progressive dies. This practice, however, rapidly work hardens copper alloys and reduces their formability. Die progressions that include the forming of contacts after a coining operation must incorporate more generous minimum bend radii than those suggested in the product literature of the supplier.

Figure 18 shows this change in formability for a mill-hardened temper of Alloy C17200 that was subjected to coining up to 50% reduction in area and simulated by cold rolling after mill hardening. To avoid this formability problem, strip can be purchased with variable gage across the slit width, which is produced by profile milling or skiving or by the longitudinal electron beam welding of dissimilar thicknesses of strip. The need for localized high formability can also be met by the longitudinal electron beam welding of dissimilar metals, combining, for example, ductile C19500 with high-strength mill-hardened C17200.

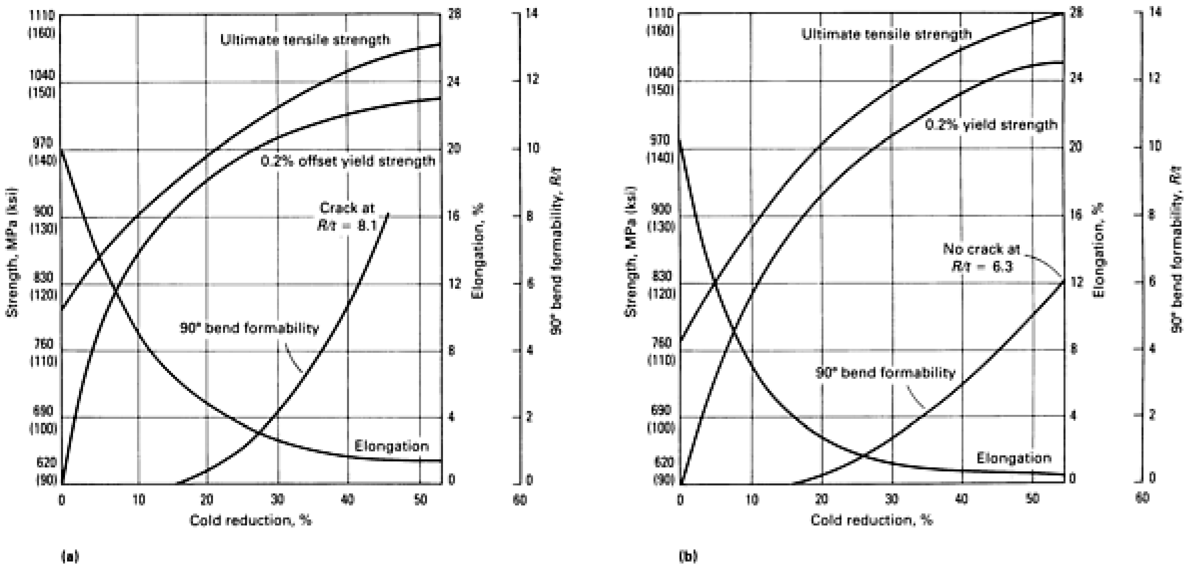

Fig. 18 Change in formability as a function of the coining of Alloy C17200 in longitudinal (a) and transverse (b) directions. The effect of coining is simulated by cold reduction. Original strip thickness in both cases was 0.41 mm (0.016 in.). Bend formability is measured as the ratio of bend radius *R* to strip thickness *t*.

An emerging electron beam application is the localized thermal softening of mill-hardened copper alloy strip to provide increased formability with no sacrifice in strength in the remainder of a contact. Examples of these unique copper alloy strip forms are shown in Fig. 19.

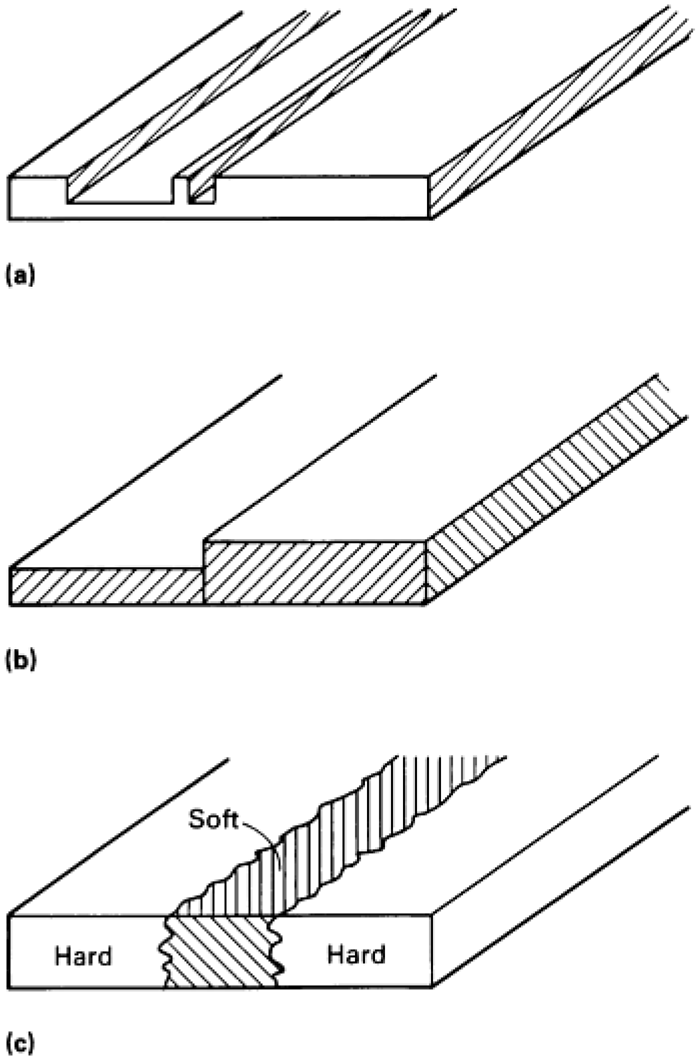

Fig. 19 Special treatment of copper alloy strip for optimized combinations of formability and spring characteristics. (a) Profile milled strip. (b) Dissimilar thicknesses longitudinally welded; this method can also be used to join dissimilar alloys. (c) Localized heat treatment (electron beam softening).

Springback

Springback is the elastic recovery that occurs in a plastically deformed part when it is released from tooling. It causes the final part to have a geometry different from that of the press tooling. The springback that occurs in a bending operation is shown schematically in Fig. 20. Springback must be taken into account in design and materials selection.

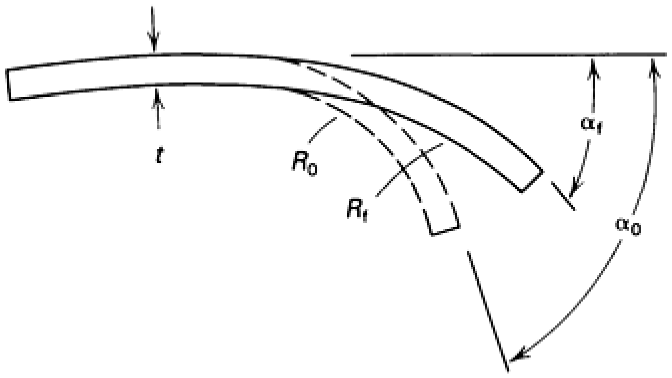

Fig. 20 Schematic of springback in a bending operation. *t* is sheet thickness, R_o and, α_o are the die radius and bend angle, and R_f and α_f are the part radius and bend angle after springback.

Springback depends on alloy, temper, thickness, bend radius, and the angle of bend. For fixed tooling and press conditions, springback increases as the strength of the copper alloy strip increases. Therefore, springback is increased by cold rolling to increase strip temper and/or by alloy additions that increase strength. The springback behavior of three copper alloys (C21000, C26000, and C35300) is shown in Fig. 21. These data indicate that springback increases with increasing bend radius and decreasing strip gage. Springback values for tempers or bend radii not shown can be interpolated from Fig. 21. Some strip suppliers provide springback data upon request.

Three techniques are commonly used to compensate for springback: overbending, restriking, and the use of special dies. Over-bending simply deforms the part to a larger bend angle so that it is at the desired value after springback. Restriking in original dies reduces springback in much the same manner as overbending, that is, by the introduction of additional plastic deformation. Special dies often use coining action at bend radii to deform the metal plastically in the bend area beyond the elastic limit. In other die modifications, the metal is pinched slightly at the bend region. When special dies are used, careful control must be exercised because excessive thinning can cause part failure during bending or can make the part susceptible to early failure in service.

Forming of Copper and Copper Alloys

Frank Mandigo and Jack Crane, Olin Corporation

Forming Limit Analysis

Forming limit analysis provides the means to assess sheet metal formability over a wide range of forming conditions, including drawing, bending, and stretching. The amount of deformation that occurs during sheet forming, that is, the strain state, is given in terms of, or related to, major and minor strains (e_1 and e_2, respectively) measured from fiducial markings printed or etched onto strip surfaces prior to fabrication. The analysis requires two curves:

- A forming limit curve (FLC), which indicates the ability of the material to distribute localized strain
- A limiting dome height (LDH) curve, which indicates the overall ductility for forming of the material

These empirically determined curves show the biaxial strain or deformation limits beyond which failure may occur in sheet metal forming. More information on the development and use of these curves is available in the article "Formability Testing of Sheet Metals" in this Volume; the use of computers to generate such data is described in the article "Process Modeling and Simulation for Sheet Forming" in this Volume.

Forming limit and limiting dome height curves for 13 copper alloys are shown in Fig. 22 and 23. Table 8 lists UNS designations, common names, alloy compositions, and tempers for the alloys tested. These data indicate that, in annealed tempers, high-copper and copper-zinc alloys exhibit the highest FLC values, followed closely by Alloys C72500, C51000, and C74300; these materials in turn are slightly better than Alloys C19400, C75200, and C70600. Increasing the temper by cold rolling decreases forming capability, as shown in Fig. 22. The LDH data essentially follow the trend shown in FLC behavior.

Table 8 Coppers and copper alloys evaluated using forming limit analysis

See Fig. 22 and 23 for results of analysis.

UNS designation	Common name	Material conditions applicable to FLCs and LDH curves
C10200	Oxygen-free copper	**Annealed, 0.66 mm (0.026 in.) thick, 0.014 mm (0.0006 in.) grain, 234 MPa (34 ksi) UTS[(a)]**
C11000, lot 1	ETP copper	**Annealed, 0.74 mm (0.029 in.) thick, 0.016 mm (0.00063 in.) grain, 224 MPa (32.5 ksi) UTS[(b)]**

C11000, lot 2	ETP copper	**Half hard, 0.69 mm (0.027 in.) thick, 268 MPa (38.8 ksi) UTS, 20% tensile elongation[c]**

Solving Forming Problems. In addition to displaying the relative formability of one material versus that of another, forming limit and limiting dome height curves are valuable for identifying the cause of a sudden production problem that might arise from changes in tooling, lubrication, or material suppliers. This permits the forming process to be modified to maximize formability and productivity.

The most direct approach for determining if a sudden forming problem is materials related is to compare the LDH curve for the material with that of the control lot of known good material. If only one region of the part is subject to critical strains, it may be necessary only to test the blank width that will produce that critical value of minor strain. If the LDH curve of the new material is the same as that of the control lot, then tooling or lubrication are suspect. If the LDH curve of the new material is below that of the control lot, the material is the problem.

The best way to determine whether tooling or lubrication conditions have changed is to form a gridded sample under current tool conditions from a control lot held in inventory. Strain distribution and critical grid strains measured on this sample can be placed on the established forming limit curve and compared with those before the problem arose in order to establish their relationship to known, safe strain levels. If changes are detected, they can often be remedied by adjusting press conditions to change the magnitude of stretch or draw components.

This is illustrated in Fig. 24. Point A on this forming limit curve represents the strains in the critical region of a part when the part was being formed satisfactorily. Point B represents the critical strains when forming became a problem because the major and minor strains were too high. Draw beads, blank hold-down pressure, blank size, and/or lubrication can be modified to change the amount of major and minor strains. The effects on critical strain can be compared on the forming limit curve to ensure that the adjustments will indeed enable the part to be formed.

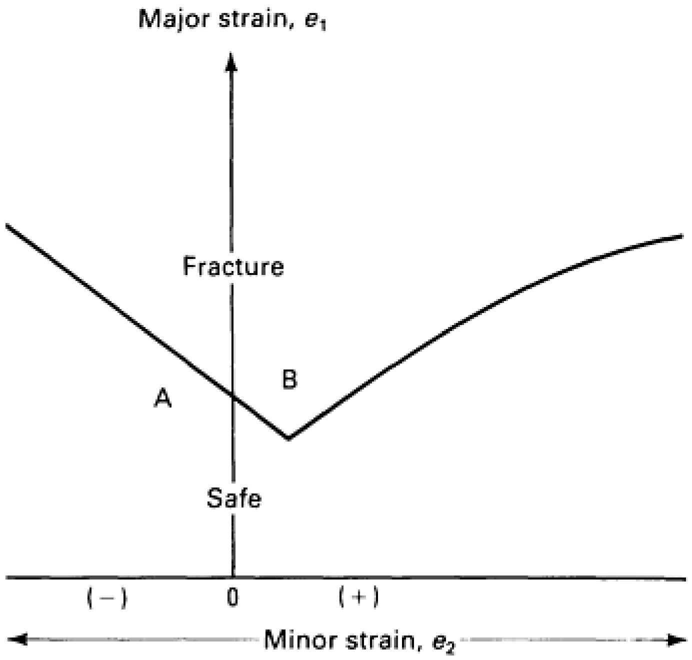

Fig. 24 Effect of tooling or lubrication on critical strain. Inadvertent changes in tooling or lubrication can shift strain from Point A to Point B, causing parts that previously were readily formed to fail during forming. Source: Ref 5, 6.

A similar approach can be used to adjust the forming operation so that a less ductile material can be formed. Figure 25, for example, shows forming limit curves for two materials (A and B) and the critical strain combination (point X) measured on a formed part. Material A forms successfully, but Material B fractures during forming, as indicated by the location of point X relative to the forming limit curve of each material.

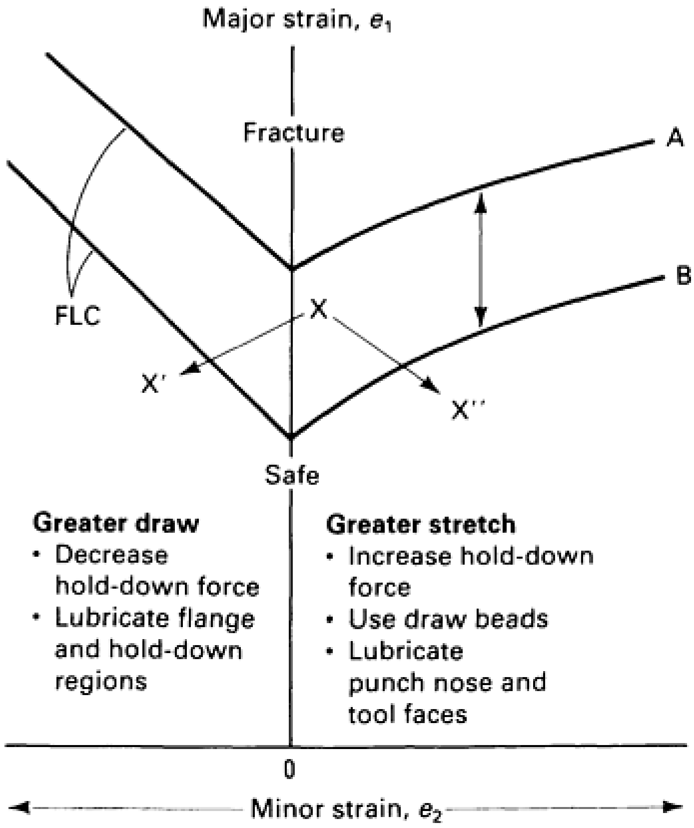

Fig. 25 Effect of changes in forming operation on critical strain. Shifting strain from X to X' by increasing draw or from X to X" by increasing stretch permits Material B to be used in place of Material A despite its lower ductility. Source: Ref 5, 6.

Because of the shape of the forming limit curves, it is possible to maintain approximately the same e_1 value for point X but to fall in the safe region by changing e_2, as indicated by points X' and X". In this case, moving toward X' requires that the draw component be increased during forming; moving toward X" requires that the stretch component be increased. Either can be accomplished by altering lubrication, tooling, and/or blank hold-down pressure, thus enabling the part to be formed in Material B.

Forming of Copper and Copper Alloys

Frank Mandigo and Jack Crane, Olin Corporation

Property Requirements for Various Formed Products (Ref 7)

Because the selection of an alloy begins with performance requirements even before formability is considered, this section offers a brief discussion of alloy effects relative to the performance of copper alloys. When these factors are matched with the best formability considerations, optimal material selection is attained.

Electrical Conductors. High conductivity is a primary requisite for many conductors, but not all conductors require high conductivity. Strength and resistance to creep or softening can be traded for some loss of conductivity. Thermal conductivity goes hand in hand with electrical conductivity and is usually required in all conductors operating in the high-amperage range.

Terminals and connectors are used in both electronic and electrical applications. Electrical circuits require greater current-carrying ability than electronic circuits, for which low-to-moderate conductivity will often suffice. Good formability at the required strength level, well-defined load deflection characteristics, and resistance to stress relaxation are usually required for both electrical and electronic connectors. Corrosion and stress-corrosion resistance and solderability are also often demanded.

Other Electronic Applications. The primary electronic application for copper and copper alloys, other than connectors and printed circuits, is as leadframes for semiconductor devices. Transistors, diodes, and integrated circuits can be fabricated on a semiconductor chip often less than 5 mm (0.2 in.) square. The chip is bonded to a substrate or leadframe, which serves both structurally and electrically to connect it to the outside world. Where copper alloys can be used, the materials requirements are expressed in terms of cost, conductivity, strength, softening resistance, formability, low-cycle fatigue resistance, and surface characteristics (such as plating, wire bonding, and plastic molding compound adherence).

Hollow Ware, Flatware, and Decorative Applications. The production of hollow ware products requires materials with good drawability. In addition, the material must have good solderability, corrosion resistance, sufficient strength to resist denting during manufacture or use, and good buffing and plating characteristics; most hollow ware products are silver or gold plated. The least expensive alloys that meet these criteria are the 10 to 30% Zn brasses. The lower zinc levels are used for multiple-redrawing applications, and the higher zinc levels are for parts demanding higher strength and/or deep-drawing capability. Copper and phosphorus-deoxidized copper are significantly softer and are primarily used for decorative applications without plating, where the red color of the metal is considered appealing. They have adequate drawability for parts that do not require sidewall ironing and a high work-hardening rate. Phosphorus-deoxidized copper is required where brazing is needed.

Flatware items are generally produced by roll forming. In addition to good formability, flatwork alloys must have good solderability, corrosion resistance, good buffing and plating characteristics, and low cost. Embossed items use annealed tempers of materials with sufficiently low work-hardening rates to give faithful reproduction of detailed patterns. Copper-zinc and copper-nickel-zinc alloys offer the required combination of properties; the zinc content is varied to suit the work hardening needed. A copper-nickel-zinc alloy that has a silvery color is generally used for silver-plated flatware, and Cu-30Zn is used for gold-plated flatware to minimize the color contrast between base metal and plate if damage to the plate occurs.

Heat exchangers require good thermal conductivity, corrosion and stress-corrosion resistance, joinability, and strength at modest cost. These requirements vary in importance for each application. Copper and copper alloys offer good combinations of these properties. The two major heat exchanger applications are steam condenser tubing and automotive radiators.

Condenser tubing must withstand potentially corrosive cooling water as well as the volatile components carried by the steam, which condense on the tubing. Corrosion requirements are paramount, but strength at elevated temperature and thermal conductivity are also required.

The copper alloys commonly used in power utility condensers include arsenic-, antimony-, or phosphorus-inhibited brasses; aluminum bronzes; or copper-nickels, depending on corrosion and stress-corrosion requirements. For automotive radiators, corrosion resistance, thermal conductivity, and fabricability are the primary requisites. Certain applications require strength at elevated temperature. Fabricability demands the ability to solder and to braze. Resistance to both atmospheric corrosion and corrosion by heat-transfer media and their decomposition products is required. Cooling fins are made of pure copper or high-copper copper alloys.

Coinage. General requirements include low cost, attractive appearance and high density for high denominations (to give the impression of intrinsic value), tarnish and corrosion resistance, modest strength, and ability to be coined easily. Specific additional requirements for vending machine use include control of conductivity, density, magnetic permeability, and eddy-current response. Apart from those few coins that are fabricated from stainless steel, most non-precious metal coins are made of copper alloys, which can meet these requirements.

Ammunition. The cartridge case that contains the explosive powder and primer for ammunition is made by a cup and draw process; a blanked disk is cupped, drawn to extend the sidewall, and redrawn for the same purpose. The drawing process is repeated until the wall is sufficiently thinned and extended. The case can be annealed between a series of draws to permit sufficient extension without cracking. The primary materials requirements are related to fabricability, but stress-corrosion resistance and strength are also needed.

Cartridge brass (Cu-30Zn) is the most widely used copper alloy for shells and other ammunition; hence its name. Cartridge brass offers the best materials compromise for such applications, having excellent deep drawability, moderate redrawability, and sufficient strength. In press operations, its low coefficient of friction and absence of refractory oxides contribute toward low press forces, low tool maintenance, and good surfaces on the parts being formed. It is also low in cost. Formed cartridge cases must be stress-relief annealed to minimize the possibility of stress-corrosion cracking.

Forming of Magnesium Alloys

Introduction

THE PRINCIPAL DIFFERENCE between forming magnesium alloys and forming steel, aluminum, or copper is temperature. Although some forming of magnesium alloys can be done at room temperature, elevated temperatures are used in most applications.

Cold Forming

Cold forming of magnesium alloys is restricted to mild deformation with a generous bend radius.

Bend Radii. Cylinders and cones can be formed from magnesium alloys at room temperature by using standard power rolls. Simple flanges can be press formed at room temperature. Table 1 gives minimum radii for fast bending at room temperature, as in a press brake. Slightly smaller bend radii than those given in Table 1 may be used when forming speeds are slower, as in a hydraulic press or when proved by trial and error.

Surface Protection. In low-production cold forming, a common method of preventing surface damage is to apply tape to critical areas of the work metal and, if feasible, to tool surfaces. It is especially important to keep the die clean and free from particles of foreign metal that can become embedded in the surface of the workpiece and impair its corrosion resistance.

Hard rubber inserts in dies are sometimes helpful in preventing damage to the work metal and in forming large radii. However, this practice is not recommended for high production, because the inserts wear rapidly and cause nonuniform workpieces.

Reworking of bends by straightening and rebending the same portion should not be done in cold forming, because of the possibility of failure.

Springback can be as much as 30° for a 90° bend in cold forming of magnesium alloys.

Effect of Bending on Length. Unlike aluminum alloys and steel, which lengthen in bending, magnesium alloys shorten, because the neutral axis moves slightly toward the tension side of the bend. For thin sheet, the extent of this shortening is small, because the axis shifts only 5 to 10%. However, in thicker sheet when several bends are made, the amount of shortening can be significant and must be allowed for in the development of the blank.

Stress Relieving. Magnesium-aluminum-zinc (AZ) alloys should be stress relieved after cold forming to prevent stress corrosion. It may be desirable to stress relieve workpieces formed from the magnesium-thorium (HM, HK) alloys, particularly if they require straightening in fixtures. Recommended temperatures and times for stress relieving the magnesium alloys that are most commonly cold formed are given in Table 2.

Forming of Magnesium Alloys

Hot Forming

Magnesium alloys, like other alloys with hexagonal crystal structures, are much more workable at elevated temperatures than at room temperature. Consequently, they are usually formed at elevated temperatures. The methods and equipment used in forming magnesium alloys are the same as those commonly employed in forming other metals, except for differences in tooling and technique that are required when forming is done at elevated temperatures.

Working of metals at elevated temperatures has several advantages over cold working. Magnesium alloy parts usually are drawn at elevated temperature in one operation without repeated annealing and redrawing, thus reducing the time involved for making the part and also eliminating the necessity for additional die equipment for extra stages. Hardened dies are unnecessary for most types of forming. Hot-formed parts can be made to closer dimensional tolerances than can cold-formed parts because of less springback. Table 3 lists suggested maximum forming temperatures and times for various wrought magnesium alloys. The times given indicate the maximum time the alloy can be held at temperature without adversely affecting mechanical properties.

Sheet and Plate. Rolled magnesium alloy products include flat sheet and plate, coiled sheet, circles, tooling plate, and tread plate. These products are supplied in a variety of sizes.

The ability to use increased section thickness without weight penalty is of particular importance in designs that employ magnesium sheet. Thick-sheet construction provides the rigidity necessary in a structure, without the need for costly assembly of ribs and similar reinforcing members.

Rolled magnesium-alloy products can be worked by most conventional methods. For severe forming, sheet in the annealed (O temper) condition is preferred. However, sheet in the partially annealed (H24 temper) condition can be formed to a considerable extent. Because heat has significant effects on properties of hard-rolled magnesium, properties of the metal after exposure to elevated temperature must be considered in forming. The design curves shown in Fig. 1 give minimum values suitable for design use. Although the curves are based primarily on tests of sheet 1.63 mm (0.064 in.) thick or less, check tests indicate reasonable applicability for thicknesses up to 6.35 mm (0.250 in.).

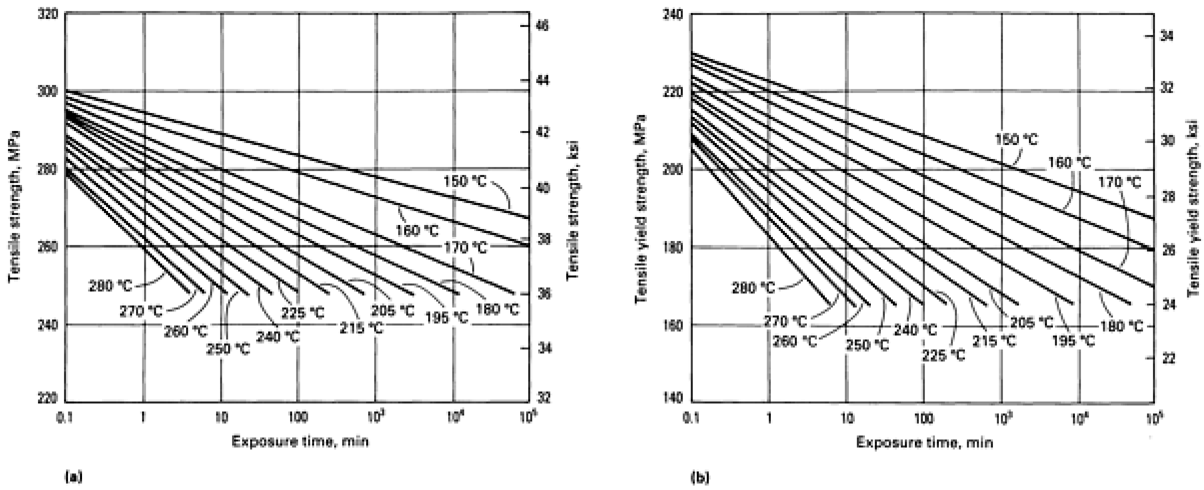

Fig. 1 Effect of exposure time at elevated temperature on the mechanical properties of AZ31B-H24 sheet at room temperature. (a) Tensile strength. (b) Tensile yield strength. Data are based on tests of sheet 1.63 mm (0.064 in.) thick, and have reasonable applicability for thicknesses up to 6.35 mm (0.250 in.).

Figure 1 shows how the properties of AZ31B-H24 change with exposure time at various temperatures. The curves have been extrapolated above the typical property levels of AZ31B-H24 sheet. Thus, if the value selected from a curve exceeds the actual property level of the material before exposure, the actual figure must be used. Also, it should be kept in mind that the effects of multiple exposures at elevated temperature are cumulative.

AZ31B-H24 sheet is commonly hot formed at temperatures below 160 °C (325 °F) to avoid annealing it to room-temperature property levels lower than the specified minimums. Annealing is a function of both time of exposure and temperature; thus, temperatures higher than 160 °C can be tolerated if exposure is carefully controlled.

Thermal Expansion. Magnesium alloys have a very high rate of thermal expansion. At 260 °C (500 °F), for example, the thermal expansion of magnesium is more than twice that of steel. Therefore, when parts made of magnesium alloys are hot formed in tool steel or cast iron dies, the difference in the thermal expansion of the tool material and the work metal must be considered.

Figure 2 shows the relation between the size of a magnesium part and the size of a steel die at 20 °C (70 °F) and at 205 °C (400 °F). The dimensional factor need not be applied when the dies are made of zinc or aluminum alloys, because the coefficients of expansion of these alloys are similar to those of magnesium alloys.

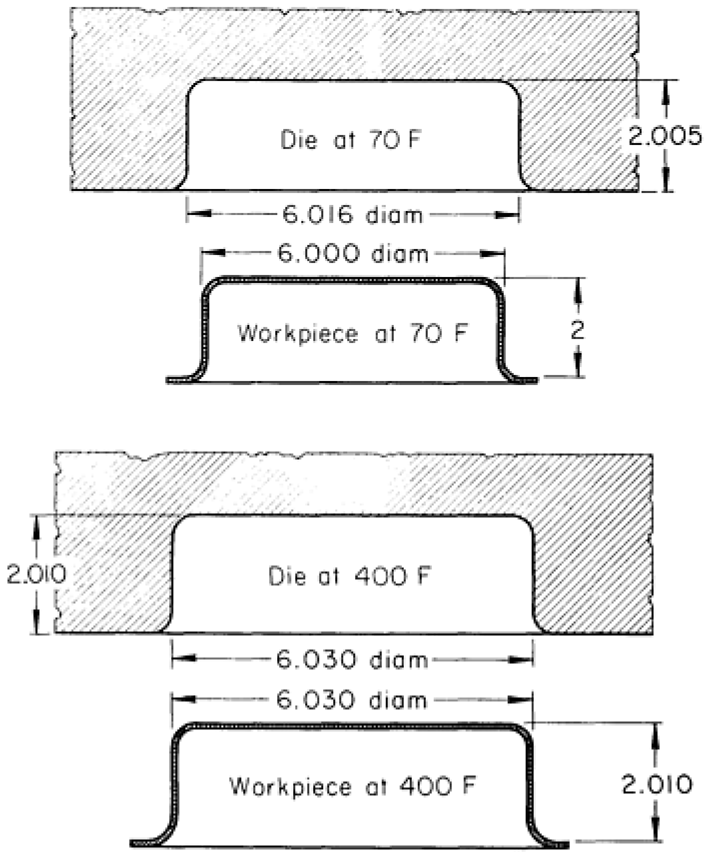

Fig. 2 Dimensional relations of a magnesium alloy workpiece and a steel die at room temperature and at a forming temperature of 205 °C (400 °F). Room-temperature dimensions of the steel die are determined by multiplying the design dimensions of the magnesium part by 1.00270. Dimensions given in inches.

Precautions. Magnesium alloy stock to be hot formed must be clean. Protective coatings, oil, dirt, moisture, or other foreign matter must be removed.

Dies, punches, and form blocks should be clean and free of scratches; tooling should be cleaned with solvent. Rust, scratches, and minor imperfections can be removed by light polishing with fine-grit abrasive cloth. However, polishing must not alter the dimensions of the tool.

In forming, the possibility of fire due to ignition of magnesium is remote. However, an ample supply of suitable fire-extinguishing material, such as dry sand or commercially available powder, must be kept in the work area.

Heating of Workpieces

In most hot-forming methods, both the tools and the magnesium alloy work metal must be heated. Heating equipment includes ovens, platen heaters, ring burners, electric heating elements, heat transfer liquids, induction heaters, and lamps and other types of infrared heating. For small lots, tools and work may be heated by hand torches. Small dies that can be handled rapidly can be heated in ovens adjacent to the forming equipment.

Heating Methods. Electric heating elements often are used for heating dies and other forming tools. Electric-resistance heating can be used for heating some dies. Low-voltage high-amperage current is passed into the die through conducting grips or clamps.

Radiant heating with electricity and gas is useful for heating dies and workpieces in some applications. Radiant heating is particularly useful for rapid heating of the workpiece and for use in rapid-action presses. Also, with this heating method, cloth covers can be used on the workpiece to minimize heat loss.

Infrared heating is also commonly used. A bank of infrared lamps is the most common method, but gas-fired units are also used.

The principal advantage of infrared heating is that only the die and workpiece are heated and not the surrounding area. Also, the cost of heating is less, and working conditions are cooler and less hazardous.

Gas heating often is advantageous, because the installation of equipment is simple and fuel cost is generally low. Burners up to 1.9 m (75 in.) long can be formed and welded from 19 mm ($\frac{3}{4}$ in.) black iron pipe; 25-mm (1-in.) pipe is suggested for burners more than 1.9 m (75 in.) long. Burners are attached to the dies so that the flames touch the die surface. Hollow punches can be heated by a burner inside the punch.

Four gas-mixing systems are used for heating tools and dies:

- Simple venturis, in which gas flows through a mixer that draws in air
- Proportional mixers, which use compressed air flowing through a venturi (or an air injector) that pulls the gas into the burner at atmospheric pressure
- A gas-air carburetor system, which uses a low-pressure turbocompressor to compress the gas-air mixture. The carburetor holds a constant fuel-to-air ratio regardless of the volume of flow
- A venturi mixing system combined with turbocompressors, which gives accurate temperature control with minimum overshoot

Heat transfer fluids are used for heating platens, form blocks, drop hammer dies, and other forming tools large enough to have passages in the die. Heating by this method is rapid and permits good temperature control. Heat transfer fluids with a working-temperature range of 150 to 400 °C (300 to 750 °F) are available. Hot oils, natural and synthetic, that can withstand temperatures up to 345 °C (650 °F) are commonly circulated in passages in the dies. Steam is readily available, and is circulated through ducts in the tools or dies, but its maximum temperature is usually about 175 °C (350 °F). Commercially available equipment for use with heat transfer fluids includes vapor generators, circulating mechanisms, and means for temperature control.

Temperature control is important. For forming a few pieces, contact pyrometers or temperature-sensitive crayons are satisfactory for determining temperature. Blue carpenter's chalk can sometimes be used. A streak of this chalk on a metal surface will turn white at approximately 315 °C (600 °F).

Automatic temperature controls are essential for most magnesium-forming operations. Radiant and infrared heat are more difficult to control than other kinds of heat. One type of infrared lamp has a control that extends or retracts the lamp when the tool or workpiece has reached the desired temperature. Another temperature control for infrared heating consists of a special radiometer that senses only the heat radiated by the surfaces being heated.

To maintain the desired temperature, controls used in gas-heating systems usually operate by adjusting a solenoid valve in the line to lower or raise the flame. Electric heating by elements, resistance heating, and heating by means of heat transfer fluids usually provide good temperature control.

Lubricants

Generally, lubrication is more important in hot than in cold forming of magnesium alloys, because the likelihood of galling increases with the increase of temperature.

Lubricants used in forming magnesium alloys include mineral oil, grease, tallow, soap, wax, molybdenum disulfide, colloidal graphite in a volatile vehicle, colloidal graphite in tallow, and thin sheets of paper or fiberglass.

Selection of a lubricant depends primarily on forming temperature. For temperatures up to 120 °C (250 °F), oil, grease, tallow, soap, and wax are generally used.

In spinning, it is essential that the lubricant cling to the work metal; otherwise the lubricant will be thrown off by centrifugal force. This is not a problem when drawing in a die or bending in a press brake.

Frequently, a lubricant that is used for other operations in the plant can be used, up to a forming temperature of 120 °C (250 °F). It is common practice to use the lubricant that can be most easily removed after forming and to apply it by roller coating or swabbing. Sometimes the lubricant is applied to both the work metal and the tools.

When forming is done at temperatures above 120 °C (250 °F), the selection of a lubricant is more limited; ordinary oil, grease, and wax are eliminated. Although colloidal graphite can be applied at any temperature that is used for forming magnesium alloys, because graphite is difficult to remove and interferes with subsequent surface treatments, its use is usually avoided.

A soap lubricant is acceptable for temperatures as high as 230 °C (450 °F). This compound is an aqueous solution and is applied to the work metal by dipping, brushing, or roller coating. After coating, the work metal blanks are dried in still or forced air. After drying, the blanks can be stored for an indefinite period for future processing because the dried lubricant is stable. Lubricant that remains after forming can be completely removed by cleaning in hot water.

When forming temperatures are higher than 230 °C (450 °F), the choice of lubricant is restricted to colloidal graphite or molybdenum disulfide. Graphite in a vehicle such as spirits (2% graphite) is widely used; for spinning, the graphite is mixed with tallow to improve adherence.

Lubricants should be cleaned from parts as soon as possible after forming, to prevent corrosion and to avoid difficulty in their removal. Colloidal graphite is particularly difficult to remove if allowed to remain on parts for any length of time.

Because for some work lubricants cannot be tolerated at any forming temperature, thin sheets of paper or fiberglass (depending on temperature) are placed between the work metal and the tools. More information on lubricants for sheet forming is available in the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume.

Press-Brake Forming

The press-brake forming of magnesium alloys is the same as it is for other metals, except that the work metal and the dies are usually heated. Top and bottom dies can be made of steel, or if the workpiece permits cold forming, the steel punch can be bottomed in a rubber die held in a retaining box. Metal punches and dies should be highly polished to prevent marking of workpiece surfaces.

A preferred method of heating the punch and die for hot forming is shown in Fig. 3. When only a few workpieces are to be formed, heating with a gas torch is satisfactory; however, care must be taken to ensure that the area of the workpiece to be formed is uniformly heated. If the press-brake die is not heated, the workpiece should be heated to the maximum allowable temperature and formed quickly before the tools can cool the work metal too much.

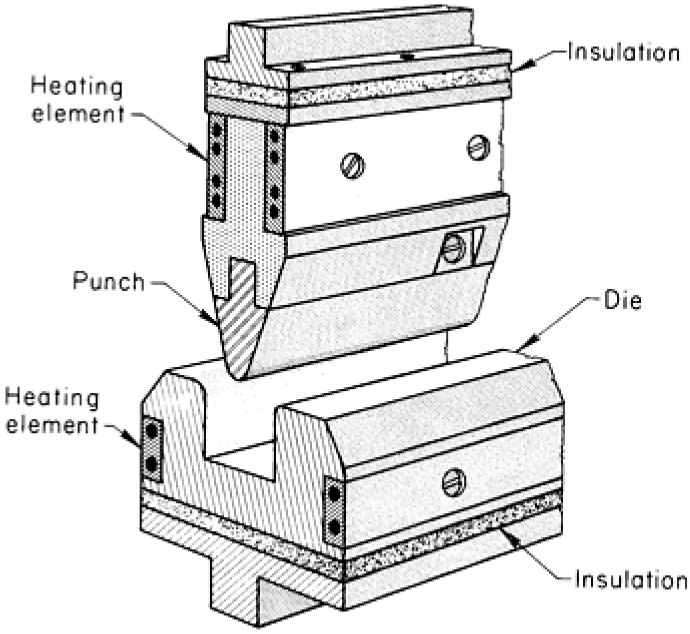

Fig. 3 Preferred method of heating a punch and die for hot forming magnesium alloys on a press brake.

Deep Drawing

Magnesium alloys can be cold drawn to a maximum reduction of 15 to 25% in the annealed condition. The cold drawability limit of alloy AZ31B-O is about 20%. The drawability, or percentage of reduction in blank diameter, is calculated by the formula:

$$\text{Percentage reduction} = \frac{D - d}{D} \times 100$$

where D is the blank diameter before drawing and d is the diameter of the punch.

Die Heating. Electric heating elements are usually used for heating the tools, although when intricate parts are drawn, gas-ring burners provide more flexibility, particularly if the work metal is likely to pucker. The base of the punch sometimes can be heated.

Another type of differential heating is used in the production of workpieces that have a slight crown. When the crown must be held to close tolerance, burners with separate controls are provided inside and outside the die. For more crown, the outside of the mating die is heated to a higher temperature than the inside. When the workpiece reaches die temperature and the outside of the sheet is hotter than the inside, the work metal retracts upon removal of the die, thus causing the crown to form. Alternatively, to eliminate crowning and obtain flatness, the inside of the die is heated to a higher temperature than the outside.

Blankholder pressures for magnesium alloys vary from the lowest obtainable to as much as 5 MPa (700 psi). In average draws, the blankholder pressure is usually 345 to 1380 kPa (50 to 200 psi). To secure proper wall thinning, blankholder pressures are obtained by trial and error.

Drawability. Annealed magnesium alloy sheet can be cold drawn to 25% reduction (blank diameter to cup diameter). With heat, drawability is greatly improved, and up to 70% reduction is possible.

Drawability is also influenced by the shape of the workpiece. A maximum drawability of 70% is for drawing a round cup. Square and rectangular boxes, for example, seldom are drawn as severely.

Effect of Speed on Drawability. Drawability at any temperature varies with the speed of drawing, which ranges from 0.6 to 405 mm/s ($1\frac{1}{2}$ to 960 in./min). Large reductions (70%, for example) require slower speeds than do moderate reductions (up to 55%).

Reductions up to about 55% can often be made on high-speed hydraulic or mechanical presses. Also, milder draws permit lower forming temperatures, and costs can be reduced, because strip feeding, blanking, lubrication, trimming, and cleaning can be simplified.

For most parts, however, depth of draw is not a primary consideration, and usually no trouble is experienced in drawing to the depth required. More trouble is encountered in keeping the metal free from puckers in parts with rounded corners or contours. Temperatures above those required for maximum drawability are often necessary to eliminate these puckers. On unusual or difficult jobs, it may be necessary to vary the procedure to obtain minimum scrap.

Redrawing. The possibilities inherent in two-step draws are illustrated by the following parts: In the first operation, 610 mm (24 in.) blanks of 0.64 mm (0.025 in.) annealed sheet were drawn to a cup 200 mm (8 in.) in diameter by 400 mm (16 in.) in depth; they were redrawn to a cup 140 mm ($5\frac{1}{2}$ in.) in diameter by 585 mm (23 in.) in depth. Starting with a rectangular blank of 1.3 mm (0.051 in.) AZ31B-O, 455 × 485 mm (18 × 19 in.), a rectangular box 111 × 273 × 165 mm ($4\frac{3}{8} \times 10\frac{3}{4} \times 6\frac{1}{2}$ in.) in depth was drawn in the first operation. This box was then redrawn into a rectangular box 89 × 254 × 171 mm ($3\frac{1}{2} \times 10 \times 6\frac{3}{4}$ in.) in depth having 5.6 mm ($\frac{7}{32}$ in.) corner radii.

Choice of die materials is chiefly influenced by the severity of the operation and the number of parts to be produced. For most applications, unhardened low-carbon steel boiler plate or cast iron is satisfactory. For runs of 10,000 parts or more, for maximum surface smoothness, or for close tolerances where no significant die wear can be allowed, hardened tool steels are recommended. Tool steels W1 or O1 are satisfactory for extremely long runs (1 million parts). For the most severe draws, however, the more abrasion-resistant tool steels, such as A2 or D2, will probably be more satisfactory and economical. For room-temperature drawing, it is usually desirable for die steels to be heat treated to obtain near-maximum hardness in service. However, for elevated-temperature drawing, the maximum temperature to which the dies will be exposed in drawing must also be considered. In this situation, the dies must be tempered slightly above the maximum service temperature, even though some hardness may be sacrificed.

Manual Spinning

Various conical and hemispherical shapes can be produced from magnesium alloys by manual spinning. Because tooling is inexpensive, manual spinning of small quantities is often more economical than press forming. When press tooling would be complex, manual spinning may be used for medium to large production quantities.

Equipment and tooling for manual spinning of magnesium alloys are essentially the same as those used for other metals (see the article "Spinning" in this Volume), except that when magnesium alloys are to be heated, the mandrels (spin blocks) should be made of metal, with provision for controlled heating of the work metal.

For spinning a few pieces, it is common practice to heat the blanks with a hand torch, using temperature-sensitive crayons to indicate the temperature. For production spinning, however, the use of a thermostatically controlled burner on the lathe is preferred.

Procedure. Annealed sheet is usually used in spinning. Manual spinning depends to a large extent on operator skill, especially when spinning magnesium alloys, which are more temperature sensitive than most metals.

Many shapes can be spun from unheated blanks by a skilled operator, especially when thin sheet is used, because friction between the spinning tool and workpiece generates a substantial amount of heat. As severity of sheet thickness increases, the work metal must be heated. Temperatures of 260 to 315 °C (500 to 600 °F) are common.

Whether spinning is done hot or cold, a lubricant should be used (see the section "Lubricants" in this article). Spindle speed should be such that the speed of the edge of the blank is about 610 m/min, or 2000 surface feet per minute (sfm) when spinning begins.

Tolerances. Typical tolerances that can be maintained in manual spinning of magnesium alloys are as follows:

Workpiece diameter		Tolerance	
mm	**in.**	**mm**	in.
<455	<18	±0.8	$\pm\frac{1}{32}$
455-915	18-36	±1.6	$\pm\frac{1}{16}$
>915	**>36**	**±3.2**	$\pm\frac{1}{8}$

Spinning Extrusions. Manual spinning can be used either to close or flare the ends of extruded round tubing.

Closing the ends of tubes is done by slowly forcing a rotating hemispherical cup over the end of the tube until the end is closed and has assumed the hemispherical shape of the cup (spinning tool). This can be done on almost any machine that can hold the workpiece and rotate the cuplike tool. A drill press is frequently used. The use of grease or soap as a lubricant is helpful in producing a better workpiece finish and prolonging the life of spinning tools. In most applications, tube ends can be closed without the use of heat.

Tube flaring is done either by inserting a stationary mandrel into the tube and pushing it out against a stationary die on the outside, or by spinning or rolling the flare against a stationary outside die with a conical, rotating, inside mandrel. The shape required for the flare usually determines the preferred procedure.

Tube-flaring machines have a stationary outside die and conical, rotating, inside spindle with adjustable eccentricity, the axis of which rotates off center at approximately 1600 rpm. The eccentric spindle forces the tube against the outer die to form the flare. In the flaring of magnesium alloy tubes, the outer die should be heated, preferably by electric heating elements in the die holder, to a preferred temperature of about 260 °C (500 °F). The tube to be flared is preheated to the same temperature. Lubrication may be required during tube flaring. The lubricants recommended for spinning can be used.

Forming of Magnesium Alloys

Power Spinning

Power spinning (shear spinning) can be used for magnesium alloys. Both cone spinning (spinning in accordance with the sine law) and tube spinning (spinning in which metal displacement is strictly volumetric) are used for magnesium alloys.

Equipment and Tooling. Special machines are used in the cone and tube spinning of magnesium alloys. However, the equipment used in power spinning is the same as that used for other metals (see the article "Spinning" in this Volume), except when hot spinning is done; then, torches or other heating equipment must be added to the machine. Consequently, the mandrels and rollers must be made from an alloy tool steel that will not be softened by heat. Tool steels such as H12 or H13 hardened to 54 to 58 HRC are used in many applications.

Procedure. Magnesium alloys are sometimes power spun without heat, but more often the major portion of the reduction is performed hot and finished cold, or is rough worked hot and then finished at a somewhat lower temperature (warm). For the most successful results, a definite procedure of alternate spinning and heating should be followed, whether the metal is finished cold or warm. Table 4 gives recommended procedures for the two methods often used for alloys HK31A and HM21A. The use of the procedures outlined in Table 4 has resulted in total wall thickness reductions as high as 80%.

Table 4 Procedures for power spinning two magnesium alloys to obtain acceptable properties[(a)]

Alloy	Procedure
Cold finishing	
HK31A	**Hot work roughly to shape at 425 ± 30 °C (800 ± 50 °F). Heat treat for 30-60 min at 455-480 °C (850-900 °F)[(b)]. Cold work to a total reduction in thickness of at least 25% using low reductions per pass. Heat 1 h at 315-330 °C (600-625 °F)**
HM21A	**Hot work roughly to shape at 455 ± 10 °C (850 ± 50 °F). Heat treat for 30-60 min at 480-510 °C (900-950 °F)[(c)]. Cold work to a total reduction in thickness of 15-25% using low reductions per pass. Heat 1 h at 370 ± 16 °C (700 ± 25 °F)**
Warm Finishing	
HK31A	**Hot work roughly to shape at 425 ± 30 °C (800 ± 50 °F) if necessary. Heat treat for 30-60 min at 455-480 °C (850-900 °F)[(b)]. Warm work at 315-370 °C (600-700 °F) to a total reduction in thickness >50% with a minimum number of passes. Heat 16 h at 205 °C (400 °F)**
HM21A	**Hot work roughly to shape at 455 ± 30 °C (850 ± 50 °F) if necessary. Heat treat for 30-60 min at 480-510 °C (900-950 °F)[(c)]. Warm work at 315-370 °C (600-700 °F) to a total reduction in thickness >50% with a minimum number of passes. Heat 16 h at 230 °C (450 °F)**

(a) Properties obtained will approach those of the H24 temper for HK31A and the T8 temper for HM21A.

(b) Fairly rapid cooling is desirable, but less critical than for HM21A.

(c) Should be cooled from the heat-treating temperature to 315 °C (600 °F) or below within 5 min

Forming of Magnesium Alloys

Rubber-Pad Forming

Hydraulic presses are generally used for the rubber-pad forming of magnesium alloys. Tooling is simple because only a form block is used (see Fig. 4). A conventional die is not needed.

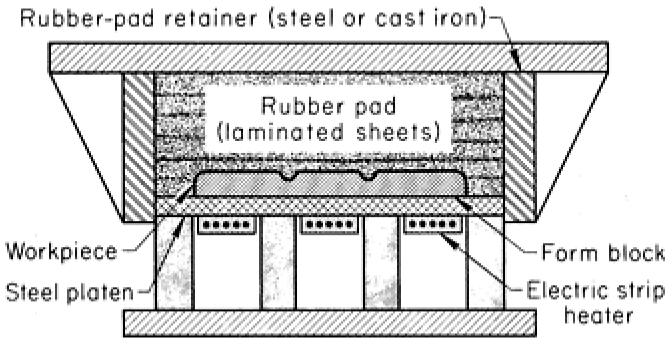

Fig. 4 Tooling and heating setup for rubber-pad forming of magnesium alloys at elevated temperature.

For forming at room temperature, particularly for limited use, form blocks can be made of wood or masonite; or for higher production runs, they can be made of aluminum, zinc, or magnesium, which are more durable than wood or masonite. However, large radii must be used in cold forming.

When rubber-pad forming at elevated temperature form blocks must be made from metal that will not creep excessively at the working temperature and pressure; magnesium, aluminum, or zinc can be used up to about 230 °C (450 °F). However, forming at temperatures higher than 230 °C (450 °F) requires steel form blocks.

Specially compounded grades of solid rubber or laminated sheets are used for the rubber pad when forming at temperatures up to 315 °C (600 °F). Hardness of the rubber is important--Durometer A 40 to 70 is the common range.

Heating. As shown in Fig. 4, the heating elements heat the steel platen, and the heat is transferred to the form block, which is not fastened to the platen, by conduction. Alternatively, the form block can be heated separately in an oven and then placed on the platen. With this method, a fireproof blanket often is placed between the heated form block and the cold platen for insulation. Usually blanks are heated in ovens situated near the press to minimize loss of heat.

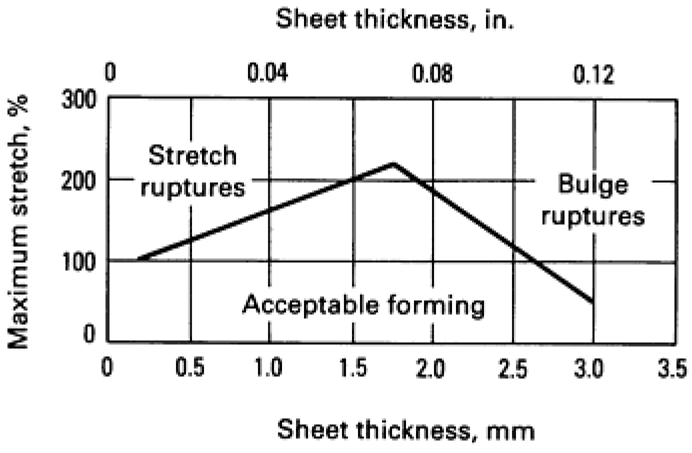
Forming Pressure. Pressure for rubber-pad forming is a function of sheet thickness and forming temperatures; 6200 kPa (900 psi) is adequate for most work.

Rubber-pad forming is generally done by shaping the blank around a form block with pressure from the rubber pad. However, when pressure must be concentrated at one point, or metal flow must start before general pressure is applied, deflector bars are used (see the article "Rubber-Pad Forming" in this Volume).

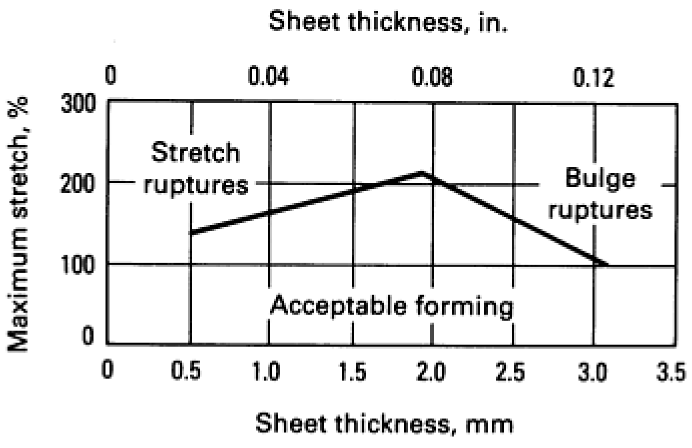
Some severe forming is done in two operations: The workpiece is partly formed, is removed from the press for hand smoothing of wrinkles, and then is returned to the press for final forming under full pressure. In one-operation forming, thin throw sheets of heat-resistant rubber can be placed over the blank, or attached to the pad, to protect the rubber.

Shrink flanges that are wrinkle-free can be made with a higher percentage of compression from magnesium alloys than from other metals, such as aluminum, of the same gage. Minor wrinkles can be hand corrected after flanging. If the part is likely to wrinkle severely, scalloped cutouts or recesses in the form blocks may correct this condition. A draw plate to iron out wrinkles during forming is often helpful.

Stretch flanges of up to 40% stretch in hard-rolled magnesium alloy sheet (H24 temper) and 70% in annealed sheet (O temper) can be made by rubber-pad forming. The ranges of stretch flange limits for various thicknesses of AZ31B-O and AZ31B-H24 alloy sheet rubber pad formed at 150 °C (300 °F) are shown in Fig. 5.



(a)



(b)

Fig. 5 Stretch flange limits for various thicknesses of magnesium alloys AZ31B-O and AZ31B-H24 rubber pad formed at 150 °C (300 °F). (a) Alloy AZ31B-O. (b) Alloy AZ31B-H24.

A minimum flange radius of 5*t* is suggested for alloy AZ31B-H24 at 160 °C (325 °F). The radius of the die should be approximately $\frac{1}{2}t$ less to compensate for springback.

Beads. In rubber-pad forming, both internal and external beads can be formed in magnesium alloy sheet. Usually external beads are easier to produce, although wrinkling is slight in both types.

Severity of forming internal and external beads is expressed as the ratio w/h where w is the width of the bead and h is the height of the bead. Beading is essentially a stretching operation, and this w/h ratio is related to the maximum percentage of stretch obtained in a given bead.

External beads can be made to equal or more severe ratios; the minimum bead margin should be 9.6 mm (0.38 in.), and beads should be separated by a minimum center-point distance of 19.3 mm (0.76 in.).

Hand forming can slightly improve the definition of a part after rubber-pad forming, while the form block and workpiece are still hot. A leather or plastic forming tool can be used to correct minor irregularities or improve flange angles. To avoid damage to the form block, hard tools should not be used.

Stretch Forming

The stretch forming of magnesium alloys is the same as it is for other metals, except that magnesium alloys are generally stretch formed at elevated temperatures. The fundamentals of stretch forming, compression forming, and radial draw forming are described in the article "Stretch Forming," in this Volume.

Dies, or form blocks, made from magnesium, aluminum, or zinc alloys are suitable for forming at temperatures up to 230 °C (450 °F). Concrete form blocks containing wire mesh heated by electrical resistance may also be used at temperatures up to 230 °C (450 °F). For temperatures higher than 230 °C (450 °F), cast iron form blocks are used.

Grippers used in the forming of magnesium alloys should not have serrated jaws, to prevent tearing of the work metal. Coarse emery paper or cloth can be placed between the work metal and the jaws to preclude tearing.

Tools and work metal can be heated by electric heating elements or by radiant heat. Proper distribution of heat is important, and units should be placed at critical forming areas.

For differential stretching of sheet over forms of low curvature, the practical maximum stretch is about 15%. The maximum is 12% if allowance (overstretch) is made for springback; however, normally little springback is encountered at elevated temperatures; therefore an addition of 1% to the total stretch usually compensates for any springback that may occur.

Although freedom from wrinkles is an advantage of stretch forming in most applications, wrinkles can be a problem when making asymmetrical low-curvature parts. Wrinkles can be controlled by including proper restraints in the die. The skill of the operator largely determines where such restraints are needed.

Drop Hammer Forming

Drop hammer forming is used for producing shallow depths and asymmetrical shapes in magnesium alloys when quantities are small and for applications requiring minimum springback. Successful results depend on operator skill. Except for heating, drop hammer forming of magnesium alloys is the same as it is for other metals, (see the article "Drop Hammer Forming" in this Volume).

Zinc alloy can be used for both punch and die. Lead punches are sometimes used, but lead pickup can cause corrosion of the sheet. For production quantities greater than about 50 pieces, however, cast iron punches and dies are recommended, because zinc alloy tools lose their shape at these quantities.

Annealed sheet is preferred for drop hammer forming. Blanks should be heated near the hammer, because the work cools rapidly--usually 16 to 25 °C (30 to 45 °F) in 5 s. Ten blows may be needed to form a part, with reheating between blows--5 min for metal thicknesses up to 1.3 mm (0.051 in.) and 9 min for thicknesses of 1.3 to 3.18 mm (0.051 to 0.125 in.).

Heat-resistant rubber pads are often used in the dies for preliminary forming and removed before final forming.

Dies can be heated in an oven near the hammer, or by torches or ring burners during operation. Small dies can be used on an electrically heated cast iron platen on the hammer bed, but this method is not practical for large dies. Heating of the punch and die by electric heating elements or by a heat transfer fluid is also used.

The elevated temperatures used in drop hammer forming of magnesium alloys can reduce or eliminate springback; therefore, the maximum practical temperature should always be used. The rate of deformation must be carefully controlled, especially when deformation of the work metal is severe, or when the metal is in the H24 temper. For workpieces that require severe forming, the punch is lowered slowly and forming is completed with subsequent blows. Tolerances of ±0.76 mm (±0.030 in.) can be maintained in production.

Impact Extrusion

Impact extrusion is used for producing symmetrical tubular workpieces, especially those with thin walls or irregular profiles for which other methods are not practical. Information on the application of this process to magnesium is described in the section "Impact Extrusion of Magnesium Alloys" of the article "Cold Extrusion" in this Volume.

Forming of Nickel-Base Alloys

R. William Breitzig, INCO Alloys International, Inc.

Introduction

THE DUCTILITY of nickel-base alloys in the annealed condition makes them adaptable to virtually all methods of cold forming. Within this group of alloys (see Table 1 for compositions), other engineering properties vary sufficiently to cause the alloys to range from moderately easy to difficult to form, compared to other materials.

Table 1 Nominal compositions of some nickel-base alloys

Alloy	**UNS designation**	Composition, %[(a)]						
		C	**Fe**	**Co**	**Cr**	**Ti**	**Mo**	Others
Nickel 200	N02200	0.10 max	0.4 max	. . .	. . .	. . .	. . .	**0.25 max Cu, 0.10 max Ti, 0.15 max Si**
Nickel 201	N02201	0.02 max	0.4 max	. . .	. . .	. . .	. . .	**0.25 max Cu, 0.10 max Ti, 0.15 max Si**

(a) All compositions contain balance Ni.

Strain Hardening. Because strain hardening is related to the solid-solution strengthening afforded by alloying elements, strain-hardening rate generally increases with the complexity of the alloy. Accordingly, strain-hardening rates range from moderately low for nickel and nickel-copper alloys to moderately high for the nickel-chromium, nickel-chromium-cobalt, and nickel-iron-chromium alloys. Similarly, the age-hardenable alloys have higher strain-hardening rates than their solid-solution equivalents. Figure 1 compares the strain-hardening rates of six nickel alloys, in terms of the increase in hardness with increasing cold reduction, with those of four other materials. Note that the strain-hardening rates of the nickel-base alloys are greater than that of 1020 steel, and most are less than that of AISI-type 304 stainless steel.

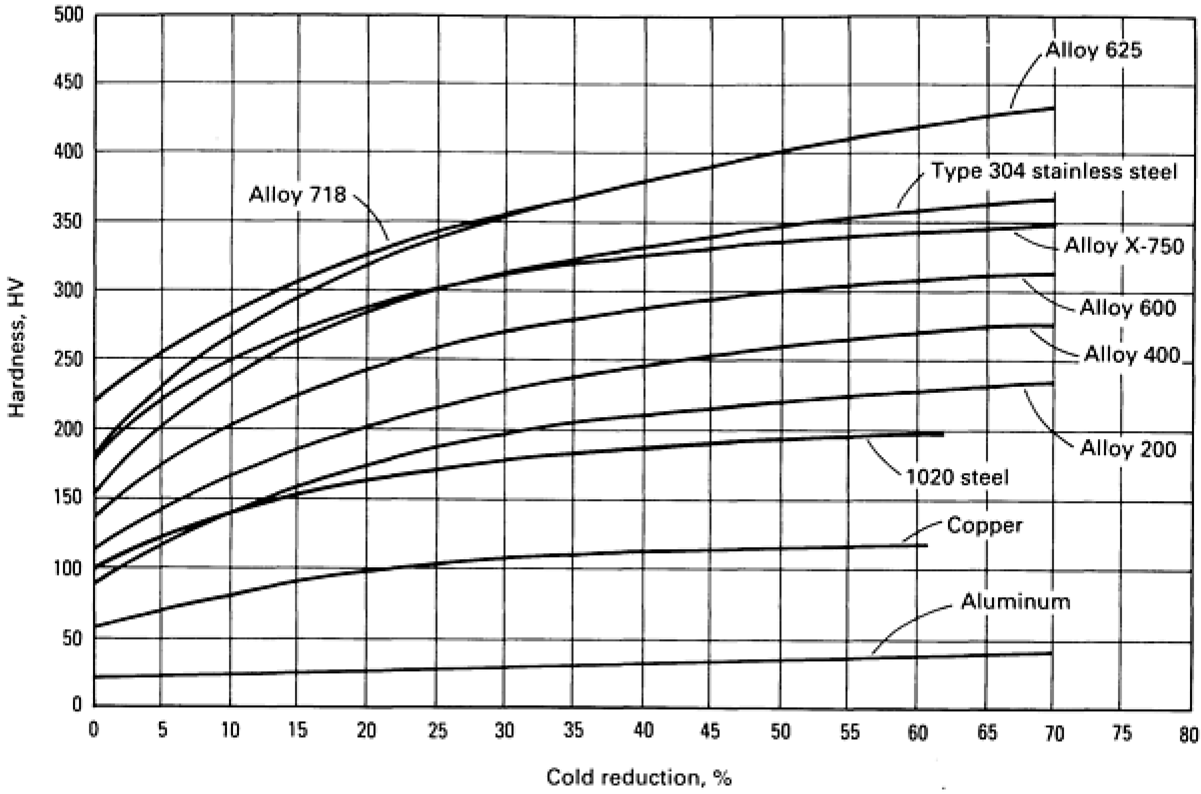

Fig. 1 Effect of cold work on the hardness of various nickel-base alloy sheet materials.

Because the modulus of elasticity of the high-nickel alloys is relatively high (similar to that of steel), a small amount of springback in cold-forming operations might be expected. However, springback is also a function of proportional limit, which can increase greatly during cold working of strain-hardenable materials. For instance, a yield strength of 170 MPa (25 ksi) of an alloy in the annealed condition might increase to 520 MPa (75 ksi), during a drawing operation. Therefore, the amount of springback for this alloy must be computed from the 520 MPa (75 ksi) flow stress, rather than from the initial value of the yield strength.

Temper. Most cold-forming operations require the use of annealed material. However, the softer alloys, such as Nickel 200, the NILO alloys, and alloy 400, are frequently used in $\frac{1}{8}$-hard and $\frac{1}{4}$-hard tempers for improved shearing and piercing. For similar reasons, alloy 400 is usually cold headed in No. 1 or 0 temper for fastener applications.

Galling. Because nickel-base alloys do not readily develop an oxide film that would present a barrier to diffusion bonding, they cold weld (gall) easily to materials of similar atomic diameter. When a cold weld is formed, the high shear strength and ductility of the alloys prevent the weld from being easily broken. For these reasons, the coefficient of friction between nickel-base alloys and other metals, including most die materials, is usually high.

Alloying with highly reactive elements that readily form oxide films, such as chromium, reduces the galling, or cold welding, propensity of nickel alloys. Accordingly, the nickel-chromium and nickel-iron-chromium alloys are less likely to gall than are the nickel and nickel-copper alloys. However, chromium oxide films are thin and brittle and provide only limited protection because they are easily broken when the substrate is deformed. The use of heavy-duty lubricants will minimize galling in most cold forming.

R. William Breitzig, INCO Alloys International, Inc.

Lubricants

Heavy-duty lubricants are required in most cold forming of nickel-base alloys. Although sulfur- and chlorine-containing additives can improve lubricants, they can also have harmful effects if not completely removed after forming. Sulfur will embrittle nickel-base alloys at elevated temperatures such as might be encountered in annealing or age hardening, and chlorine can cause pitting of the alloys after long exposure. Therefore, sulfurized and chlorinated lubricants should not be used if any difficulty is anticipated in cleaning the formed part. Neither are these lubricants recommended for use in spinning, as this operation may burnish the lubricant into the surface of the metal. Similarly, molybdenum disulfide is seldom recommended for use with nickel alloys because of difficulty in removal.

Pigmented oils and greases should be selected with care, because the pigment may be white lead (lead carbonate), zinc oxide, or similar metallic compounds that have low melting points. These elements can embrittle nickel alloys if the compounds are left on the metal during heat treatment. Inert fillers such as talc can be used safely.

Metallic Coatings. Maximum film strength can be obtained by using a coating of copper. However, because application and removal are expensive, metallic coatings are used as lubricants only in severe cold-forming operations and then only when they can be properly removed.

Ordinary petroleum greases are seldom used in forming nickel-base alloys. These greases do not necessarily have the film strength indicated by their viscosity, and they do not have a strong polar attraction for metals.

Phosphates do not form usable surface compounds on nickel-base alloys and cannot be used as lubricant carriers.

Light mineral oils and water-base lubricants have limited film strength and lubricity and can be used only in light forming operations. More information on lubricants for sheet forming is available in the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume.

R. William Breitzig, INCO Alloys International, Inc.

Tools and Equipment

Nickel-base alloys do not require special equipment for cold forming. However, the physical and mechanical properties of these materials frequently necessitate modification of tools and dies used for cold forming other metals. These modifications are discussed in this section. Information applying to specific forming operations is presented in the sections covering those operations.

Die materials used in forming austenitic stainless steels (see the article "Forming of Stainless Steel" in this Volume) are suitable for similar operations on nickel-base alloys. Soft die materials such as aluminum bronze, nickel-aluminum bronze, and zinc alloys are used when superior surface finishes are desired. However, these materials have a relatively short service life. Parts formed with zinc alloy dies should be flash-pickled in dilute nitric acid to remove any traces of zinc picked up from the dies during forming. Zinc can cause embrittlement of nickel alloys during heat treatment or high-temperature service. For similar reasons, parts formed with brass or bronze dies should be pickled if the dies impart a bronze color to the workpiece.

Tool Design. Because nickel-base alloys are likely to gall, and because of the high pressures developed in forming, tooling should be designed with liberal radii, fillets, and clearances. The radii and clearances used in the cold forming of nickel-base alloys are usually larger than those for brass and low-carbon steel, and about equal to those for the austenitic stainless steels.

Because nickel-base alloys, particularly the nickel-chromium alloys, have higher yield strengths and strain-hardening rates, they require stronger and harder dies and more powerful forming equipment than does low-carbon steel. Generally, 30 to 50% more power is required for nickel-base alloys than is needed for low-carbon steel.

Equipment Operation. The strain-rate sensitivity and frictional characteristics of nickel-base alloys dictate that all forming operations be performed at relatively slow speeds. For instance, the slide speed in shearing, deep drawing, and press-brake bending is usually 9 to 15 m/min (30 to 50 ft/min). Cold heading, piercing, and similar operations are normally done at speeds of 60 to 100 strokes per minute.

R. William Breitzig, INCO Alloys International, Inc.

Shearing, Blanking, and Piercing

The optimum temper of nickel-base alloys for shearing, blanking, and piercing varies from skin hard to full hard, depending on the alloy and thickness. For instance, thin strip of Nickel 200 and the NILO alloys should be blanked in full-hard temper for maximum die life and minimum edge burr, but alloy 600 (UNS N06600) usually gives best results in skin-hard temper. Annealed temper is usually suitable for blanking of the precipitation-hardenable alloys such as alloy X-750 (UNS N07750).

Punch-to-die clearance per side should be 3 to 5% of stock thickness for thin material and 5 to 10% of stock thickness for thick ($\geq$3.2 mm, or $\frac{1}{8}$ in.) material. The clearance between the punch and the stripper plate should be as small as is practicable.

Shears should have a low-carbon steel rating of 50% greater than the size of the nickel alloy material to be sheared. For example, a shear with a low-carbon steel rating of 9.5 mm ($\frac{3}{8}$ in.) should be used to cut 6.4 mm ($\frac{1}{4}$ in.) thick alloy 400 (UNS N04400) plate.

Lubricants are not usually used in shearing but should be used in blanking and piercing. A light mineral oil fortified with lard oil can be used for material less than 3.2 mm ($\frac{1}{8}$ in.) thick. A heavier sulfurized oil should be used for material that is thicker than 3.2 mm ($\frac{1}{8}$ in.).

Procedure. In piercing, the minimum hole diameter is usually equal to or greater than the thickness of the material, depending on the thickness, temper, and specific alloy. Minimum hole diameters for given thicknesses of alloys 200, 400, and 600 are:

Sheet thickness, *t*		Minimum hole diameter
mm	**in.**	
0.46-0.86	0.018-0.034	**1.5*t***
0.94-1.78	0.037-0.070	**1.3*t***
1.98-3.56	0.078-0.140	**1.2*t***

Hole diameters equal to the thickness of the sheet have been produced in material as thin as 0.46 mm (0.018 in.), but only after considerable experience and with proper equipment.

The softer alloys, such as Nickel 200, have greater impact strength than do the harder, chromium-containing alloys. Consequently, the softer alloys are more sensitive to the condition of dies and equipment. Shear knives may penetrate 65 to 75% of the material thickness before separation occurs in shearing Nickel 200, whereas penetration may be only 20 to 30% in shearing the harder alloys.

Laboratory tests have indicated that the shear strength of nickel-base alloys in double shear averages about 65% of the tensile strength. However, these values were obtained under essentially ideal conditions using laboratory testing equipment with sharp edges and controlled clearances. Shear loads on nickel-base alloys ranged from 113 to 131% of those on low-carbon steel in production shearing based on tests using a power shear with a rake of 31 mm/m ($\frac{3}{8}$ in./ft) of blade length. More information on shearing is available in the article "Shearing of Plate and Flat Sheet" in this Volume.

Forming of Nickel-Base Alloys

R. William Breitzig, INCO Alloys International, Inc.

Deep Drawing

Nickel-base alloys can be drawn into any shape that is feasible with deep drawing steel. The physical characteristics of nickel-base alloys differ from those of deep drawing steel, but not so much as to require different manipulation of dies for the average deep drawing operation.

Most simple shapes can be deep drawn in nickel-base alloys using dies and tools designed for use on steel or copper alloys. However, when intricate shapes with accurate finished dimensions are required, minor die alterations are necessary. These alterations usually involve increasing clearances and enlarging the radius of the draw ring or of the punch nose.

Double-Action Drawing. In drawing and redrawing of thin stock ($\leq$1.6 mm, or $\frac{1}{16}$ in.) into cylindrical shells with no ironing, the diameter reduction should be 35 to 40% on the first operation and 15 to 25% on redraws. If the walls are held to size, the first and second operations may be the same as suggested above, but the amount of reduction should be diminished by about 5% on each successive redraw.

Although reductions of up to 50% can be made in one operation, this is not advisable because of the possibility of excessive shell breakage. Also, large reductions may open the surface of the metal and cause difficulty in finishing.

The number of redraws that can be made before annealing is necessary depends on the alloy being drawn. The alloys with the lower rates of work hardening (Fig. 1) can often be redrawn more than once without intermediate annealing. Trial runs may be needed to determine when annealing is necessary.

Single-Action Drawing. As with all metals, the depth to which nickel-base alloys can be drawn in single-action presses without some means of blank restraint is controlled by the blank-thickness-to-diameter ratio. For single-action drawing without holddown pressure, the blank thickness should be at least 2% of the blank or workpiece diameter for reductions of up to 35%. With properly designed dies and sufficiently thick material, the reduction on the first (cupping) operation with a single-action set-up may be made equal to those recommended for double-action dies--that is, 35 to 40%. Redraws should not exceed a 20% reduction.

If the shell wall is to be ironed, the increased pressure on the bottom of the shell usually necessitates a decrease in the amount of reduction to prevent shell breakage. With reductions of 5% or less, the shell wall may be thinned by as much as 30% in one draw. With medium reductions of about 12%, the thickness of the shell wall can be decreased by about 15%. If the wall is to be reduced by a large amount, the shell should first be drawn to the approximate size with little or no wall thinning and the ironing done last. If a good surface finish is desired, the final operation should have a burnishing effect with only a slight change in wall thickness.

Clearances. Because nickel-base alloys have higher strengths than do low-carbon steel of drawing quality, nickel alloys have greater resistance to the wall thinning caused by the pressure of the punch on the bottom of the shell. Consequently, greater die clearance is required than is the case for steel if the natural flow of the metal is not to be resisted. However, the clearances required for nickel-base alloys are only slightly greater than those required for steel, and if dies used for steel have greater-than-minimum clearances, they are usually satisfactory for drawing nickel-base alloys, depending primarily on the mechanical properties of the alloy.

For ordinary deep drawing of cylindrical shells, a punch-die clearance per side of 120 to 125% of the blank thickness is sufficient and will prevent the formation of wrinkles. In the drawing of sheet thicker than 1.6 mm ($\frac{1}{16}$ in.), it is general practice to have the inside diameter of the draw ring larger than the diameter of the punch by three times the thickness of the blank (150% of stock thickness per side).

Draw-Ring and Punch Radii. Because nickel-base alloys work harden rapidly, relatively large draw-ring and punch radii should be used, especially for the early operations in a series of draws. Nickel-base alloys require more power to draw than does steel; consequently, the punch imposes a greater stress on the bottom corner of the shell. Small punch radii cause thinning of the shell at the line of contact, and if such a shell is further reduced, the thinned areas will appear farther up the shell wall, and may result in visible necking or rupture. Also, buffing a shell having thinned areas will cause the shell wall to have a wavy appearance. For redraws, it is preferable to draw over a beveled edge and to avoid round-edged punches except for the final draw.

The draw-ring radius for a circular die is principally governed by the thickness of the material to be drawn and the amount of reduction to be made. A general rule for light-gage material is to have the draw-ring radius from 5 to 12 times the thickness of the metal. Insufficient draw-ring radius may result in galling and excessive thinning of the wall.

Drawing Rectangular Shells. As with other materials, the depth to which rectangular shapes can be drawn in nickel-base alloys in one operation is principally governed by the corner radius. To permit drawing to substantial depths, the corner radii should be as large as possible. Even with large corner radii, the depth of draw should be limited to from two to five times the corner radius for alloys 400, 200, and 201, and to four times the corner radius for alloy 600 and alloy 75 (UNS N06075). The permissible depth also depends on the dimensions of the shape and on whether the shape has straight or tapered sides. The depth of draw for sheet less than 0.64 mm (0.025 in.) thick should not exceed an amount equal to three times the corner radius for alloys 400, 200, and 201 and should be less than that for alloy 600.

The corner radius on the drawing edge of the die should be as large as possible--approximately four to ten times the thickness of the material. To avoid wrinkles around the top corner of the shape, it is essential that the blank not be released prematurely.

In redrawing for the purpose of sharpening the corners or smoothing out wrinkles along the sides, only a small amount of metal should be left in the corners.

Frequently, it is necessary to draw shapes on dies designed to make a deeper single draw than is practical for nickel-base alloys. With such dies, the general practice is to draw about two-thirds of the full depth, to anneal the shape after this draw, and to complete the draw to full depth on the same dies. This same practice can be used to avoid wrinkling in drawing to lesser depths.

More information on the deep-drawing process is available in the article "Deep Drawing" in this Volume.

R. William Breitzig, INCO Alloys International, Inc.

Spinning

Power spinning is preferred over manual spinning for nickel-base alloys (see the article "Spinning" in this Volume). However, thin material, particularly alloys 200 and 400, can be manually spun with no difficulty. Table 2 gives practical limits on blank thickness for manual spinning of seven nickel-base alloys.

Table 2 Maximum blank hardness and thickness for manual spinning of nickel-base alloys

Alloy	**Maximum hardness, HRB**	Maximum thickness	
		mm	in.
Nickel 200	64	1.57	**0.062**
Nickel 201	55	1.98	**0.078**
Alloy 400	68	1.27	**0.050**
Alloy 600	80	0.94	**0.037**
Alloy 722	94	0.94	**0.037**
Alloy X-750	94	0.94	**0.037**

Alloy 801	**88**	**0.94**	**0.037**

Tools. Except for small, light shapes, the required pressure cannot be exerted with the ordinary bar or hand tool pivoted on a fixed pin. Most shapes require the use of a tool that is mechanically adapted for the application of greater force, such as a compound-lever tool or roller tools that are operated by a screw. For small jobs, a ball-bearing assembly can be used on the end of a compound lever to make a good roller tool. Roller tools should be used whenever practical in order to keep friction at a minimum and exert maximum pressure. Roller tools should also be used to perfect contours in the spinning of press-drawn shapes.

When possible, tools used for spinning nickel-base alloys should be broader and flatter than those used for softer materials. The broader tool distributes plastic flow over a greater area and reduces overstraining. Except for this consideration, bar and roller tools should be designed the same as those used for spinning copper or brass.

Correct tool materials are essential for successful spinning. The most suitable material for bar tools is a highly polished, hard alloy bronze. Hardened tool steels are preferred for roller and beading tools. Chromium-plated hardened tool steel is recommended, as it decreases metal pickup by the tool. Tools of common brass and carbon steel, which are used for spinning softer materials, are unsatisfactory for use with nickel-base alloys.

Rotary cutting shears are preferred for edge trimming. If rotary shears are not available, hand trimming bars hard faced with cobalt-base alloy may be used, but the trimming speed must be reduced. Hand trimming bars should be ground so that they have a back-rake angle of 15° to 20° from the cutting edge, and the edge must be kept sharp. A tool shaped like a thread-cutting lathe tool can be used for trimming. This tool also has a back rake from the cutting edge. With this type of tool, the material is not sheared off the edge; instead, the tool is fed into the side of the workpiece, and a narrow ring is cut from the edge. The workpiece should be supported at the back during all trimming operation.

Mandrels. Hardened alloy cast iron and steel mandrels give longer life and better results than softer materials such as wood. Hard maple or birch mandrels may be used for intermediate operations if production quantities are small and tolerances are liberal.

Spinning nickel-base alloys over mandrels that are the same as those used for copper alloys will not necessarily result in spun shapes of exactly the same dimensions as those of the softer metal. Most nickel-base alloy shapes will have slightly larger peripheries than those of softer metals spun over the same mandrel. This is caused by the greater springback of the nickel-base alloys.

Lubricants. Heavy-bodied, solid lubricants, such as yellow laundry soap, beeswax, and tallow, are recommended for spinning. These lubricants can be manually applied to the blank as it rotates. Blanks can be electroplated with 5 to 18 μm (0.2 to 0.7 mils) of copper to improve lubrication on difficult shapes.

Procedure for spinning nickel-base alloys is essentially the same as that used for other metals (see the article "Spinning" in this Volume).

As a general rule, in laying out a spinning sequence for alloy 400, an increase in height of 25 to 38 mm (1 to $1\frac{1}{2}$ in.) on the article being spun constitutes an operation if spinning is being done in the usual way with a bar tool. Approximately twice that depth per operation may be obtained with a compound-lever or roller tool. The workpiece should be trimmed and annealed before it is spun to greater depths.

A hard-surfaced mandrel should be provided for each operation so that the metal can always be pushed firmly against the surface of the mandrel. This procedure keeps the workpiece surface smooth and dense, and ensures the best results in annealing. With an insufficient number of intermediate mandrels, the material is subjected to an excessive amount of cold working. This may result in either spinning a buckle into the material or formation of a pebbled surface. It is virtually impossible to smooth out the former by additional cold work, or to correct the latter by annealing.

Figure 2 illustrates the number of mandrels and annealing operations necessary for spinning deep cups from 0.94 mm (0.037 in.) thick alloy 200, 400, and 600 blanks using hand tools. Figure 2 also shows the amount of forming that can be done before annealing and between intermediate anneals. The spinnability of other alloys can be estimated from their relative work-hardening rates (Fig. 1) and from their tensile properties.

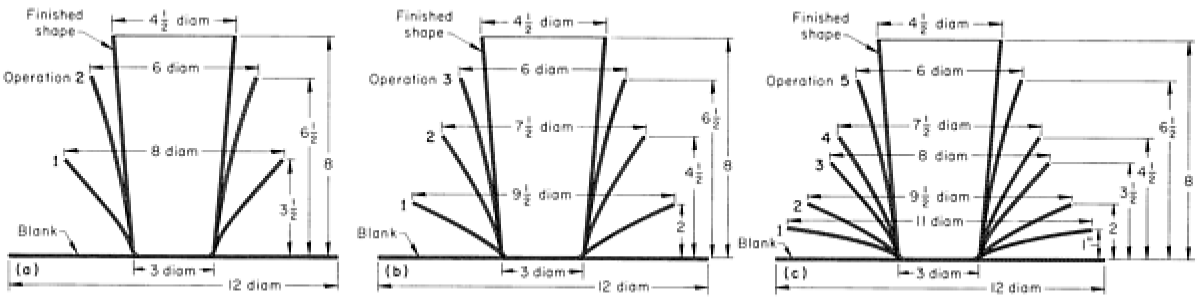

Fig. 2 Spinnability of three nickel-base alloys, as shown by the number of operations required for manual spinning of a deep cup from a 0.94 mm (0.037 in.) thick blank of each alloy. Workpieces were annealed between all operations. Dimensions given in inches. (a) Alloy 200. (b) Alloy 400. (c) Alloy 600.

In spinning, the optimum speed of the rotating blank is governed by its diameter and thickness. Small, thin blanks can be spun at greater speeds than larger or thicker pieces. Nickel-base alloys are often spun at speeds of one-half to three-fourths those normally used in spinning the same shape from softer metals. Lathe speeds of 250 to 1000 rpm are usually satisfactory. Trimming speeds must necessarily be slow; ordinarily, trimming is done at the minimum speed of the lathe.

Forming of Nickel-Base Alloys

R. William Breitzig, INCO Alloys International, Inc.

Bending Tube and Pipe

All common forming operations such as bending, coiling, and expanding can be performed readily on nickel-base alloy tube and pipe, using the same type of equipment as is used for other metals (see the article "Bending and Forming of Tubing" in this Volume). In general, material in the annealed condition is recommended. Alloys 400, 200, and 201 can be formed in the stress-relieved temper; however, the amount of deformation will be limited by the higher tensile strength and lower ductility. In bending, the minimum radius to which stress-relieved tubing can be bent is 25 to 50% greater than it is for annealed tubing of the same size.

The minimum radii to which nickel-base alloy tubing can be bent by various methods are given in Table 3. Depending on equipment design, tube size, and quality of the finished bend, it is possible to bend to smaller radii than those listed; however, trial bends should be made to determine whether the smaller radii are practicable.

Table 3 Minimum bend radii for nickel-base alloy tubes

Bending method	**Minimum mean bend radius[(a)]**	Maximum included angle of bend, degrees
Press bending, unfilled tube	6*D*	**120**
Roll bending, filled tube	4*D*	**360**
Compression bending		

Unfilled tube	2.5*D*	**180**
Filled tube(b)	2*D*	**180**
Draw bending		
Unfilled tube	3*D*	**180**
Filled tube(b)	**2*D***	**180**

(a) *D,* tube outside diameter.

(b) Or using mandrel

Bending Without Mandrels or Filler. When bending with no internal support, the dies should be slightly smaller than those used for bending with a mandrel or filler. Bending without use of a mandrel or filler is suitable only for tube and pipe that have a wall thickness greater than 7% of the outside diameter, or for large-radius bends. Nickel-base alloy tube in sizes within the above ratio can be bent with no mandrel or filler to a minimum mean radius of three times the outside diameter of the tube (3*D*) through 180°.

Bending With Mandrels or Fillers. Thin-wall tubing can be bent to small radii with freedom from wrinkles by use of a mandrel or filler. Thin-wall tubing of nickel alloys can be mandrel-bent through 180° to a minimum mean radius of 2*D.*

To minimize galling of the inside surface of the tube, mandrels should be made of hard alloy bronze rather than of steel. If steel mandrels are used, they should be chromium plated to reduce galling.

Mandrels must be lubricated before use; chlorinated oils with extreme-pressure (EP) additives are recommended for severe bending. For less severe bending or for ease of removal, water-soluble lubricants are used.

Any conventional filler material, such as sand, resin, and low-melting alloys, can be used. Sand is the least desirable because it is difficult to pack tightly and thus can lead to the formation of wrinkles or kinks during bending.

Low-melting alloy fillers produce the best bends. The expansion characteristics of these fillers ensure that voids are eliminated and a sound carrier is created.

Alloy fillers are removed by heating the bent tube in steam or hot water. Metallic fillers must not be removed by direct torch heating, because they contain elements such as lead, tin, and bismuth that will embrittle nickel alloys at elevated temperatures. It is imperative that all traces of metallic fillers be removed if the tube is to be subjected to elevated temperatures during subsequent fabrication or during service.

Press Bending. Press or ram bending, in which the tube is held by two supporting dies and a force is applied between the dies, is normally used only for heavy-wall tubing in which some flattening is tolerable. This method does not provide close tolerances and is applicable only to large-radius bends. The bend is limited to 120°, and the radius of the bend should not be less than six times the outside diameter of the tube (6*D*) if a smooth bend is desired. A filler material should be used for bends of radii less than 6*D.*

Pressure dies used in press bending should be at least two times longer than the outside diameter of the tube. Press bending with wing dies is used for unfilled, thin-wall, large-diameter tube.

Annealed tubing is not always preferred for press bending. Annealed tubing of low base hardness is not stiff enough to withstand deformation without excessive flattening. Consequently, nickel and nickel-copper alloys are usually press-bent in the stress-relieved temper. Nickel-chromium alloys have higher mechanical properties in the annealed condition than do nickel and nickel-copper alloys and should be press-bent in the annealed temper. Ideally, the choice of temper for a specific bend should be determined from the results of several trial bends.

Roll bending is the principal method of producing helical coils, spirals, and circular configurations because an included angle of 360° can be obtained. Bending may be done on either unfilled or filled tube. The minimum bend radius that can be attained on unfilled tube is approximately six times the outside diameter of the tube.

Compression bending uses a stationary bending form and a movable wiper shoe. This method is unsuitable for thin-wall tubing and is generally used with no mandrel support.

Compression bending can produce bend radii down to $2\frac{1}{2}D$ but is normally used only for large-radius bends. The maximum included angle that can be produced is 180°.

Draw bending is the most common bending process and the preferred method for bending nickel-base alloy tube. The process is similar to compression bending, except that the bending form revolves and the pressure die either remains stationary or slides along a straight line. The sliding pressure die is preferred, because it distributes the applied stresses more evenly.

Bends of up to 180° with a minimum radius of $2D$ can be produced by draw bending. Bending can be done with or without a mandrel. In general, a mandrel is preferred and must be used when the ratio of tube diameter to wall thickness is above the limit suitable for bending without tube wrinkling or collapsing. Various types of mandrels are used, including ball and plug types.

Hot Bending. When possible, tube and pipe should be formed by cold bending. If hot bending is necessary, it is performed by standard hot bending methods.

Hot bending is normally limited to tube and pipe larger than 2 in. schedule 80 (60.5 mm, or 2.375 in., OD and 5.54 mm, or 0.218 in., wall thickness). Thin-wall tubing should not be bent hot, because it is difficult to retain sufficient heat to make the bend.

Hot bending should be done on filled tube only. Sand is the normal filler material. The sand must be free of sulfur, because contamination of nickel-base alloys by sulfur causes cracking during bending. Sulfur can be removed from sand by heating to about 1150 °C (2100 °F) in an oxidizing atmosphere. Tubing must be cleaned thoroughly before filling or heating.

Sand-filled tube and pipe in small sizes (60.2 to 72.9 mm, or 2.37 to 2.87 in., OD) can be bent hot to a minimum mean radius of two times the outside diameter of the tube. Larger sizes require greater bend radii.

In hot bending, the metal should be worked as soon as possible after removal from the furnace, to avoid cooling before bending is completed.

Forming of Nickel-Base Alloys

R. William Breitzig, INCO Alloys International, Inc.

Bending of Plate, Sheet, and Strip

Table 4 lists minimum, bend diameters for hot-rolled and annealed nickel-base alloy sheet, plate, and strip. In compiling these data, a sample was judged to have passed the 180° bend test if its surface showed no ductile fracturing. Because of the effects of various surface conditions and heat treatments on bendability, the data in Table 4 should be regarded as general guidelines. Many of the materials can in fact be bent in stages to tighter radii than those suggested provided initial bending is not too severe.

Table 4 Minimum bend diameters for annealed sheet and strip and hot-rolled, annealed plate

Alloys were bent 180°; minimum bend diameters are given in terms of material thickness.

Alloy	**Product form**	**Thickness, *t***		Minimum bend diameter[(a)]
		mm	**in.**	
Nickel 200	Sheet, strip	0.30-6.35	0.012-0.250	**1*t***
	Plate	4.75-6.35	0.187-0.250	**2*t***
Alloy 400	Sheet, strip	0.30-2.77[(b)]	0.012-0.109[(b)]	**1*t***
		2.79-6.35	0.110-0.250	**2*t***
	Plate	4.75-6.35[(c)]	0.187-0.250[(c)]	**2*t***
Alloy 600	Sheet, strip	0.30-6.35	0.012-0.250	**1*t***
	Plate	4.75-6.35	0.187-0.250	**2*t***
Alloy 625[(d)]	Sheet, strip	0.30-6.35	0.012-0.250	**2*t***
	Plate	4.75-6.35	0.187-0.250	**2*t***
Alloy 718[(d)]	Sheet, strip	0.30-1.24	0.012-0.049	**1*t***
		1.27-6.35	0.050-0.250	**2*t***
Alloy X-750	Sheet, strip	0.30-1.24	0.012-0.049	**1*t***
		1.27-6.35	0.050-0.250	**2*t***
Alloy 800	Sheet, strip	0.30-6.35[(b)]	0.012-0.250[(b)]	**1*t***
	Plate	4.75-6.35[(b)]	0.187-0.250[(b)]	**2*t***
Alloy 825	Sheet, strip	0.30-6.35[(b)]	0.012-0.250[(b)]	**2*t***
	Plate	**4.75-6.35[(b)]**	**0.187-0.250[(b)]**	**2*t***

(a) Bend tests performed according to ASTM E 290 with a guide bend jig as described in ASTM E 190.

(b) Successful bending depended on surface condition of the samples, with particular regard to freedom from oxidation.

(c) Samples were descaled.

(d) Sheared edges were ground or machined.

The importance of surface condition is demonstrated by the alloys from which scale or oxides must be removed to ensure successful bending. As indicated in Table 4, scale can be removed either by chemical or mechanical means depending on the alloy.

Forming of Nickel-Base Alloys

R. William Breitzig, INCO Alloys International, Inc.

Expanding

Nickel-base alloy tubing can be expanded into tube sheets for heat exchanger applications by any conventional method. The oversize allowance on tube sheet holes to the nominal outside diameter of the tube should be kept to a minimum. The tube sheet hole should be 0.10 to 0.20 mm (0.004 to 0.008 in.) larger than the nominal outside diameter of the tube for tubing less than 38 mm ($1\frac{1}{2}$ in.) in outside diameter. For tubing 38 mm ($1\frac{1}{2}$ in.) or larger in outside diameter, the oversize allowance should be 0.23 to 0.25 mm (0.009 to 0.010 in.).

Procedure. Expanding may be done by drifting with sectional expanders or by rolling with three-roll expanders. Three-roll expanders are preferred. The ends of rolled-in tubing are flared in the conventional manner.

The tube sheet hole and both the outside and inside surfaces of the tube must be free of all foreign matter such as oxides, dirt, and oil. The ends of the tube should also be deburred before rolling.

Lubrication should be provided between the rollers of the tool and the inside surface of the tube. Any sulfur-free mineral oil or lard oil, either diluted or straight, can be used. Lubricants that contain embrittling or contaminating elements such as sulfur or lead should be avoided, because of the difficulty in cleaning the finished assembly.

Controlled rolling equipment should be used to prevent overexpanding, which may distort the tube sheet and deform the tube sheet ligaments, causing loose-fitting tubes. This is particularly true when the tube has a higher hardness than the tube sheet or a significantly higher rate of work hardening.

Temper. The tube sheet should be harder than the tube being rolled into it. Otherwise, springback in the tube may be greater than in the tube sheet, causing a gap between the two when the expanding tool is removed. For this reason, tube sheets are usually supplied in the as-rolled or as-forged temper and tube is supplied in the annealed temper. The need for the tube sheet to be harder than the tube is greatest when the thickness of the tube sheet is less than the outside diameter of the tube, and when the center-to-center spacing of the tubes (tube pitch) is less than $1\frac{1}{4}$ times the outside diameter of the tube or the outside diameter plus 6.4 mm ($\frac{1}{4}$ in.), whichever is greater.

Stress-relieved tubing may be slightly harder than the tube sheet but can be expanded to form a satisfactory connection if greater care is exercised in expanding. For greater assurance of pressure tightness, a seal weld may be placed around the end of the tube after expanding. The stress-relieved temper is suitable for either welding or silver brazing.

Tubing in the annealed condition is used when optimum rolling or expanding characteristics are desired or for severe cold bending and flaring.

Forming of Rod and Bar

Rod and bar in the annealed condition are preferred for cold forming. Material in other tempers may be required for some forming operations or when properties that cannot be obtained by heat treatment after forming are desired in the end product.

Bending. Rod and bar may be bent in the same manner as tubing. The possibility of collapsing or wrinkling is eliminated, because the solid section provides its own internal support.

Most nickel-base alloys have suitable mechanical properties in the hot-finished condition for moderate bending. The annealed temper should always be used for extremely small-bend radii or low radius-to-thickness ratios. Cold drawn, annealed material should be used if surface roughening (orange peeling) related to coarse grain structure is undesirable.

Coiling of rod and bar is limited almost entirely to the production of springs. Nickel-base alloy springs for high-temperature service are usually annealed or solution treated and aged after forming. Consequently, they may be produced from annealed material (or even produced by hot coiling) with no adverse effect on final properties.

If the desired properties cannot be obtained by heat treating after forming, the spring must be coiled from tempered, cold-worked material. The use of tempered material greatly increases the minimum radius to which the rod or bar can be coiled.

Pressures and speeds encountered in production coiling usually require the use of high-grade lubricants with good film strength. Wire rod is often coated with copper to reduce friction and improve retention of organic lubricants.

The severe cold forming involved in producing coils and the severe service conditions in which these products are often used demand a high-grade starting product. Centerless-ground or ground and cold-drawn material is used to obtain the necessary quality.

Forming of Nickel-Base Alloys

R. William Breitzig, INCO Alloys International, Inc.

Cold Heading and Cold Extrusion

Cold heading and cold extrusion are most often used in the production of fasteners and similar cold upset parts. Cold extrusion is rarely done except in conjunction with cold heading.

The high strength and galling characteristics of nickel-base alloys require slow operating speeds and high-alloy die materials. Cold heading machines should be operated at a ram speed of about 10 to 15 m/min (35 to 50 ft/min). These ram speeds correspond to operating speeds of 60 to 100 strokes per minute on medium-size equipment.

Tools should be made of oil-hardening or air-hardening die steel. The air-hardening types, such as AISI D2, D4, or high-speed steel (M2 or T1), tempered to 60 to 63 HRC, are preferred.

Material. Rod stock (usually less than 25 mm, or 1 in., in diameter) in coils is used for starting material, as cold heading is done on high-speed automatic or semiautomatic equipment. Although alloy 400 is sometimes cold headed in larger sizes, 22 mm ($\frac{7}{8}$ in.) is the maximum diameter in which alloys 400 and K-500 can be cold headed by most equipment. Limiting sizes in harder alloys are proportionately smaller, depending on their hardness and yield strength in the annealed condition. Stock sizes in excess of these limits are normally hot formed.

Cold-heading equipment requires wire rod with diameter tolerances in the range of 0.076 to 0.127 mm (0.003 to 0.005 in.). Because alloy 400 should be cold headed in the 0 or No. 1 temper to provide resistance to crushing and buckling during forming, these tolerances can normally be obtained with the drawing pass used to develop this temper. For tighter tolerances or harder alloys, fully cold-drawn material must be used.

The surface quality of regular hot-rolled wire rod, even with a cold sizing pass, may not be adequate for cold heading. Consequently, a special cold heading quality wire rod is usually recommended. Configurations that are especially susceptible to splitting, such as rivets, flat-head screws and sockethead bolts, require shaved or centerless-ground material.

Lubricants. To prevent galling, high-grade lubricants must be used in cold heading of nickel-base alloys.

Lime and soap are usually used as a base coating on alloy 400. Better finish and die life can be obtained by using copper plating 7.5 to 18 μm (0.3 to 0.7 mils) thick as a lubricant carrier. Copper plating may be used also on the chromium-containing alloys 600 and 800, but oxalate coatings serve as an adequate substitute.

Regardless of the type of carrier, a base lubricant is best applied by drawing it on in a light sizing pass to obtain a dry film of the lubricant. Any of the dry soap powders of the sodium, calcium, or aluminum stearate types can be applied this way.

If the wire rod is to be given a sizing or tempering pass before the cold-heading operations, the heading lubricant should be applied during drawing.

Lubrication for cold heading is completed by dripping a heavy, sulfurized mineral oil or a sulfurized and chlorinated paraffin on the blank as it passes through the heading stations.

R. William Breitzig, INCO Alloys International, Inc.

Straightening

Rod and bar in straight lengths are usually straightened by conical rolls, stretchers, or punch presses. Material in coil form is straightened with staggered-roll straighteners or rotating-die straighteners.

Like other forming equipment, straighteners require about 50% more power for nickel-base alloys than they do for low-carbon steel; a straightener having a capacity of 12.7 mm ($\frac{1}{2}$ in.) diameter in steel will be limited to about 9.5 mm ($\frac{3}{8}$ in.) diam in nickel alloys.

A lubricant should be used with rotating-die straighteners to reduce scratching and scoring and to improve die life. Spiral scoring may become quite severe on large sizes of harder alloys. If scoring cannot be held to an acceptable level by the use of lubricants, material in the softest temper available should be used.

Staggered-roll straightening involves lower contact velocities than do rotating-die types, and lubrication is less critical. Coil stock is often straightened without lubricant, for better grip on rolls.

Dies for rotary-die straighteners may be either bronze or cast iron. Cast iron dies must be used if contamination from rubbed-off bronze occurs in the end product, and no pickling is done after straightening.

Forming of Nickel-Base Alloys

R. William Breitzig, INCO Alloys International, Inc.

Cold-Formed Parts for High-Temperature Service

A part that is highly stressed from cold forming may require heat treatment to avoid excessive creep in service above its recrystallization temperature. Recrystallization of a specific alloy is determined largely by the extent of cold work and the temperature to which the part is exposed during service. The grain size and exact composition of the material also complicate prediction of the recrystallization temperature.

The nickel-base alloys most likely to be subjected to high temperatures in service are the iron-nickel-chromium and nickel-chromium alloys (see Table 1). These alloys are frequently used in the grain-coarsened condition at service temperatures above 595 °C (1100 °F).

Generally, cold-formed nickel-base alloys should be heat treated if they have been strained in either tension or compression by more than 10% and will be subject to service temperatures above 650 °C (1200 °F). Producers should be consulted for the proper thermal treatments.

In certain alloys, heavy cold working (for example, highly restrained bending) followed by exposure at moderate to high temperatures (for example, stress relieving or age hardening) can lead to cracking. In age-hardenable alloys, for example, the combination of high residual tensile stress and the stress associated with the aging response may exceed the stress-rupture strength of the material. In nonage-hardenable alloys, excessive cold working of coarse-grain material (grain size of ASTM No. 5 or coarser) without the recommended intermediate annealing can cause cracking during subsequent exposure at stress-relieving or annealing temperatures. Testing the material under actual conditions of forming and heating will determine its susceptibility to cracking.

Springs can be cold formed from age-hardenable alloys in the annealed or cold-drawn temper. For service at temperatures above 315 °C (600 °F), springs should be solution annealed before aging to prevent loss of strength from relaxation.

Forming of Titanium and Titanium Alloys

Revised by the ASM Committee on Forming of Titanium Alloys*

Introduction

TITANIUM AND ITS ALLOYS can be formed in standard machines to tolerances similar to those obtained in the forming of stainless steel. However, to reduce the effect of springback variation on accuracy and to gain the advantage of increased ductility, the great majority of formed titanium parts are made by hot forming or by cold preforming and then hot sizing.

The following characteristics of titanium and titanium alloy sheet materials must be considered in forming:

- Notch sensitivity, which may cause cracking and tearing, especially in cold forming
- Galling (more severe than with stainless steel)
- Relatively poor ability to shrink (a disadvantage in some flanging operations)
- Potential embrittlement from overheating and from absorption of gases, principally hydrogen (scale and the surface layer adversely affected by the slower penetration of oxygen can be removed readily)
- Limited workability

- Higher springback than that encountered in ferrous alloys at the same strength level

However, as long as these limitations are recognized and established guidelines for hot and cold forming are followed, titanium and titanium alloys can be successfully formed into complex parts.

The mechanical properties, and therefore the formabilities, of titanium and its alloys vary widely. For example, the tensile strength of different grades of commercially pure (CP) titanium ranges from 240 to 550 MPa (35 to 80 ksi); correspondingly large differences in the minimum bend radius are obtainable at room temperature. The tensile strength and ductility of CP titanium are largely dependent on its oxygen content. Table 1 lists the common designations, compositions, and selected mechanical properties of some titanium alloys.

Table 1 Designations, nominal compositions, and selected mechanical properties of some titanium alloys

Forming of Titanium and Titanium Alloys

Revised by the ASM Committee on Forming of Titanium Alloys*

Titanium Materials

There are several grades of unalloyed titanium (see Table 1). The primary difference between the grades is in the amounts of interstitial elements (for example, oxygen and nitrogen) and iron. Grades of higher purity (lower interstitial content) are lower in strength, hardness, and transformation temperature than those higher in interstitial content. The high solubility of the interstitial elements oxygen and nitrogen makes titanium rather unique among metals and creates problems that are not of concern in most other metals. For example, heating titanium in air at high temperature results not only in oxidation but also in solid-solution hardening of the surface as a result of inward diffusion of oxygen. A surface-hardened zone (α case) is formed. This layer is usually removed by machining, chemical milling, or other mechanical means prior to placing a part in service because the presence of a case reduces fatigue strength and ductility.

Alloy Ti-6Al-4V is the most widely used titanium alloy, accounting for about 60% of total titanium production. Unalloyed grades constitute about 20% of production, and all other alloys make up the remaining 20%. Selection of an unalloyed grade of titanium, an α or near-α alloy, an α-β alloy, or a near-β or β alloy depends on desired mechanical properties, service requirements, cost considerations, and the other factors that enter into any material selection process.

Commercially pure titanium is usually selected for its excellent corrosion resistance, especially in applications in which high strength is not required. The yield strengths of CP grades (Table 1) vary from less than 170 to more than 480

MPa (25 to 70 ksi) simply as a result of variation in the interstitial and impurity levels. Oxygen and iron are the primary variants in these grades; strength increases with increasing oxygen and iron contents.

Alpha and Near-Alpha Alloys. Alpha alloys that contain aluminum, tin, and/or zirconium are preferred for high-temperature and cryogenic applications. Alpha-rich alloys are generally more resistant to creep at high temperature than α-β or β alloys. The extra-low-interstitial α alloys (ELI grades) retain ductility and toughness at cryogenic temperatures, and Ti-5Al-2.5Sn-ELI has been extensively used in such applications.

Unlike α-β and β alloys, α alloys cannot be strengthened by heat treatment. Generally, α alloys are annealed or recrystallized to remove residual stresses induced by cold working.

Alpha alloys that contain small additions of β stabilizers (for example, Ti-8Al-1V-1Mo or Ti-6Al-2Nb-1Ta-0.8Mo) are sometimes classed as near-α alloys (Table 1). Although they contain some retained β phase, these alloys consist primarily of α and behave more like conventional α alloys than α-β alloys.

Alpha-beta alloys contain one or more α stabilizers or α-soluble elements plus one or more β stabilizers. These alloys retain more β phase after final heat treatment than near-α alloys; the specific amount depends on the amount of β stabilizers present and on heat treatment.

Alpha-beta alloys can be strengthened by solution treating and aging. Solution treating is usually done at a temperature high in the two-phase α-β field and is followed by quenching in water, oil, or other suitable quenchant. As a result of quenching, the β phase present at the solution-treating temperature may be retained or may be partly transformed during cooling by either martensitic transformation or nucleation and growth. The specific response depends on alloy composition, solution-treating temperature (β-phase composition at the solution temperature), cooling rate, and section size. Solution treatment is then followed by aging, usually at 480 to 650 °C (900 to 1200 °F).

Solution treating and aging can increase the strength of α-β alloys 30 to 50%, or more, over the annealed or overage condition. Response to solution treating and aging depends on section size; alloys relatively low in stabilizers (Ti-6Al-4V, for example) have poor hardenability and must be quenched rapidly to achieve significant strengthening. For Ti-6Al-4V, the cooling rate of a water quench is not rapid enough to cause significant hardening of sections thicker than about 25 mm (1 in.). Hardenability increases as the content of β stabilizers increases.

Beta alloys are richer in β-phase stabilizers and leaner in α stabilizers than α-β alloys. They are characterized by high hardenability, with β phase completely retained upon the air cooling of thin sections or the water quenching of thick sections. Beta alloys in sheet form can be cold formed more readily than high-strength α-β or α alloys. An example of this is the Ti-15V-3Sn-3Cr-3Al alloy, which is formed almost exclusively at room temperature. After solution treating, β alloys are aged at temperatures of 450 to 650 °C (850 to 1200 °F) to partially transform the β phase to α. The α forms as finely dispersed particles in the retained β, and strength levels comparable to or superior to those of aged α-β alloys can be attained.

In the solution-treated condition (100% retained β), β alloys have good ductility and toughness, relatively low strength, and excellent formability. Solution-treated β alloys begin to precipitate α phase at slightly elevated temperatures and are therefore unsuitable for elevated-temperature service without prior stabilization or overaging treatment.

Forming of Titanium and Titanium Alloys

Revised by the ASM Committee on Forming of Titanium Alloys*

General Formability

Titanium and titanium alloy sheet is strain hardened by cold forming. This normally increases tensile and yield strengths and causes a slight drop in ductility. Titanium metals exhibit a high degree of springback in cold forming. To overcome this characteristic, titanium must be extensively overformed or, as is done most frequently, hot sized after cold forming.

Hot forming does not greatly affect final properties. Forming at temperatures ranging from 595 to 815 °C (1100 to 1500 °F) allows the material to deform more readily and simultaneously stress relieves the deformed material; it also minimizes springback. The net effect in any forming operation depends on total deformation and actual temperature during forming. Because titanium metals tend to creep at elevated temperature, holding under load at the forming temperature (creep forming) is another alternative for achieving the desired shape without the need to compensate for extensive springback.

The Bauschinger Effect. In all forming operations, titanium and its alloys are susceptible to the Bauschinger effect--a drop in compressive yield strength subsequent to tensile straining in the same or another direction. The Bauschinger effect, unlike the strain-hardening behavior observed in other metals, involves stress-strain asymmetry that results in hysteretis stress-strain loops such as those shown schematically in Fig. 1. The Bauschinger effect is most pronounced at room temperature; plastic deformation (1 to 5% tensile elongation) at room temperature always introduces a significant loss in compressive yield strength, regardless of the initial heat treatment or strength of the alloys. At 2% tensile strain, for example, the compressive yield strength of Ti-6Al-4V drops to less than one-half the value for solution-treated material. Increasing the temperature reduces the Bauschinger effect; subsequent full thermal stress relieving completely removes it.

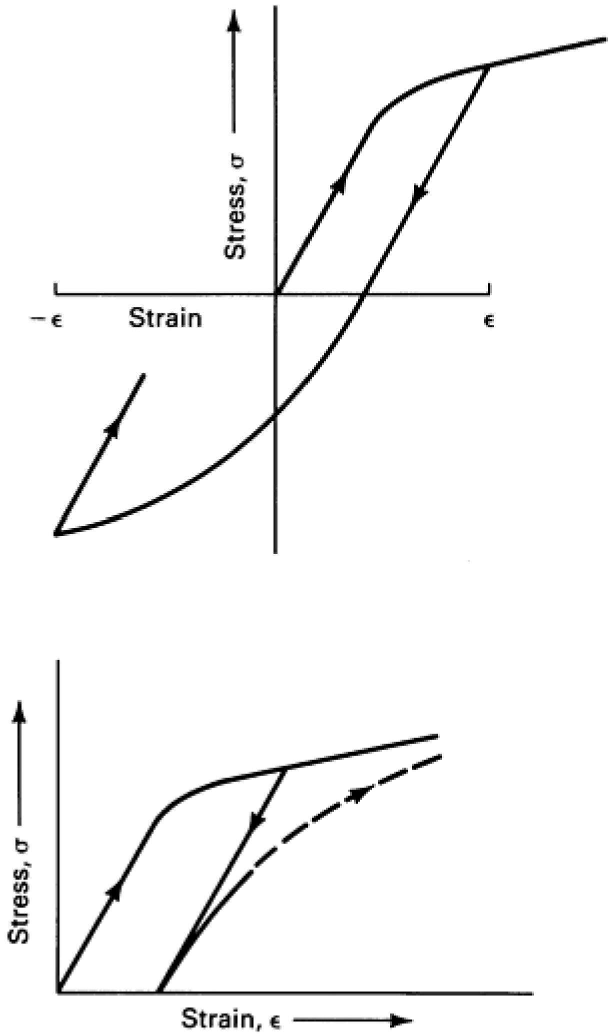

Fig. 1 Schematics showing two types of hysteresis stress-strain loops resulting from the Bauschinger effect in titanium alloys. Source: Ref 1.

Temperatures as low as the aging temperature will remove most of the Bauschinger effect in solution-treated titanium alloys. Heating or plastic deformation at temperatures above the normal aging temperature for solution-treated Ti-6Al-4V will cause overaging; as a result, all mechanical properties will decrease.

Forming of Titanium and Titanium Alloys

Revised by the ASM Committee on Forming of Titanium Alloys*

Preparation of Sheet for Forming

Before titanium sheet is formed, it should be inspected for flatness, uniformity, and thickness. Some plants test incoming material for hardness, strength, and bending behavior.

Critical regions of titanium sheet should not be nicked, scratched, or marred by tool or grinding marks, because the metal is notch sensitive. All scratches deeper than the finish produced by 180-grit emery should be removed by sanding the surface. Edges of the workpieces should be smooth, and scratches, if any, should be parallel to the edge of the blank to prevent any concentration of stress that could cause the workpiece to break. To prevent difficulty in forming, as by increased notch sensitivity, surface oxide or scale should be removed before forming.

Cleaning. Grease, oil, stencils, fingerprints, dirt, and all chemicals or residues that contain halogen compounds must be removed from titanium before any heating operation. Salt residues on the surface of the workpiece can cause hot-salt cracking in service or in heat treating; even the salt from a fingerprint can cause problems. Therefore, titanium is often handled with clean cotton gloves after cleaning and before hot forming, hot sizing, or heat treatment.

Ordinary cleaners and solvents such as isopropyl alcohol and acetone are used on titanium. Halogen compounds, such as trichlorethylene, should not be used, unless the titanium is pickled in acid after cleaning.

Titanium that has been straightened or formed with tools made of lead or low-melting alloy should be cleaned in nitric acid. Detailed information on the cleaning of titanium is given in the article "Surface Engineering of Titanium and Titanium Alloys" in *Surface Engineering,* Volume 5 of the *ASM Handbook.*

Removal of Tool Marks. Tool and grinding marks in titanium can be moderated in an aqueous acid bath containing (by volume) 30% concentrated nitric acid and not more than 3% hydrofluoric acid. Failure to keep the ratio of nitric to hydrofluoric acid at 10 to 1 or greater (to suppress the formation of hydrogen gas during pickling), or the use of any pickling bath that produces hydrogen, can result in excessive hydrogen pickup. The acid bath should remove 0.025 to 0.075 mm (0.001 to 0.003 in.) of thickness from each surface to eliminate the marks made by abrasives. Titanium should be washed or cleaned before it is immersed in acid.

Removal of Scale. Heavy gray and black scale and similar hard oxides that form on titanium at temperatures of 540 °C (1000 °F) and higher can be removed chemically or by wet or dry mechanical methods that use fine abrasives. Wire brushing and coarse abrasives are generally not used, because they can leave stress-raising marks; if these techniques are used, the damaged surface layer can be removed by pickling in nitric-hydrofluoric acid, as described above.

Thin oxides that form at temperatures below 540 °C (1000 °F) can be removed by acid pickling. Very tenacious oxides may require gritblasting prior to pickling.

Tool Materials and Lubricants

Tool materials for forming titanium are chosen to suit the forming operation, forming temperature, and expected quantity of production. The cost of tool material is generally only a small fraction of the cost of tools, unless forming temperature is such that heat-resistant alloy tooling is required.

Cold forming can be done with epoxy-faced aluminum or zinc tools. Hot-forming tools are fabricated from ceramic, cast iron, tool steel, stainless steel, and nickel-base alloys.

Tool materials for the superplastic forming of titanium alloys are a special case (see the section "Superplastic Forming" in this article). They must be able to withstand the high temperatures (870 to 925 °C, or 1600 to 1700 °F) required for superplastic forming, but must not contain more than about 6% Ni, because of the possibility of nickel migration into the work metal at superplastic forming temperatures. Cast ceramics, 22-4-9 stainless steel (Fe-0.5C-22Cr-9Mn-4Ni), and 49M steel are used for this purpose.

Lubricants. Galling is the most severe problem to be overcome in hot forming. Lubricants may react unfavorably with titanium when it is heated, although molybdenum disulfide suspended in a volatile carrier, colloidal graphite, and graphite-molybdenum disulfide mixtures have been successfully used. Boron nitride slurries also are used. If the lubricant reacts with oxidation products to produce a tenacious surface coating, it must be removed by sandblasting with garnet grit or 120-mesh aluminum oxide, followed by acid pickling.

Boron nitride is the preferred temperature-resistant lubricant because of its higher lubricity, as well as ease of application and removal. Other lubricants used for hot forming have a graphite or molybdenum disulfide base. Zinc phosphate conversion coatings are sometimes first produced on the work metal surface to aid in the retention of lubricants during severe forming.

Lubricants for the cold forming of titanium are generally similar to those used for the severe forming of aluminum alloys (see the articles "Forming of Aluminum Alloys" and "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume). Tool materials and lubricants for the cold and hot forming of titanium alloys are given in Table 2.

Table 2 Tool materials and lubricants used for forming titanium alloys

Operation(s)	**Tool materials**	Lubricants
Cold forming		
Press forming, drawing, drop hammer forming	Cast zinc die or lead punch with stainless steel caps	**Graphite suspension in a suitable solvent**
Press-brake forming	4340 steel (36-40 HRC)	**Graphite suspension in a suitable solvent**
Contour roll forming, three-roll forming	AISI O2 tool steel	**SAE 60 oil**
Stretch forming	Epoxy-faced cast aluminum, cast zinc, cast bronze	**Grease-oil mixtures, wax; 10:1 wax-graphite mixture**

Hot forming		
Press forming, drawing, drop hammer forming	High-silicon cast iron, stainless steels, heat-resistant alloys	**Graphite suspension, boron nitride**
Sizing	Low-carbon steel, high-silicon gray or ductile iron, AISI H13 tool steel, stainless steels, heat-resistant alloys	**Graphite suspension, boron nitride**
Press-brake forming	AISI H11 or H13 tool steel, heat-resistant alloys	**Graphite suspension, boron nitride**
Contour roll forming, three-roll forming	AISI H11 or H13 tool steel	**Graphite suspension, boron nitride**
Stretch forming	Cast ceramics, AISI H11 or H13 tool steel, high-silicon gray iron	**Graphite suspension, 10:1 wax-graphite mixture, boron nitride**
Superplastic forming	**Ceramics, 22-4-9 stainless steel, 49M heat-resistant steel**	**Boron nitride**

Forming of Titanium and Titanium Alloys

Revised by the ASM Committee on Forming of Titanium Alloys*

Blank Preparation

Most blanking of titanium alloy sheet 6.4 mm ($\frac{1}{4}$ in.) thick or less is done in a punch press. As with other metals, maximum blank size depends on stock thickness, shear strength, and available press capacity.

Dies must be rigid and sharp to prevent cracking of the work metal. Hardened tool steel must be used for adequate die life.

In one application, holes 6.35 mm (0.25 in.) in diameter were punched in 1.02 to 3.56 mm (0.040 to 0.140 in.) thick annealed alloy Ti-6Al-4V sheet to within ±0.051 mm (±0.002 in.) of diameter and with surface roughness of less than 1.3 μm (50 μin.). The best holes were produced with flat-point punches having 0.025 mm (0.001 in.) die clearance.

Shearing. Titanium sheet up to 3.56 mm (0.140 in.) thick can generally be sheared without difficulty; with extra care, titanium sheet as thick as 4.75 mm (0.187 in.) can be sheared. Shears intended for low-carbon steel may not have enough hold-down force to prevent titanium sheets from slipping. A sharp shear blade in good condition with a capacity for cutting 4.8 mm ($\frac{3}{16}$ in.) thick low-carbon steel can cut 3.2 mm ($\frac{1}{8}$ in.) thick titanium sheet. Cutters should be kept sharp to prevent edge cracking of the blank.

Sheared edges, especially on thicker work metal, can have straightness deviations of 0.25 to 5 mm (0.01 to 0.20 in.), usually because the shear blade is not stiff enough. Shearing can cause cracks at the edges of some titanium sheet thicker than 2.0 mm (0.080 in.). If cracks or other irregularities develop in a critical portion of the workpiece, an alternative method of cutting should be used, such as band sawing, abrasive waterjet cutting, or laser cutting (see the articles "Abrasive Waterjet Cutting" and "Laser Cutting" in this Volume).

Slitting of titanium alloy sheet can be done with conventional slitting equipment and with draw-bench equipment. Slitting shears are capable of straight cuts only; rotary shears can cut gentle contours (minimum radius: ~250 mm, or 10 in.). The process can be used for sheet thicknesses to 2.54 mm (0.100 in.). However, an individual machine must be restricted to titanium thicknesses of low-carbon steel for which the machine is rated.

Band sawing prevents cracking at the edges of titanium sheet but causes large burrs. Band sawing is generally used to cut titanium sheet that is 3.18 mm (0.125 in.) or more in thickness.

Nibbling can be used to cut irregular blanks of titanium, but most blanks need filing or grinding after nibbling.

Edge Preparation. All visual evidence of a sheared or broken edge on a part should be removed by machining, sanding, or filing before final deburring or polishing. All rough projections, scratches, and nicks must be removed. Extra material must be allowed at the edges of titanium blanks so that shear cracks and other defects can be removed. On sheared parts, a minimum of 0.25 mm (0.010 in.) must be removed from the edge; on punched holes, 0.35 mm (0.014 in.). On parts cut by friction band sawing or abrasive sawing, 6.35 mm (0.25 in.) or one thickness of sheet should be removed, whichever is the smaller.

The lay of the finish on the edges of sheet metal parts should be parallel to the edge surface of the blank, and sharp edges should be removed. Edges of shrink flanges and stretch flanges must be polished before forming. To prevent scratching the forming dies, edges of holes and cutouts should be deburred on both sides and should be polished where they are likely to stretch during forming.

Forming of Titanium and Titanium Alloys

Revised by the ASM Committee on Forming of Titanium Alloys*

Cold Forming

Commercially pure titanium and the most ductile titanium alloys, such as Ti-15V-3Sn-3Cr-3Al and Ti-3Al-8V-6Cr-4Zr-4Mo, can be formed cold to a limited extent. Alloy Ti-8Al-1Mo-1V sheet can be cold formed to shallow shapes by standard methods, but the bends must be of larger radii than in hot forming and must have shallower stretch flanges. The cold forming of other alloys generally results in excessive springback, requires stress relieving between operations, and requires more power. Titanium and titanium alloys are commonly stretch formed without being heated, although the die is sometimes warmed to 150 °C (300 °F). For the cold forming of all titanium alloys, formability is best at low forming speeds.

To improve accuracy, cold forming is generally followed by hot sizing. Hot sizing and stress relieving are ordinarily needed to reduce stress and to avoid delayed cracking and stress corrosion. Stress relief is also needed to restore compressive yield strength after cold forming. Hot sizing is often combined with stress relieving, with the workpiece being held in fixtures or form dies to prevent distortion. Stress-relief treatments for CP titanium and some titanium alloys are given in Table 3. Detailed information on the heat treatment of titanium alloys is available in the article "Heat Treating of Titanium and Titanium Alloys" in *Heat Treating*, Volume 4 of the *ASM Handbook.*

Table 3 Recommended stress-relief treatments for titanium and some titanium alloys

Alloy	**Temperature**		Time
	°C	**°F**	
CP titanium (all grades)	480-595	900-1100	**15 min-4 h**
α or near-α alloys			

Ti-5Al-2.5Sn	540-650	1000-1200	**15 min-4 h**
Ti-8Al-1Mo-1V	595-705	1100-1300	**15 min-4 h**
Ti-6Al-2Sn-4Zr-2Mo	595-705	1100-1300	**15 min-4 h**
Ti-6Al-2Nb-1Ta-0.8Mo	595-650	1100-1200	**15 min-2 h**
Ti-0.3Mo-0.8Ni (ASTM grade 12)	480-595	900-1100	**15 min-4 h**
α-β alloys			
Ti-6Al-4V	480-650	900-1200	**1-4 h**
Ti-6Al-6V-2Sn (Cu + Fe)	480-650	900-1200	**1-4 h**
Ti-3Al-2.5V	540-650	1000-1200	**30 min-2 h**
Ti-6Al-2Sn-4Zr-6Mo	595-705	1100-1300	**15 min-4 h**
β or near-β alloys			
Ti-13V-11Cr-3Al	705-730	1300-1350	**5-15 min**
Ti-11.5Mo-6Zr-4.5Sn (Beta III)	720-730	1325-1350	**5-15 min**
Ti-3Al-8V-6Cr-4Zr-4Mo (Beta C)	705-760	1300-1400	**10-30 min**
Ti-10V-2Fe-3Al	675-705	1250-1300	**30 min-2 h**
Ti-15V-3Al-3Cr-3Sn	**790-815**	**1450-1500**	**5-15 min**

The only true cold-formable titanium alloy is Ti-15V-3Sn-3Cr-3Al. Hot sizing is usually not used for this alloy; however, properties must be developed with an aging treatment (8 h at 540 °C, or 1000 °F, is typical). Because of the high springback rates encountered with this alloy, more elaborate tooling must be used.

Forming of Titanium and Titanium Alloys

Revised by the ASM Committee on Forming of Titanium Alloys*

Hot Forming

Heating titanium increases formability, reduces springback, takes advantage of a lesser variation in yield strength, and allows for maximum deformation with minimum annealing between forming operations. Severe forming must be done in hot dies, generally with preheated stock.

The greatest improvement in the ductility and uniformity of properties for most titanium alloys is at temperatures above 540 °C (1000 °F). At still higher temperatures, some alloys exhibit superplasticity (see the section "Superplastic Forming" in this article). However, contamination is also more severe at the higher temperatures. Above about 650 °C (1200 °F), forming should be done in vacuum or under a protective atmosphere, such as argon, to minimize oxidation.

As shown in Table 4, most hot-forming operations are done at temperatures above 540 °C (1000 °F). For applications in which the utmost in ductility is required, temperatures below 315 to 425 °C (600 to 800 °F) are usually avoided.

Table 4 Temperatures for the hot forming of titanium and some annealed titanium alloys

Alloy	Forming temperature	
	°C	°F
CP titanium (all grades)	480-705	**900-1300**
α and near-α alloys		
Ti-8Al-1V-1Mo	790 ± 15	**1450 ± 25**
Ti-5Al-2.5Sn	620-815	**1150-1500**
α-β alloys		
Ti-6Al-6V-2Sn	790 ± 15	**1450 ± 25**
β alloy		
Ti-13V-11Cr-3Al	**605-790**	**1125-1450**

Source: Ref 2

Temperatures generally must be kept below 815 °C (1500 °F) to avoid marked deterioration in mechanical properties. Superplastic forming, however, is performed at 870 to 925 °C (1600 to 1700 °F) for some alloys, such as Ti-6Al-4V. At these temperatures, care must be taken not to exceed the β transus temperature of Ti-6Al-4V. Heating temperature and time at temperature must be controlled so that the titanium is hot for the shortest time practical and the metal temperature is in the correct range.

Scaling and Embrittlement. Titanium is scaled and embrittled by oxygen-rich surface layers formed at temperatures higher than 540 °C (1000 °F). Generally, for heating in air, 1 h is the longest time at 705 °C (1300 °F) that should be permitted, and 20 min at 870 °C (1600 °F) should be the limit; these times are cumulative and include all time that the metal is at that temperature for all the operations on a given workpiece. The subsequent removal of scale and embrittled surface, or a protective atmosphere, should be considered for any heating above 540 °C (1000 °F). Argon gas is a commonly used atmosphere for superplastic forming.

Aging. Some hot-forming temperatures are high enough to age a titanium alloy. Heat-treatable β and α-β alloys generally must be reheat treated (solution annealed) after hot forming. Alpha-beta alloys should not be formed above the β transus temperature.

Because of aging, scaling, and embrittlement, as well as the greater cost of working at elevated temperatures, hot forming is ordinarily done at the lowest temperature that will permit the required deformation. When maximum formability is required, the forming should be done at the highest temperature practical that will retain the mechanical properties and serviceability required of the workpiece.

Tools. Titanium alloys are often formed hot in heated dies in presses that have a slow, controlled motion and that can dwell in the position needed during the press cycle. Hot forming is sometimes done in dies that include heating elements or in dies that are heated by the press platens. Press platens heated to 650 °C (1200 °F) can transmit enough heat to keep the working faces of the die at 425 to 480 °C (800 to 900 °F). Other methods of heating include electrical-resistance heating and the use of quartz lamps and portable furnaces.

Accuracy. Hot forming has the advantage of improved uniformity in yield strength, especially when the forming or sizing temperature is above 540 °C (1000 °F). However, care must be taken to limit the accumulation of dimensional errors resulting from:

- Differences in thermal expansion
- Variations in temperature
- Dimensional changes from scale formation
- Changes in dimensions of tools
- Reduction in thickness from chemical pickling operations

Hot Sizing

Hot sizing is used to correct inaccuracies in shape and dimensions in cold preformed parts. Hot sizing uses the creep-forming principle to force irregularly shaped parts to assume the correct shape against a heated die by the controlled application of horizontal and vertical forces over a period of time. Buckles and wrinkles can be removed from preforms in this way. A combination of creep and compression forming is used when reducing bend radii by hot sizing.

Hot sizing is used to correct for springback in parts formed by other methods. The correction of springback depends on time and temperature; the higher the temperature, the shorter the time for processing. However, the effect of temperature on the properties of the metal limits the maximum useful temperature. The pressure applied to the part during hot sizing should be high enough to keep the part firmly against the fixture or die. Any additional pressure above the clamping requirement has no effect on the part and can cause deformation of the tooling.

Hot platen presses are commonly used for the hot sizing of titanium. The tooling is designed for the hot sizing of preforms; that is, it must only hold the workpiece to the required shape for the necessary time at temperature. Hot sizing in hot platen presses is done in the following sequence of operations:

- The preformed parts are loaded on hot form blocks that are heated by the platen in the press

- The press is closed, and it heats the parts without applying the forming force
- Force is applied by the upper platen and auxiliary side rams, and is held as long as necessary to complete the forming

---

Forming of Titanium and Titanium Alloys

Revised by the ASM Committee on Forming of Titanium Alloys*

Superplastic Forming

The superplastic forming of titanium is currently being used to fabricate a number of sheet metal components for a range of aircraft and aerospace systems. Hundreds of parts are in production, and significant cost savings are being realized through the use of superplastic forming. Other advantages of superplastic forming over other forming processes include the following:

- Very complex part configurations are readily formed
- Lighter, more efficient structures are possible
- It is performed in a single operation, reducing fabrication labor time
- Depending on part size, more than one piece can be produced per machine cycle
- The force needed for forming is supplied by a gas, resulting in the application of equal amounts of pressure to all areas of the workpiece

The limitations of the process include:

- Heat-resistant tool materials that contain minimal amounts of nickel are required
- Equipment requirements are extensive
- Long preheat times are necessary to reach the forming temperature
- A protective atmosphere, such as argon, is required

Several processes are used in the superplastic forming of titanium alloys. Among these are blow forming, vacuum forming, thermo-forming, deep drawing, and superplastic forming/diffusion bonding (see the section "Superplastic Forming/Diffusion Bonding" in this article). All of these processes are discussed in more detail in the article "Superplastic Sheet Forming" in this Volume.

Superplastic Titanium Alloys

The workhorse superplastic titanium alloy is Ti-6Al-4V, and the state-of-the-art in titanium superplastic forming is largely based on this alloy. However, a number of titanium alloys, especially the α-β alloys, exhibit superplastic behavior. Many of these materials, such as Ti-6Al-4V, are superplastic without special processing. Table 5 illustrates the superplastic behavior of some titanium alloys and lists the characteristics used to describe superplastic properties in engineering alloys: strain rate sensitivity factor *m* and tensile elongation. The *m* value is a measure of the rate of change of flow stress with strain rate; the higher the *m* value of an alloy, the greater its superplasticity. Titanium alloys that have exhibited superplasticity but are not listed in Table 5 include Ti-3Al-2.5V (ASTM grade 9), Ti-4.5Al-1.5Cr-5Mo (Corona 5), and Ti-0.3Mo-0.8Ni (ASTM grade 12).

Table 5 Superplastic characteristics of titanium alloys

Metallurgical variables that affect superplastic behavior in titanium alloys include grain size, grain size distribution, grain growth kinetics, diffusivity, phase ratio in α-β alloys, and texture (Ref 3). Alloy composition is also significant and can have a pronounced effect on α-β phase ratio and on diffusivity.

Grain size is known to have a strong influence on the superplastic behavior of Ti-6Al-4V (Ref 4, 5). This is illustrated in Fig. 2, which shows flow stress and strain rate sensitivity factor *m* as a function of strain rate for Ti-6Al-4V materials with four different grain sizes. Increasing grain size increases the flow stress, reduces maximum *m* value, and reduces the strain rate at which maximum *m* is observed.

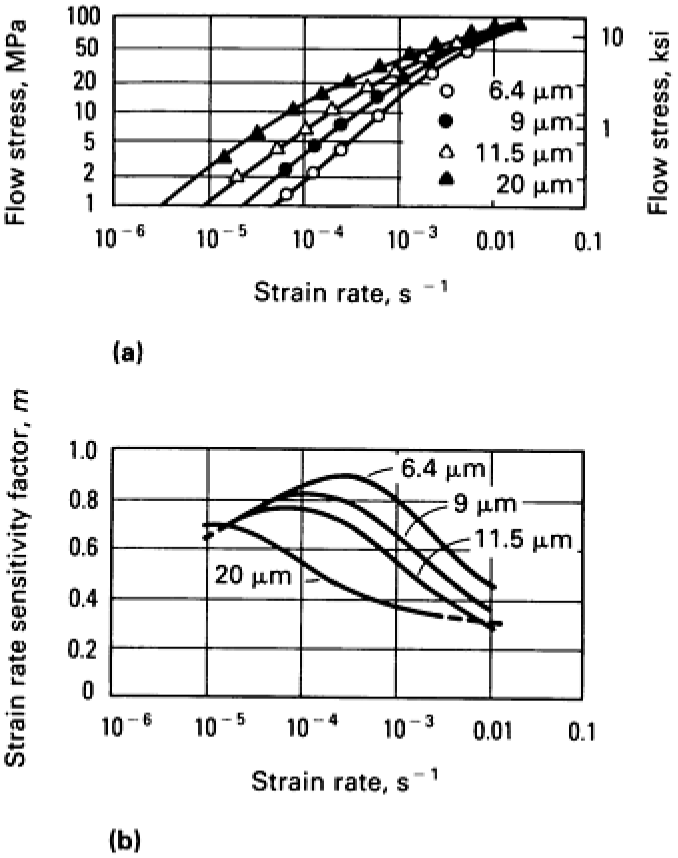

Fig. 2 Flow stress (a) and strain rate sensitivity factor *m* (b) versus strain rate for Ti-6Al-4V materials with four different grain sizes. Test temperature: 927 °C (1700 °F). Source: Ref 5.

Grain Size Distribution. Figure 3 shows flow stress versus strain rate for Ti-6Al-4V alloys with two different grain size ranges. The material with the smaller grain size distribution (lot A) exhibits significantly lower flow stresses than the material with the larger grain size distribution (lot B). Maximum *m* value is also higher for the lot A material.

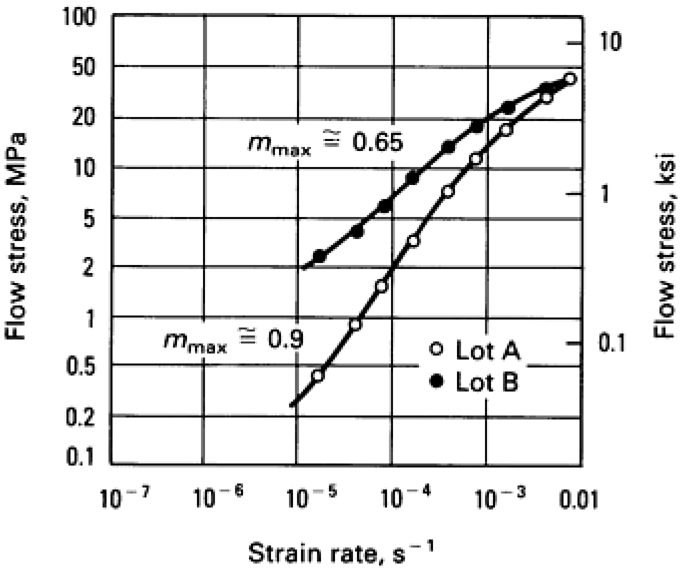

Fig. 3 Effect of grain size distribution on flow stress versus strain rate data for Ti-6Al-4V at 927 °C (1700 °F). Lot A, average grain size of 4 μm and grain size range of 1 to 10 μm; lot B, average grain size of 4.6 μm but grain size range of 1 to > 20 μm. Source: Ref 6.

Grain growth kinetics affect superplastic behavior in direct relation to the grain size developed in the material. A study of grain growth effects on Ti-6Al-4V found that the flow hardening observed during constant strain rate superplastic flow was the direct result of grain growth (Ref 5). It was also observed that grain growth accelerated with increasing strain rate. This grain growth causes an increase in flow stress and a decrease in maximum *m* value.

Diffusivity is an important quantity in the superplastic flow of titanium alloys (and other engineering materials). The best indicator of diffusivity is usually activation energy *Q*, which can be determined from the change in strain rate with temperature (Ref 3). Values of *Q* have been determined for several titanium alloys and for the α and β phases of titanium alloys. As indicated in Table 6, the activation energies determined from superplastic data are consistently higher than those for self-diffusion. It has been suggested that the higher *Q* values seen in superplastic alloys are due to the fact that the volume fraction of β phase in the alloys investigated increases with temperature, exaggerating the strain rate increase and resulting in falsely high *Q* values. This complicates efforts to establish specific deformation mechanisms.

Table 6 Activation energies for superplastic deformation and self-diffusion in titanium alloys

Alloy	**Temperature range**		**Activation energy (*Q*), kcal/mol**	Ref

Self-diffusion, β phase	. . .	. . .	36.5	**12**
Self-diffusion, β phase	**. . .**	**. . .**	**31.3**	**13**

Phase Ratio Effects. Table 5 shows that the two-phase (α-β) titanium alloys seem to exhibit greater superplasticity than other titanium alloys. The α and β phases are quite different in terms of crystal structure (hexagonal close-packed for α, and body-centered cubic for β) and diffusion kinetics. Beta phase exhibits a diffusivity approximately two orders of magnitude greater than that of α phase. For this reason alone it should be expected that the amount of β phase present in a titanium alloy would have an effect on superplastic behavior.

Figure 4 shows elongations and *m* values for several titanium alloys as a function of the volume fraction of β phase present in the alloys. It can be readily seen that elongation values reach a peak at approximately 20 to 30 vol% β phase (Fig. 4a), while *m* values peak at β contents of about 40 to 50 vol% (Fig. 4b). Because *m* is usually considered to be a good indicator of super-plasticity, this discrepancy in the location of maxima of the curves in Fig. 4 may be surprising. It is believed that the difference stems from a grain growth effect during superplastic deformation. Beta phase is known to exhibit more rapid grain coarsening than α, and the maximum ductility may be the result of a balance between moderated grain growth (due to the presence of α phase) and enhanced diffusivity (due to the presence of β).

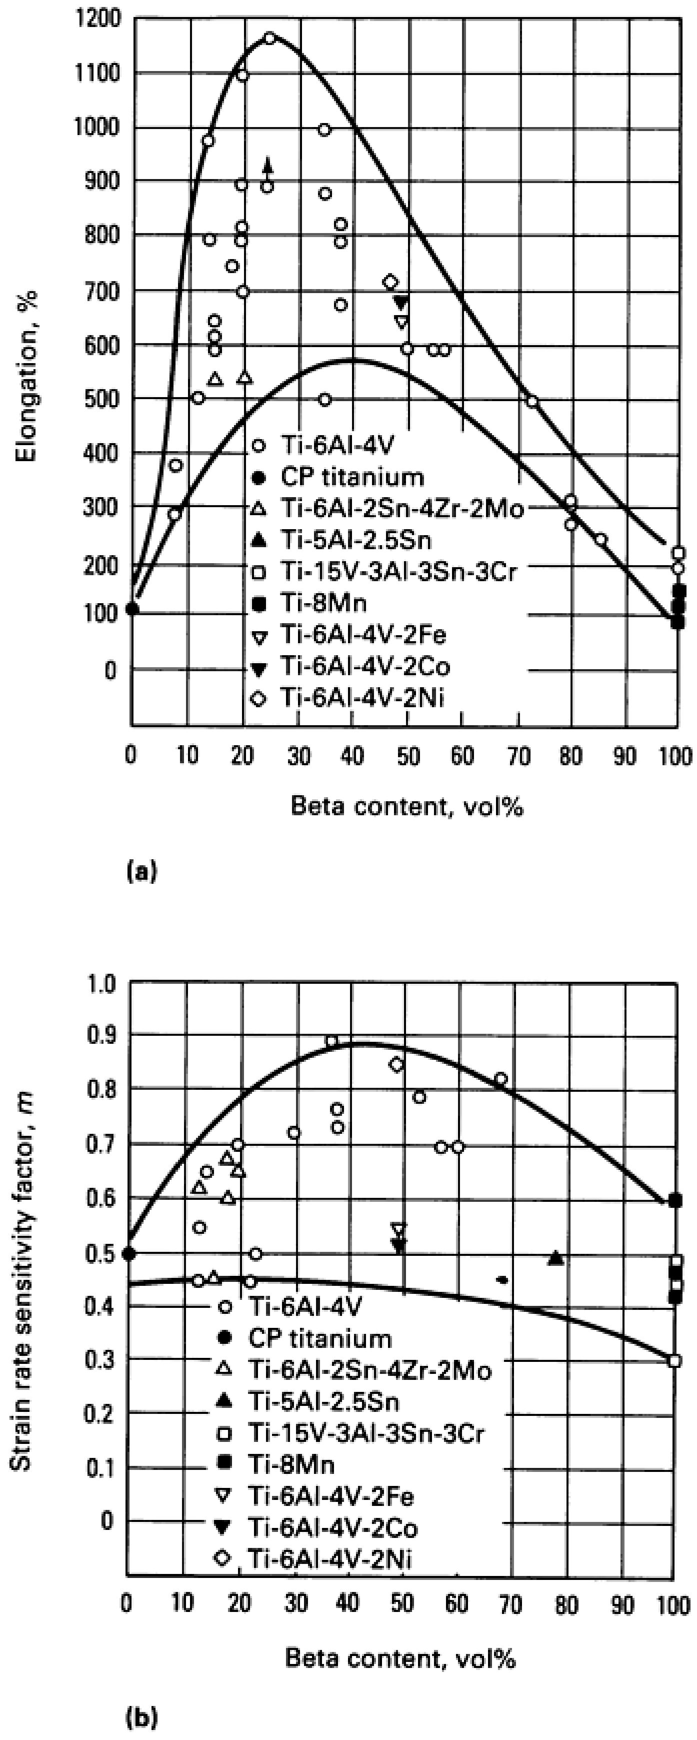

Fig. 4 Elongation (a) and *m* value (b) as a function of β-phase content for several titanium alloys. See text for details.

Crystallographic Texture. Although some studies (Ref 6, 8) did not report a noticeable effect of crystallographic texture on the superplastic behavior of titanium alloys, a more recent study (Ref 14) indicated that strongly textured Ti-6Al-5V alloy exhibited significantly higher total elongations (up to 200% difference) than the weakly textured material did. This was especially true at intermediate temperatures and in certain crystallographic directions (with the rolling direction and 45° to the rolling direction). No noticeable difference was observed normal to the rolling direction.

Superplastic Forming/Diffusion Bonding (SPF/DB)

The versatility of the superplastic forming process for titanium can be enhanced by combining it with diffusion bonding (solid-state joining). Both processes require similar conditions, that is, heat, pressure, clean surfaces, and an inert environment. The combined process is referred to as superplastic forming/diffusion bonding. Diffusion bonding is carried out simultaneously with superplastic forming, thus eliminating the need for welding or brazing for complex parts.

The SPF/DB process has greatly extended the applicability of superplastic forming. Using SPF/DB, a sheet can be formed onto pre-placed details and diffusion bonded, or two or more sheets can be formed and bonded at selected locations. Figure 5 illustrates the SPF/DB process for three-sheet parts.

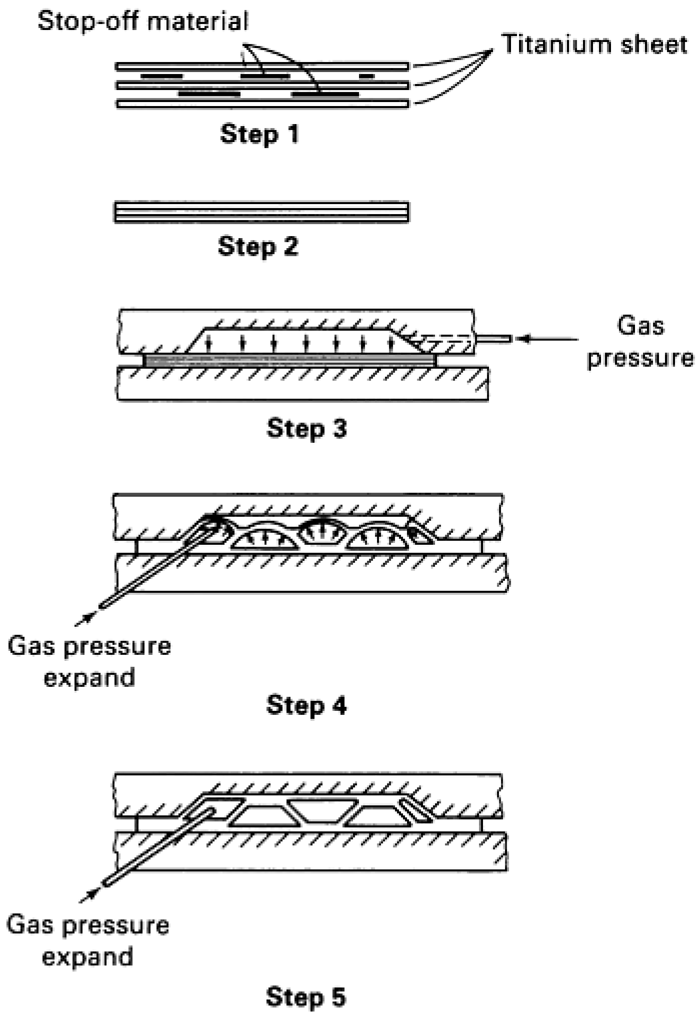

Fig. 5 Schematic showing the sequence of operations for SPF/DB of three-sheet titanium parts.

Diffusion bonding can be applied only to selected areas of a part by using a stop-off material (Fig. 5) that is placed between the sheets at locations where no bonding is desired. Suitable stop-off materials depend on the alloy being bonded and the temperatures employed; yttria and boron nitride have been successfully used.

Applications

Superplastic forming and SPF/DB are rapidly gaining acceptance in the aircraft/aerospace industry. Figure 6 shows the increase in applications for superplastically formed titanium parts in four military aircraft since 1980; applications for commercial aircraft and in the aerospace industry also are increasing.

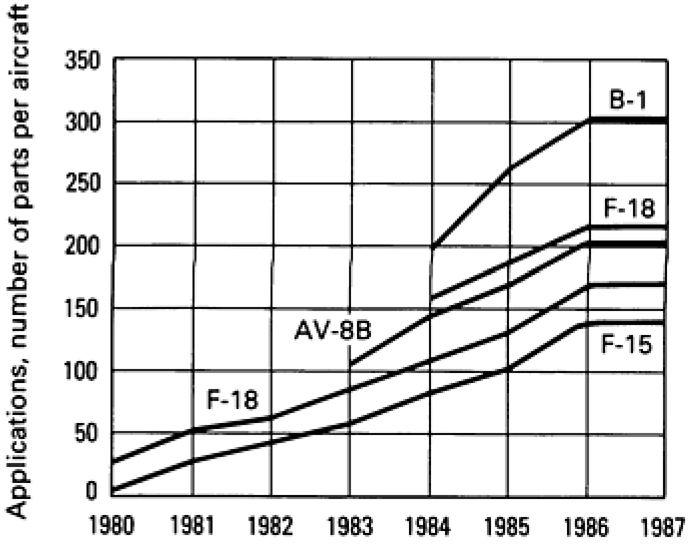

Fig. 6 Applications of superplastically formed titanium parts in military aircraft. Source: Ref 15.

Applications range from simple clips and brackets to airframe components and other load-bearing structures. Figures 7 and 8 show current applications for superplastically formed parts and illustrate the cost and weight savings that can be realized by using superplastic forming.

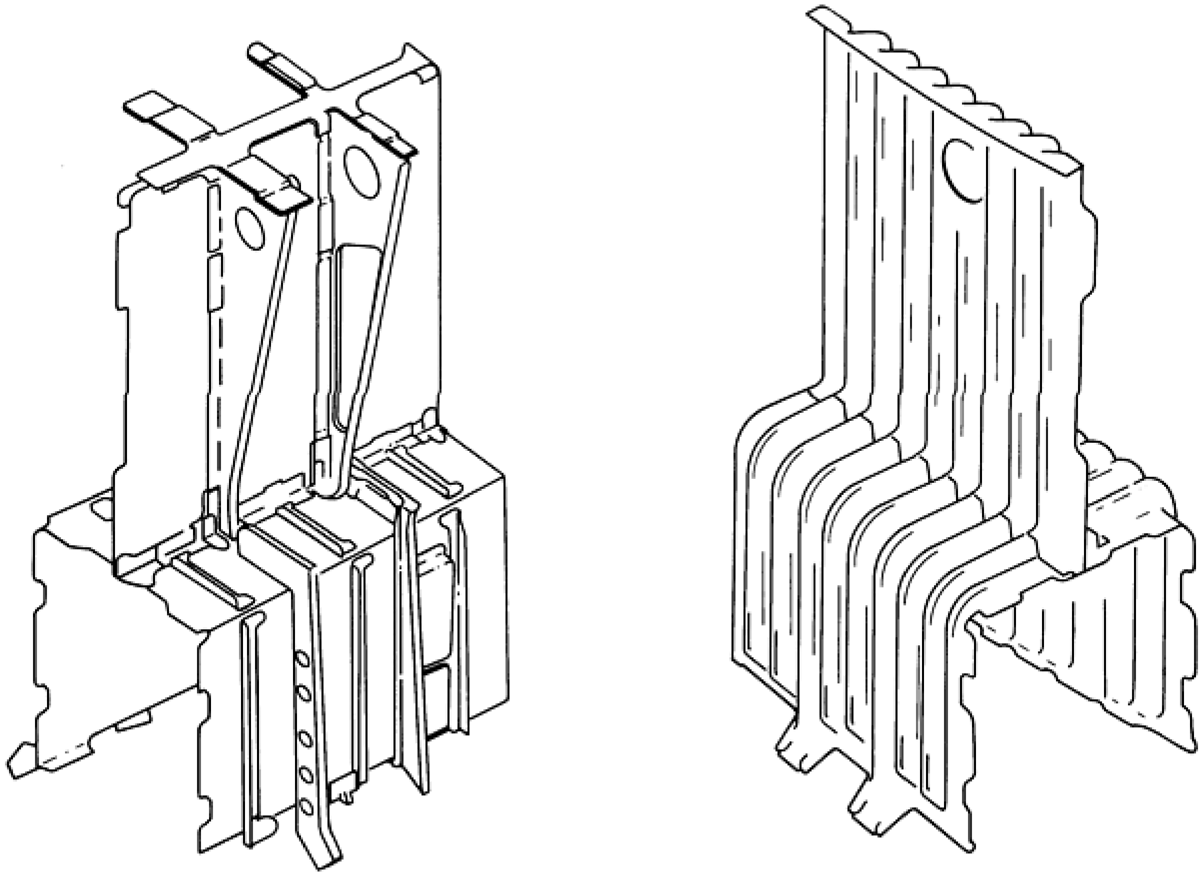

Fig. 7 Original keel design (left) and superplastically formed titanium keel section (right) for F-15 fighter aircraft. The change to the SPF part resulted in a 58% cost savings and a 31% weight savings. Source: Ref 15

Forming of Titanium and Titanium Alloys

Revised by the ASM Committee on Forming of Titanium Alloys*

Press-Brake Forming

Titanium alloys cold formed in a press brake behave like work-hardened stainless steel, except that springback is considerably greater (see the article "Forming of Stainless Steel" in this Volume). If bend radii are large enough, forming can be done cold. However, if bend radii are small enough to cause cracking in cold forming, either hot forming or the process of cold forming followed by hot sizing must be used.

The setup and tooling for press-brake air bending are relatively simple because the ram stroke determines the bend angle. The only tooling adjustments are the span width of the die and the radius of the punch. The span width of the die affects the formability of bend specimens and is determined by the punch radius and the work metal thickness, as shown in Fig. 9. Acceptable conditions for dies in press-brake forming are shown as the shaded area between the upper and lower limits in Fig. 9.

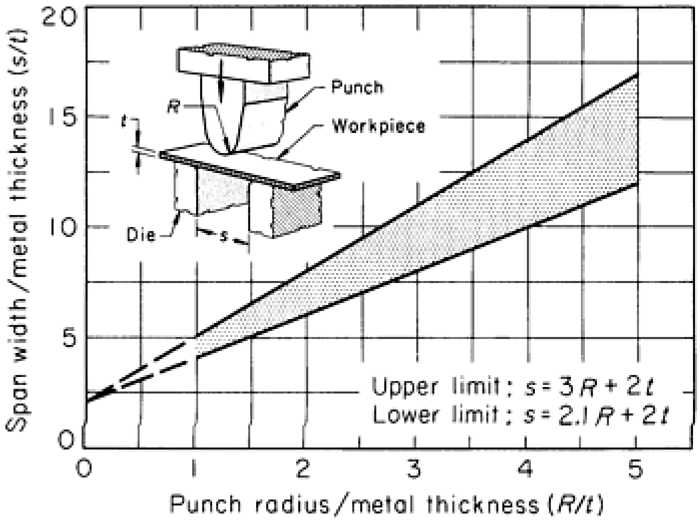

Fig. 9 Optimal relationships among span width of die, punch radius, and work metal thickness in the press-brake forming of titanium alloys. Shaded area indicates acceptable forming limits.

The minimum bend radius obtainable in press-brake forming depends on the alloy, work metal thickness, and forming temperature (Table 7). Springback in press-brake forming depends on the ratio of punch radius (bend radius) to stock thickness and on forming temperature, as shown in Fig. 10 for alloy Ti-6Al-4V (Fig. 10 is not to be used for minimum bend radii).

Forming of Titanium and Titanium Alloys

Revised by the ASM Committee on Forming of Titanium Alloys*

Deep Drawing

The deep drawing of titanium alloys has been largely replaced by the superplastic forming process. However, general guidelines for the deep drawing of titanium alloy dome shapes at room temperature are:

- The edges of the blank should be smooth to prevent cracking during forming
- The flange radius should be at least 9.5 to 12.7 mm ($\frac{3}{8}$ to $\frac{1}{2}$ in.)
- The workpiece should be clean before each forming operation
- An overlay can be used to prevent wrinkles
- Severe forming and localized deformation should be avoided; forming pressure should be applied slowly
- The punch should be polished to prevent galling, regardless of lubrication

The deep drawing of dome and hemisphere shapes has also been accomplished at room temperature in a rubber-diaphragm press. A detailed description of rubber-diaphragm forming is available in the article "Rubber-Pad Forming" in this Volume. Deep drawing is discussed in more detail in the article "Deep Drawing" in this Volume.

Hot Drawing. Titanium can be drawn deeper when hot, and more difficult forming can be done, than at room temperature. Generally, depth of draw depends on composition, workpiece shape, required radii, forming temperature, die design, die material, and lubricant. Temperature to 675 °C (1250 °F) have been used.

Power (Shear) Spinning

Most titanium alloys are difficult to form by power spinning. Alloys Ti-6Al-4V and Ti-13V-11Cr-3Al and some grades of CP titanium are the most responsive to forming by this method.

Tooling. Most tools for the power spinning of titanium are made of high-speed steel and hardened to 60 HRC. Mandrels are heated for hot spinning, although the work metal can also be heated by torches. Tube preforms can be heated by radiation. The hot power spinning of titanium is done at 205 to 980 °C (400 to 1800 °F), depending on the alloy and the operation.

Lubricants for the power spinning of titanium depend on the forming temperature used. At temperatures up to 205 °C (400 °F), heavy drawing oils, graphite-containing greases, and colloidal graphite are used. Colloidal graphite and molybdenum disulfide are employed at temperatures to 425 °C (800 °F); above this temperature, colloidal graphite, powdered mica, and boron nitride are used. More information on power spinning is available in the article "Spinning" in this Volume.

Rubber-Pad Forming

The cold forming of titanium in a press with tooling that includes a rubber pad is used mostly for flanging thin stock and for forming beads and shallow recesses. The capacity of the press controls the range in size, strength, and thickness of blanks that can be formed. Within this range, however, additional limits will be set by buckling and splitting.

Auxiliary devices, such as overlays, wiper rings, and sandwiches, are usually needed in rubber-pad forming to improve the forming and to reduce the amount of wrinkling and buckling. Rubber-pad forming is generally done at room temperature or with only moderate heat. Forming is almost always followed by hot sizing to remove springback, to sharpen radii, to smooth out wrinkles and buckles, and to complete the forming. Hand work is sometimes needed to complete the forming. The cold-formed workpiece should be stress relieved or hot sized within 24 h after forming.

Sharp bends can be made at higher forming pressures. Figure 11 shows the effect of pad pressure on bend radius for two titanium alloys.

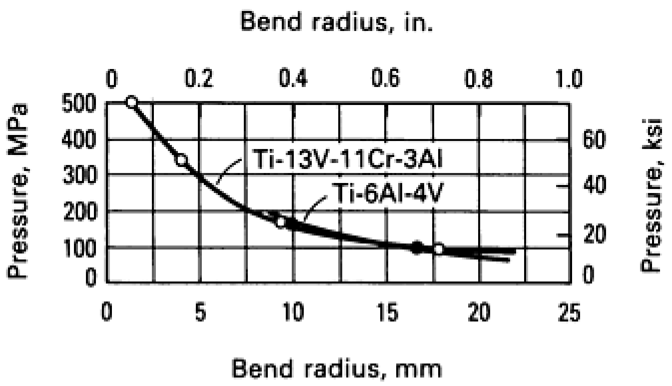

Fig. 11 Effect of pad pressure on radii formed in 1.60 mm (0.063 in.) thick titanium alloy sheets at room temperature.

Springback behavior of titanium and its alloys in rubber-pad forming differs somewhat from that observed in other methods of forming. In general, springback in forming titanium varies directly with the ratio of bend radius to work metal thickness, and inversely with forming temperature. Springback is also inversely proportional to forming pressure.

Beads can be formed to a limited extent in titanium alloy sheet by rubber-pad forming. However, beads are readily formed by superplastic forming, and this process is preferred. Additional information on rubber-pad forming is available in the article "Rubber-Pad Forming" in this Volume.

Stretch Forming

Tooling that is generally used for the stretch forming of stainless steel is also suitable for the cold stretch forming of titanium, when used with a high clamping force that will prevent slipping and tearing. Titanium may exhibit irregular incremental stretch under tension loads; therefore, optimal results are obtained when titanium is stretch formed at slow strain rates. The rate of wrapping around a die should be about 205 mm/min (8 in./min).

In the stretch forming of angles, channels, and hat-shaped sections, deformation occurs mainly by bending at the fulcrum point of the die surface; compression buckling is avoided by applying enough tensile load to produce about 1% elongation in the inner fibers. The outer fibers elongate more, depending on the curvature of the die and on the shape of the workpiece. It is sometimes preferable or required (especially if sufficient forming power is not available) to stretch wrap at elevated temperature. Again, the wrapping speed must be slow to prevent local overheating or necking.

Formability limits can be extended by permitting small compression buckles to occur at the inner fibers and removing them later by hot sizing. The buckled region represents a condition of overforming and should be limited to the amount that can be effectively removed by hot sizing.

Compression buckling is not a problem when sheet is stretch formed to produce single or compound curves. The ductility of sheet varies with orientation and is generally better in the direction of rolling. In the stretch forming of compound curves, the stretching force should be applied in the direction of the smaller radius. The rate of wrapping around the die should be about 205 mm/min (8 in./min).

Stretch forming is being replaced in many applications by superplastic forming. Additional information on the stretch forming process is available in the article "Stretch Forming" in this Volume.

Forming of Titanium and Titanium Alloys

Revised by the ASM Committee on Forming of Titanium Alloys*

Three-Roll Forming

Three-roll forming is an economical method of forming titanium alloy sheet into aircraft skins, cylinders, or parts of cylinders. The sheet should be flat within 0.15 mm (0.006 in.) for each 51 mm (2 in.) of length. The corners of the sheet should be chamfered to prevent marking of the rolls.

The upper roll of the three-roll assembly can be adjusted vertically. The radius of the bend is controlled by the roll adjustment. Premature failure will occur if the contour radius is decreased too rapidly; however, too many passes through the rolls may cause excessive work hardening of the work metal. Several trial parts must sometimes be made in a new material or shape to establish suitable operating conditions.

Three-roll forming is also used to form curves in channels that have flanges of 38 mm (1.5 in.) or less. Figure 12 shows the use of the process for curving a channel with the heel in. Transverse buckling and wrinkling are common failures in the forming of channels. The article "Three-Roll Forming" in this Volume contains more information on this process.

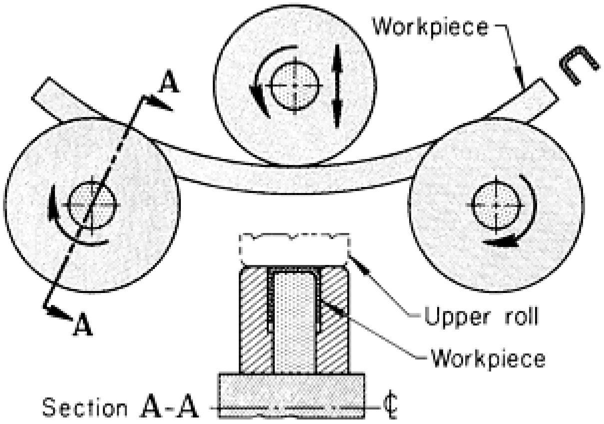

Fig. 12 Use of three-roll forming to produce a curve in a U-section channel.

Contour Roll Forming

Titanium sheet can be contour roll formed like any other sheet metal, but with special consideration for allowable bend radius and for the greater springback that is characteristic of titanium. Springback is affected to some extent by roll pressure. Often, hot rolling must be done on heated work metal with heated rolls. Additional information is available in the article "Contour Roll Forming" in this Volume.

Forming of Titanium and Titanium Alloys

Revised by the ASM Committee on Forming of Titanium Alloys*

Creep Forming

In creep forming, heat and pressure are combined to cause the slow forming of titanium sheet into various shapes, such as double-curve panels, channel sections, Z-sections, large rings, and small joggles. The metal flows plastically at a stress below its yield strength. At low temperature, creep rates are ordinarily very low (for example, 0.1% elongation in 1000 h), but the creep rate of titanium accelerates sharply with increasing temperature.

Creep forming can be done by three different methods:

- A blank is clamped at the edges, as for stretch forming, and a heated male tool is loaded to press against

the unsupported portion of the blank; the metal yields under the combination of heat and pressure and slowly creeps to fit the tool
- A set of dies containing heating elements or coils is used in a hydraulic press in a manner similar to hot sizing
- A heated female die is used with a vacuum diaphragm, as in vacuum forming (see the section "Vacuum Forming" in this article)

Temperatures for creep forming are the same as those used in hot forming (Table 4). Generally, titanium must be held at the creep-forming temperature for 3 to 20 min per operation; creep forming sometimes takes as long as 2 h.

Vacuum Forming

Large panels (some as much as 18 m, or 60 ft, long) for aircraft are sometimes vacuum formed from titanium alloy sheet. Vacuum forming, however, has been largely replaced by superplastic forming. For vacuum forming, the blank is laid on a die of heated concrete, ceramic, or metal, and a somewhat larger flexible diaphragm is laid on top of the blank to provide a seal around its edges. After the blank has been heated to forming temperature, the air is pumped out from between the blank and the die so that atmospheric pressure is used to form the work. This method, a kind of creep forming, cannot bend the work to sharp radii.

Forming of Titanium and Titanium Alloys

Revised by the ASM Committee on Forming of Titanium Alloys*

Drop Hammer Forming

Titanium should not be permitted to rub against lead, zinc, or other low-melting metals that contaminate titanium. Drop hammer tools can be capped with sheet steel, stainless steel, or nickel alloy, depending on the expected tool life. Nickel-base alloys, in thicknesses of 0.635 to 0.813 mm (0.025 to 0.032 in.), have the longest life.

As shown in Table 4, severe forming of most titanium alloys, which includes drop hammer forming, is done at about 500 to 800 °C (900 to 1500 °F). Thermal expansion of the dies must be considered in the design. The approximate rate of expansion for steel dies is 0.006 mm/mm (0.006 in./in.) as temperature is increased from 20 to 540 °C (70 to 1000 °F).

Multistage tools can be used if the part shape is complex and cannot be formed in one blow. Workpieces are then finished by hot sizing.

The minimum thickness of titanium sheet for drop hammer forming is 0.635 mm (0.025 in.); thicker sheet is used for complex shapes. Total tolerance on parts formed in drop hammers is usually 1.6 mm ($\frac{1}{16}$ in.). More information on the drop hammer forming process is available in the article "Drop Hammer Forming" in this Volume.

Joggling

Joggling is frequently done on titanium alloy sheet. A joggle is an offset in a flat plane, consisting of two parallel bends in opposite directions at the same angle (Fig. 13). Generally, the joggle angle is less than 45°.

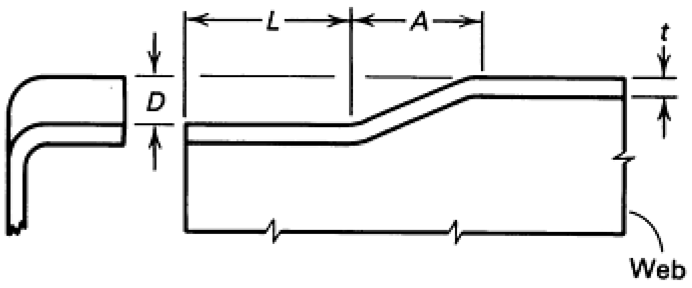

Fig. 13 Details of a joggle. See Table 8 for room-temperature joggle limits of several titanium alloys. *t*, sheet thickness, *D*, joggle height; *L*, joggle length; *A*, joggle allowance. Source: Ref 2.

Depending on joggle depth, joggles can be either formed completely at room temperature or at elevated temperature in press brakes and mechanical or hydraulic presses. Table 8 lists room-temperature joggle limits for several titanium alloys. Common practice is to preform at room temperature and then hot size ("set" the joggle) in a heated die. The sizing operation is usually done under conditions that result in stress relieving or aging.

Table 8 Room-temperature joggle limits for several annealed titanium alloys

See Fig. 13 for definitions of joggle dimensions given here, and Table 7 for minimum bend radii.

Alloy	Sheet thickness, *t*		***A*, minimum**	***D*, maximum**	*L*, minimum
	mm	**in.**			
CP titanium[(a)]	Up to 4.75	Up to 0.187	6*D*	3*t*	**5*D***

Source: Ref 2

(a) Minimum yield strength: 483 MPa (70 ksi).

(b) Minimum yield strength: <483 MPa (70 ksi).

In press-brake formed or stretch-formed angles and channels, and in machined extrusions, joggles with radii smaller than the minimum bend radii for the metal at room temperature, or joggles with length-to-depth ratios of less than about 6 to 1, arc more successfully formed at elevated temperature. Forming temperature varies between 315 and 650 °C (600 and 1200 °F), depending on the alloy and its heat-treated condition. Annealed alloys are joggled at 315 to 425 °C (600 to 800 °F). Heat-treated or partly heat-treated alloys are joggled at, or near, their aging temperature.

Forming of Titanium and Titanium Alloys

Revised by the ASM Committee on Forming of Titanium Alloys[*]

Dimpling

Dimpling produces a small conical flange around a hole in sheet metal parts that are to be assembled with flush or flathead fasteners. Dimpling is most commonly applied to sheets that are too thin for countersinking. Sheets are always dimpled in the condition in which they are to be used because subsequent heat treatment may cause distortion of the holes or dimensional changes in the sheet.

The hot ram-coin dimpling process is generally used, although dimples have been produced at room temperature by swaging. In hot ram-coin dimpling, force in excess of that required for forming is applied to coin the dimpled area and to reduce the amount of springback.

Titanium is dimpled at up to 650 °C (1200 °F) with tool steel dies. If higher temperatures are required, heat-resistant alloy or ceramic tooling is needed in order to prevent deformation of the dies during dimpling. The work metal is usually heated by conduction from the dimpling tools, which are automated to complete the dimpling stroke at a predetermined temperature.

Pilot holes must be drilled, rather than punched, and must be smooth, round, cylindrical, and free of burrs. Because of the notch sensitivity of titanium, care must be taken in deburring the holes.

The amount of stretch required to form a dimple varies with the head and body diameters of the fastener and the bend angle. If the metal is not ductile enough to withstand forming to the required shape, cracks will occur radially in the edge of the stretch flange, or circumferentially at the bend radius. Circumferential cracks are more common in thin sheet; radial cracks are more common in thick stock.

Explosive Forming

Within the limits set by its mechanical properties, titanium can be explosive formed like other metals. Explosive forming is most commonly used for cladding titanium to other metals. Titanium is explosive formed using techniques similar to those used for other metals and alloys (see the article "Explosive Forming" in this Volume).

Forming of Titanium and Titanium Alloys

Revised by the ASM Committee on Forming of Titanium Alloys*

Bending of Tubing

Round tubing of commercially pure titanium and alloy Ti-3Al-2.5V can be formed at room temperature in ordinary draw bending machines. When hot bending is required, the equipment is modified by adding some means of heating the tools. Minimum and preferred conditions for bending tubing of commercially pure titanium at room temperature and at elevated temperatures are given in Table 9. As shown in Table 9, tubing up to 63.5 mm (2.5 in.) in diameter ordinarily is bent at room temperature, while larger sizes are bent at temperatures of 175 to 205 °C (350 to 400 °F). In either case, bend radius is limited chiefly by tubing diameter, but maximum bend angle is affected by both diameter and wall thickness.

(a) Maximum bend angles are based on the use of a clamp section three times as long as the diameter of the tubing and on maximum mandrel-ball support of the tubing.

Commercially pure titanium deforms locally if tension is not applied evenly. Bending should be slow; rates of $\frac{1}{4}$° to 4° per minute are suitable. A lubricant should be used.

Tools used in bending titanium and titanium alloy tubing are shown in Fig. 14. In this type of apparatus, the tubing is gripped between the clamp and the straight portion of the rotating form block tightly enough to prevent axial slipping during bending. The clamped end of the tubing is supported by a plug. The cleat insert in the clamp and that attached to the end of the plug (see Fig. 14) are used only in bending the larger sizes of tubing that have thin walls, for which greater gripping power is needed.

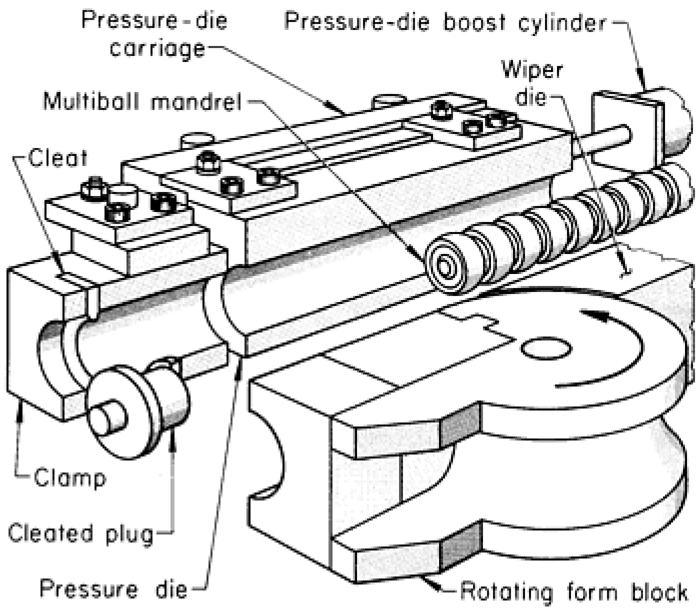

Fig. 14 Tools used for bending titanium tubing. The cleats on the clamp and plug are used only for bending of large-diameter tubing with thin walls. For hot bending, the pressure die and mandrel are integrally heated.

Computers are also being applied to titanium tube bending, especially at large aircraft and aerospace companies. Computer measurement systems are used during bending, and software packages are available that can design bend geometries. Completely automated precision bending can be performed using computers and numerically controlled (NC) bending equipment. More information on automated tube bending is available in the article "Bending and Forming of Tubing" in this Volume.

Lubrication. Drawing oils are used as lubricants for forming commercially pure titanium tubing at room temperature. Grease with graphite is used as a lubricant for the hot bending of commercially pure titanium tubing, but is not recommended for temperatures above 315 °C (600 °F). Phosphate conversion coatings are sometimes used for hot bending of titanium tubing.

Introduction

FOUR of the platinum metals--platinum, palladium, rhodium, and iridium--have face-centered cubic crystal structures. This crystal structure is usually associated with ductility. However, only platinum and palladium can be cold worked from the cast condition. Rhodium must be broken down at a high temperature before it can be cold worked, and iridium can be cold worked, with difficulty, only after a fibrous structure has been imparted by careful hot working.

Ruthenium and osmium have hexagonal close-packed crystal structures. Osmium is completely unworkable and ruthenium very nearly so.

In general, the only problems that are peculiar to the working of the platinum metals are those resulting from surface contamination derived from rolls, swaging dies, and other tools. Base metal impurities such as iron, which may be smeared on the surface or picked up as slivers or fine dust during hot working or annealing, will alloy with the surface layers and diffuse inward. Therefore, physical characteristics such as electrical resistivity are affected and surface cracking may develop.

The platinum metals do not scale during hot working. Nevertheless, cracks usually are not easily welded or healed, probably because of the slight, inevitable contamination by iron, iron oxide, or even films of adsorbed gas. In the following sections, working procedures for each of the platinum group metals are considered separately.

Working of Platinum Group Metals

Platinum

Hot Working. Platinum ingots are normally broken down by hot forging or rolling. Ingots are heated to 1205 to 1510 °C (2200 to 2750 °F), usually in a gas-fired furnace, supported on high-grade alumina.

In forging, particular care is taken to keep the anvil surfaces smooth and bright. After the first few blows, the forging is cooled, and any surface cracks or folds are carefully gouged out with a chisel. The work is then reheated, and forging is continued to the finished size. The freedom of platinum from scaling is not without disadvantages; surface imperfections do not oxidize and flake away, but persist.

Platinum is hot rolled to sheet in simple slab rolls. Rod is hot rolled between grooved rolls, which may be provided with half-round sections throughout or, more frequently, with half-round sections for the finishing passes only. The early passes are formed with gothic sections alternating with oval sections.

Cold Working. Platinum responds readily to cold working and can be reduced 98% or more by rolling or wiredrawing. The rate of work hardening is slow, as shown in Fig. 1 and in Table 1.

Table 1 Influence of cold work on the hardness of platinum, palladium, and the more important platinum alloys, with recommended annealing temperatures

Values for hardness and annealing temperature will vary, because of differences in working procedures and degree of purity of the alloy.

(a) ZGS, zirconia grain stabilized

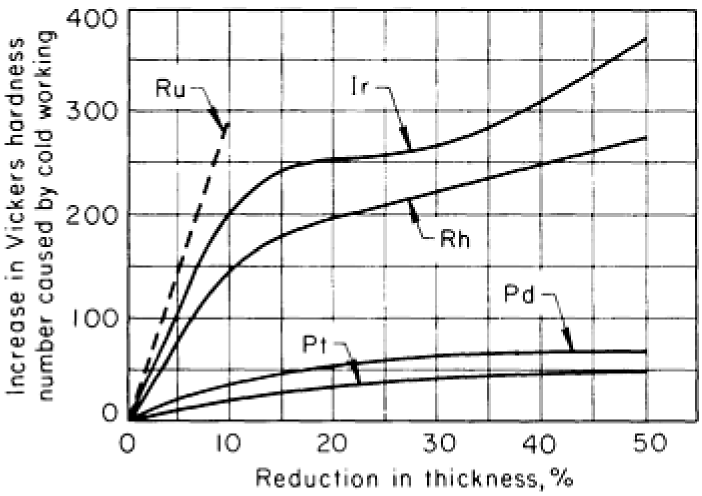

Fig. 1 Effect of cold work in increasing the hardness of the platinum group metals

In cold rolling, the response of platinum is similar to that of copper, and similar rolling programs are followed. It is seldom desirable to interpose annealing stages.

Foil thinner than about 0.038 mm (0.0015 in.) is sometimes made in small amounts by book rolling. A sheet of copper about 1.6 mm ($\frac{1}{16}$ in.) thick is folded back on itself, a platinum sheet about 0.25 mm (0.01 in.) thick is slipped into the fold, and the "book" is then rolled down as far as required, with the copper and platinum being reduced together. The finish of book-rolled strip (when separated) is poor, but the method requires no special equipment. For good surfaces, direct rolling in a Sendzimirtype mill is preferred.

In wiredrawing, platinum is handled in almost exactly the same manner as copper. Solid lubricants are used for drawing to about 2.4 mm ($\frac{3}{32}$ in.); for smaller diameters, water-base lubricants of the soluble-oil type are suitable. Diamond dies, with profiles similar to those used for drawing copper wire, are used below about 3.2 mm ($\frac{1}{8}$ in.), and platinum wires are drawn direct to sizes down to 0.01 mm (0.0004 in.) in diameter.

Wires smaller in diameter than 0.01 mm (0.0004 in.) can be made by the Wollaston process. In this process, a platinum rod is sheathed with a thick-wall closely fitting cylinder of silver about ten times its diameter. The composite is drawn without annealing. In the finished wire, the average diameter of the platinum core is nearly in the same ratio to that of the outer silver coating as in the original assembly, although the platinum core is not quite round or uniform. Wollaston wire is usually supplied without removing the silver coating, which is dissolved in dilute nitric acid after the wire has been mounted for use.

The usual press operations of blanking, piercing, bending, and deep drawing are used to form platinum, palladium, and their commercial alloys through the use of techniques and tools that are similar in all respects to those for cartridge brass or silver. Production methods have not been used to form the other platinum group metals. These other metals are more difficult to fabricate, and the demand for press-formed parts is small.

When steel tools are used, tool life may be shortened by cold welding between the platinum metal and the working surface of the tool. In blanking and cutting operations, the cold welding impairs tool edges and necessitates frequent regrinding. In cold-heading operations, it may cause pickup on the hammer heads, which must be removed by grinding, as shown in the following example.

Example 1: Life of Steel Hammers for Cold Heading Silver and Platinum.

The electrical contact illustrated in Fig. 2 was formed from both platinum and silver wires in the same cold-heading machine, using identical heading tools made from a conventional die steel containing 2% C and 12% Cr and hardened to 62 to 63 HRC. The platinum was lubricated with a smear of kerosene; the silver was run dry. About 15,000 parts could be headed from silver between tool regrinds, and only 5000 could be headed from platinum, because the steel tools picked up platinum, which had to be removed by grinding. Total tool life was 150,000 parts from platinum and 1 million from silver.

	Number of parts formed	
	Platinum	Silver
Between tool repolishings	5,000	**15,000**
During total tool life	**150,000**	**1,000,000**

Fig. 2 Electrical contact that was produced from platinum wire and silver wire by cold heading using steel punches. Dimensions given in inches

Pickling. Platinum is often pickled before annealing to remove surface contaminants that might otherwise alloy with and diffuse into the metal. A hot 10% solution of sulfuric acid in water is usually used. A 10% solution of hydrochloric acid is occasionally preferred if iron contamination alone is suspected. More rarely, hot aqua regia solution is used, particularly if slight surface alloying is suspected.

Annealing does not require a protective atmosphere and is done at about 1000 °C (1830 °F). The platinum should be supported on clean refractories. Silica refractories can be used if fully oxidizing conditions are maintained in the heating chamber, but alumina is preferred. Flash annealing techniques are often used for platinum wire and sheet to minimize grain growth.

Palladium

Hot Working. Palladium can be hot forged or rolled at 1200 to 1400 °C (2190 to 2550 °F). It deforms less readily than platinum but appreciably more readily than low-carbon steel. It should be quenched in water from above 815 °C (1500 °F) in order to retain a bright surface. A tarnish film of PdO forms on palladium in air between 400 to 850 °C (750 to 1560 °F), and this film is therefore found on metal that has cooled slowly through this temperature range. The oxide decomposes above 850 °C (1560 °F); metal can be cleaned from tarnish by heating above 850 °C (1560 °F) and quenching.

Palladium is readily cold worked. Small ingots are frequently reduced to the finished size by cold working, although larger ingots are usually broken down by hot working.

Cold Working. In cold rolling and wire-drawing, palladium behaves much like platinum, although the rate of work hardening of palladium is slightly higher, as shown in Fig. 1 and Table 1.

Annealing. Palladium can be annealed in air at about 850 °C (1560 °F), but to retain a bright surface, it must be quenched in water, as described above. Palladium is more often annealed in a protective atmosphere.

Hydrogen can be used as a protective atmosphere. Although palladium absorbs very large quantities of hydrogen at room temperature, with a notable increase in volume, the solubility at 850 °C (1560 °F) is low and remains low if the metal is quenched from the annealing temperature. A 95:5 mixture of nitrogen and hydrogen is, however, equally effective in preventing tarnish and is usually preferred. Vacuum annealing of palladium is done to a limited extent, and flash annealing techniques are used to minimize grain growth.

Pickling. Tarnish films of PdO on palladium that has been slowly cooled or slack quenched can be removed by a hot 10% solution of sulfuric acid or by a 10% tartaric acid solution. Hot dilute sulfuric acid dissolves palladium slowly and can therefore be used to remove contaminated surface layers.

Rhodium

Hot Working. Ingots cast from melted rhodium, as well as sintered powder metallurgy compacts, can be worked by hot forging at high temperature. Above 1300 °C (2370 °F), the metal is soft and malleable. The small ingots are usually heated to about 1500 °C (2730 °F), either in an electric resistance furnace in an atmosphere of hydrogen, in a gas-fired furnace, or even in a blowpipe; the ingots are frequently reheated during the early stages of reduction. A tarnish film of RhO_2 begins to form on rhodium when it is heated above about 500 °C (930 °F), and this film persists to much higher temperatures than the film on palladium. The metal must be quenched from above about 1400 °C (2550 °F) to be entirely bright and free from oxide. After preliminary forging, rhodium can be hot rolled to sheet or hot swaged to rod.

Cold Working. Once the cast structure of polycrystalline rhodium has been broken down by hot working, it becomes amenable to further reduction by cold working. However, the rate of hardening by cold work is high, as shown in Fig. 1.

In both cold rolling and wiredrawing, it is necessary to anneal frequently. For the first few reductions, annealing should follow each reduction in area of 10 to 20%; as the workpiece size decreases, the reduction in area between anneals can be gradually increased to 30 to 40%. Single crystals of rhodium, made by vertical floating-zone melting, can be readily cold swaged, rolled, or drawn, and they respond as readily as pure nickel. However, if this cold-worked rhodium is then recrystallized by full annealing, intercrystalline brittleness develops, and further cold working becomes as difficult as with normal polycrystalline rhodium. Partial softening, with reasonable ductility, can be achieved by stress-relief annealing at 595 to 815 °C (1100 to 1500 °F) and is sometimes helpful.

Annealing. Rhodium is usually annealed in hydrogen at about 1205 °C (2200 °F) and cooled to below about 200 °C (390 °F) in hydrogen in order to retain its bright surface. Rhodium wire is preferably continuously annealed in a tube furnace that has a cooling extension and is fed with hydrogen. Rhodium must always be bright annealed; no satisfactory method of chemical or electrochemical pickling is available.

Working of Platinum Group Metals

Iridium

Hot Working. Iridium, either as argonarc cast ingots or as powder metallurgy compacts, can be hot forged, like rhodium, but with greater difficulty. The tarnish film of IrO_2 forms at about 400 °C (750 °F) and persists in the temperature region of 400 to 1120 °C (750 to 2050 °F). Above 1120 °C (2050 °F), it dissociates. The surface remains bright when the metal is quenched from temperatures above 1120 °C (2050 °F).

Ingots that have been broken down by forging can be hot rolled by small reductions to sheet or can be hot swaged to rod if precautions are taken to keep the material hot until it enters the swaging die. After hot forging, iridium, like tungsten, can be hot drawn through heated dies; the wire is heated to about 700 °C (1290 °F) just before it enters each die. After working has started, iridium is embrittled if it is heated above its recrystallization temperature of 1350 °C (2460 °F).

Cold Working. Iridium that has been broken down by hot working to a fibrous structure and not recrystallized will withstand only a very small amount of cold work, such as that imparted by a planishing pass. Single crystals of iridium (made by vertical-zone melting), like single crystals of rhodium, can be cold worked to reductions of about 50%. They cannot then be softened by annealing, because intercrystalline brittleness develops upon recrystallization.

Ruthenium

Hot Working. Small ingots of ruthenium can be deformed by small amounts by careful hot working at about 1500 °C (2730 °F), but dense fumes of the oxide are evolved and cracks invariably develop. Ruthenium powder compact and cast ingots have been successfully hot rolled at 1205 °C (2200 °F) after enclosure in an envelope of stainless steel. The resulting sheet has little ductility.

Platinum Alloys

The alloys of platinum with up to about 40% Rh, 30% Ir, or 10% Ru constitute those of chief industrial use. All are worked by the same general methods used for platinum; allowance is made for the greater stiffness and hardness of the alloys.

Hot Working. The alloys can be forged, hot rolled, and hot swaged, usually at temperatures higher than those for platinum. The platinum-ruthenium alloys give off fumes of ruthenium oxide above about 1095 °C (2000 °F) in air and are preferably heated in a protective atmosphere.

Cold Working. All of the alloys respond to cold working by rolling, swaging, and wiredrawing. The effects of cold work on the hardness of some typical alloys are given in Table 1.

Annealing. The alloys can be annealed in air, but all need to be quenched to prevent tarnishing by the oxide film of the alloying metal. Wires are usually continuously annealed and cooled in a hydrogen atmosphere. Annealing temperatures for the alloys are shown in Table 1.

Grain-stabilized platinum and platinum alloys--zirconia grain-stabilized (ZGS) platinum, ZGS Pt-10Rh, and ZGS Pt-5Au--have been developed for the glass industry for applications requiring prolonged component life. Temperatures for these alloys are about 200 °C (360 °F) greater than those for the corresponding nonstabilized alloys. Data on hardness and recommended annealing temperatures are included in Table 1.

Superplastic Sheet Forming

C.H. Hamilton, Washington State University; A.K. Ghosh, Rockwell International

---

Introduction

SUPERPLASTICITY is a term used to indicate the exceptional ductility that certain metals can exhibit when deformed under proper conditions. The term is most often related to the ductile tensile behavior of the material; however, superplastic deformation has the characteristic of easy deformation under low pressures, and compression deformation characteristics are also described as superplastic. The tensile ductility of superplastic metals typically ranges from 200 to 1000% elongation, but ductilities in excess of 5000% have been reported (Ref 1). Elongations of this magnitude are one to two orders greater than those observed for conventional metals and alloys, and they are more characteristic of plastics than metals.

Because the capabilities and limitations of sheet metal fabrication are most often determined by the tensile ductility limits, it is clear that there are significant advantages potentially available for forming such materials, provided the high-ductility characteristics observed in the tensile test can be used in production forming processes. This is of course being done, and the number of applications of parts formed by these methods is increasing each year. This article will discuss many of the processes and related considerations involved in the forming of superplastic sheet metal parts.

Superplastic Sheet Forming

C.H. Hamilton, Washington State University; A.K. Ghosh, Rockwell International

Requirements for Superplasticity

Before discussing the details of the superplastic forming (SPF) processes, it is necessary to review the more important aspects of superplastic material behavior because some of the specific forming parameters are determined by this behavior. There are several different types of superplasticity in terms of the microstructural mechanisms and deformation conditions, including the following (Ref 2, 3):

- Micrograin superplasticity
- Transformation superplasticity
- Internal stress superplasticity

At this time, only the micrograin superplasticity is of importance in the fabrication of parts, and the discussion will be limited to this type. For micrograin superplasticity, the high ductilities are observed only under certain conditions, and the basic requirements for this type of superplasticity are:

- Very fine grain size material (of the order of 10 μm, or 400 μin.)
- Relatively high temperature (greater than about one-half the absolute melting point)
- A controlled strain rate, usually 0.0001 to 0.01 s^{-1}

Because of these requirements, only a limited number of commercial alloys are superplastic, and these materials are formed using methods and conditions that are different from those used for conventional metals.

Characteristics of Superplastic Metals. For a superplastic metal that is tensile tested under proper conditions of temperature, the observed ductility is seen to vary substantially with strain rate, as shown in Fig. 1 for a zinc-aluminum eutectoid alloy (Ref 4). As shown, there is a maximum in ductility at a specific strain rate, with significant losses in ductility as the strain rate is increased or decreased relative to this maximum. It is well known that the primary factor related to this behavior is the rate of change of flow stress with strain rate, usually measured and reported as *m,* the strain rate sensitivity exponent:

$$m = \frac{\partial \ln \sigma}{\partial \ln \dot{\epsilon}} \quad \textbf{(Eq 1)}$$

where σ is the flow stress and $\dot{\epsilon}$ is the strain rate.

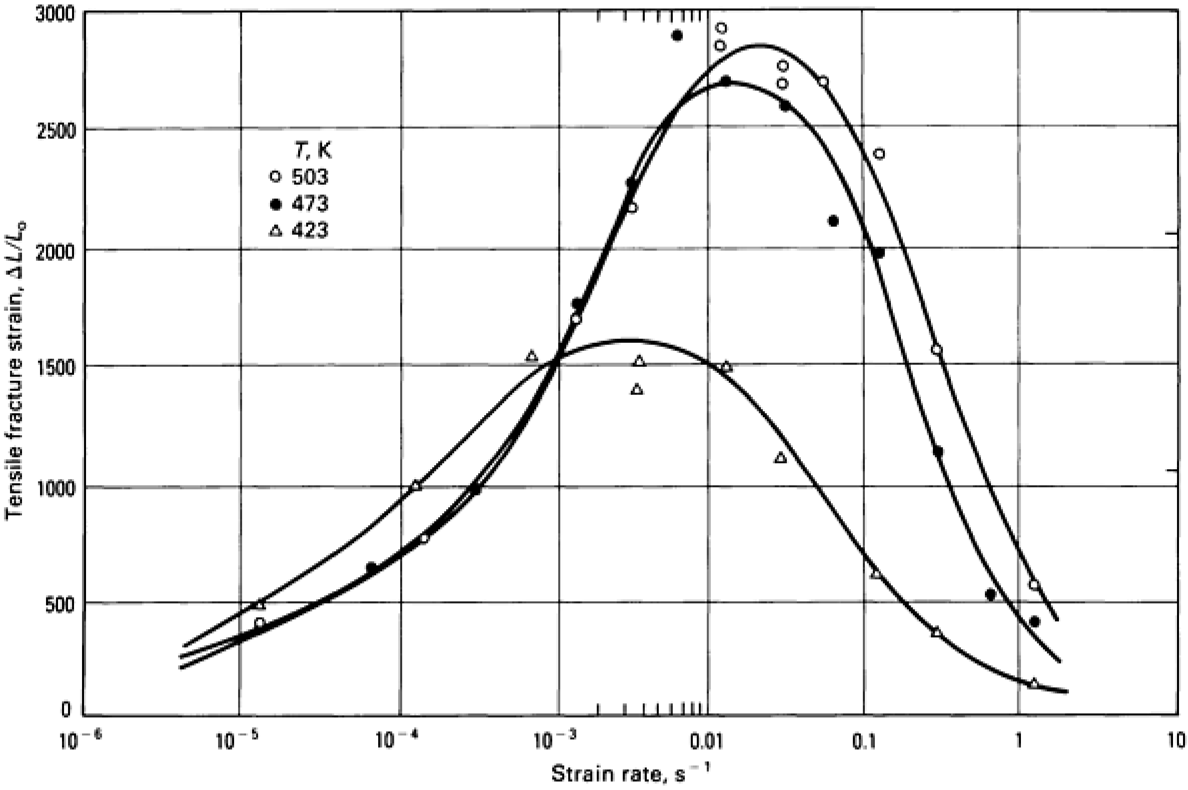

Fig. 1 Tensile fracture strain versus initial strain rate for a Zn-22Al alloy having a grain size of 2.5 μm (100 μin.) tested at temperatures ranging from 423 to 503 K.

The above characteristics of a superplastic alloy indicate that unusual forming capability should be possible with superplastic alloys but that control of the forming process parameters is important to obtain the full potential of this class of material. Such process controls are more demanding than corresponding requirements for conventional forming processes, and the superplastic forming of sheet metals is a new technology that is different from the conventional processes. However, superplastic forming offers advantages over other fabrication methods for a number of applications as a result of its unique capability of fabricating complicated components in a single step.

Superplastic Alloys. Because of the stable grain size requirement for a superplastic metal, not all commercially available alloys are superplastic. In fact, very few such alloys are superplastic. Many materials have been produced with laboratory or pilot-plant processing, but very few of these have been produced commercially (Ref 3). Nonetheless, there are some alloys that can be obtained (or are expected to be available in the future). As SPF technology develops, it is anticipated that additional alloys will be produced specifically for this process.

A summary of several superplastic alloys is presented in a Table 1, along with some of their characteristics. Particularly noteworthy are Ti-6Al-4V, aluminum alloy 7475, and the Supral alloys, which are quite superplastic and are commercially available. The titanium alloys have been found to be superplastic as conventionally produced, and there has not been a need to develop alloy modifications nor special mill-processing methods to make them superplastic. However, this has not been the case with the aluminum alloys, and either special processing (Ref 5) or alloy development (Ref 6) has been necessary to produce superplastic materials. The Zn-22Al alloy has been the focus of substantial research because it can be readily processed into the superplastic condition; this alloy has also been made available commercially by several different suppliers.

Characterization of Superplastic Alloys

The characteristic flow properties of a superplastic metal are exemplified in Fig. 2 for a Ti-6Al-4V alloy tested at 927 °C (1701 °F). The very strong dependence of *m* on strain rate at various grain sizes (Fig. 3) is typical of superplastic metals, and there is a good relationship between the *m* value and superplastic ductility. This relationship is demonstrated most clearly in Ref 7 in a graph of data for a large number of alloys in which the *m* value is graphed as a function of elongation. Although the total elongation can also be affected by fracture, the strain rate sensitivity is a first-order effect. The influence of *m* on the ductility is understood through mechanics to be due to the stabilizing effect of the strain rate sensitivity of flow stress on the diffuse necking process (Ref 8, 9, 10). The strong effect temperature has on superplastic deformation is demonstrated most clearly in Ref 11, in which the ductility of a titanium alloy is graphed as a function of temperature. The elongation of the titanium alloy rises and falls rapidly over a relatively short temperature range, and outside the limits of this temperature span, the ductility is quite modest and within the range of conventional material behavior.

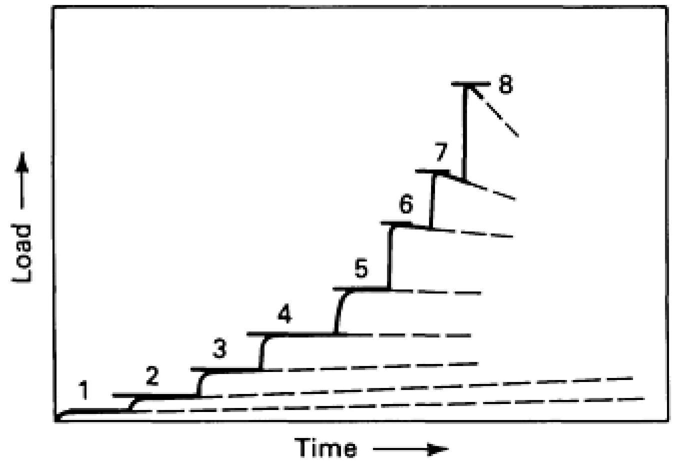

Fig. 2 Schematic plot of load versus time for the tensile deformation of a superplastic Ti-6Al-4V alloy at 927 °C (1701 °F) and at progressively increasing crosshead velocities (step strain rate test)

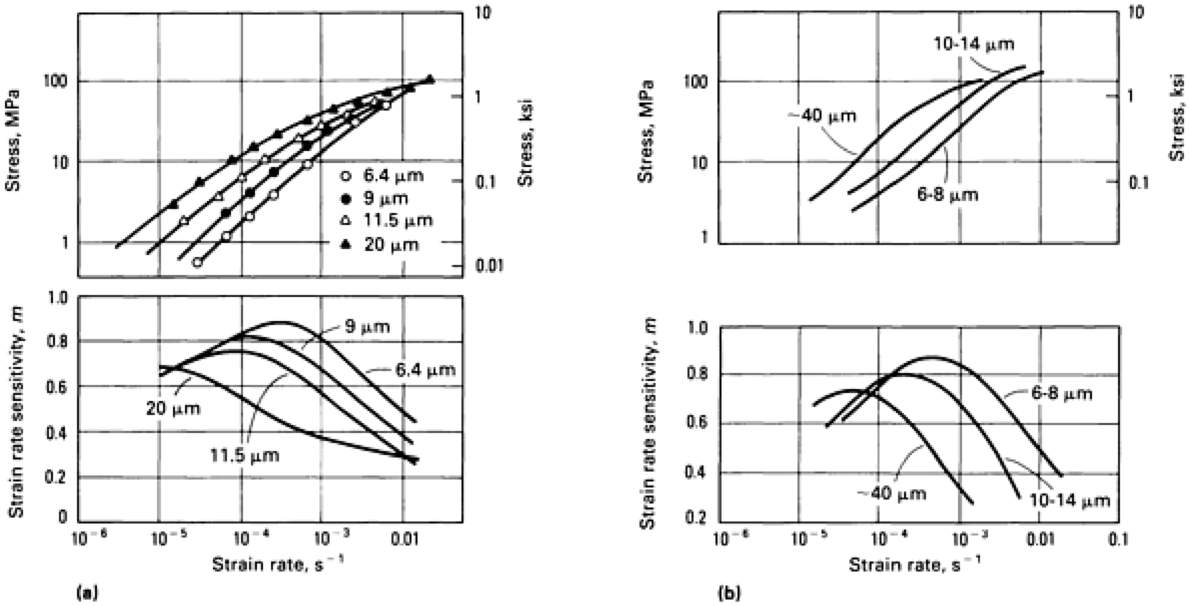

Fig. 3 Stress-strain rate plots and the corresponding strain rate sensitivity plots from step strain rate tests for Ti-6Al-4V at 927 °C (1701 °F) (a) and 7475 aluminum alloy at 516 °C (961 °F) (b), which are both at superplastic temperature

The characterization of superplastic behavior includes the characterization of plastic flow, internal cavitation, and fracture behavior. The processing variables needed for an overall characterization of superplastic behavior are introduced in this section. The parameter that is commonly selected as a measure of superplastic formability is the tensile elongation at the optimum superplastic temperature and strain rate. Because this is a highly strain rate sensitive property and because real components can experience significant variations in strain rate during forming, tensile elongation is measured as a function of strain rate. Although this is somewhat time consuming, an alternative is to determine the strain rate sensitivity of the flow stress, *m*, which has been shown to correlate well with tensile elongation for different classes of materials (Ref 7, 8). Measurements of flow stress and strain rate sensitivity of flow stress can be conducted in a single test and can be used to determine the optimum strain rate for superplastic forming (where *m* is a maximum). Although strain rate sensitivity is the dominant parameter in superplastic forming, more recent results show that a significant amount of hardening can occur as a function of superplastic strain even at a constant strain rate (Ref 9, 10). This type of strain hardening is believed to be related primarily to the grain growth that occurs during superplastic forming. At higher strain rates, strain hardening is associated with dislocation cell formation in the classical manner.

Forming temperature is just as important a variable in superplastic forming as the strain rate. Temperature variation in a forming die is a primary source of localized thinning. Characterization of material behavior should therefore include not only determination of the optimum superplastic temperature but also the sensitivity of flow stress and elongation to temperature. A large temperature sensitivity of flow stress is not desirable, because local hot spots will lead to severe strain localization. When strain localization and necking are the dominant modes of failure, it has been shown that tensile elongation is related to the *m* value in a predictable manner (Ref 11). However, when fracture intervenes, the *m* value does not provide sufficient quantitative characterization, although within the same alloy system it still provides a qualitative comparison. Fracture is therefore an important consideration in most superplastic materials of engineering application. An exception is materials with anomalously high diffusivity (for example, Ti-6Al-4V alloys), which do not show any evidence of internal cavitation or fracture. Superplastic materials that exhibit cavitation at inclusions, triple points, and second-phase particles generally fail by the interlinking of growing cavities.

Stress-strain rate behavior is usually characterized by a step strain rate test, in which strain rate is increased in successive steps and an attempt is made to measure the corresponding steady (or saturated) flow stress. A constant flow stress indicates a negative loading rate, which occurs at a point somewhat beyond the load maximum. However, even if the load maximum is used as a criterion for calculating these stresses, it can be shown that the error is negligible. Various arguments have been put forward for the proper selection of flow stress from transient loading response (Ref 12, 13, 14). However, because of the changing plastic-strain rate during this test, selection of data at the elastic limit from the rapidly rising portion of the load curve is thought to be inappropriate.

Figure 2 shows a schematic load versus time plot during a step strain rate test of a typical superplastic alloy. The interesting features are:

- At the low crosshead speeds, the load does not reach a maximum but continues to show a gradual rise
- At some intermediate speed, load reaches a constant plateau
- At higher speeds, it peaks and begins to show a sharp drop

The load increase at the low strain rates, in spite of a decrease in applied strain rate, indicates hardening of the material with imposed strain. A part of this hardening is due to a rise in plastic-strain rate, which occurs gradually when crosshead speed is low. However, the extent of hardening observed is considerable and does not saturate even after significant plastic strain, which suggests other possible sources of hardening. This type of hardening has been observed in other superplastic materials, such as aluminum-copper eutectic, and is generally attributed to grain growth occurring during deformation (Ref 15, 16).

The criticism against the use of strain rate jump tests and the selection of maximum load points for obtaining stress values is that the strain automatically becomes a variable along the σ-$\dot{\epsilon}$ curve. This could be avoided if load relaxation test results were used to derive σ-$\dot{\epsilon}$ curves. However, more complex transient effects might be associated with load relaxation tests, and the results might not be meaningful for a forming application in which strain rate generally increases with accompanying strain. The step strain rate test is therefore believed to be a logical test method for use in superplastic forming applications, provided the data are obtained with very little strain accumulation.

The σ-$\dot{\epsilon}$ data for Ti-6Al-4V alloy and 7475 aluminum alloy deformed in the superplastic temperature range are presented in Fig. 3 for a variety of grain sizes. The total accumulated strain is generally less than 0.25 in these tests. At lower strain rates ($<5 \times 10^{-4}$ s^{-1}), strain hardening does not permit the establishment of a load maximum. To characterize flow stress free from grain-growth hardening effects, stresses must be selected soon after the elastic portion. If the load rises slowly, the plastic-strain rate, $\dot{\epsilon}_p$, can be obtained from:

$$\dot{\epsilon}_p = \dot{\epsilon}_t - \frac{1}{E}\left[\frac{\dot{P}}{A} + \frac{P}{A}\dot{\epsilon}_t\right] \quad \textbf{(Eq 2)}$$

where $\dot{\epsilon}_t$ is the applied strain rate, E is Young's modulus, P is the load, $\dot{P}$ is the loading rate, and A is the instantaneous area.

The second term within the brackets in Eq 2 can generally be neglected, and even the first term can be neglected for most metals where $\dot{P}/A$ < 0.015 MPa s^{-1} (0.0022 ksi s^{-1}). Therefore, for most purposes, $\dot{\epsilon}_p = \dot{\epsilon}_t$ is a reasonable assumption as long as the loading rate is low (it need not be zero). The stress versus strain rate data plotted on the basis of such small strain accumulation serve as the initial behavior of the superplastic material. Deformation produces changes in this behavior, however, and a stress versus strain rate plot taken after a considerable plastic strain exhibits a higher stress level compared with the initial curve (Ref 9).

The proper method for determining *m* from step strain rate test results is to obtain the slope of the curve of best fit through the log σ versus log $\dot{\epsilon}$ data. The determination of *m* from two consecutive strain rate jumps assumes a constant *m* over that strain rate range and introduces an error that is dependent on the size of the range of jump strain rates. Figure 3 shows that grain size has a strong effect on flow stress and *m* value in the superplastic range. Because of the sigmoidal shape of the stress-strain rate curves, *m* values exhibit a maximum at an intermediate strain rate, and the *m* peak shifts to higher strain rates with decreasing grain size. In the titanium and aluminum alloys, the value of the *m* peak is typically in the range of 0.7 to 0.9 and increases with decreasing grain size. The value of *m* also exhibits a maximum as a function of temperature. The effects of grain size and temperature are closely tied to the diffusional creep contribution during superplastic flow (Ref 17, 18). In the power-law creep regime (at higher strain rates), however, the stress values tend to converge as the grain size dependence decreases.

Grain Size Distribution Effects on Stress-Strain Rate. Grain size has a profound influence on the superplasticity of metals. When the grain size is fine, the flow stress is low, the value of *m* is generally high, and the tensile elongation is greater. Characterization of grain size is therefore important in the overall characterization of superplasticity. However, because polycrystalline aggregates, in general, possess a distribution of grain size, it is not very meaningful to assign a fixed grain size to metals. The nature of the distribution has also been shown to influence the stress-strain rate curve (Ref 19, 20). A few coarse grains in an otherwise fine grain structure can control the strain rate range over which *m* is high, and may in some cases cause the appearance of a threshold stress. The important effect of grain size distribution in real materials is to produce a relatively high *m* (*m* > 0.5) over almost three decades in strain rate; this is a transition region between power-law creep and diffusional creep (Fig. 4).

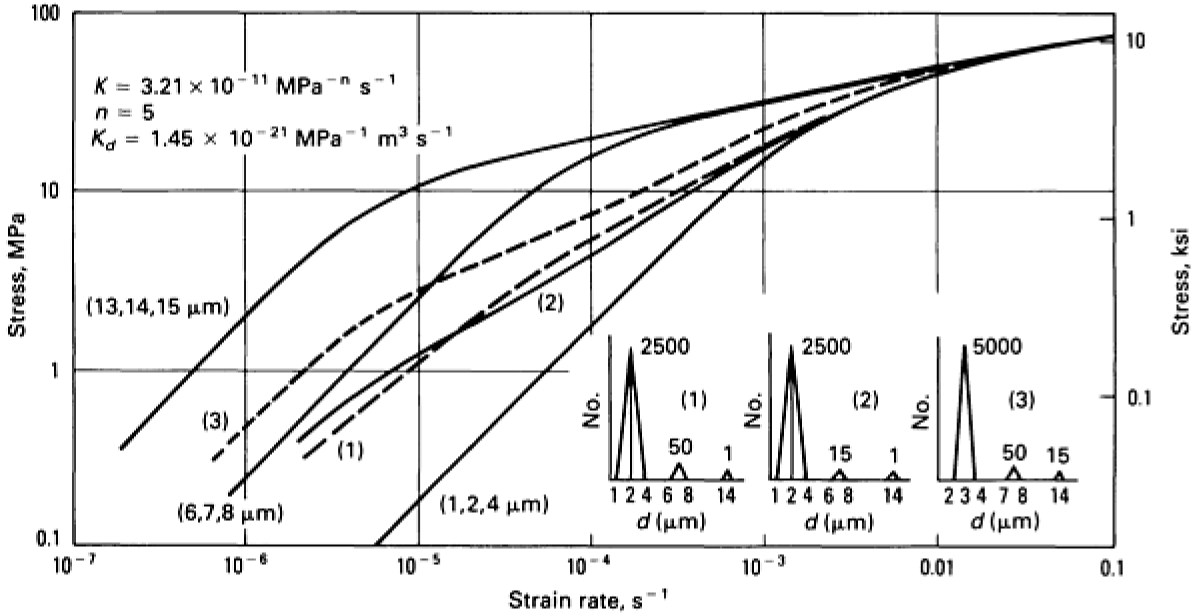

Fig. 4 Influence of different grain size distributions on the steady-state stress-strain rate curves. The solid lines

are for essentially singular grain sizes. Distribution in grain size yields a gradual transition in stress-strain rate curves.

Stress-Strain Behavior. Superplastic metals are generally regarded as ideally rate sensitive; that is, no strain hardening occurs during deformation. However, grain growth induced strain hardening has been observed, and it can be quite significant in some cases (Ref 9, 10, 15, and 16). In testing superplastic materials, constant crosshead speed leads to a decreasing strain rate within the specimen gage length, particularly at large tensile strains. An effort to maintain constant strain rate requires that:

- The specimen fillet region be reduced to a minimum to reduce its contribution to the overall extension
- The crosshead speed be programmed to increase with specimen elongation in order to maintain a constant strain rate (assuming the elongation to arise uniformly out of the gage length)

An on-line computer serves this function by altering the crosshead speed, *v*, in the following manner:

$$v = l_o \dot{\epsilon}_t \exp(\dot{\epsilon}_t t) \qquad \textbf{(Eq 3)}$$

where l_o is the initial gage length, $\dot{\epsilon}_t$ is the applied strain rate, and t is the time from the start of test. Temperature control during the test also must be accurate (within 2 °C, or 4 °F) in order to avoid any localized deformation.

Figure 5 shows the stress-strain curves for titanium and aluminum alloys obtained at various constant strain rates. The extent of hardening is quite large and appears to produce a linear stress-strain behavior. In diffusional creep, one can expect $\sigma \sim d^2$; if grain growth kinetics are such that $d \propto t^p$, where t is time, p is the exponent, and d is grain size, then $\sigma \propto t^{2p}$. When p is about 0.5, a linear hardening behavior would be expected. If diffusional creep due to grain-boundary transport is considered, $\sigma \propto d^3$, and p may be as low as 0.33, thus causing the appearance of linear hardening. In reality, the value of the hardening exponent, 2*p* or 3*p*, may be somewhat less than unity. A small component of strain rate dependent increase of flow stress also influences these experimental results because strain rate does not remain absolutely constant during the tests. The last portion of the stress-strain curves (shown dashed or with stress drop) is where nonuniformity of deformation within the gage length makes stress measurements incorrect.

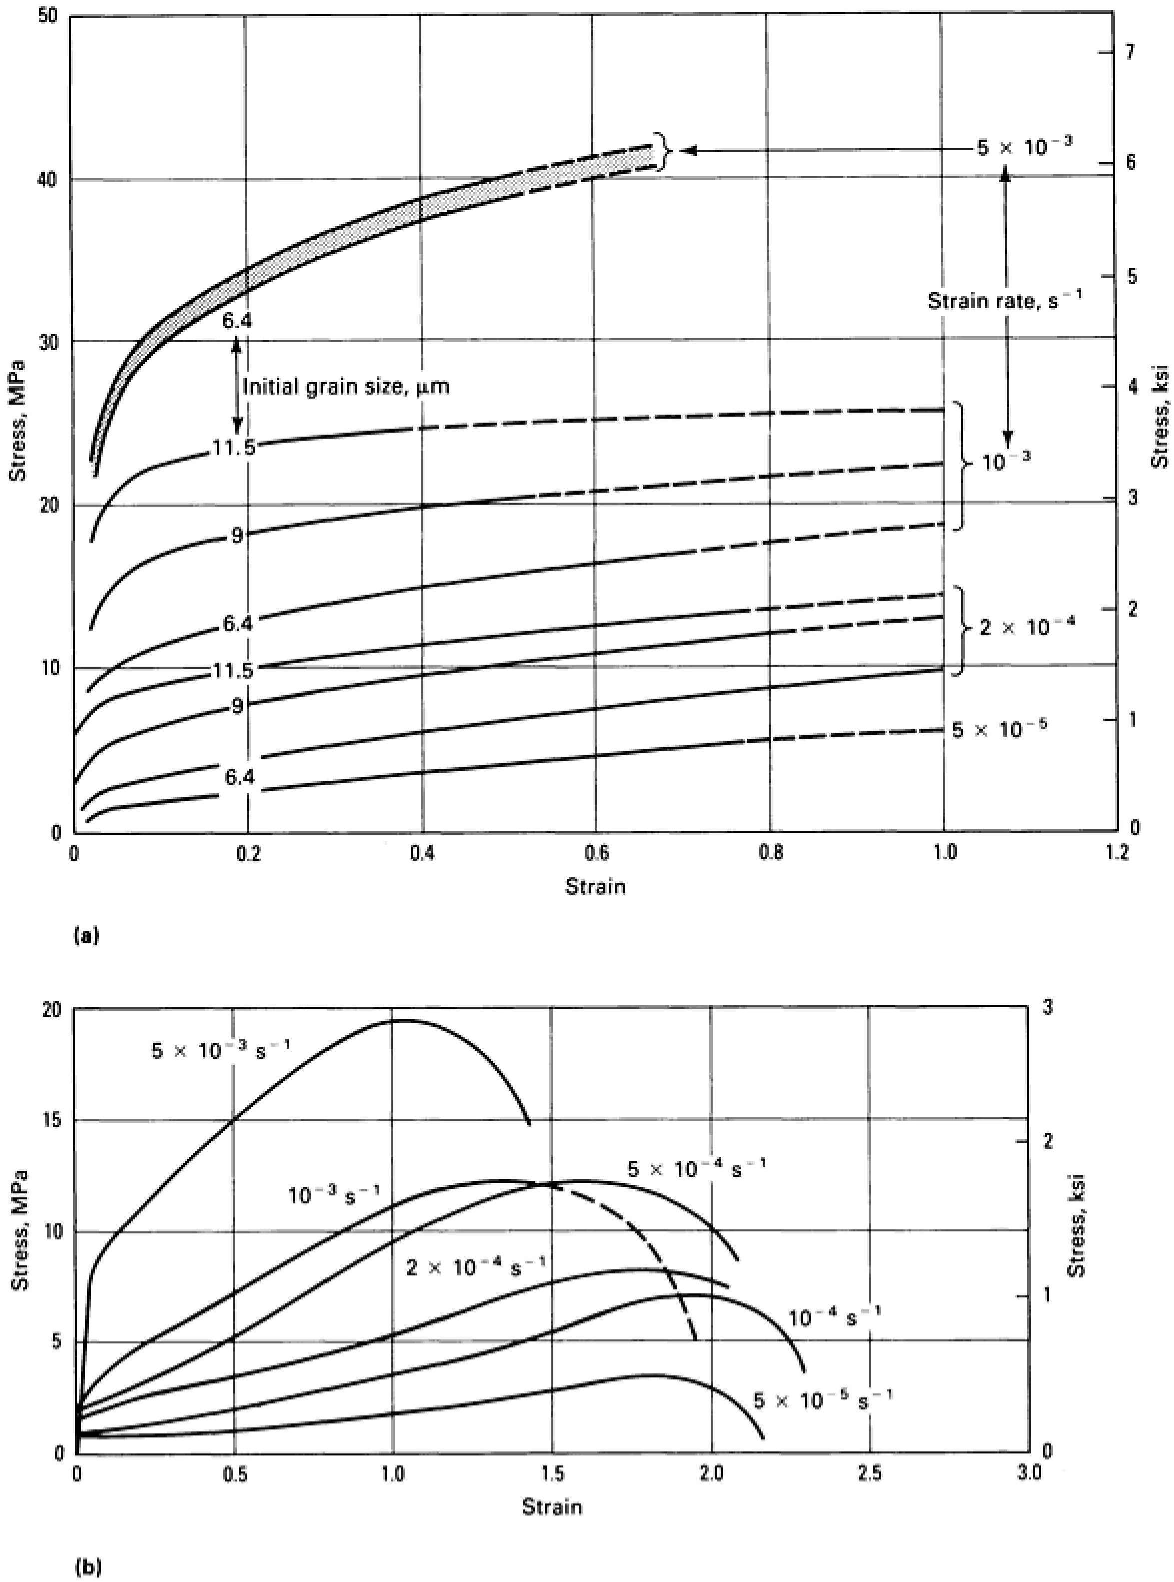

Fig. 5 Stress-strain curves at various constant strain rates for Ti-6Al-4V at 927 °C (1701 °F) (a) and 7475 aluminum alloy at 516 °C (961 °F) (b). Initial grain size: ~10 to 14 μm

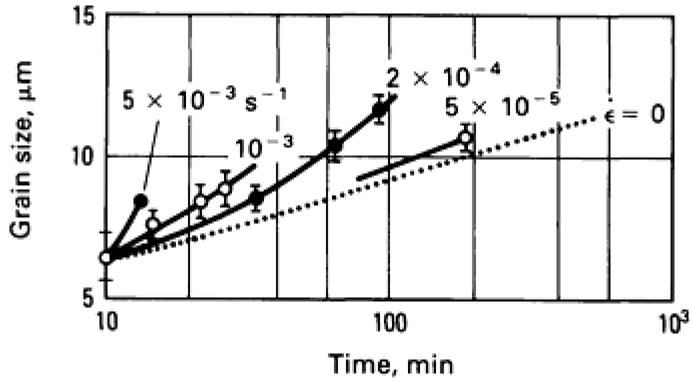
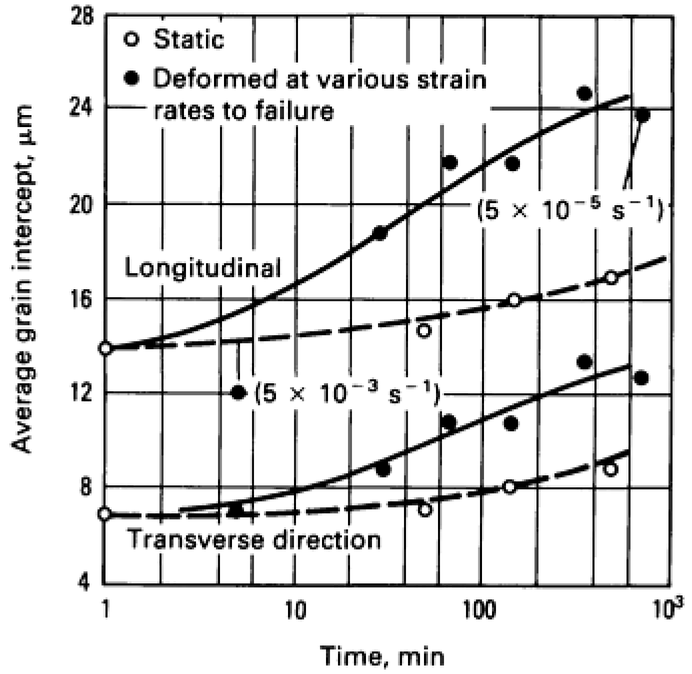
The significant strain hardening observed in Fig. 5 is believed to be due to concurrent grain growth, the evidence for which is shown in Fig. 6. In the case of Ti-6Al-4V, the grain growth kinetics appear to some degree to be a function of strain rate as well. It is clear, however, that slower strain rates produce the largest grain sizes, particularly because of the long exposure times, and in all cases, dynamic grain growth is significantly greater than static growth.



(a)



(b)

Fig. 6 Grain growth kinetics at four different tensile strain rates compared with static kinetics for Ti-6Al-4V at 927 °C (1701 °F) with 6.4 μm (250 μin.) initial grain size (a) and 7475 aluminum at 515 °C (959 °F) (b)

Concurrent grain growth effects can also influence the stress-strain rate data measured at the low strain rates. This can be understood from the consideration of a constitutive equation of the form:

$$\dot{\epsilon} = \frac{A\Omega D_{eff}}{kTd^3}\sigma + K\sigma^n \qquad \textbf{(Eq 4)}$$

where A is a constant, Ω is the atomic volume, D_{eff} is the effective diffusion coefficient, k is Boltzmann's constant, T is absolute temperature, K is the constant for power-law creep (containing dependencies on temperature and shear modulus), and n is the power-law creep exponent. Designating ($A\Omega D_{eff}/kT$ by A', and if dynamic grain growth is given by $d \sim d_o t^p$, the diffusional creep portion can be rewritten as:

$$\dot{\epsilon}_d = \frac{A' \sigma}{d_o^3 \, t^{3p}} \qquad \textbf{(Eq 5)}$$

where d_o refers to the initial grain size. During the step strain rate test with constant strain rate segments, if a stress of σ_1 is obtained at a strain rate $\dot{\epsilon}_1$ and a strain of ϵ_1, and σ_2 at $\dot{\epsilon}_2$ and ϵ_2, from Eq 4, then:

$$\frac{\sigma_2}{\sigma_1} = \left(\frac{\epsilon_2}{\epsilon_1}\right)^{3p} \left(\frac{\dot{\epsilon}_2}{\dot{\epsilon}_1}\right)^{(1 - 3p)} \qquad \textbf{(Eq 6)}$$

because $t = \epsilon/\dot{\epsilon}$ for a constant strain rate test. The strain rate sensitivity *m* can be given by:

$$m = \frac{\log\left(\frac{\sigma_2}{\sigma_1}\right)}{\log\left(\frac{\dot{\epsilon}_2}{\dot{\epsilon}_1}\right)} = (1 - 3p) + 3p \frac{\log\left(\frac{\epsilon_2}{\epsilon_1}\right)}{\log\left(\frac{\dot{\epsilon}_2}{\dot{\epsilon}_1}\right)} \qquad \textbf{(Eq 7)}$$

Therefore, the amount of strain accumulated in each strain rate step will influence the value of *m* through its influence on dynamic grain growth kinetics. If p = 0.25 (Ref 9), then in the limit, *m* could vary between 0.25 and 1 and might be responsible for the apparent threshold stress-like behavior at low strain rates. The concurrent grain growth induced hardening thus makes it difficult to describe superplastic flow behavior accurately.

Step strain rate tests conducted with minimum strain accumulation are used as the initial stress-strain rate behavior of the materials, and the strain-hardening component is measured and added separately. The rationale for this is seen in Fig. 7, in which two step strain rate tests conducted with intermediate superplastic deformation clearly show that the hardening effect is not negligible. Although it may not be obvious from the slopes of these plots that *m* is also influenced by strain, a drop in *m* would be expected on the basis of grain growth (Fig. 3). The strain dependence of *m* can also be determined during constant strain rate tests by making incremental strain rate changes (Fig. 8a) of a small magnitude. With strain rate changes of 25 to 40% maintained over a 2 to 3% plastic strain, the microstructure may not be altered significantly after return to the original strain rate. Figure 8(b) shows the decrease in *m* measured from these tests. Similar results have also been observed in aluminum alloys (Ref 21). The drop in *m* is usually more rapid at the higher strain rates and may be related to classical hardening due to dislocation buildup, which is also faster at high strain rates. Even though strain hardening has important implications for superplastic flow, the rate sensitivity of strain hardening is usually small, and *m* is still the parameter of greater interest.

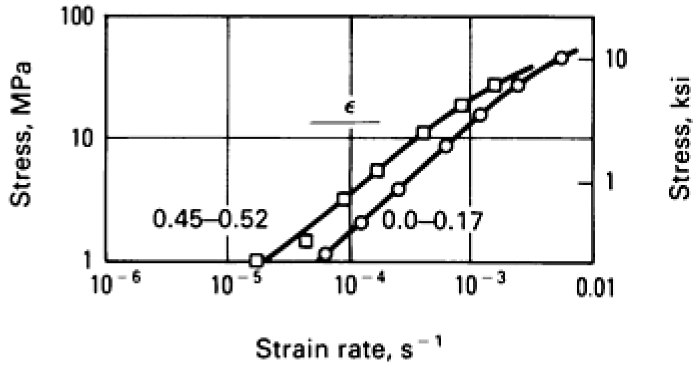


Fig. 7 Stress versus strain rate plots for 6.4 μm (250 μin.) grain size Ti-6Al-4V at 927 °C (1701 °F) initially (that is, up to ϵ = 0.17) and after a strain of 0.45 at a rate of 2 × 10^{-4} s^{-1} showing the hardening contribution due to the deformation.

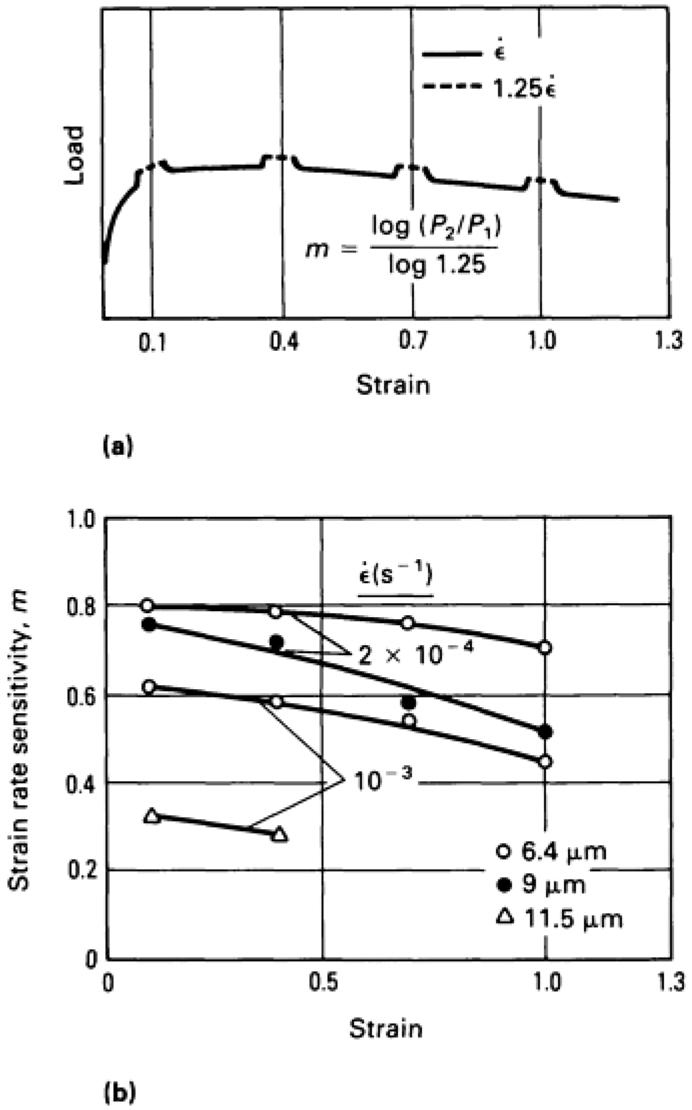

Fig. 8 Schematic representation (a) showing how instantaneous measurements of *m* can be made at periodic intervals during the tensile test by strain rate increments of 25%. (b) Corresponding *m* value as a function of strain for Ti-6Al-4V at 927 °C (1701 °F)

Important considerations in the selection and use of a superplastic alloy are the total elongation capability, the stability of the superplastic microstructure at high temperature, the latitude of the temperature and strain rate range over which superplasticity is observed, and the rate of development of cavitation during superplastic deformation. All of these factors can change from lot to lot of the material, and it is generally advisable to check each lot for the superplastic properties as well as design properties. Information on superplasticity in specific materials is available in the articles "Forming of Aluminum Alloys" and "Forming of Titanium and Titanium Alloys" in this Volume.

Superplastic Sheet Forming

C.H. Hamilton, Washington State University; A.K. Ghosh, Rockwell International

---

SPF Processes

A number of methods and techniques have been reported for forming superplastic materials, each of which has a unique capability and develops a unique set of forming characteristics (Ref 3, 22). The following are forming methods that have been used with superplastic alloys:

- Blow forming
- Vacuum forming
- Thermo-forming
- Deep drawing
- Superplastic forming/diffusion bonding (DB)
- Forging
- Extrusion
- Dieless drawing

Only those processes that relate to sheet metal forming will be described in this section. Superplasticity as related to bulk forming operations is discussed in the Appendix to this article and in the article "Isothermal and Hot-Die Forging" in this Volume.

Blow forming and vacuum forming are basically the same process (sometimes called stretch forming) in that a gas pressure differential is imposed on the superplastic diaphragm, causing the material to form into the die configuration (Ref 3, 22, 23, and 24). In vacuum forming, the applied pressure is limited to atmospheric pressure (that is, 100 kPa, or 15 psi), and the forming rate and capability are therefore limited. With blow forming, additional pressure is applied from a gas pressure reservoir, and the only limitations are related to the pressure rating of the system and the pressure of the gas source. A maximum pressure of 690 to 3400 kPa (100 psi to 500 psi) is typically used in this process.

The blow forming method is illustrated in Fig. 9, which shows a cross section of the dies and forming diaphragm. In this process, the dies and sheet material are normally maintained at the forming temperature, and the gas pressure is imposed over the sheet, causing the sheet to form into the lower die; the gas within the lower die chamber is simply vented to atmosphere. The lower die chamber can also be held under vacuum, or a back pressure can be imposed to suppress cavitation if necessary. The use of back pressure to control or prevent cavitation is discussed in the sections "Pressure Profiling" and "Cavitation and Cavitation Control" in this article.

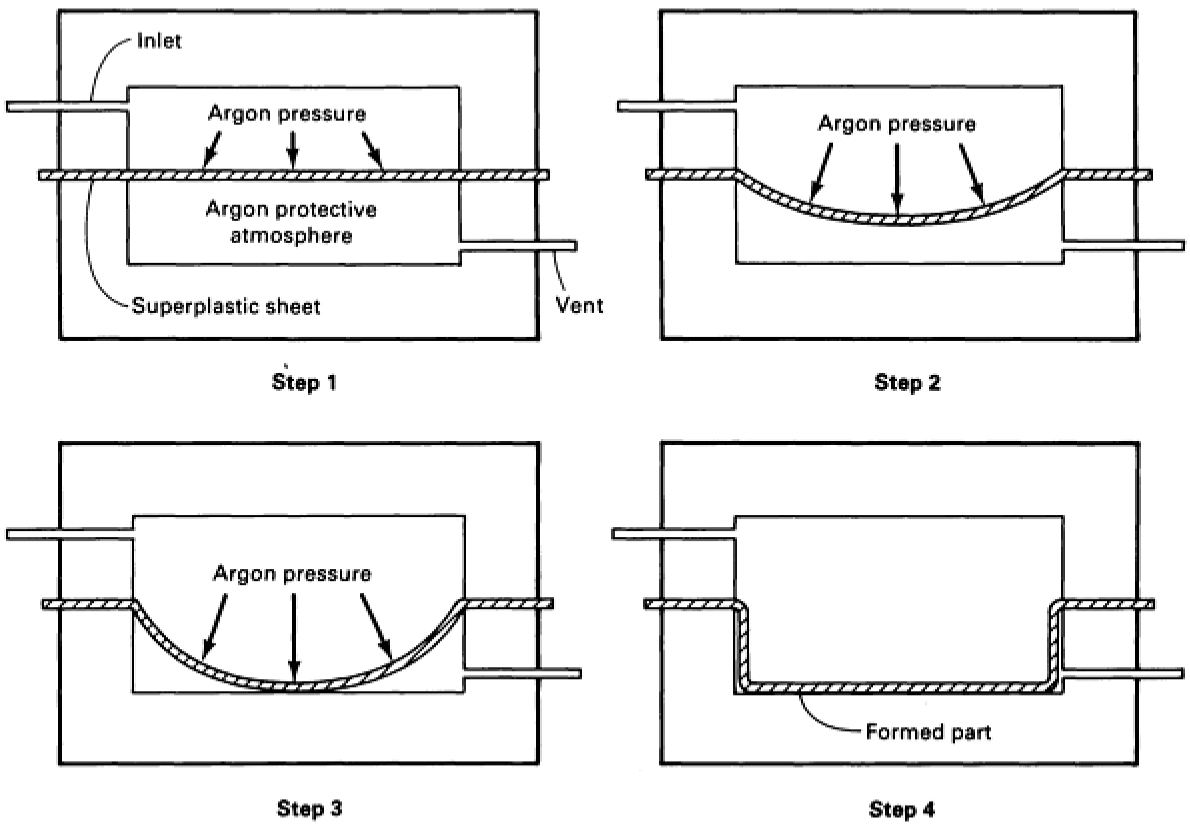

Fig. 9 Schematic of the blow forming technique for superplastic forming

The rate of pressurization is normally established such that the induced strain rates in the forming sheet are maintained in the superplastic range. The rate of pressurization is determined by trial and error or by the application of analytical modeling methods (Ref 25, 26, 27, and 28). This pressure is generally applied slowly rather than abruptly in order to prevent too rapid a strain rate and consequent rupturing of the part.

The periphery of the sheet is held in a fixed position and does not draw-in, as would be the case in typical deep-drawing processes. It is common to use a raised land (seal bead) machined into the tooling around the periphery as shown in Fig. 10 to secure the sheet from slippage and draw-in and to form an airtight seal in order to prevent leakage of the forming gas. Therefore, the sheet alloy stretches into the die cavity, and all of the material used to form the part comes from the sheet overlying the die cavity. This results in considerable thinning of the sheet for complex and deep-drawn parts, and it can also result in significant gradients in the thickness in the finished part.

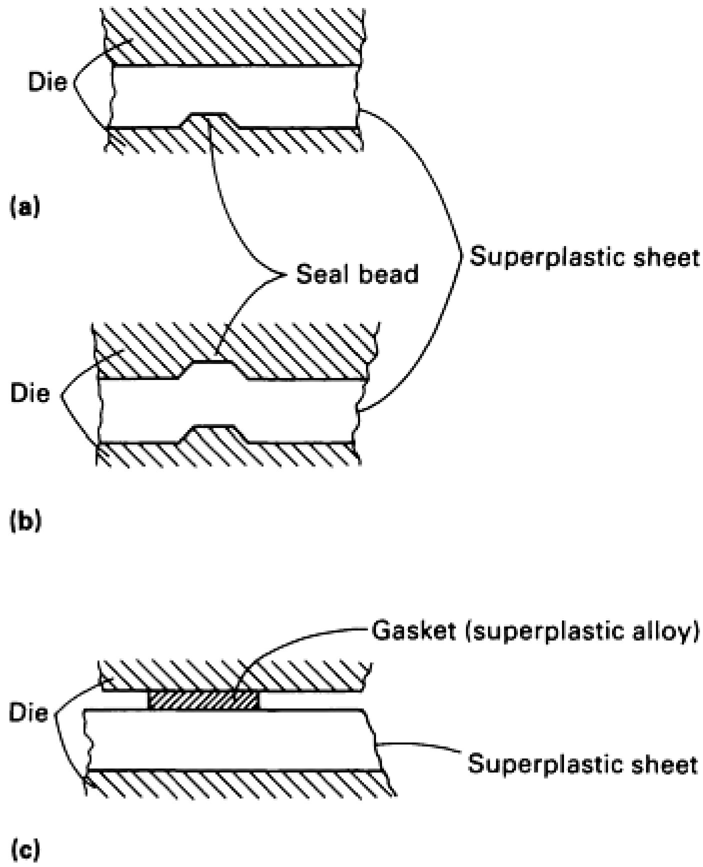

Fig. 10 Various sealing methods that have been used around the sheet to provide a pressure seal suitable for containing the gas pressure during forming. Sections (a) and (b) utilize seal beads machined into the tooling, and (c) shows the use of a superplastic frame used as a soft gasket.

This process is being increasingly used to fabricate structural and ornamental parts from titanium, aluminum, and other metals. An example of the process applied to the forming of a titanium aircraft nacelle frame is illustrated in Fig. 11 (Ref 29). In this case, the forming is conducted at about 900 °C (1650 °F), and inert gas (argon) is used on both sides of the sheet to minimize oxidation and related detrimental surface degradation due to the reactivity of titanium. The use of such protective gases is not usually necessary for aluminum alloys.

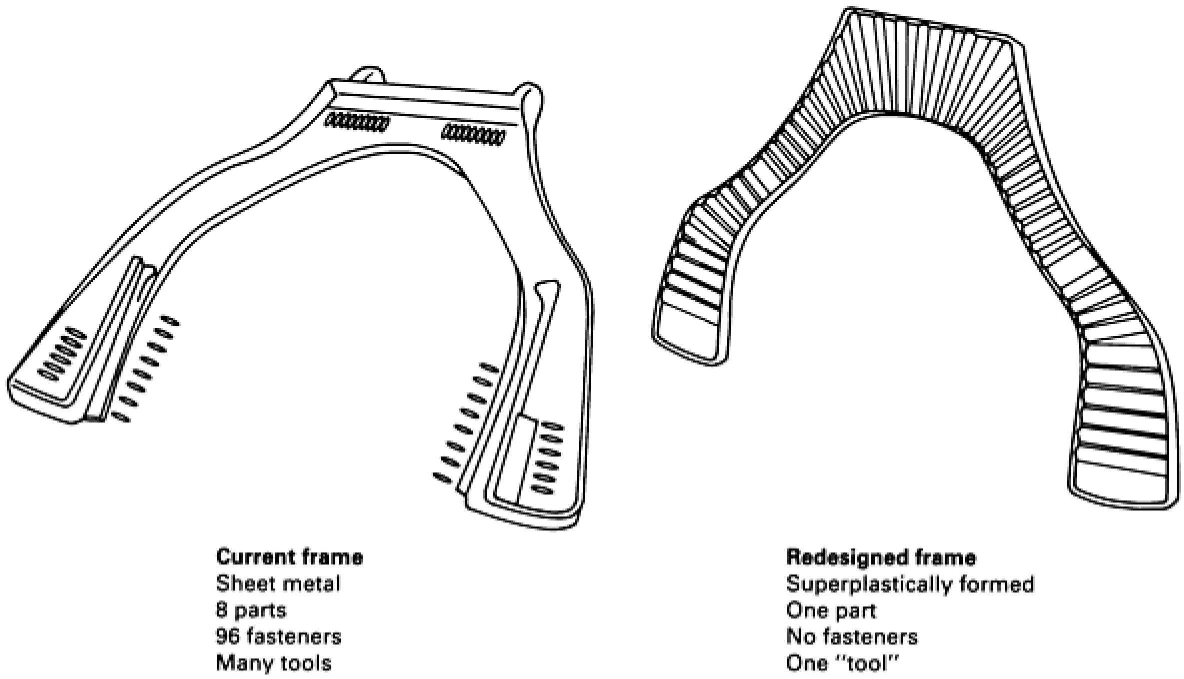

Fig. 11 Ti-6Al-4V aircraft nacelle frame that was redesigned from a conventional configuration to one suitable for superplastic forming having fewer parts and fasteners. The redesigned version of this B-1B aircraft component, having 0.161 m^2 (250 $in.^2$) plan view area, resulted in a 33% weight savings and a 55% cost savings over a conventional multiple-piece assembly.

Large, complex parts can be readily formed by this method; it has the advantage of no moving die components (that is, no double-acting mechanisms) and does not require mated die components. Multiple parts can be formed in a single process cycle, thus permitting an increase in the production rate for some parts.

Thermo-forming methods have been adopted from plastics technology for the forming of superplastic metals, and these methods sometimes use a moving or adjustable die member in conjunction with gas pressure or vacuum (Ref 23, 24, 30). Figure 12 shows two examples of thermo-forming methods. In Fig. 12(a), an undersize male die punch is used to stretch form the superplastic sheet, followed by application of gas pressure to force the sheet material against the configurational die to complete the shaping operation. In Fig. 12(b), the first step involves blowing a bubble in the sheet away from the tool. The male tool is then moved into the bubble, and the pressure is reversed to cause the bubble to conform to the shape of the tool.

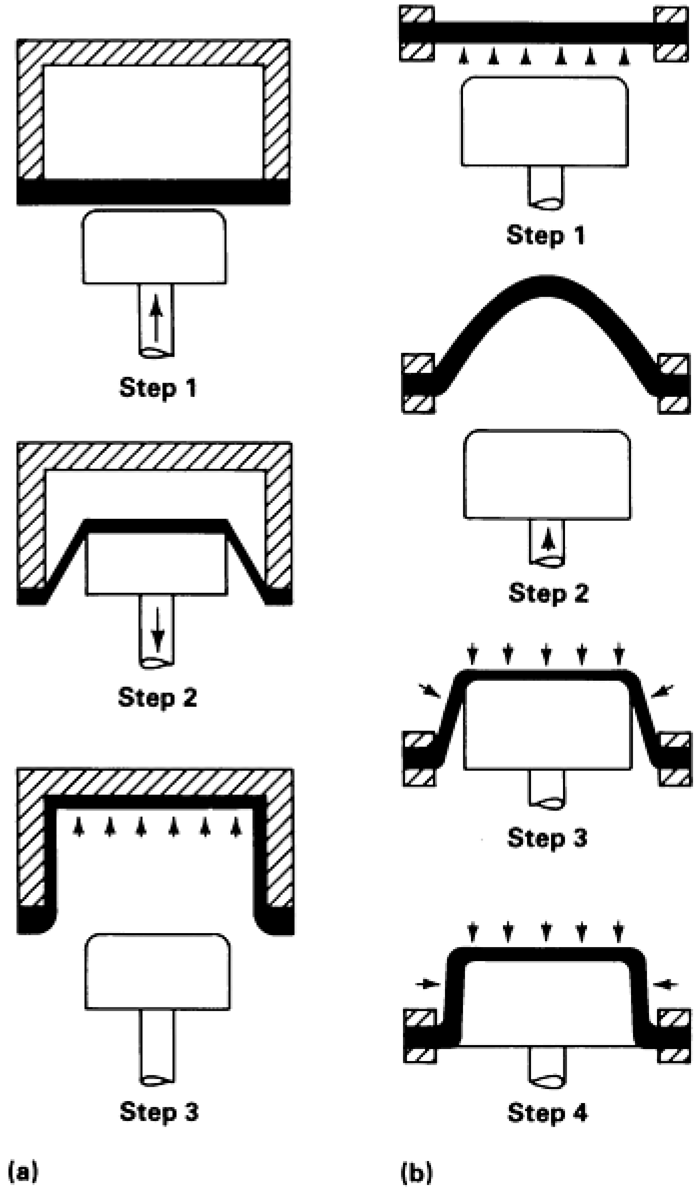

Fig. 12 Examples of thermo-forming methods used for superplastic forming. (a) Plug-assisted forming into a female die cavity. (b) Snap-back forming over a male die that is moved up into the sheet

Figure 13 illustrates two other methods that employ a movable die member that aids in prestretching the sheet material before gas pressure is applied. In this case, the gas pressure is applied from the same side of the sheet as the moving die. These techniques provide ways of producing different shapes of parts and are effective for controlling the thinning characteristics of the finished part.

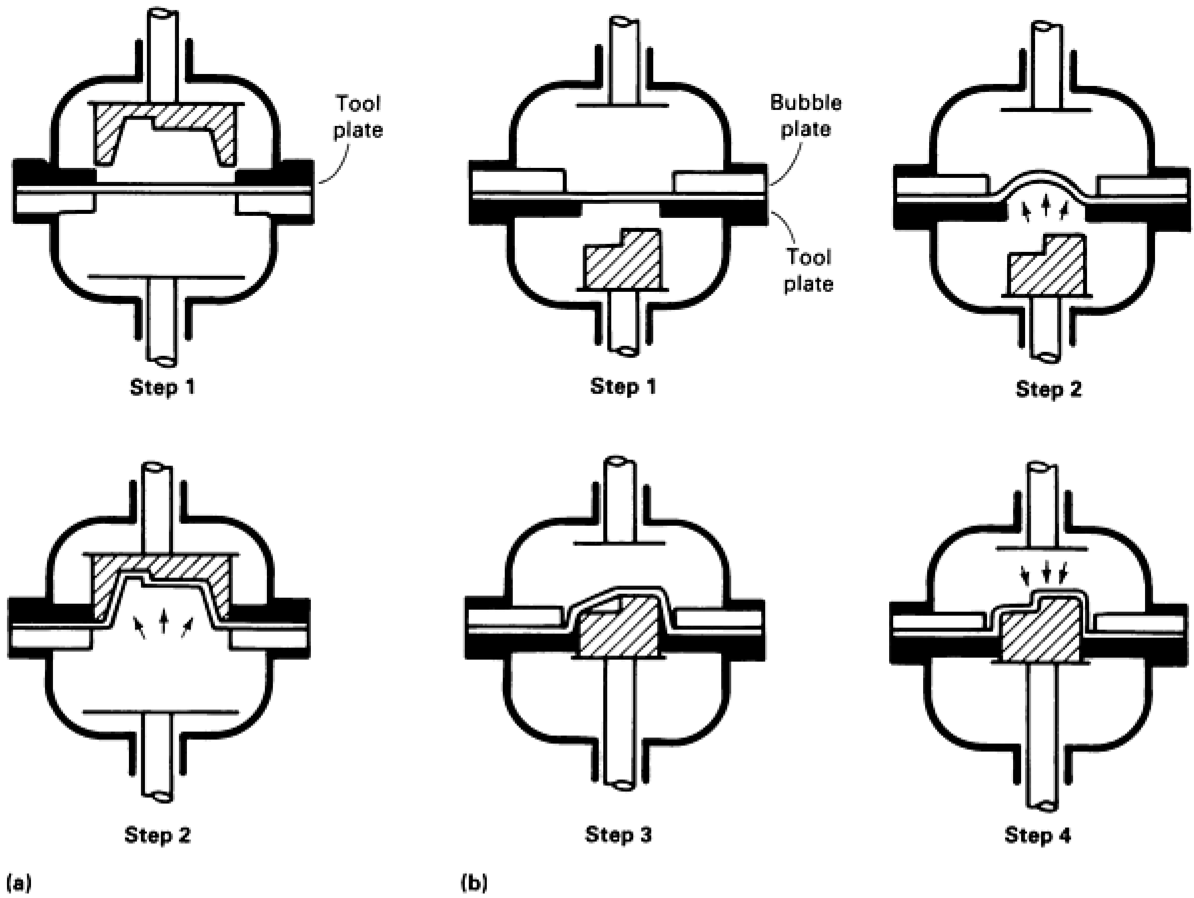

Fig. 13 Thermo-forming methods that use gas pressure and movable tools to produce parts from superplastic alloys. (a) Female forming. (b) Male forming

Deep Drawing. Although deep-drawing studies have been conducted with superplastic metals, this process does not appear to offer many significant advantages in the forming of superplastic materials. Deep drawing depends on strain hardening to achieve the required formability and to prevent thinning and rupture during forming. Superplastic materials do not strain harden to any great extent, but they depend on the high strain rate hardening for their forming characteristics, and this property seems to offer little aid to deep drawing.

The difficulty is that, in order to draw-in the flange, the material in contact with the punch nose, as well as that in the sidewall, must work harden to carry the increasing stresses required to draw-in increasing amounts of the flange. At superplastic temperatures, no significant work hardening occurs, and the punch typically pierces the blank, or the blank fails in the cup walls if the frictional constraint between the punch and the blank is high. However, in studies on the zinc-aluminum alloy, a maximum draw ratio of 2:1 has been developed under optimized conditions (Ref 31).

A technique that tends to improve the drawability of superplastic alloys is discussed in Ref 32. This method (Fig. 14) uses a punch cooled to a temperature below that of the forming blank, while the hold-down tooling is maintained at the forming temperature. It was demonstrated that this differential temperature technique permitted an increase in the limiting draw ratio from less than 2.4:1 for isothermal conditions to more than 3.75:1 for the differential temperature method. The thinning characteristics for this process are also shown in Fig. 14. Slight thinning can be seen to occur over the (cold) punch nose, and substantial thinning is seen in the material adjacent to the punch. The extent of the thinning in the material adjacent to the punch depends on the blank hold-down load, but increases with increasing blank diameter (draw ratio) and decreasing punch speed. Because ironing was not used in these forming tests, thickness increases were observed at the greater distances from the pole of the cup where substantial draw-in of the material occurred.

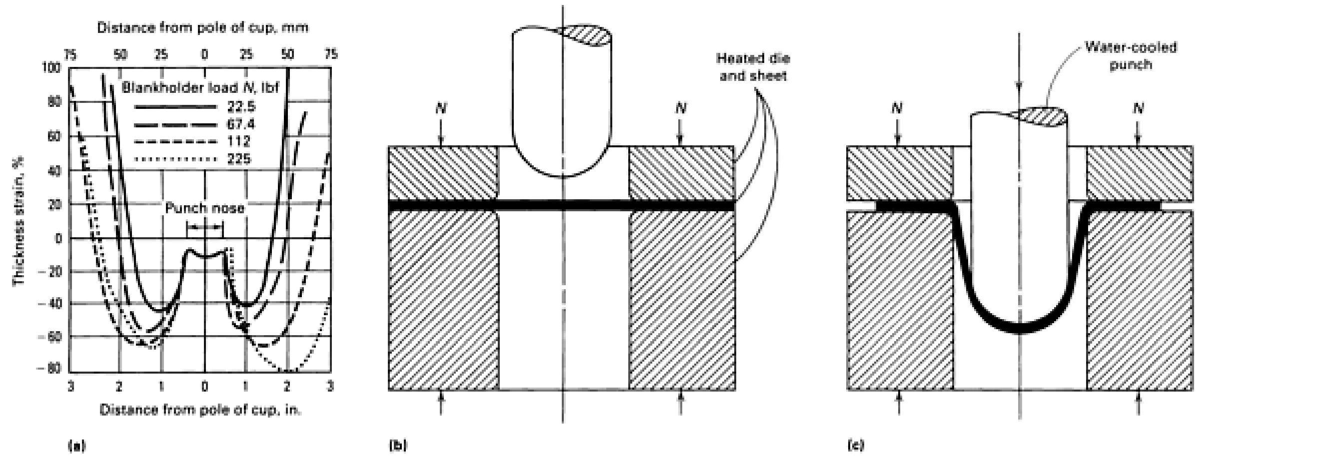

Fig. 14 Punch setup for deep drawing a superplastic sheet. (a) Plot showing thinning characteristics of a 59.9 mm (2.36 in.) diam Zn-21Al-1Cu-0.1Mg heated sheet that was formed using the 160 mm (6.3 in.) diam water-cooled punch setup illustrated in (b) and (c). *N*, blankholder load. Both the die and zinc alloy sheet were heated to 230 °C (445 °F). Punch speed was 33.0 mm/min (1.3 in./min), and maximum punch load was 2150 N (483 lbf). Draw ratio was 3.75. See text for discussion.

Another concept evaluated to explore the deep-drawing capability is discussed in Ref 33. This method uses high-pressure oil around a blank periphery to aid in the drawing. It is actually a combined extrusion and drawing process. In this study, a tin-lead eutectic was used, which permitted processing at ambient temperature. Good control of wall thickness was achieved, but the applicability of the process to alloys requiring high temperatures has yet to be demonstrated.

SPF/DB Processes. Recent developments have demonstrated that a number of unique processes are available if joining methods, such as diffusion bonding, can be combined with superplastic forming; these processes are generally referred to as SPF/DB processes (Ref 22, 34, 35). Although diffusion bonding is not a sheet metal process, it complements and enhances superplastic forming to such an extent that the two processes must be discussed together.

The SPF/DB processes have evolved as natural combinations of the SPF and DB processes because the process temperature requirements of both are similar. The low flow properties characteristic of the superplastic alloys aid the DB pressure requirements, and it has been found that many superplastic alloys can be diffusion bonded under pressures in the same low range as that used for SPF processing (that is, of the order of 2100 to 3400 kPa, or 300 to 500 psi). The SPF method used with SPF/DB to date is that of blow forming.

The resulting SPF/DB process consists of the following variations:

- Forming of a single sheet onto pre-placed details, followed by diffusion bonding (Fig. 15)
- Diffusion bonding of two sheets at selected locations, followed by the forming of one or both into a die (Fig. 16); the reverse sequence can also be used
- Diffusion bonding of three or more sheets at selected locations under gas pressure, followed by expansion under internal gas pressure, which forms the outer two sheets into a die; in the process, the center sheet(s) is stretched into a core configuration (Fig. 17)

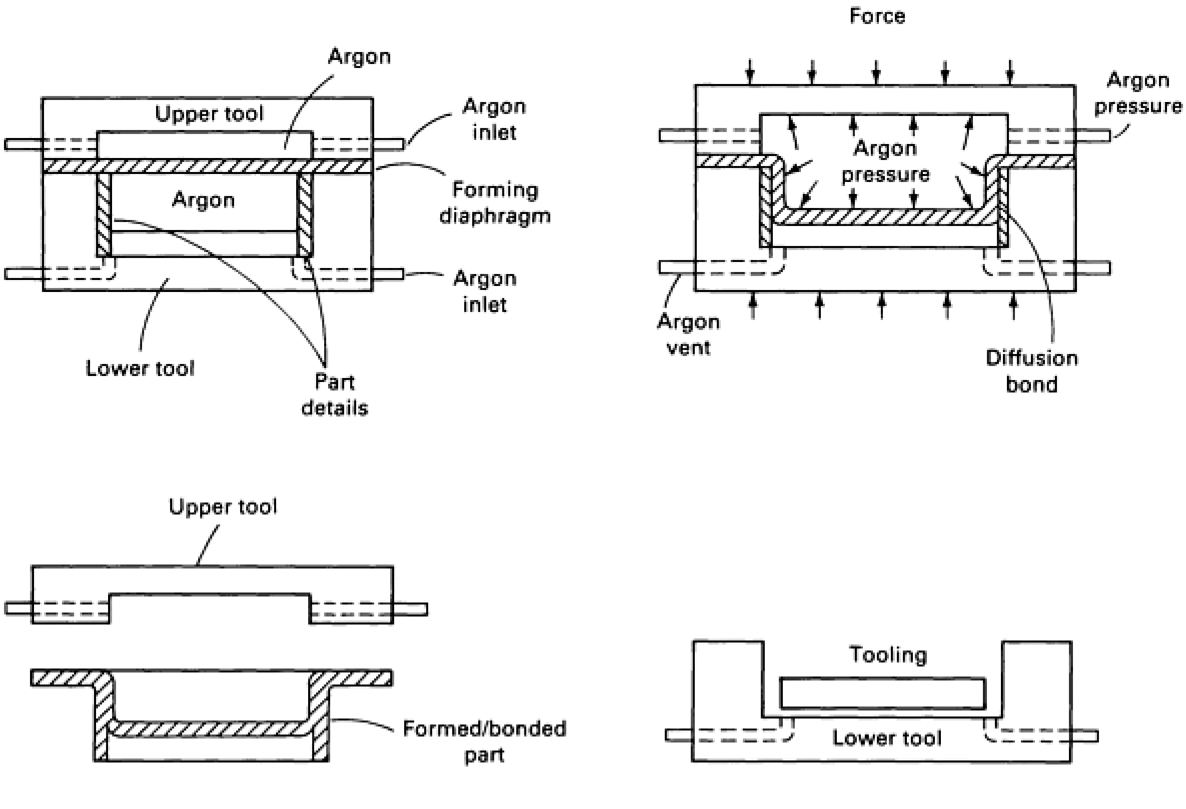

Fig. 15 Cross section of the SPF process combined with diffusion bonding (SPF/DB). The process shown utilizes pre-placed details to which the superplastic sheet is bonded.

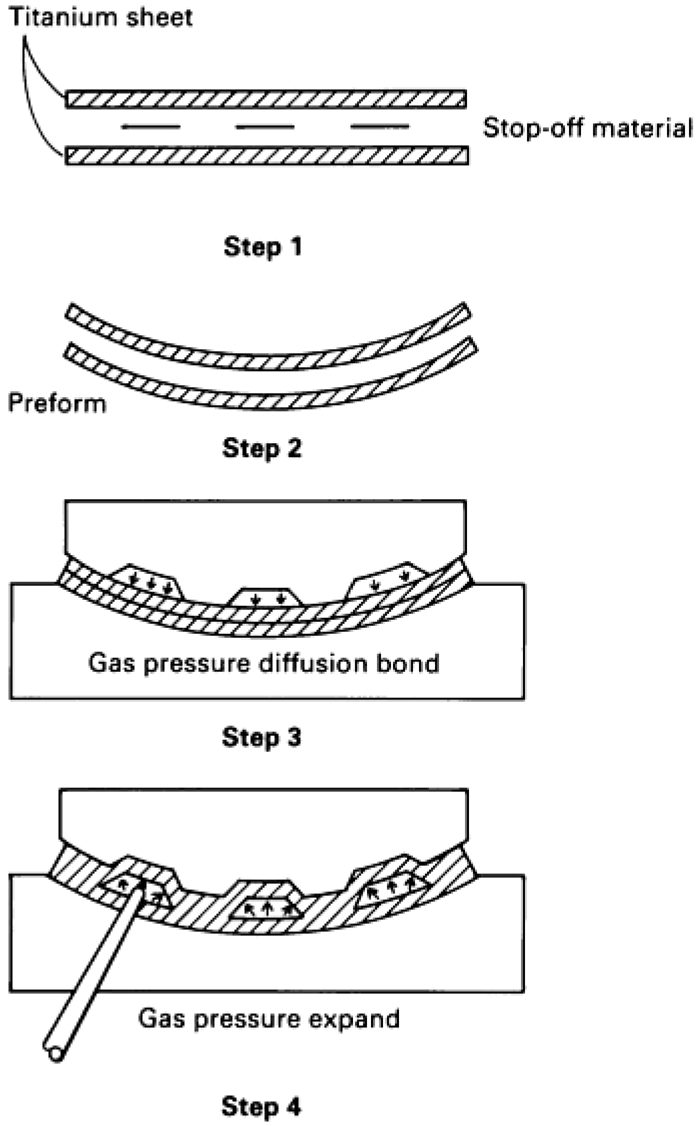

Fig. 16 Operations required for joining two sheets of superplastic alloy using the SPF/DB process.

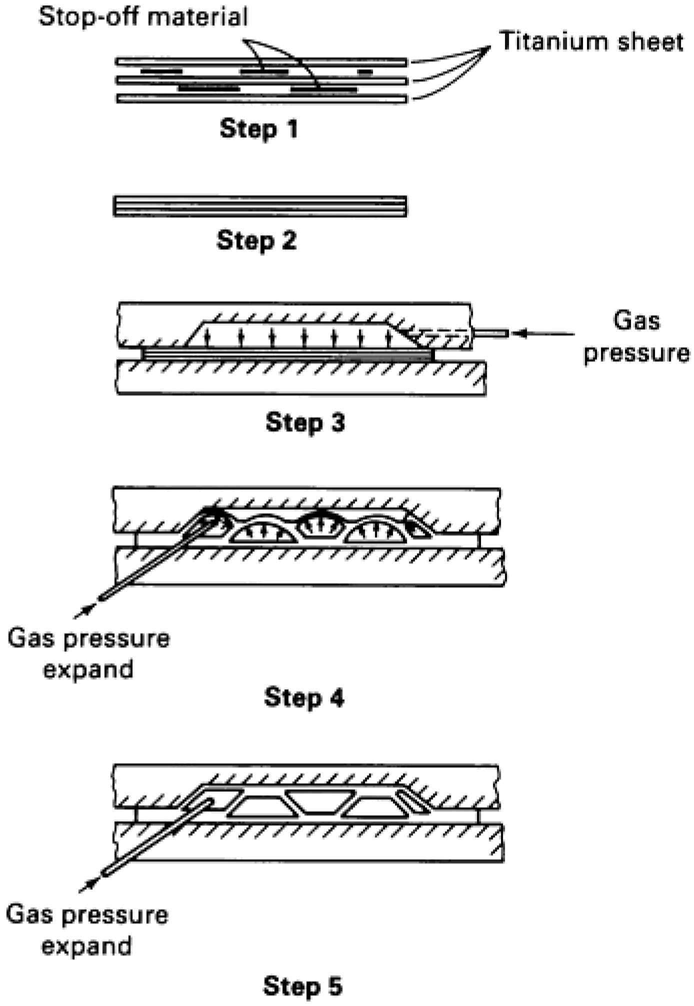

Fig. 17 Operations required for joining three sheets of superplastic alloy using the SPF/DB process

A few techniques have been used to develop diffusion bonds in predetermined local areas. One of these involves the use of a parting agent, or stop-off material, between the sheets in the local areas where no bonding is desired. Suitable stop-off materials may depend on the alloy being bonded and the temperature being used. For example, yttria or boron nitride has been successfully employed to stop-off titanium alloys processed to temperatures of at least 930 °C (1705 °F). Such stop-off materials can be suspended in an appropriate binder, such as acrylic. After a DB operation, the area of the stop-off pattern is not bonded, and gas can be applied internally along this pattern, thus causing the external sheets to be separated and formed by expanding into a surrounding die.

A variation of the above method involves the use of a minimum of four sheets to make a sandwich panel. The external (for example, skin) sheets are expanded, the inner two sheets are then bonded (or welded) to define the core structure, and finally the core is expanded to bond with the external sheets and to complete formation of the sandwich structure. This sequence is shown in Fig. 18.

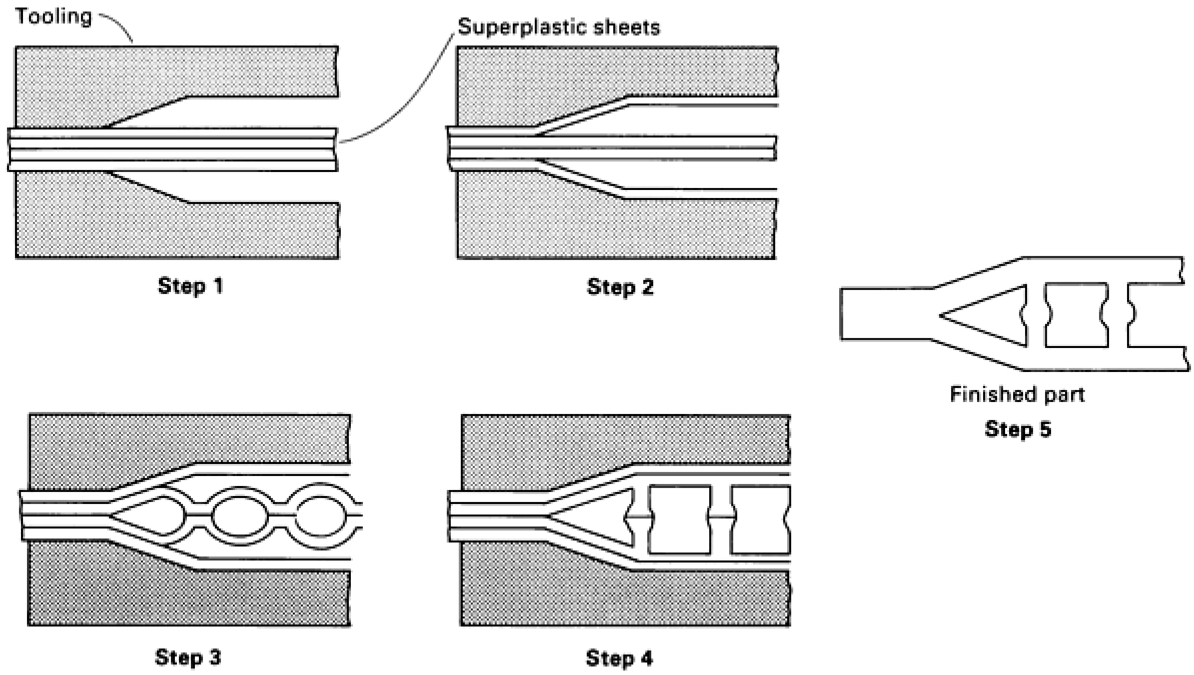

Fig. 18 Example of a four-sheet SPF/DB process in which the outer sheets are formed first and the center sheets are then formed and bonded to the outer two sheets.

Forming Equipment and Tooling

The forming of superplastic sheet materials involves methods that are generally different from those used in other, more conventional sheet forming processes. The forming environmental conditions are also different. Therefore, the equipment and tooling used are generally different.

Forming Equipment. For the blow forming and vacuum forming methods, there is a need to provide constraint to the forming tools in order to counteract the forming gas pressure. In addition, a seal is generally required at the interface between the sheet and the tool around the periphery in order to prevent leakage of the gas pressure. A press is typically used to meet these requirements. Hydraulic presses and mechanical clamping systems have been used, and each has advantages and disadvantages. The hydraulic press can be loaded and unloaded fairly rapidly, but it requires a significant capital investment. The mechanical clamping systems are much less expensive, but are more cumbersome to load and unload. Recently, robotic systems have been coupled with a hydraulic press to aid the loading and unloading, and this type of advanced system is especially beneficial for high-temperature forming operations such as titanium alloy SPF processing.

The hydraulic presses used include both single-action and multiple-action systems (Ref 22, 23, 30). In the single-action press, the press applies the constraining pressure only. In the multiple-action press, the press can also move dies into the forming sheet and effectively aid in the control of the thinning gradients (Fig. 12 and 13).

The heating system used must be tailored to the temperature required and the allowable thermal gradients. The most common heat source is electrical heating, in which resistance heating elements are embedded in ceramic or metal pressure plates placed between the tooling and the press platens. This allows for good control of the temperature and provides a clean source of energy. The heating platens can be arranged in sections of heating elements, and each section can be controlled by independent temperature controllers to minimize thermal gradients in the forming die assembly. Significant thermal gradients can lead to excessive thinning or rupture of the sheet during forming.

Tooling Materials. The tooling used in the SPF process is generally heated to the forming temperature, and it is subjected to internal gas pressure and pressing clamping loads. The internal gas pressure is typically less than about 3400 kPa (500 psi), and this is usually not the critical design factor for SPF tools. More important are the clamping loads and thermal stresses encountered during heat-up and cool-down and the environmental conditions. The thermal stresses can cause permanent distortions in the die, and this is controlled by selection of a material that has good strength and creep resistance at the forming temperature. Slow heating and cooling of the tooling can reduce the thermal stresses. Materials with a low coefficient of thermal expansion and those that do not undergo a phase transformation during heating and cooling are preferred for the high-temperature SPF processes.

The environmental conditions can be severe for the forming of high-temperature materials, such as the titanium alloys, iron alloys, nickel alloys, and other high-temperature metals. Oxidation can alter the surface condition of the tooling, thus affecting the surface quality of the SPF part produced and eventually affecting the dimensional characteristics.

Another important environmental factor is the compatibility between the superplastic sheet and the tooling, and the compatibility of these with the stop-off materials that may be used. Interdiffusion at the tooling/sheet interface can result in the degradation of both of these materials. Reactive metals, such as titanium alloys, are especially prone to this type of problem. Tooling materials that have been found to be successful with titanium alloys are the Fe-22Cr-4Ni-9Mn alloy and similar materials. Parting, or stop-off, agents are also helpful in minimizing the interaction, and materials such as boron nitride and yttrium oxide have been successfully used. Generally, materials with a low solid solubility in the sheet are good candidates for compatibility.

A variety of materials have been used for SPF tooling, including metals and alloys, ceramics, and graphite (Ref 36). Metal tools are preferred for large production quantities, such as 100 parts or more. Graphite tools are suitable for about 100 parts, and they are readily hand worked, although there is a problem with shop cleanliness with graphite. Ceramics can be cast into the desired shape and are therefore inexpensive for a variety of large parts. Because the ceramic is subject to cracking and rapid degradation, it requires frequent repair. Ceramic tools are considered for small production quantities, usually less than about 10 parts.

Superplastic Sheet Forming

C.H. Hamilton, Washington State University; A.K. Ghosh, Rockwell International

Thinning Characteristics

To take advantage of the very high elongations possible with superplastic metals, it is necessary to accept the accompanying significant thinning in the sheet material. This thinning is a natural consequence of the deformation conditions. For superplastic deformation, elastic strains are negligible; therefore, constancy of volume can be assumed. From this consideration, the sum of the plastic strains is 0, and tensile strain in one direction must be balanced by compressive (negative) strains in another. The strains are:

$$\epsilon_1 + \epsilon_2 + \epsilon_3 = 0 \quad \textbf{(Eq 8)}$$

where ϵ is the strain, and the subscripts indicate the principal directions. For example, in a sheet forming operation under plane-strain conditions, $\epsilon_2 = 0$ and $\epsilon_3 = -\epsilon_1$. In this case, the thinning strain (for example, ϵ_3) is equal and opposite to the longitudinal tensile strain, and the thinning will therefore match the tensile deformation. For large tensile strains, the thinning will be correspondingly large. Accordingly, as the thinning increases, the tendency to develop thinning gradients also increases.

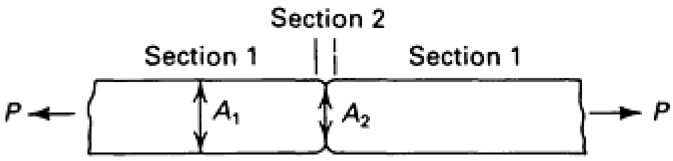
Although the superplastic materials are effective in resisting the necking process, they nonetheless do neck (in relation to the *m* value), and thinning gradients do develop. Therefore, in the design and processing of SPF parts, it is important that the thinning be understood and considered.

Uniaxial Tensile Test. It has been shown that superplastic deformation occurs when *m* is large and that under these conditions the deformation process is predominately postuniform, in contrast to conventional metal tensile behavior. In most cases, virtually all deformation is nonuniform, and the issue in the tensile behavior is the extent of this nonuniformity. The thinning in the tensile specimen can be assumed to be the result of a preexisting inhomogeneity, which can grow under the imposed deformation (Ref 37, 38).

The rate of thinning in the tensile specimen is therefore determined not only by the size of the inhomogeneity but also by the *m* value. This has been demonstrated analytically for an idealized tensile specimen (Fig. 19) containing a geometric inhomogeneity, *f* (for example, a machining defect) (Ref 9). This analysis follows the strain development both inside and outside the inhomogeneity, assuming that the applied load is fully transferred along the length of the specimen and that the material obeys the following constitutive equation:

$$\sigma = K \epsilon^n \dot{\epsilon}^m \quad \textbf{(Eq 9)}$$

where *n* is the strain-hardening exponent (*n* is small in this case). The results of calculations using Eq 9 are shown in Fig. 20, in which the strain in the inhomogeneity is graphed as a function of the strain outside the inhomogeneity for a number of different *m* values. The extent of the thinning in the tensile specimen is shown to be strongly related to the *m* value, although thinning gradients will develop at all *m* values if the strain is sufficiently large. It will be seen that this is also the case for sheet forming in which the inhomogeneity is caused by stress gradients resulting from the part geometry and tool interactions. The inhomogeneities in tensile specimens have also been found to relate to the *m* value (Ref 39), as shown in Fig. 21 for the Zn-22Al eutectoid alloy. In Fig. 21, the results are presented for the same alloy tested at different strain rates, for which the *m* values are known to differ.



$$f = \frac{A_1 - A_2}{A_1}$$

$$\sigma_1 = \frac{P}{A_1};\ \sigma_2 = \frac{P}{A_2} = \frac{P}{A_1(1 - f)}$$

Fig. 19 Geometric inhomogeneity, *f*, in a tensile specimen

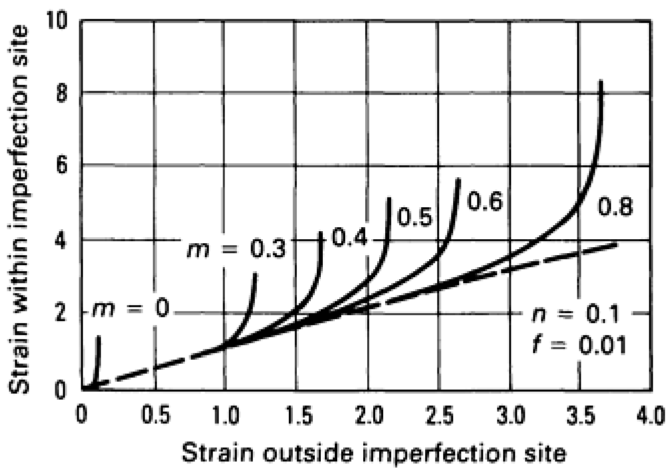


Fig. 20 Calculated strains inside and outside an inhomogeneity in a tensile specimen, such as that shown in Fig. 19, for various *m* values

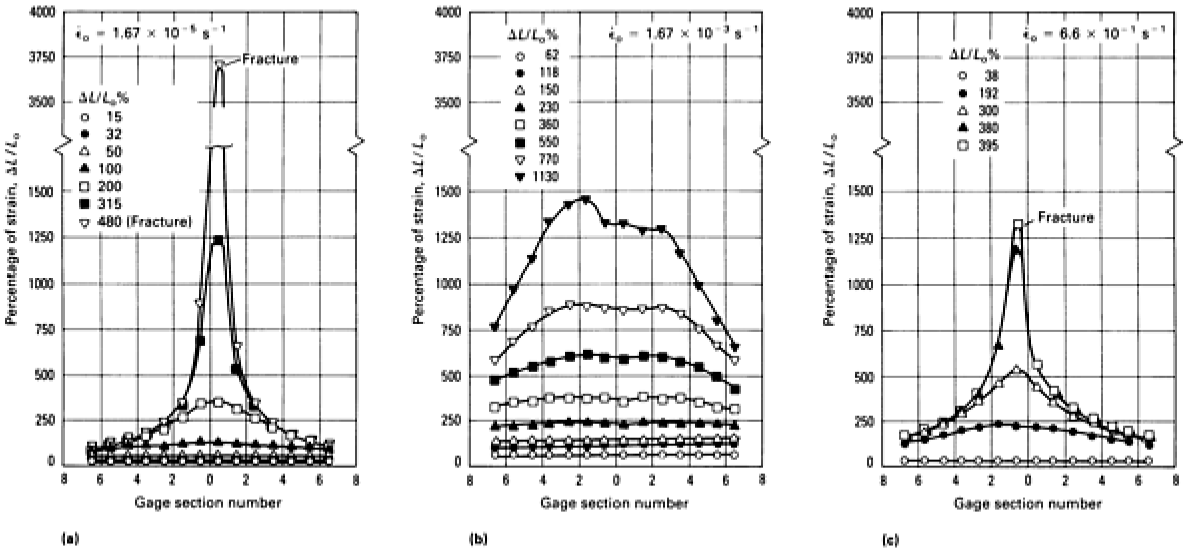

Fig. 21 Local elongation gradients in tensile specimens of Zn-22Al alloy at *T* = 473 K with initial gage length L_o of 12.7 mm (0.500 in.) that were tested within the superplastic strain rate range (b) and outside the superplastic strain rate range (a) and (c). The total percentage of strain at each termination point is given by $\Delta L/L_o$, where ΔL is the overall increase in gage length. The percentage of strain in each of the 14 individual segments of the gage length is given by $\Delta l/l_o$ %, where Δl is the increase in length of each small segment of the specimen. The initial strain rate was $\dot{\epsilon}_o$.

Spherical Domes. Although the thinning in superplastic tensile test specimens is the result of geometric inhomogeneities, the corresponding thinning in biaxially formed parts is usually the result of local stress state differences, which subsequently lead to the development of geometric inhomogeneities. In all of these cases, however, the difference in the local stresses leads to strain rate gradients, and the strain rate gradients develop directly into thickness gradients. A major difference between the tensile specimen and the part configuration is that, in the former, the stress gradients can be varied (that is, reduced) by dimensional control during machining. In the part forming, however, the configuration determines the stress state, and the stress state is not adjustable without changing the geometry.

The concept of thinning during SPF processing is perhaps best understood in terms of the bulging of a sheet (Ref 25, 26, 30, 40, 41, 42, 43, 44, 45, and 46). In this geometry, there is a stress state gradient from the pole of the dome to the edge, as shown in Fig. 22. If the dome is assumed to develop into a part of spherical symmetry, the stress state can be readily described. At the pole, the orthogonal stresses are equal, and the stress state is that of equibiaxial tensile. At the edge of the dome, there is constraint around the periphery, leading to a plane-strain stress state. Because the flow behavior of superplastic metals has been found to obey the von Mises criterion (Ref 47), it is helpful to examine the effective stress, $\overline{\sigma}$, which will determine the corresponding strain rate:

$$\bar{\sigma}_p = \frac{1}{\sqrt{2}}[(\sigma_\theta - \sigma_\phi)^2 + (\sigma_\phi - \sigma_t)^2 + (\sigma_t - \sigma_\theta)^2]^{1/2} \quad \textbf{(Eq 10)}$$

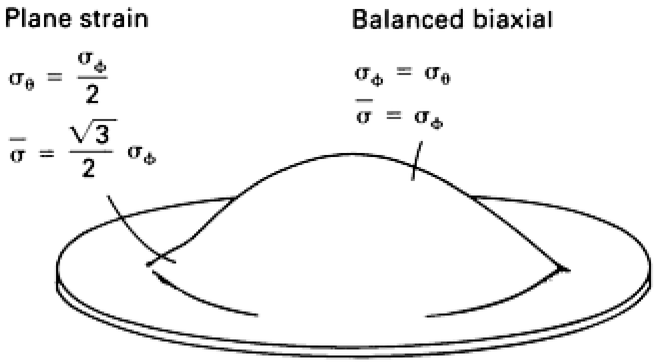

Fig. 22 Illustration of a spherical dome indicating the range of stress states existing between the pole and the edge

If it is assumed that the through-thickness stress is small with respect to the in-plane stresses, the effective stresses at the pole and the edge can be expressed in terms of the meridional stress, $\sigma\theta$, as follows:

$$\overline{\sigma}_p = \sigma\theta$$

and

$$\bar{\sigma}_e = \frac{\sqrt{3}}{2}\sigma_\theta = 0.87\sigma_\theta \quad \textbf{(Eq 11)}$$

where the subscripts *p* and *e* indicate the pole and the edge, respectively, of the dome. Therefore, the pole is experiencing a 15% higher flow stress than the edge, resulting in a higher strain rate, the initial magnitude of which depends on the *m* value.

The stress state difference between the pole and the edge of the dome is roughly the equivalent of the tensile specimen, which has a local geometric inhomogeneity, *f*, of 0.13. The initial strain rate difference between these two areas is dependent on the *m* value, the larger the *m* value, the smaller the strain rate difference and the less the tendency to develop a thickness gradient. For example, the ratio of $\dot{\epsilon}_e/\dot{\epsilon}_p$ is 0.87 for m = 1, and the value is 0.5 for m = 0.2--both for the same initial effective stress difference.

Therefore, the stress gradient in a forming dome causes a more rapid thinning rate at the pole, and it may be expected that the thinning difference will accelerate with time, leading to a thickness gradient in the formed dome. There are abundant experimental results to show that this is the case and that the thinning gradient is a function of the *m* value. Profiles of thickness for bulge-formed sheets are shown in Fig. 23 for *m* values of 0.57 and 0.23 (Ref 40). The thickness gradient is in agreement with expectations, and the effect of the high *m* value in impeding localized thinning at the pole can be seen. Other results for a titanium alloy and a stainless steel for which *m* values are 0.75 and 0.4, respectively, are shown in Fig. 24, in which the thickness strain is plotted as a function of the position along the dome cross section (Ref 21). The position along the dome is measured as the fractional height, h/h_o, where h_o is the full height of the dome and h is the height on the dome at which the thickness measurement is made.

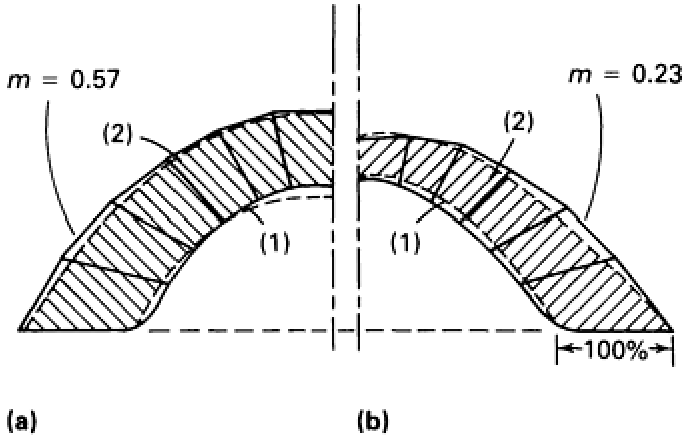

Fig. 23 Experimentally observed thickness profiles for a hemispherical dome formed from materials with two different *m* values (solid lines). The smaller, broken outlines confined mainly within the experimental data silhouette represent bulge profiles (1) and sheet thickness distributions (2) that were calculated using *m* = 0.50 (a) and *m* = 0.20 (b).

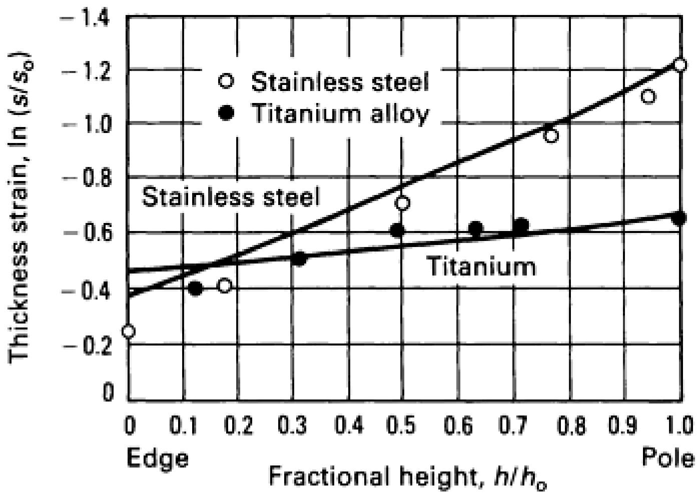

Fig. 24 Thickness strain as a function of the fractional height for dome-shaped parts formed from a stainless steel with an *m* value of 0.4 and a titanium alloy with an *m* value of 0.75. The values *s* and s_o in ln(s/s_o) represent dome thickness and initial sheet thickness, respectively.

A number of analytical developments have been reported that predict the thinning for the superplastic forming of this type of geometry (Ref 26, 30, 42, 44, 45, and 46). These models result in relations for thicknesses that are not closed-form, but require numerical integration of strain increments. The models predict the thinning characteristics reasonably well, as can be seen by the comparison of experimental and analytical data shown in Fig. 24 and 25.

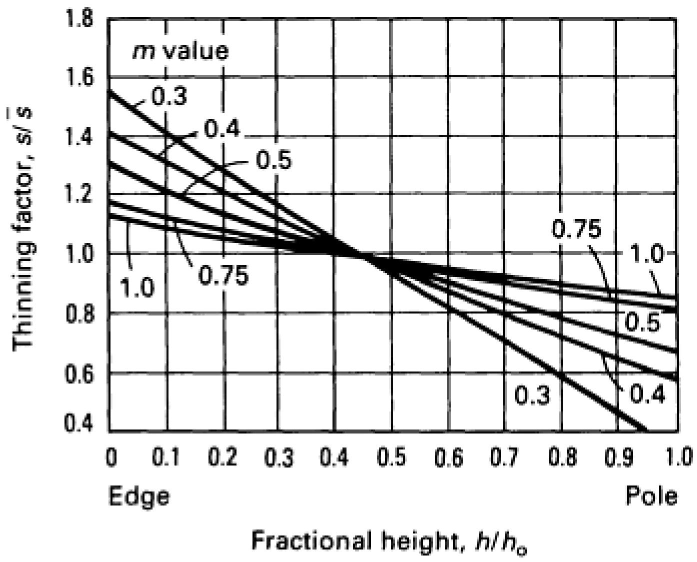

Fig. 25 Theoretical relations for a hemisphere showing the thinning factor as a function of the fractional height for a range of *m* values from 0.3 to 1.0

The theoretical predictions can be used to show the influence of the strain rate sensitivity of flow stress on the thinning gradient. For example, the thinning for a hemisphere formed from materials of differing *m* values is illustrated in Fig. 25. In Fig. 25, the thinning factor $s/\bar{S}$ is plotted as a function of the fractional height, where s is the local thickness and $\bar{S}$is the average dome thickness. The maximum thinning occurs at the pole because of the stress state, as mentioned previously, and the strain rate sensitivity is a crucial parameter in determining not only the initial strain rate difference but also the subsequent rate of thinning, as shown in Fig. 26, in which the thinning factor at the pole can be seen to be increasingly influenced by *m* as the dome height is increased.

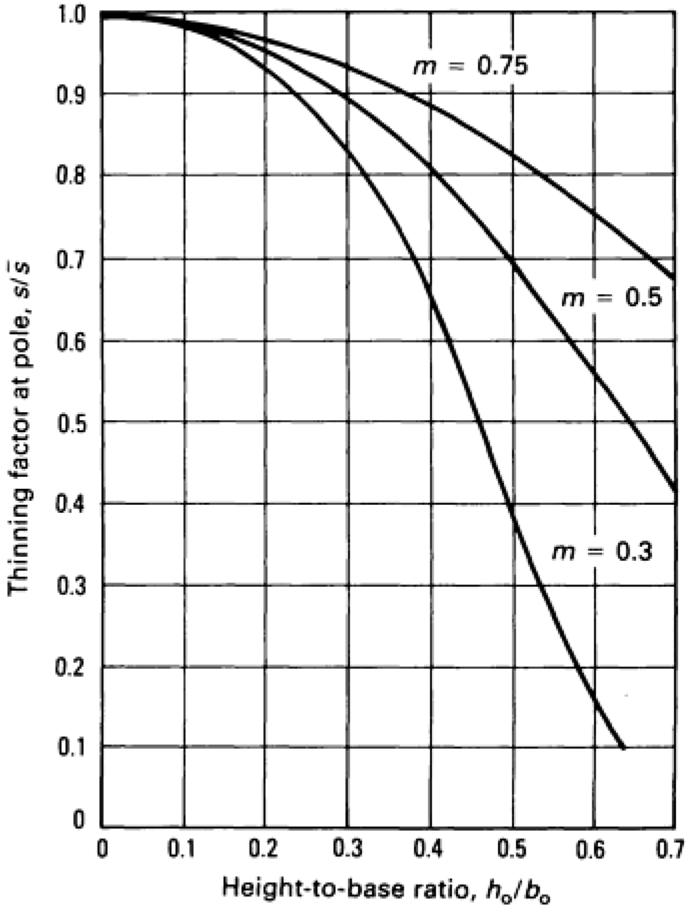

Fig. 26 Theoretical curves showing the thinning factor at the pole as a function of the bulge height-to-base ratio for *m* = 0.3, 0.5, and 0.75

The initial stress state differences and the corresponding strain rate differences along the meridian of a forming dome lead to a predictable thinning gradient in this type of geometry. The magnitude of the thinning gradient, however, is determined by the strain rate sensitivity, *m*, and the height to which the part is formed.

Rectangular Shapes. The factors that contribute to the thinning characteristics in rectangular parts, as well as other shapes, are the same as those for the spherical dome-shaped parts discussed in the previous section in this article. It is the specific geometry that determines the initial stress state gradients, and different geometries will be expected to develop different stress states in the forming part.

The rectangular shape is one that is common to many parts or sections of parts; therefore, it has been studied by experimental and analytical methods similar to those used for the spherical dome (Ref 22, 27, 47). For the long rectangular shape, there is a plane-stress state throughout the width of the sheet; for the case in which the die entry radius does not cause a significant stress concentration, the sheet will not experience an initial stress state gradient. This case is very similar to that of the tensile test, in which only thickness variations or material inhomogeneities will cause local stress differences leading to localized thinning. Because these are small in comparison to the magnitude of the stress variation in the forming dome, it may be expected that the thinning gradients would be less pronounced. Experimental results for the free-forming cylindrical section show this to be the case, as illustrated in Fig. 27, and virtually no thinning gradient is seen for hemicylindrical shapes.

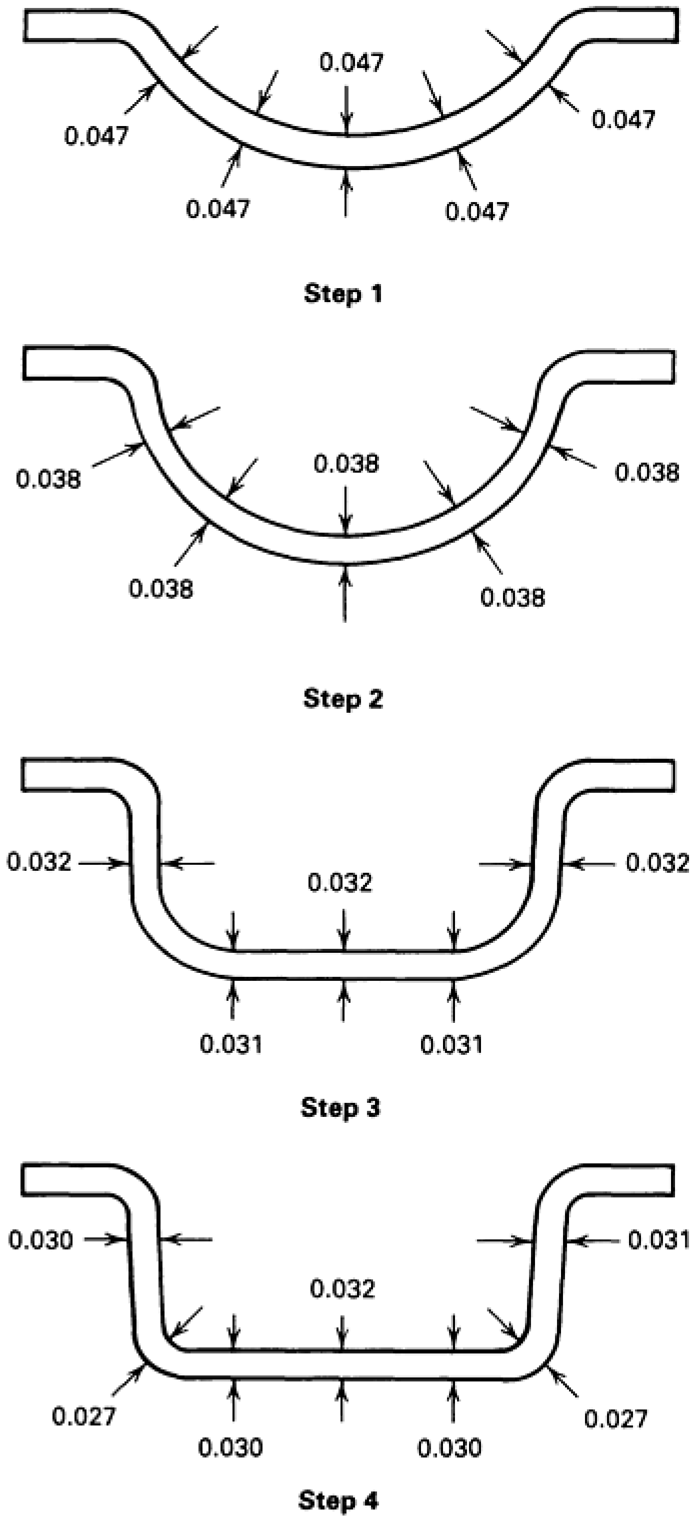

Fig. 27 Thinning development in a 1.37 mm (0.054 in.) thick superplastic formed Ti-6Al-4V part having a rectangular cross section and semi-infinite length. Formed at 870 °C (1600 °F) using a boron nitride lubricant, the sheet required 20 min to fabricate at an average strain rate of 5.8 × 10^{-4}. Dimensions given in inches

Interactions with the tooling do, however, cause local stress variations that can lead to thinning gradients, as shown in Fig. 27. This effect can be considered as two different types resulting from different areas of the die--the die surface at the bottom and sidewall, and the die entry radius.

Die Bottom and Sidewall. Ignoring the die entry effects, the die surface can be considered to restrict deformation in the forming sheet where contact has been made and where friction is non-zero. If the friction is large, the forming characteristic is as illustrated in Fig. 28. When the sheet makes contact with the die wall surface, the deformation in that contact area is restricted, and thinning is localized in the noncontact areas, leading to a greater degree of thinning in the last area to contact the die than in the first areas to make contact (Fig. 28). This results in a thickness gradient, as shown in Fig. 29, for a titanium alloy part formed in a die with no lubricating compounds present.

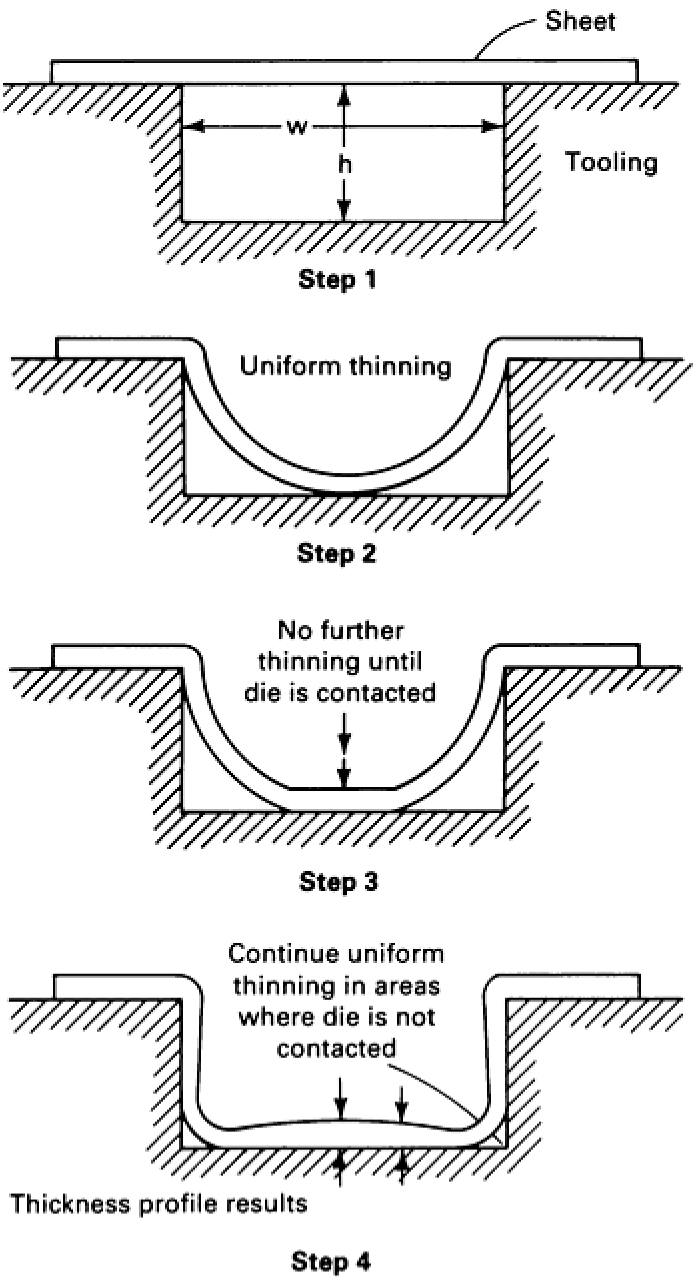

Fig. 28 Illustration of thinning characteristics in the blow forming of an unlubricated part of rectangular cross section and semi-infinite length

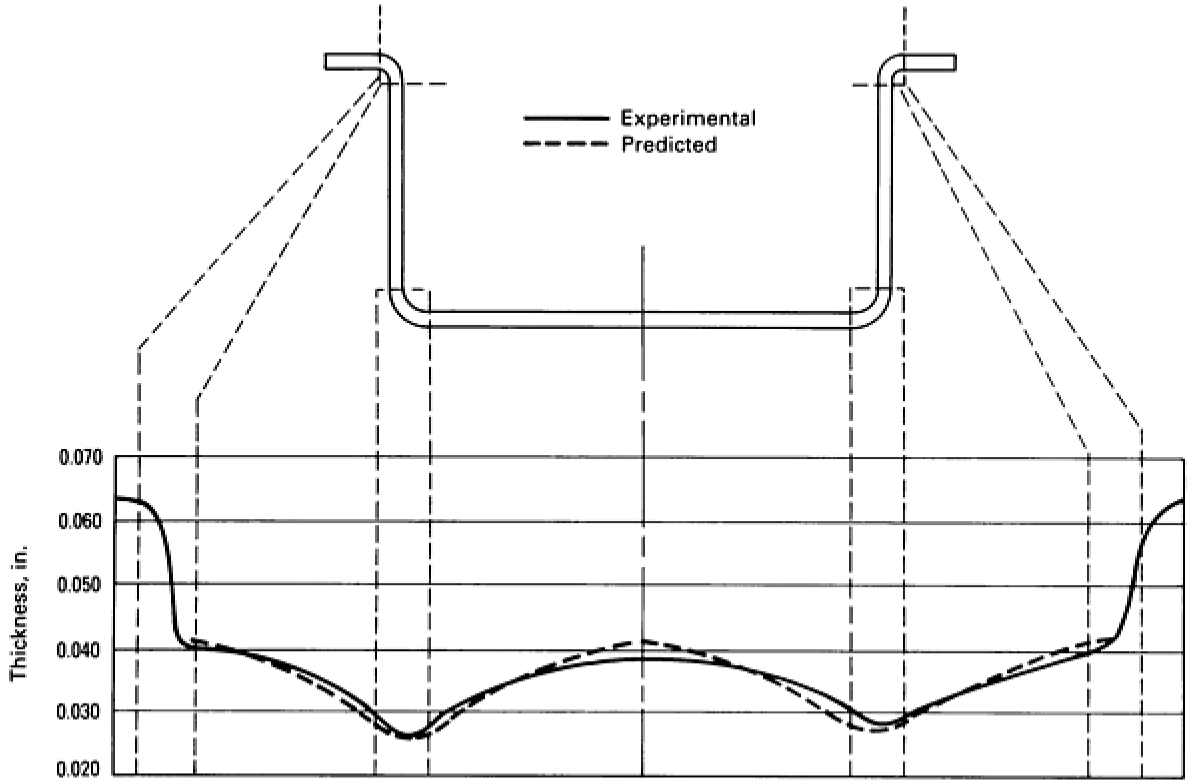

Fig. 29 Observed and predicted thinning profiles in an unlubricated blow-formed Ti-6Al-4V alloy part of rectangular cross section. Forming of the sheet, which had an initial thickness of 1.68 mm (0.066 in.), required 20 min at 925 °C (1700 °F).

This type of thinning is readily predicted analytically if it is assumed that the sheet sticks to the die surface after contact is made by using an incremental method (Ref 27). Results of this type of model show that there are a variety of thinning variations corresponding to various width and depth ratios of the rectangular shape, as shown in Fig. 30. It is apparent from Fig. 30 that the narrow and deep parts develop the greatest amount of thinning. In this specific case, the thickness profiles can be predicted quite well without referring to the strain rate sensitivity, *m*. This is the result of the dominant effect of the die friction coupled with the uniform initial stress state.

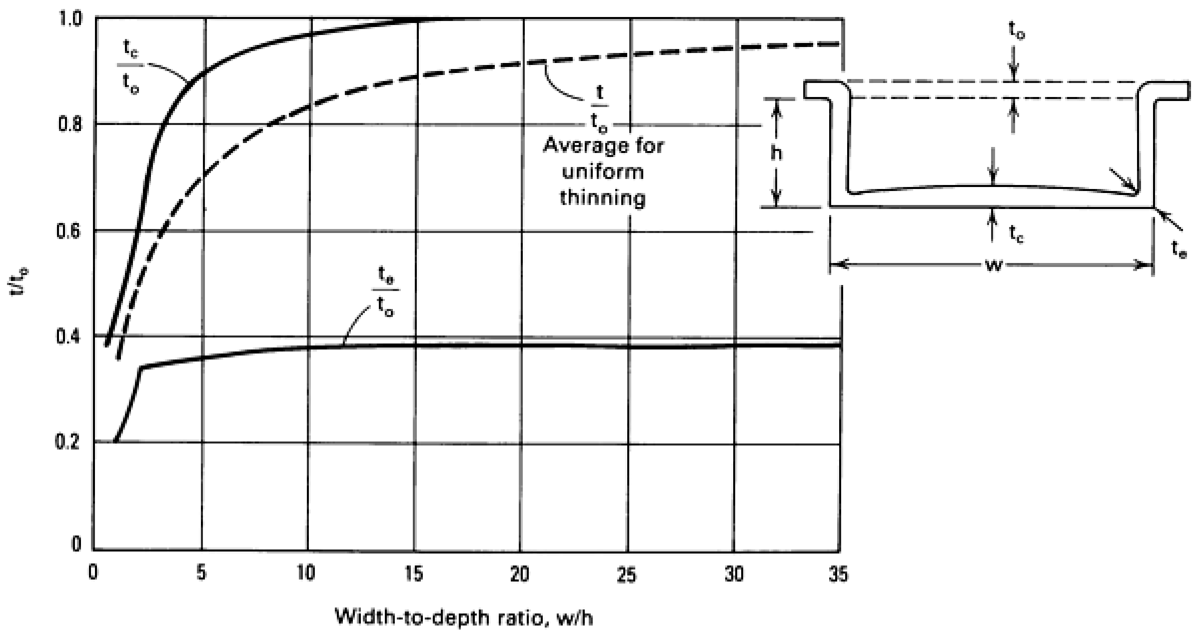

Fig. 30 Predicted minimum thicknesses as function of the width-to-depth (*w/h*) ratio for unlubricated blow-forming part of rectangular cross section.

If the interfacial friction is reduced, the thinning gradient will be reduced in the sidewall and bottom areas because continued deformation after die contact is possible. An example of the thinning in a formed rectangular titanium part is shown in Fig. 31, for which forming was conducted with a boron nitride solid lubricant (Ref 22, 27).

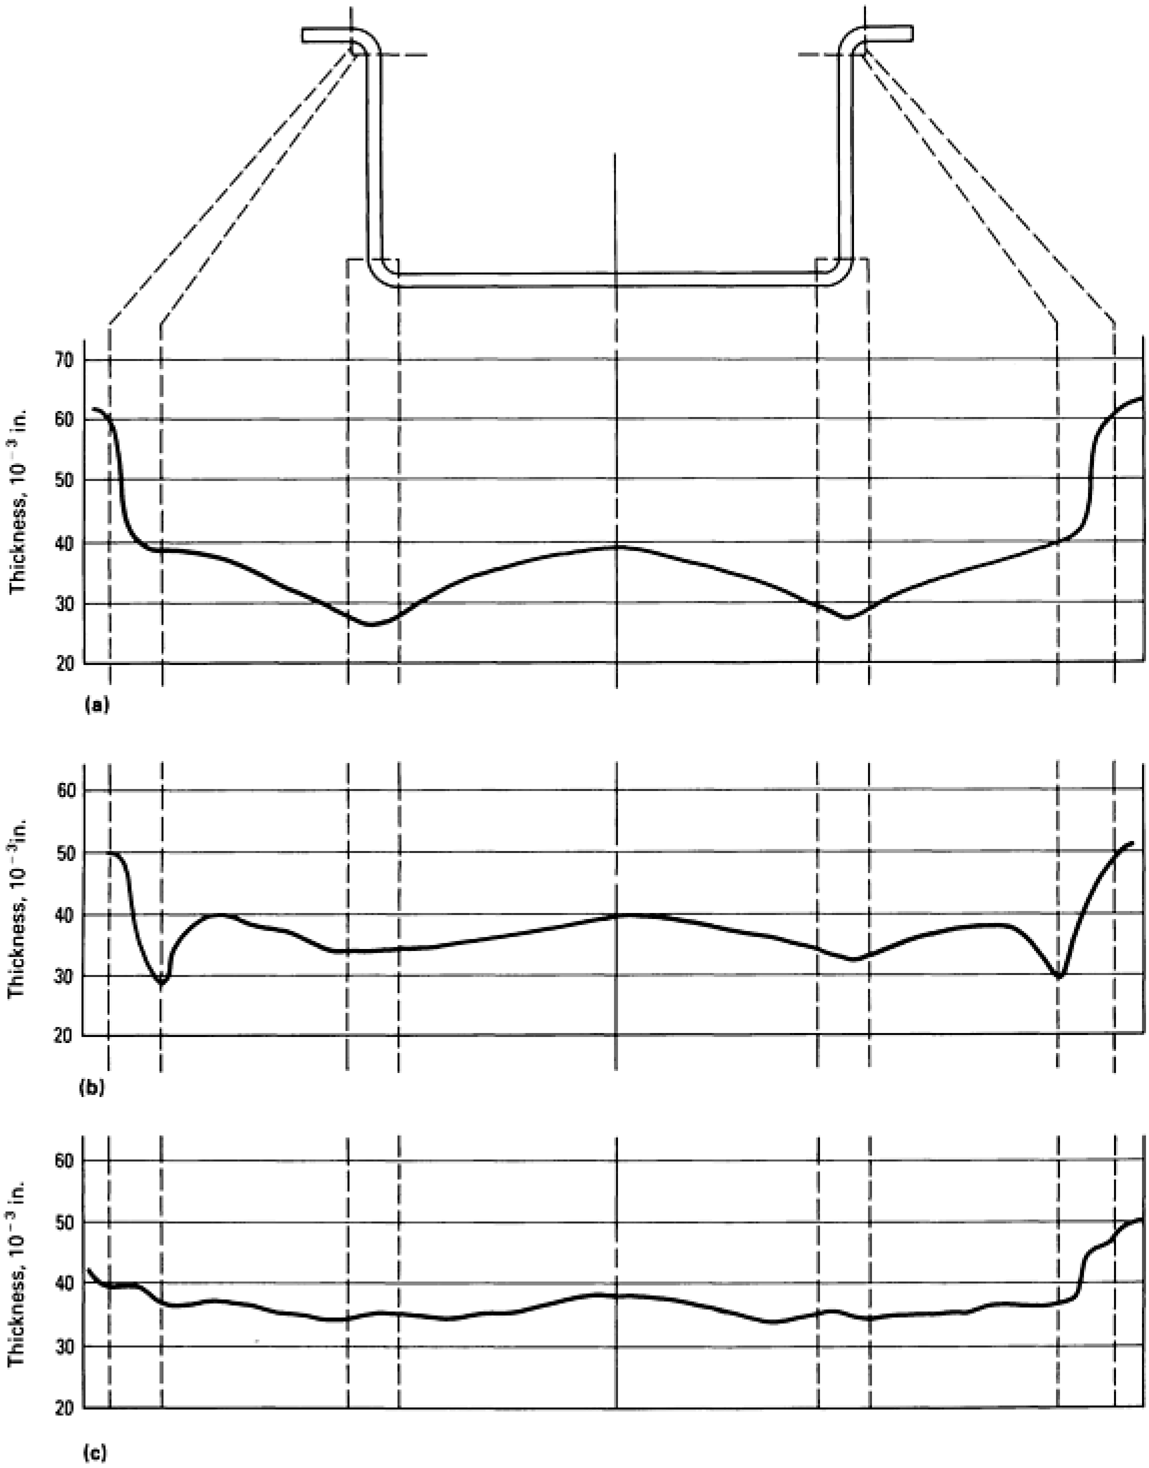

Fig. 31 Observed thickness profiles for 1.68 mm (0.066 in.) thick Ti-6Al-4V blow-formed parts of rectangular cross section formed under different average strain rates, $\bar{\dot{\varepsilon}}_t$, and with different lubrication conditions. (a) $\bar{\dot{\varepsilon}}_t$ = -7 × 10^{-4} s^{-1} no lubricant. (b) $\bar{\dot{\varepsilon}}_t$ = -5.6 × 10^{-4} s^{-1}; boron nitride lubricant. (c) $\bar{\dot{\varepsilon}}_t$ = -5.4 × 10^{-5} s^{-1}; boron nitride lubricant

A die entry radius causes a local stress concentration in the forming sheet, which then creates a stress state gradient in the forming sheet, and this can lead to localized thinning, especially if the ratio of die radius to sheet thickness is small and if the surface is lubricated. The source of the stress concentration is the back pressure exerted by the die radius on the forming sheet and the gas pressure on the opposite side of the sheet from the die. The pressure exerted by the die radius has been shown to be (Ref 27):

$$P_r = \frac{\sigma_w h}{R_1} \qquad \textbf{(Eq 12)}$$

where P_r is the pressure of the die entry radius, σ_w is the in-sheet stress in the width direction, h is the sheet thickness, and R_1 is the die entry radius. This and the applied gas pressure, g, develop an average through-thickness stress σ_h of:

$$\sigma_h = \frac{g + P_r}{2} \qquad \textbf{(Eq 13)}$$

The magnitude of σ_w will be dependent on the local friction coefficient, μ_r, and the position on the radius, so that the effective stress will vary around the die entry radius. A detailed analytical model of this somewhat complex condition is available in Ref 27, but it has been shown that a local stress increase is developed in this area, causing a tendency toward local thinning. If the friction is sufficiently low, the initially thinned section can continue to thin after die contact is made. Therefore, significant localized thinning can occur, and even rupture may take place if the conditions are sufficiently severe.

Thinning over the die entry radius is the result of stress gradients; therefore, the strain rate sensitivity *m* is an important parameter in determining the extent of thinning that will develop. The influence of these variables is illustrated in Fig. 32 for a titanium alloy part formed under the indicated conditions of lubrication and strain rate. The strain rate variations resulted in corresponding variations in the *m* value during the respective forming process. The thinning for the unlubricated part is in agreement with that expected from the discussion in the previous section in this article. For this case where lubricant is used, the strain rate, which determines the corresponding *m* value, is a factor in determining the extent of thinning over the die entry radius. The average *m* value corresponding to the die entry radius was higher for the forming process that developed the lower average strain rate, resulting in a significantly reduced tendency toward local thinning in that area.

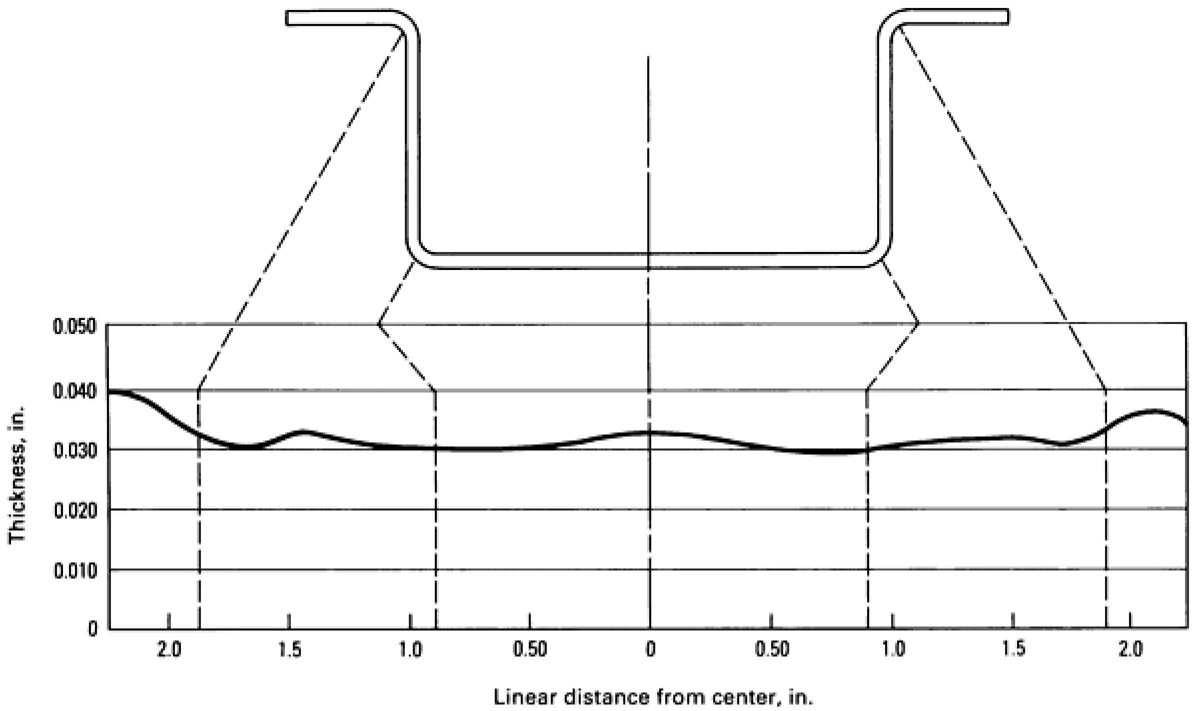

Fig. 32 Observed thickness distribution for Ti-6Al-4V parts with 1.14 mm (0.045 in.) initial thickness at 927 °C (1700 °F) formed at 10^{-3} s^{-1} with boron nitride lubrication

Thinning Control. Because SPF parts are typically stretched to very large elongations, the thickness variations are potentially large for a part. Therefore, it is often important to control the thickness variations in order to meet part tolerance requirements. Although it is seldom possible to prevent thickness variations, there are techniques that can be utilized to control this problem. In addition to such methods, the designer can often accommodate variations in thickness if he knows in advance what they might be. This latter approach is an important and viable one, but will not be addressed in this article because it is a very specialized field of metallurgy.

The methods used to control thinning are:

- Processing of the superplastic material to achieve a high *m* value
- Use of surface lubrication, as discussed above
- Use of thermo-forming methods to control the localized deformation
- Modification of the die or part design to minimize local stress concentrations
- Forming a thickness-profiled sheet
- Application of pressure in a controlled and profiled manner to control strain rate to a value corresponding to a high *m* value

Because the raw sheet material is generally obtained from a commercial supplier, the material superplastic properties are under the control of the mill. However, it may be judicious for the forming plant to obtain material under the control of an appropriate specification. The effect of lubrication is discussed in the section "Die Entry Radius" in this article, along with the effect of the die entry radius, which may, in some parts, be increased to minimize the thickness gradients.

The thermo-forming method has been shown to offer effective techniques that can control the thinning gradients in single-pocketed deep-drawn parts (Ref 24, 30). With these methods, a movable tool is usually used to contact the forming sheet before the finished shape is produced, causing the local friction to minimize deformation in some locations while free-forming sections continue to deform.

The use of thermo-forming techniques was demonstrated using apparatuses such as those shown in Fig. 33 and 34 (Ref 30). The test rig used consisted of two cylindrical chambers, each 190 mm (7.5 in.) in inside diameter by 178 mm (7 in.) deep, and a hydraulic ram, positioned in the bottom chamber, that was capable of moving up and down. The material used was Zn-22Al-1.5Cu sheet 1.27 mm (0.050 in.) thick. For the convex upward die, the deformation was restricted in the center of the sheet and concentrated at the outer area, resulting in a strain and thickness profile, as shown in Fig. 35, in which the top center is thicker than the adjacent areas. This thickness profile was substantially modified by the use of a concave upward die, as shown in the Fig. 36. In this case, the superplastic diaphragm was formed down into the concave die by gas pressure, and the die was slowly withdrawn until it reached the bottom. The preformed diaphragm was then formed into the upper cylindrical chamber in the same manner as that of the previous figure. The resulting profile is seen to be considerably more uniform across the top of the part.

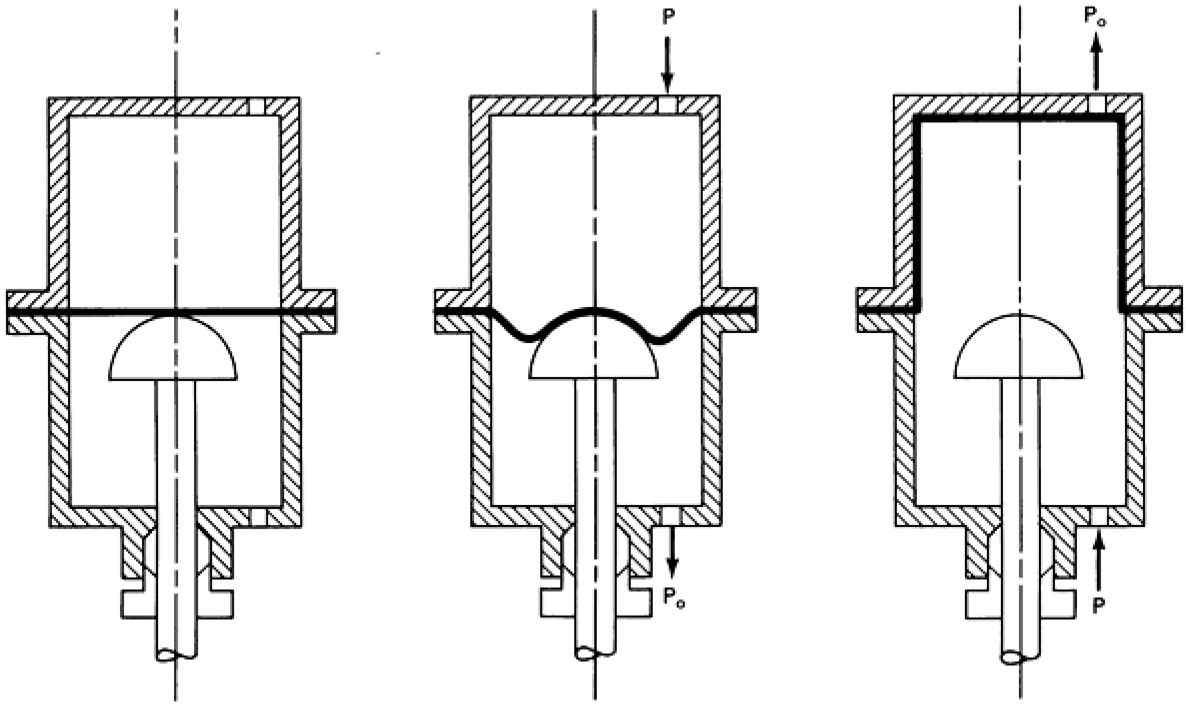

Fig. 33 Apparatus for thermo-forming superplastic sheet materials using a convex die member to control thinning in forming of a hat configuration

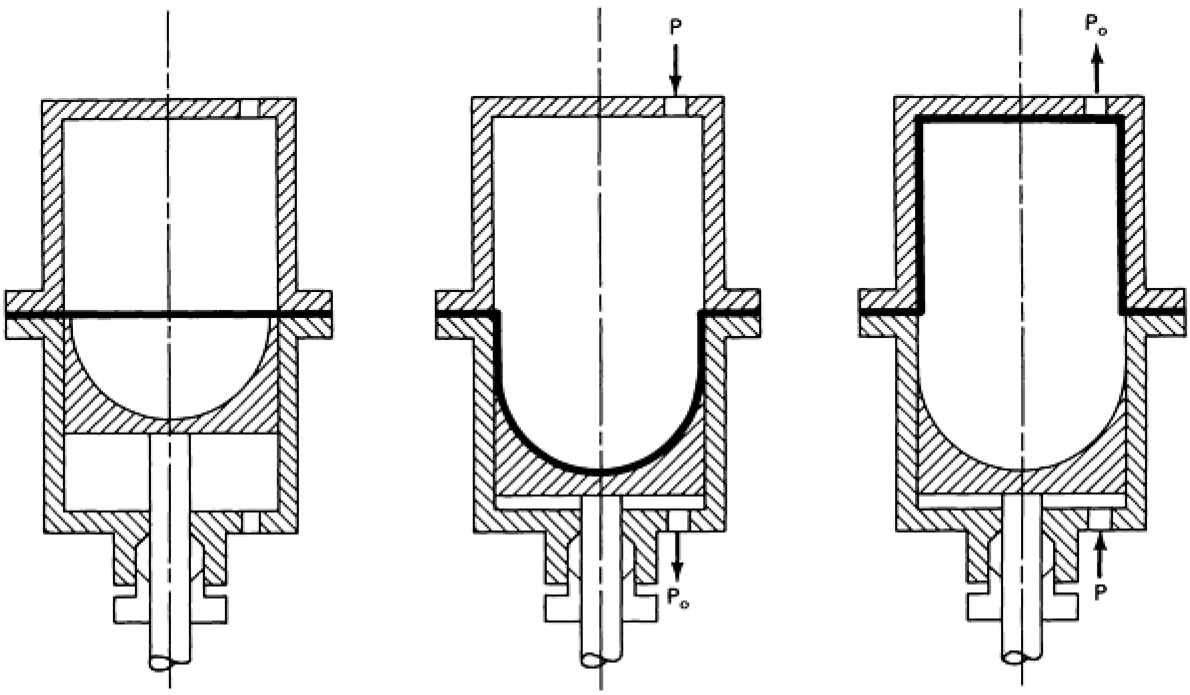

Fig. 34 Apparatus for thermo-forming superplastic sheet materials using a concave die member to control thinning in forming of a hat configuration

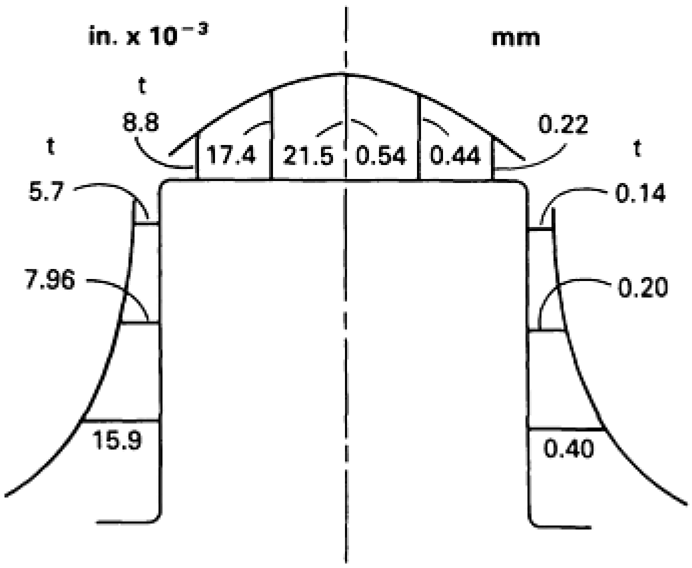

Fig. 35 Thickness profile for hat configuration formed with a convex die member, as shown in Fig. 33. Material formed is Zn-22Al-0.15Cu at a forming temperature of 250 °C (480 °F).

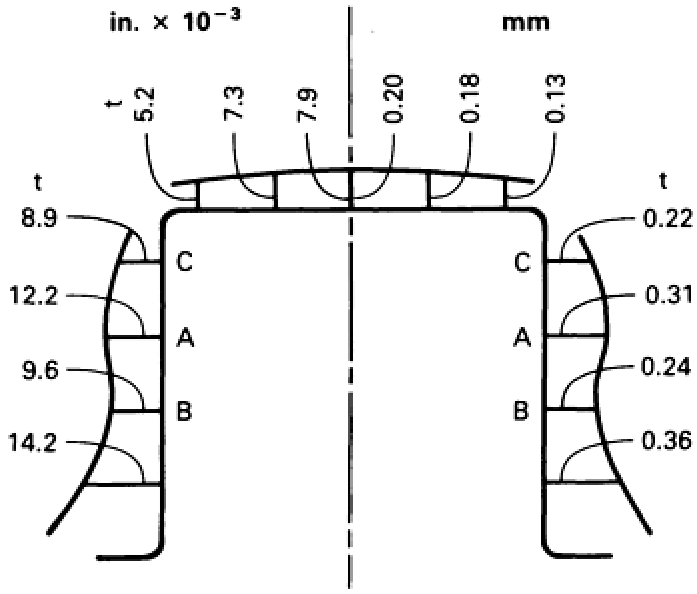

Fig. 36 Thickness profile for hat configuration formed with a concave die member, as shown in Fig. 34. Material formed is Zn-22Al-0.1Cu at a forming temperature of 250 °C (480 °F).

The use of thickness-profiled sheet has been suggested to control the thickness in the final part (Ref 44). The concept considers that the initial thickness variations can be used to offset the subsequent variations resulting from the stress state and part geometry effects on the thinning, as shown in Fig. 37. If areas that will thin excessively are thicker than surrounding areas, it is possible to develop finished part thickness profiles that are more uniform than those formed of constant thickness sheet.

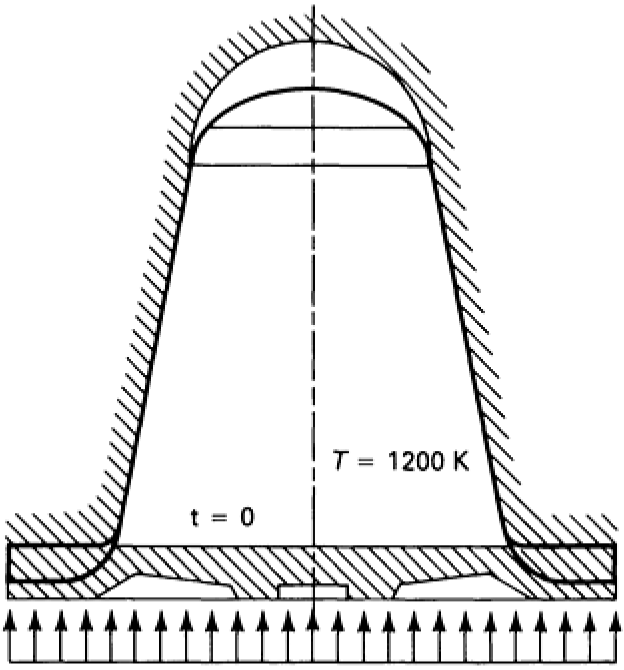

Fig. 37 Schematic of the concept of forming a sheet material that has a thickness profile before forming

Pressure Profiling. It is now well recognized that the *m* value for superplastic alloys will vary with strain rate and that it will also often vary with strain. The strain rate imposed during the forming process will therefore determine the *m* value, and if the strain rate varies during the forming process, the corresponding *m* value and related thinning uniformity will also vary. For example, the simplest pressurization concept for SPF processing is that of constant pressure. The resulting strain rate variation for a spherical dome part configuration has been shown to be as much as three orders of magnitude (Ref 25). A graph of the predicted strain rate for a spherical dome that will be generated under constant pressure for such a part is shown in Fig. 38. The strain rate drops to 0.001 of the initial value when the part becomes a hemisphere. The *m* value for a typical superplastic alloy can vary from a maximum *m* to a value of less than 0.2 over strain rate ranges of this magnitude. The consequence of forming a part under these conditions is that excessive thinning or part rupture during forming is likely. The initial strain rate corresponds to a large *m* value, and good thinning resistance is observed. However, this would be transient; other strain rates would be encountered corresponding to low *m* values, and poor resistance to localized thinning would be present.

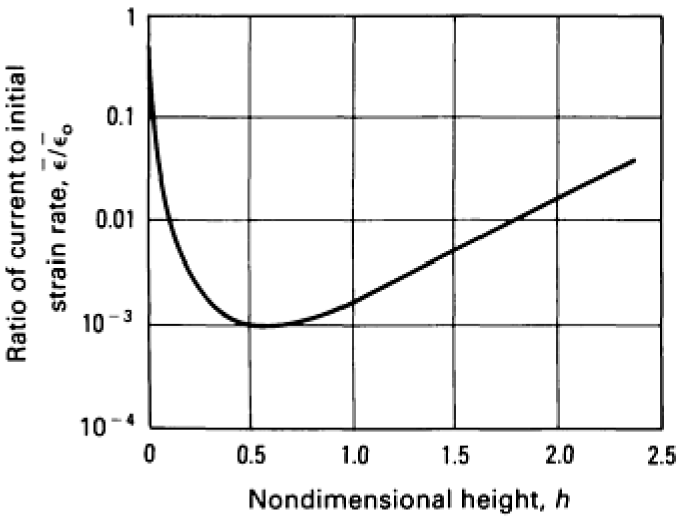

Fig. 38 Ratio of the current to initial strain rate as a function of nondimensional height for a constant pressure

application in the forming of a hemispherical configuration

This condition can be rectified if the strain rate can be maintained at a constant level corresponding to a suitably high *m* value. Because the constant pressure is seen to develop a variable strain rate, it is apparent that a variable forming pressure would be required to develop a constant strain rate. Such pressure profiles have been established analytically for the spherical dome (Ref 25, 26) and the rectangular (Ref 27) part configurations. Because most of the analytical models of the SPF process use applied gas pressure to establish the current stress and strain rate conditions, it is possible to utilize these same models to adjust the current gas pressure to develop the desired stress and strain rate.

The resulting pressure profiles for the constant strain rate forming of the spherical dome and the rectangular parts are illustrated in Fig. 39 and 40, respectively. It is typical that the pressure initially rises rapidly, followed by decrease. The rapid initial rise is due to a rapid decrease in the radius of curvature with little change in thickness, and the subsequent decrease is the result of thinning that is more rapid at this stage than the change in radius of curvature. The depth to which a part is formed will also affect the pressure profile for constant strain rate control, as shown in Fig. 41 for a rectangular part formed with no lubrication. For a deep part (w = 305 mm, or 12 in.), the applied pressure never reaches a maximum, but continues to rise during the forming process. For a shallow part (w = 50 mm, or 2 in.), the pressure is decreased for a significant time period before being increased to high levels.

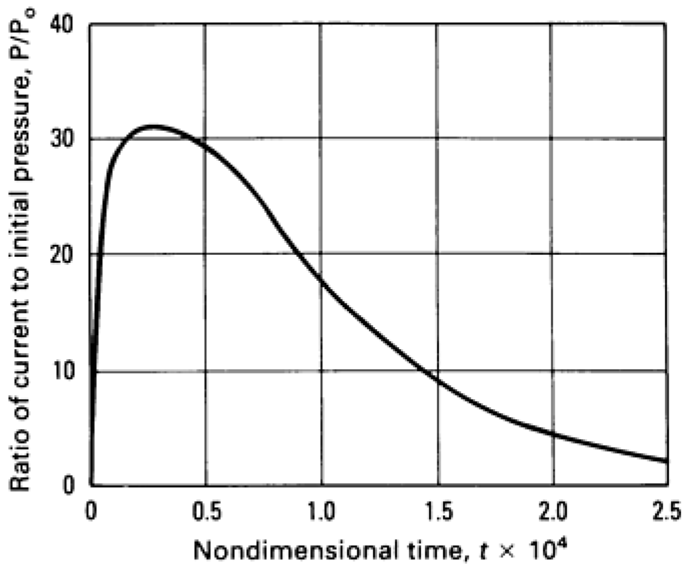

Fig. 39 Ratio of current to initial pressure as a function of a time parameter for forming a spherical configuration under constant strain rate conditions

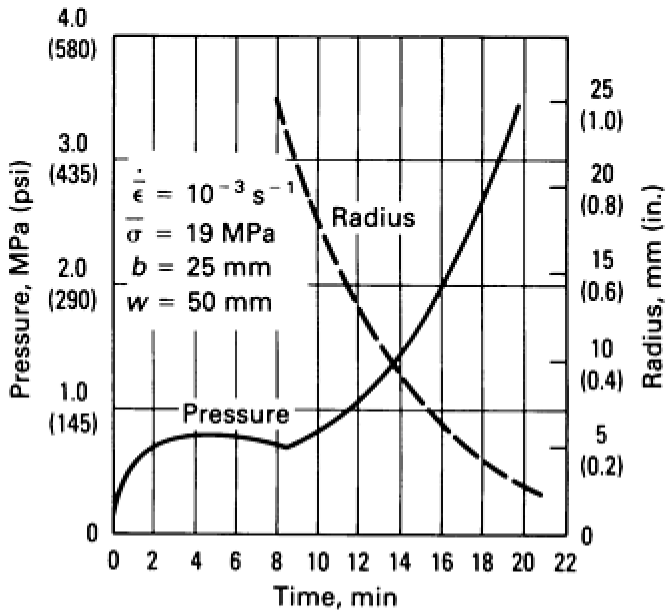

Fig. 40 Analytically predicted pressure versus time for a constant strain rate in the forming of a long, rectangular, 1.27 mm (0.050 in.) thick Ti-6Al-4V part fabricated at 870 °C (1600 °F)

Superplastic Sheet Forming

C.H. Hamilton, Washington State University; A.K. Ghosh, Rockwell International

Cavitation and Cavitation Control

Most superplastic alloys tend to form voids, or cavities, at intergranular locations during the superplastic deformation. This process is termed cavitation. Cavitation can lead to the degradation of strength and other design properties, and it is dealt with in one of two ways:

- Establishing reduced design properties
- Utilizing a back pressure technique to control cavitation

Typical cavitation as a function of strain is shown for an aluminum alloy in Fig. 42. It can be seen that the absolute amount of cavitation in terms of the volume fraction is not large but depends on the strain imposed. The use of the back pressure concept imposes a hydrostatic pressure on the sheet during forming, and if this pressure is of the order of the flow stress, cavitation can be reduced or completely suppressed. An example of the effect of back pressure on the rate of development of cavitation is shown in Fig. 43.

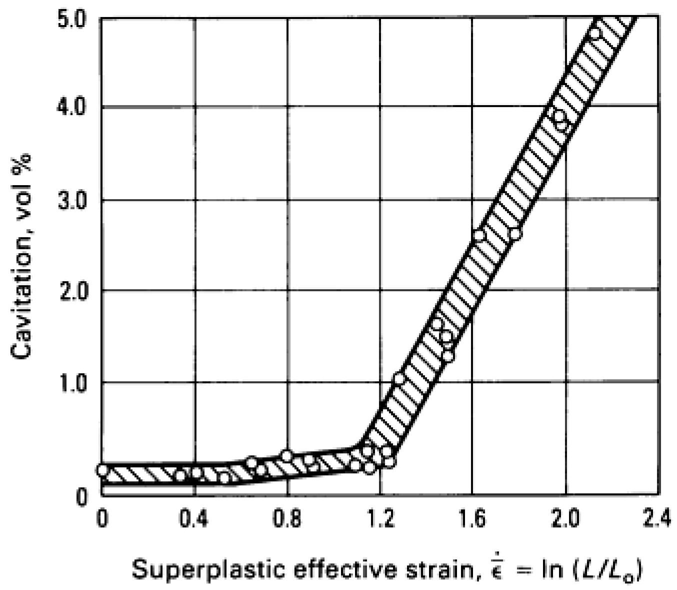

Fig. 42 Development of cavitation with uniaxial tensile strain in a 7475 aluminum alloy specimen of 0.8 cm^2 ($\frac{1}{8}$ in.^{2}) cross-sectional area deformed at 516 °C (961 °F) under a constant strain rate of 2 × 10^{-4} s^{-1}

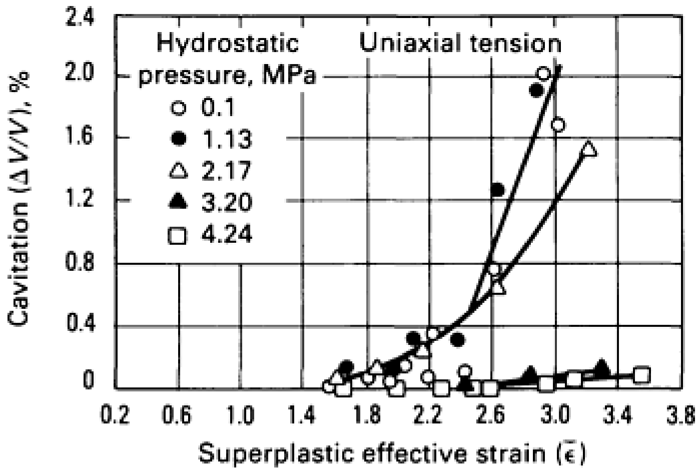

Fig. 43 Effect of hydrostatic pressure on the suppression of cavitation in a 7475 aluminum alloy specimen superplastically deformed at 516 °C (961 °F)

In practice, the back pressure is achieved by imposing a pressure on the back side of the sheet to oppose the forming pressure and by sustaining this pressure during the forming cycle. The forming pressure must be higher than the back pressure, and the same forming rates can be achieved with or without back pressure if the pressure differential is the same. For example, if a pressure profile is desired, such as that shown in Fig. 39 or 40, the pressure profile is simply raised in magnitude by an amount equal to the back pressure. Because the back pressure is normally of the order of the material flow properties, pressures of about 690 to 3400 kPa (100 to 500 psi) are generally suitable for suppressing cavitation.

Manufacturing Outlook

The SPF process is unique in terms of the complexity of parts that can be produced and the methods that can be used to shape such a material. A number of processing methods are currently being used, most of which involve significant stretching of sheet material. The high ductility that can be achieved with these types of materials also has a consequence that must be understood and dealt with, namely, thinning gradients. The thinning gradients are a natural consequence of the stress gradients that develop in the various die configurations, and the superplastic property of the strain rate sensitivity of the flow stress then determines the subsequent thinning gradient that will result in the part. Control of the forming process, die configuration, and material characteristics are all factors that can affect the thinning.

The SPF processes are being increasingly used for a wide range of structural and nonstructural applications. The availability of superplastic alloys is considered to be a major impediment to the broader use of these processes, but as the use of the technology increases, more and perhaps better superplastic alloys can be expected to become available.

Superplastic Sheet Forming

Appendix: Superplasticity in Iron-Base Alloys

Oleg D. Sherby, Stanford University; Jeffrey Wadsworth, Lockheed Missiles and Space Company; Robert D. Caligiuri, Failure Analysis Associates

Superplasticity is the ability of certain polycrystalline metallic materials to extend plastically to large strains when deformed in tension. Strains to failure in superplastic materials range from several hundred to several thousand percent. In general, superplastic materials also exhibit low resistance to plastic flow in specific temperature and strain rate regions. These characteristics of high plasticity and low strength are ideal for the manufacturer who needs to fabricate a material into a complex but sound body with a minimum expenditure of energy.

The phenomenon of superplasticity was first observed over 70 years ago (Ref 48), but active research in this field did not begin until 1962 (Ref 49). Since that time, superplastic effects have been reported in over 100 alloy systems (Ref 49). The micro-mechanisms that permit extraordinary elongations in these materials are still under investigation (Ref 50), but it is generally accepted that a major microstructural requirement for superplasticity is the development of a stable, very fine grain size (typically <10 μm, or 400 μin.) (Ref 51). This requirement also usually (but not always) leads to the necessity for a uniform distribution of a fine, second phase to inhibit matrix grain growth. Furthermore, the grain boundaries should be high angled (that is, disordered), equiaxed, mobile, and must resist separation under tensile stresses (Ref 52). To prevent cavitation around the second-phase particles, the strengths of the two phases should be similar at the temperature of deformation (Ref 52). These micro-structural characteristics can lead to a flow stress that is highly sensitive to changes in strain rate, which in turn resists the formation of instabilities during tensile deformation.

Even though superplasticity has been observed in many metallic alloy systems, only a relatively small number of them are iron-base. This is because of the difficulty in generating microstructures in these systems with the above characteristics. As a result, there have been relatively few industrial applications involving the superplastic bulk forming of ferrous alloys. Those iron-base systems in which the microstructural requirements have been met include:

- Hypoeutectoid and eutectoid plain carbon steels (ferrite-carbide two-phase system)
- Hypereutectoid plain carbon steel (ferrite-carbide and austenite-carbide two-phase systems) and white cast iron (ferrite-carbide two-phase system)
- Low-to-medium alloy steels (ferrite-austenite two-phase system)

- Microduplex stainless steels (ferrite-austenite two-phase system)

Of these, only the hypereutectoid steels have been extensively investigated for applications involving superplastic forming.

The development and existence of superplasticity in all of the above categories of iron-base alloys have been reviewed in detail (Ref 53, 54). This article will describe the key characteristics of superplastic behavior in each of these iron-base systems, with emphasis on hypereutectoid plain carbon steels, which currently have the most industrial potential.

Hypoeutectoid and Eutectoid Plain Carbon Steels

Early attempts at making superplastic plain carbon steels were not particularly successful (Ref 53). In these early efforts, extensive heat treatments were used to produce microstructures of fine ferrite grains pinned by spheroidized cementite particles in compositions containing between 0.2 and 1.0% C. Even though the overall grain structure was correct, elongations of only about 130% were observed, primarily because the grain boundaries were low-angle dislocation boundaries. The flow stress of materials with low-angle grain boundaries is usually not sensitive to changes in strain rate; therefore, superplasticity was not observed. However, later work showed that thermally cycling such materials across the eutectoid transformation temperature after thermomechanical processing changes the grain boundaries from low angle to high angle; tensile elongations of the order of 1000% have been achieved in thermally cycled, hypoeutectoid plain carbon steels (Ref 51).

Hypereutectoid Plain Carbon Steels and White Cast Irons

Hypereutectoid plain carbon steels, also known as ultrahigh-carbon (UHC) steels, will exhibit a microstructure consisting of a continuous network of proeutectoid carbide (at prior-austenite grain boundaries) surrounding pearlite colonies when slowly cooled from a temperature in the single-phase austenite region. This carbide network in turn imparts poor mechanical properties to these steels. However, work conducted in the 1970s showed that, with proper thermomechanical processing, microstructures can be achieved in UHC steels that consist of ultrafine, equiaxed grains of ferrite and a uniform distribution of fine, spherical, discontinuous proeutectoid carbide particles (Ref 55). Such microstructures in UHC steels have led to superplastic behavior; tensile elongations up to 1500% have been reported (Ref 56).

The requisite thermomechanical processing of UHC steels to obtain the desired fine spheroidized microstructure usually involves two steps. In the first step, the UHC ingot or billet is solution heat treated at typically 1150 °C (2100 °F), followed by hot and warm working during cooling down to 750 °C (1380 °F). This step refines the austenite grains, uniformly distributes the proeutectoid carbides at prior-austenite grain and subgrain boundaries, and forms pearlite in the matrix of the prior-austenite grains. The second step incorporates a divorced eutectoid transformation in which the UHC steel is heated to just above the eutectoid transformation temperature and air cooled (with or without accompanying deformation). This step transforms the fine pearlite from step 1 into a fully spheroidized fine structure. The divorced eutectoid transformation is discussed in more detail in Ref 57.

Although not yet fully commercialized, the industrial potential of UHC steels has been thoroughly investigated. One promising application is in the press forging of gears. Figure 44 illustrates a bevel gear that was warm forged from a fine-grain 1.25% C UHC steel in a single operation. An additional advantage of using superplastic UHC steels is that, because of their high carbon content, the carburization step in normal gear production is eliminated. A second example of the superplastic press forming of fine-grain UHC steels is the aft closure for a guided missile shown in Fig. 45. In this case, a 1.6% C steel casting was liquid atomized, and the resulting fine-grain powders were warm pressed into a billet at 800 °C (1470 °F). A third application for superplastically formed fine-grain UHC steels is in the manufacture of die components by superplastic hobbing operations (Ref 58).

Fig. 44 Warm precision forging of a 1.25% C UHC steel billet into a bevel gear. Forging temperature was 650 °C (1200 °F).

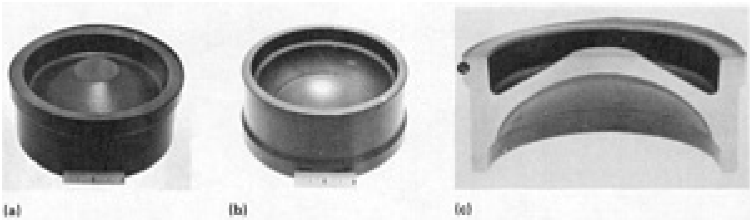

Fig. 45 Aft closure, for a guided missile, that was superplastically formed at 815 °C (1500 °F) from a 1.6% C UHC steel. The processing procedure consisted of warm pressing (800 °C, or 1470 °F) liquid-atomized powders into a billet and forging the resulting billet into plate. The plate was then superplastically formed to the final shape (a and b). (c) Cross section of the part

The original work on UHC steels demonstrated that, given the proper microstructure, superplasticity could be developed over the composition range of about 0.8 to 2.1% C and the temperature range of about 650 to 800 °C (1200 to 1470 °F). Therefore, superplastic UHC steels include both austenite-carbide as well as ferrite-carbide two-phase structures. Ultrahigh-carbon steels are generally not susceptible to cavitation, because the ferrite, austenite, and carbide all have about the same strength in the intermediate temperature range in which superplasticity occurs.

Furthermore, in the original work, superplasticity in UHC steels was limited to intermediate strain rates (that is, forming rates): 10^{-5} to 10^{-3} s^{-1}. The upper limits on strain rate and temperature are primarily related to the destruction of the fine uniform carbide structure. Commercialization of superplastic UHC steels has in fact been hampered by these somewhat limited strain rate and temperature ranges. However, more recent work has shown that these ranges could be substantially extended by careful alloying additions of silicon or aluminum (Ref 59). These elements enhance superplasticity in UHC steels because they:

- Increase the eutectoid transformation temperature (increase the stability of ferrite)
- Inhibit carbide coarsening at high temperatures (increase the activity of carbon in ferrite)
- Increase the volume fraction of proeutectoid carbides
- Do not form active sites for cavitation to occur

Ultrahigh-carbon steels containing 3% Si or 1.6% Al have exhibited superplasticity at strain rates to 10^{-2} s^{-1} at a temperature of 800 °C (1470 °F). Superplasticity has been projected to occur in a UHC 12% Al alloy at strain rates to 3 × 10^{-1} s^{-1} at 950 °C (1740 °F); this would make superplastic forming of UHC steels both economical and feasible for many operations.

An additional benefit of adding aluminum or silicon to UHC steels is a low, fairly constant (14 ± 1.5 MPa, or 2.00 ± 0.22 ksi) flow stress over the temperature range of 750 to 925 °C (1380 to 1700 °F). This suggests that thin-sheet UHC steels containing the proper amounts of aluminum or silicon can be readily blow formed over a wide temperature range.

Hypereutectoid White Cast Irons. Application of rapid solidification processing to UHC steels has also helped to extend the compositional range for superplasticity well into the white cast irons. Such techniques can create very high carbon content powders that, upon annealing at intermediate temperatures (595 to 700 °C, or 1100 to 1290 °F), exhibit the requisite fine microstructure (Ref 60). These powders are then readily consolidated into fully dense compacts at temperatures below the subcritical annealing temperature (A_1) (Ref 61). White cast irons processed in this manner have been shown to exhibit superplasticity at intermediate temperatures; a maximum tensile elongation of 1410% has been observed in a Fe-3.0C-1.5Cr (Ref 62). The shaded region on the iron-carbon phase diagram shown in Fig. 46 illustrates the range of carbon content and temperature over which superplasticity has been documented in fine-grain UHC steels and cast irons.

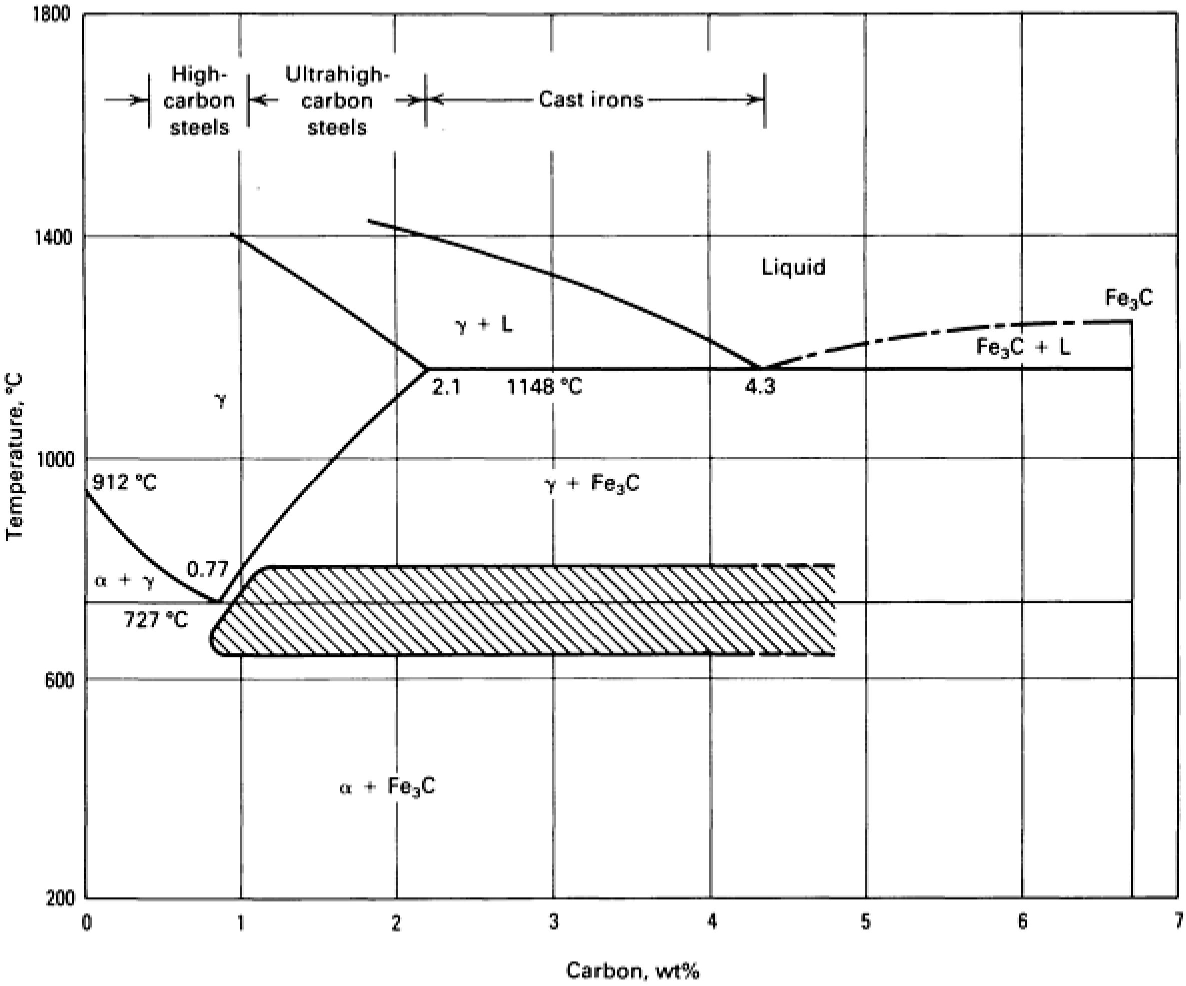

Fig. 46 Iron-carbon phase diagram. The shaded area illustrates the temperature and composition over which UHC steels and white cast irons have been made superplastic.

Hypereutectoid Steel Properties. Because of their carbon content, UHC steels, after superplastic forming, can be heat treated to very high hardness levels (65 to 68 HRC). This can be important in a wide variety of applications, including gears, tool bits, abrasion-resistant surfaces, and military vehicle armor. However, because of their very fine grain size, plain carbon UHC steels also exhibit poor hardenability. This hardenability problem can be alleviated by dilute alloying additions of hardenability-enhancing elements, such as chromium, manganese, and molybdenum. The dramatic effect of alloying additions on the hardenability of UHC steels is shown in Table 2.

Table 2 Hardenability of UHC steels as a function of alloying additions

Material composition	Austenitizing temperature (A_1 + 50)		Critical brine temperature to achieve 62 HRC, T_c		Critical cylinder diameter, D_c		M.F.[a]
	°C	°F	°C	°F	mm	in.

(a) M.F., multiplying factor = $D^{c}_{\mathrm{UHC steel alloy}} / D^{c}_{\mathrm{UHC steel}}$

The room-temperature tensile properties of fine-grain UHC steels have been extensively studied (Ref 63). As expected, the properties are very sensitive to heat treatment. Figure 47 compares the tensile properties of UHC steels in two different heat treatment conditions with the properties of other plain carbon and low-alloy structural steels. In addition, if properly heat treated to achieve an extremely fine (optically unresolvable) martensite, fully hardened UHC steels will exhibit a surprisingly high strain to failure in compression. As shown in Fig. 48, a 1.3% C steel that was water quenched from 770 °C (1420 °F) (Steel A) will exhibit a compression fracture strength of 4.5 GPa (650 ksi) and a strain to failure of 10%. However, austenitizing the same steel at 1100 °C (2010 °F) prior to water quenching from 770 °C (1420 °F) (Steel B) will coarsen the resulting martensite and reduce the compression strain to failure to less than 2%.

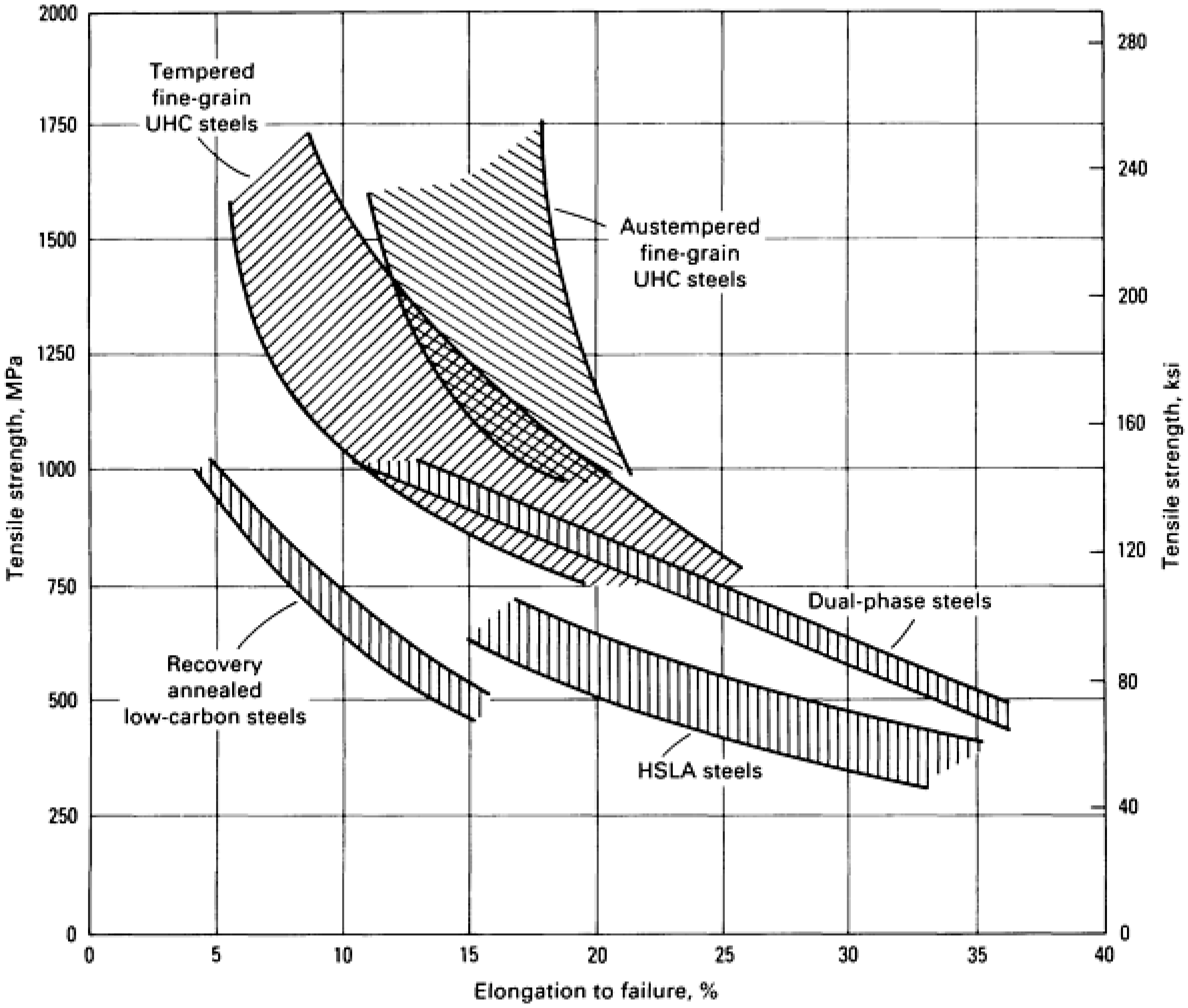

Fig. 47 Tensile strength versus elongation to failure of heat-treated fine-grain UHC steels compared to low-carbon steel, high-strength low-alloy (HSLA) steels, and dual-phase steels

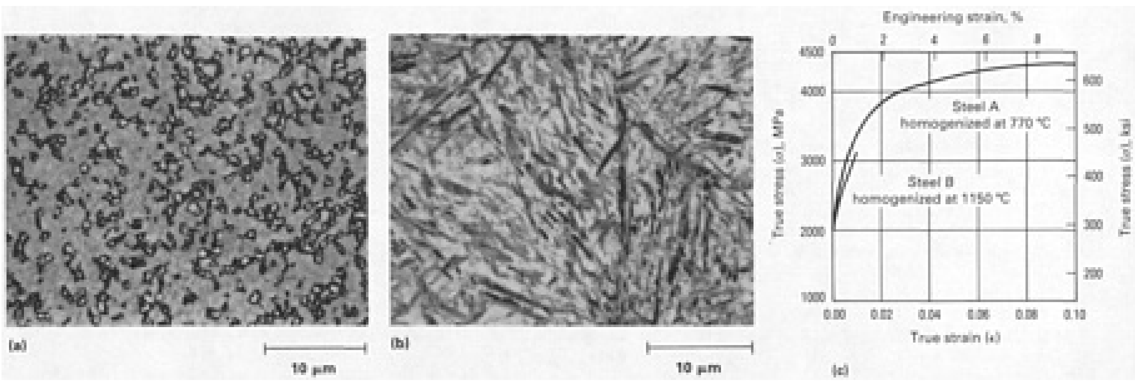

Fig. 48 Influence of prior heat treatment on the microstructure (a and b) and compression stress-strain behavior (c) of a 1.3% C UHC steel quenched from 770 °C (1420 °F)

Because they contain a high volume fraction of carbide, UHC steels exhibit only moderate impact resistance (<25 J, or 18 ft · lbf, Charpy V-notch at 25 °C, or 80 °F). The impact resistance of fine-grain UHC steels can be enhanced by laminating them to tougher (but weaker) materials. Fine-grain UHC steels can be readily solid state bonded to themselves or other ferrous materials, partly because of their superplastic nature (Ref 64). The lamination procedure can consist of conventional roll bonding, press bonding, or explosive techniques as long as a good metallurgical bond results. The effect of such lamination on the impact properties of UHC steels is illustrated in Fig. 49. The impact properties of a UHC steel/1020 steel laminated composite are clearly superior to those of either of the monolithic UHC steel or the monolithic 1020 low-carbon steel. Most UHC steel-base laminates will also exhibit superplasticity over limited temperature and strain rate ranges and therefore can be superplastically formed (Ref 65, 66). The room-temperature tensile strength of a UHC steel laminate will of course be reduced relative to that of a monolithic UHC steel by an amount governed by the rule of mixtures; however, this loss in strength can be partially compensated for by heat treating the laminate to selectively harden the UHC steel component to very high strength levels.

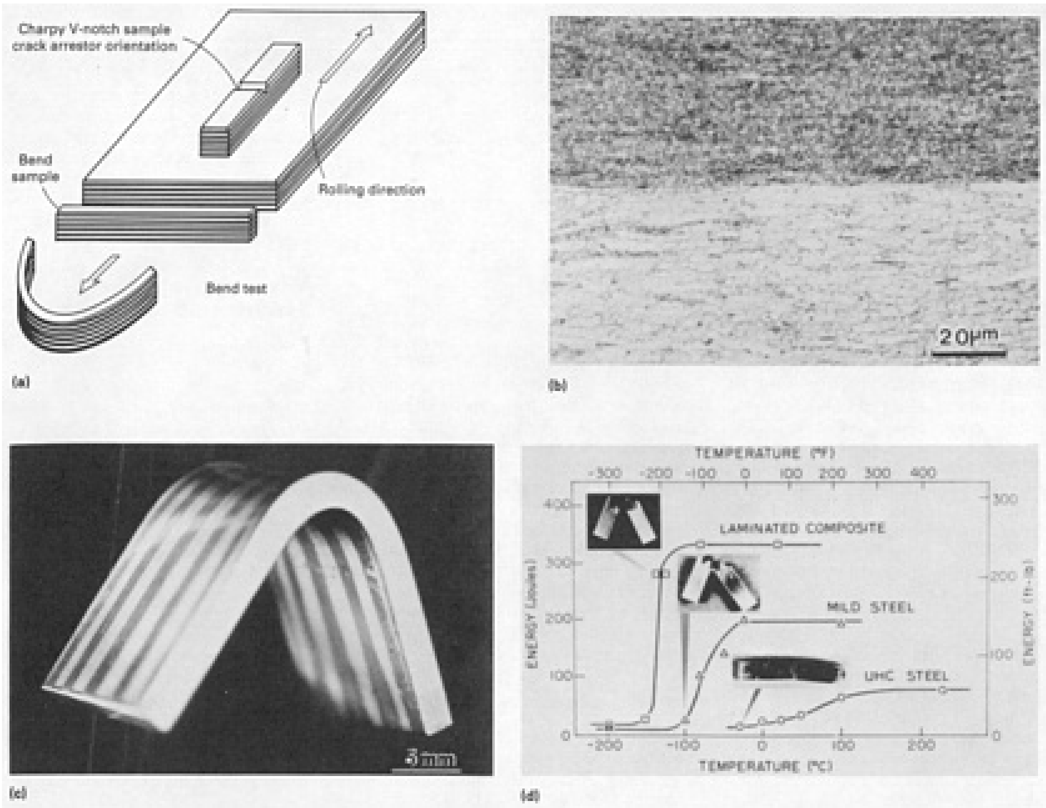

Fig. 49 UHC steel/1020 steel laminated composite to improve impact resistance of fine-grain UHC steels. (a) Orientation of mechanical test samples taken from a laminated composite of UHC steel and 1020 steel. (b) Optical photomicrograph of interface in laminated composite of UHC steel and 1020 showing an excellent metallurgical bond. (c) Bend test sample of the laminated composite. (d) Impact properties of UHC steel, 1020 steel, and UHC steel/1020 steel laminated composite including photographs of the tested samples

Low-to-Medium Alloy Steels

Superplastic studies have been conducted on several alloy steels (Ref 53). Compositions and thermomechanical processing procedures are generally chosen to generate fine-grain (1 to 2 μm, or 40 to 80 μin.) microstructures consisting of roughly equal amounts of ferrite and austenite. These phases will coexist only in a narrow temperature range, but within that range each phase will inhibit the other from growing, and superplasticity will occur. Elongations of 300 to 500% have been achieved in steels containing 1 to 2% Mn and 0.1 to 0.4% C, and elongations of up to 600% have been achieved in Fe-4Ni-3Mo-1-2Ti alloys when tested at temperatures in the dual-phase region. However, the potential of superplastic forming these alloys has not been exploited, because of the narrow temperature range over which superplastic flow occurs and because of the rapid growth that can occur even in the two-phase region at high temperatures.

Microduplex Stainless Steels

Microduplex stainless steels are so called because their stable microstructure consists of both ferrite and austenite in fine grain size form--about 2 to 3 μm (80 to 120 μin.). They typically contain 18 to 26% Cr and 5 to 8% Ni and can also contain molybdenum, titanium, copper, silicon, manganese, carbon, and diatomic nitrogen. Elongations to failure in these alloys are commonly in excess of 500% at strain rates between 10^{-3} and 10^{-2} s^{-1} and at temperatures between 900 and 1000 °C (1650 to 1830 °F) (Ref 66). Although microduplex stainless steels have found a number of commercial applications in the chemical industry because of their high strength and corrosion resistance, their superplastic forming potential has not been exploited. This is because microduplex stainless steels are susceptible to cavitation during superplastic flow due to the strength differential between the ferrite and the austenite at these high temperatures (Ref 67).

Outlook for Superplastic Ferrous Alloys

The number of iron-base alloys exhibiting superplasticity is relatively limited. This is primarily because of the difficulty in satisfying all of the microstructural requirements generally required for superplasticity in ferrous materials. Of the alloys identified to date for possible superplastic forming, the hypereutectoid (or UHC) steels show the most promise. These steels can be stretched without cavitation over 1000% at reasonable forming rates and intermediate temperatures. Ultrahigh-carbon steels are heat treatable to high hardnesses, exhibit good room-temperature mechanical properties, and can be readily laminated to other ferrous materials to enhance toughness and impact resistance. Future efforts in the superplastic forming of iron-base alloys will undoubtedly focus on this class of steels.

Introduction

SHEET METAL FORMING is the process of converting a flat sheet of metal into a part of desired shape without fracture or excessive localized thinning. The process may be simple, such as a bending operation, or a sequence of very complex operations such as those performed in high-volume stamping plants. In the manufacture of most large stampings, a sheet metal blank is held on its edges by a blankholder ring and is deformed by means of a punch and die. The movement of the blank into the die cavity is controlled by pressure between the upper and lower parts of the blankholder ring.

This control is usually increased by means of one or more sets of drawbeads. These consist of an almost semicylindrical ridge on the upper part of the blankholder and a corresponding groove in the lower part (the positions are sometimes reversed). The drawbeads force the periphery of the blank to bend and unbend as it is pulled into the die; this increases the restraining force considerably. Presses with capacities to 17.8 MN (2000 tonf) are commonly used for the manufacture of large stampings, and presses to 26.7 MN (3000 tonf) are used for heavy-gage parts.

Sheet metal forming operations are so diverse in type, extent, and rate that no single test provides an accurate indication of the formability of a material in all situations. However, knowledge of material properties and careful analysis of the various types of forming involved in making a particular part are indispensable in determining the probability of successful part production and in developing the most efficient process.

Formability Testing of Sheet Metals

Brian Taylor, General Motors Corporation

Types of Forming

Many forming operations are complex, but all consist of combinations or sequences of the basic forming operations--bending, stretching, drawing, and coining (see the Section "Forming Processes for Sheet, Strip, and Plate" in this Volume).

Bending is the most common type of deformation, and it occurs in almost all forming operations. Bending around small radii can lead to splitting in the early stages of a forming process because it localizes strain and prevents its distribution throughout the part. Ideally, strain should be distributed as uniformly as possible to maximize the amount of deformation that can be obtained. Even a slight increase in the radius in a given location can sometimes significantly improve strain distribution. Frequently, designs specify smaller radii than necessary, which results in manufacturing problems and increased costs.

Lubrication is not recommended when bending over a sharp radius, because die friction reduces strain localization by restricting metal movement away from the radius. The orientation of the sheet in relation to the rolling direction can also be important in a bending operation. During rolling, inclusions and other defects become elongated in the rolling direction, producing lines of weakness. When the axis of bending is in this direction, there is a tendency toward splitting along the lines of weakness. This lowers resistance to fracture compared to when the axis is inclined to the rolling direction. Detailed information on sheet metal lubrication is available in the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume.

The outer and inner panels of a part are frequently assembled by bending (hemming) the edges of the outer panel around the inner panel. This requires material that can be easily bent over very small radii. In the absence of other types of deformation, bending produces tensile stresses on the outside surface. These decrease to zero at an interior level known as the neutral axis. These stresses then become compressive on the inside of the bend. They can cause springback (shape distortion) upon removal of the applied forces. If tensile deformation is also present, the compressive stresses may be reversed, but through-thickness stress and strain gradients will generally still exist.

Many forming operations involve pulling metal over a die radius so that it is initially bent and subsequently straightened. The net strain resulting from this process may be quite small, depending on the size of the die radius and the tensile forces involved. However, the bending and straightening process cold works the metal, particularly at the surfaces, and reduces its subsequent formability.

Stretching is caused by tensile stresses in excess of the yield stress. These forces produce biaxial stretching when they are applied in perpendicular directions in the plane of the sheet. Balanced biaxial stretching occurs when the perpendicular forces are equal. Much higher levels of deformation, as measured by an increase in area, can be reached in balanced biaxial stretching than in any other forming mode.

Many forming operations involve stretching of some areas within the stamping. Automotive outer body panels are typical examples of parts formed primarily by stretching. Parts with regions containing domes, ribs, and embossments also involve stretching.

Plane-strain stretching results in elongation in one direction and no dimensional change in the perpendicular direction. It frequently occurs when a wide, flat area of sheet metal is stretched longitudinally--for example, in the sidewall of a stamping. In this case, strain in the transverse direction is prevented by the adjacent metal. Plane-strain stretching is an important type of deformation because most materials fracture at a lower level of strain in plane strain than in any other condition. Many of the fractures that occur in stamping operations are in the plane-strain region.

Drawing of sheet metal causes elongation in one direction and compression in the perpendicular direction. The simplest example is the drawing of a flat-bottomed cylindrical cup. In this process, a circular disk is held between two flat annular dies and impacted in the center by a flat-bottomed punch. This draws (pulls) the edges of the disk inward to form the wall of the cup. The metal is stretched radially by the tensile forces produced by the punch, but it is compressed circumferentially as its diameter decreases. Many other forming operations involve substantial drawing.

Coining occurs when metal is compressed between two die surfaces. It is extensively used for making coins and parts with similar surface features, for flattening, and for reducing springback upon removal of parts from a die. In many stretching and drawing operations, coining is undesirable, because it restricts metal movement, localizes strain, and produces surface damage. Much of the die preparation for these operations concentrates on locating and eliminating coining.

Combinations of Types of Forming. Most forming operations involve combinations of different types of forming. Figure 1 illustrates a part design that requires drawing in the corners; biaxial stretching in the dome; bending, straightening, and plane-strain stretching in the walls; and bending and plane-strain stretching at the tops and bottoms of the walls.

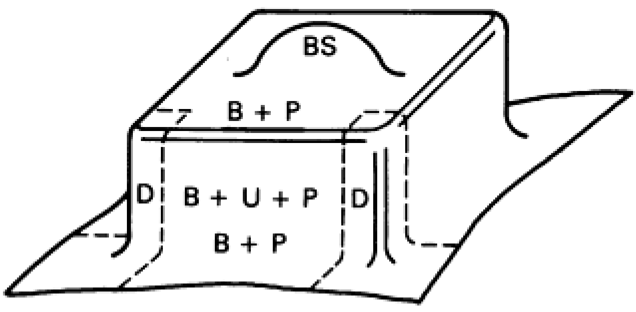

Fig. 1 Part design requiring a combination of types of forming. B, bending; BS, biaxial stretching; D, drawing; P, plane-strain stretching; U, unbending (straightening). Source: Ref 1.

Formability Testing of Sheet Metals

Brian Taylor, General Motors Corporation

Formability Problems

The major problems encountered in sheet metal forming are fracturing, buckling and wrinkling, shape distortion, loose metal, and undesirable surface textures. The occurrence of any one or a combination of these conditions can render the sheet metal part unusable. The effects of these problems are discussed below.

Fracturing occurs when a sheet metal blank is subjected to stretching or shearing (drawing) forces that exceed the failure limits of the material for a given strain history, strain state, strain rate, and temperature. In stretching, the sheet initially thins uniformly, at least in a local area. Eventually, a point is reached at which deformation concentrates and causes a band of localized thinning known as a neck, which ultimately fractures. The formation of a neck is generally regarded as failure because it produces a visible defect and a structural weakness. Most current formability tests are concerned with fracture occurring in stretching operations.

In shearing, fracture can take place without prior thinning. The most common examples of this type of fracture occur in slitting, blanking, and trimming. In these operations, sheets are sheared by knife-edges that apply forces normal to the plane of the sheet. Shearing failures are sometimes produced in stamping operations by shearing forces in the plane of the sheet, but they are much less common than stretching failures.

Buckling and Wrinkling. In a typical stamping operation, the punch contacts the blank, stretches it, and starts to pull it through the blankholder ring. The edges of the blank are pulled into regions with progressively smaller perimeters. This produces compressive stresses in the circumferential direction. If these stresses reach a critical level characteristic of the material and its thickness, they cause slight undulations known as buckles. Buckles may develop into more pronounced undulations or waves known as wrinkles if the blankholder pressure is not sufficiently high.

This effect can also cause wrinkles in other locations, particularly in regions with abrupt changes in section and in regions where the metal is unsupported or contacted on one side only. In extreme cases, folds and double or triple metal may develop. These may in turn lead to splitting in another location by preventing metal flow or by locking the metal out. Therefore, increasing the blankholder pressure often corrects a splitting problem.

Shape Distortion. In forming operations, metal is deformed elastically and plastically by applied forces. Upon removal of the external forces, the internal elastic stresses relax. In some locations, they can relax completely, with only a very slight change in the dimensions of the part. However, in areas subjected to bending, through-thickness gradients in the elastic stresses will occur; that is, the stresses on the outer surfaces will be different from those on the inner surfaces.

If these stresses are not constrained or "locked in" by the geometry of the part, relaxation will cause a change in the part shape known as shape distortion or springback. Springback can be compensated for in die design for a specific set of material properties, but may still be a problem if there are large material property or process variations from blank to blank.

Loose metal occurs in undeformed regions and is undesirable, because it can be easily deflected. A phenomenon usually referred to as oil canning, in which a local area can be either concave or convex, can also be encountered. In stampings with two or more sharp bends of the same sign in roughly the same direction, such as a pair of feature lines, a tendency exists for the metal between them to be loose because of the difficulty involved in pulling metal across a sharp radius.

It is sometimes possible to avoid the problem by ensuring that the metal is not contacted by both lines at the same time; thus, some stretching can occur before the second line is contacted (see the article "Press Forming of Coated Steel" in this Volume). There is a tendency for loose metal to occur toward the center of large, flat, or slightly curved parts. Increasing the restraining forces on the blank edges usually improves this condition.

Undesirable Surface Textures. Heavily deformed sheet metal, particularly if it is coarse grained, often develops a rough surface texture commonly known as orange peel (see the article "Press Forming of Coated Steel" in this Volume). This is usually unacceptable in parts that are visible in service. Another source of surface problems occurs in metals that have a pronounced yield point elongation, that is, materials that stretch several percent without an increase in load after yielding. In these metals, deformation at low strain levels is concentrated in irregular bands known as Lüders lines (or bands) or stretcher strains.

These defects disappear at moderate and high strain levels. However, almost all parts have some low-strain regions. These defects are unsightly and are not concealed by painting. Aged rimmed steels and some aluminum-magnesium alloys develop severe Lüders lines.

In some cases, zinc-coated steels exhibit surface defects known as spangles. This phenomenon occurs only in hot-dipped products and is caused by the development of a coarse grain size in the galvanic coating, which makes the individual grains clearly visible. This problem can be corrected in the coating process. In addition to the above occurrences, handling damage, dents caused by dirt or slivers in the die, and scoring or galling caused by a rough die surface or inadequate lubrication sometimes produce unacceptable surfaces.

Formability Testing of Sheet Metals

Brian Taylor, General Motors Corporation

Measurement of Deformation

The principal methods of measuring deformation are gage marks, strain gages, optical extensometers, and thickness and shape measurements.

Gage Marks. The most widely used method for measuring deformation is to mark the sheet by etching or scribing or by means of ink, dye, or paint and to measure the changes in the separations of the marks caused by the deformation. Rectangular grid markings and arrays of small-diameter circles (for example, 2.5 mm, or 0.1 in.) are frequently used.

In most production forming operations and in the later stages of tensile testing, deformation varies rapidly with location, which can lead to large differences in strain measurements made over different gage lengths. Therefore, small gage lengths, such as the diameters of small, closely spaced circles, are commonly used. Circular markings provide an additional advantage in that it is easy to identify the directions of the maximum (or major) and minimum (or minor) strains and thus to measure their values. Upon deforming, the circles change into ellipses with their major axes in the direction of the maximum strain and their minor axes in the direction of the minimum strain.

This information is essential in determining how close the local strain state is to the maximum the material can withstand without fracturing, which depends on the ratio of the strains. It is also useful in determining how the geometry of a die must be modified when the formability limits of the work material are exceeded.

Strain Gages and Extensometers. In some cases, a strain gage or a strain gage extensometer is attached to the sheet or test sample. Accurate strain measurements are thus obtained continuously during a forming operation or test. Optical extensometers, which are particularly effective at high strain rates, can also be used.

Thickness and Shape Measurements. Thickness measurements, which can be made rapidly by ultrasonic methods, can sometimes be used to determine strains. In practice, this method is limited to situations in which the ratio of the major and minor strains is known from previous measurements, because many different combinations of strains can lead to the same change in thickness.

Part shape is measured by using templates, checking fixtures, or shadowgraphs or by using a profile meter that employs a stylus to contact the surface. Profile meters may give two- or three-dimensional digital representations of the part. Noncontacting surface digitizers and systems for measuring deformation by locating grid markings in three dimensions are also used.

Brian Taylor, General Motors Corporation

Representation of Strain

The most common method of representing strain defines the engineering strain, *e*, as the ratio of the change in length, ΔL, to the original length, L_o:

$$e = \frac{\Delta L}{L_o} = \frac{L - L_o}{L_o} = \frac{L}{L_o} - 1 \qquad \textbf{(Eq 1)}$$

The second method defines the true strain, ε, in the region of uniform elongation as the integral of the incremental change in length, *dL*, divided by the actual (instantaneous) length, *L*:

$$\epsilon = \int_{L_o}^{L} \frac{dL}{L} = \ln\left(\frac{L}{L_o}\right) = \ln(1 + e) \qquad \textbf{(Eq 2)}$$

The engineering strain is easier to calculate and is satisfactory for many applications. The true strain is used in the theoretical analysis of formability and is advantageous in that successive strains can be added to give the cumulative strain.

The strain state of a deformed sheet is frequently represented graphically by plotting the maximum or major strain, e_1, on the vertical axis and the minimum or minor strain, e_2, which can be positive or negative, on the horizontal axis. This is illustrated in Fig. 2, which shows five strain paths, each leading to the same major strain of 40% but with minor strains ranging from -40 to +40%. The ellipses shown were originally circles (shown dashed) in the undeformed sheet.

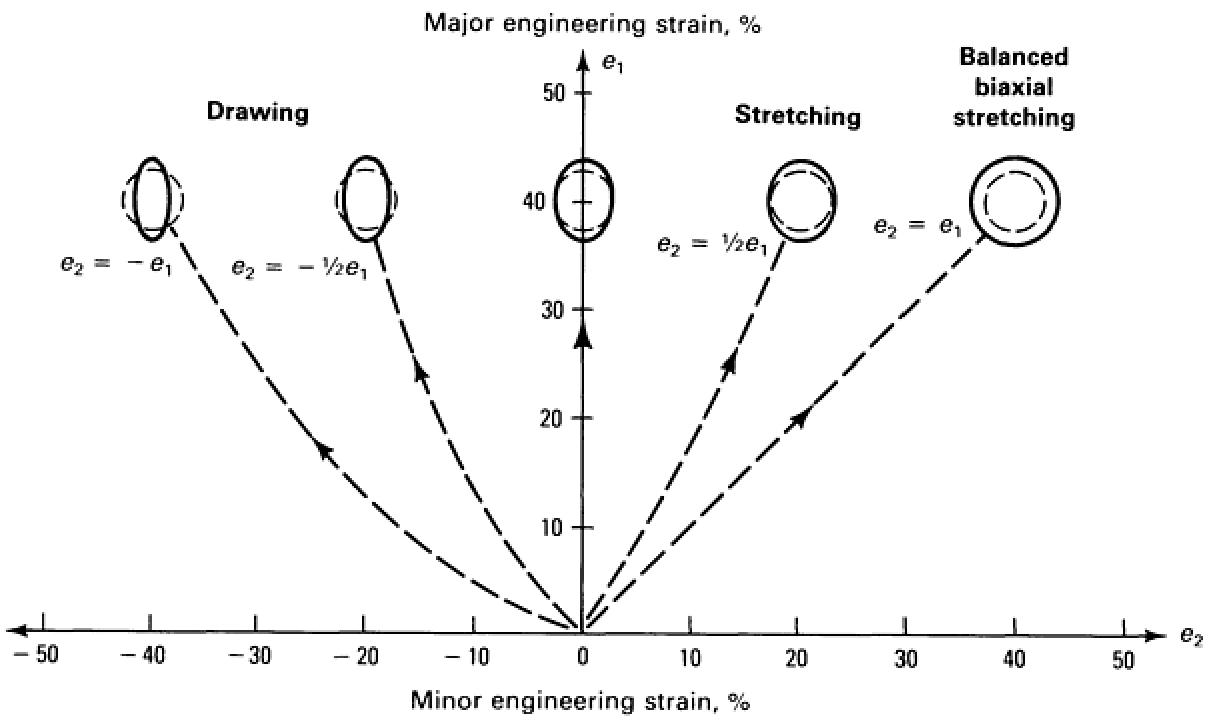

Fig. 2 Schematic of several major strain/minor strain combinations.

On the right side of Fig. 2, the circles have transformed into ellipses that are larger in all directions than the original circles. This is the region of biaxial stretching and, in the diagonal (45°) direction, of balanced biaxial stretching. In this direction, the circles have expanded without changing shape.

On the left side of Fig. 2, the circles have transformed into ellipses, which are larger in one direction but smaller in the perpendicular direction than the original circles. This is the region of drawing and is the strain state developed in the tensile test. On the vertical axis, the ellipses are larger in one direction, but unchanged dimensionally from the original circles in the perpendicular direction. This is the region of plane strain.

Formability Testing of Sheet Metals

Brian Taylor, General Motors Corporation

Effect of Material Properties on Formability

The properties of sheet metals vary considerably, depending on the base metal (steel, aluminum, copper, and so on), alloying elements present, processing, heat treatment, gage, and level of cold work (see the Sections "Forming of Stainless Steel and Heat-Resistant Alloy Sheet Materials" and "Forming of Nonferrous Sheet Materials" in this Volume). In selecting material for a particular application, a compromise usually must be made between the functional properties required in the part and the forming properties of the available materials. For optimal formability in a wide range of applications, the work material should:

- Distribute strain uniformly
- Reach high strain levels without necking or fracturing
- Withstand in-plane compressive stresses without wrinkling
- Withstand in-plane shear stresses without fracturing
- Retain part shape upon removal from the die
- Retain a smooth surface and resist surface damage

Some production processes can be successfully operated only when the forming properties of the work material are within a narrow range. More frequently, the process can be adjusted to accommodate shifts in work material properties from one range to another, although sometimes at the cost of lower production and higher material waste. Some processes can be successfully operated using work material that has a wide range of properties. In general, consistency in the forming properties of the work material is an important factor in producing a high output of dimensionally accurate parts.

Strain Distribution

Three material properties determine the strain distribution in a forming operation:

- The strain-hardening coefficient (also known as the work-hardening coefficient or exponent) or n value
- The strain rate sensitivity or m value
- The plastic strain ratio (anisotropy factor) or r value

The ability to distribute strain evenly depends on the n value and the m value. The ability to reach high overall strain levels depends on many factors, such as the base material, alloying elements, temper, n value, m value, r value, thickness, uniformity, and freedom from defects and inclusions.

The *n* value, or strain-hardening coefficient, is determined by the dependence of the flow (yield) stress on the level of strain. In materials with a high *n* value, the flow stress increases rapidly with strain. This tends to distribute further strain to regions of lower strain and flow stress. A high *n* value is also an indication of good formability in a stretching operation.

In the region of uniform elongation, the *n* value is defined as:

$$n = \frac{d \ln \sigma_T}{d \ln \epsilon} \quad \textbf{(Eq 3)}$$

where σ_T is the true stress (load/instantaneous area). This relationship implies that the true stress-strain curve of the material can be approximated by a power law constitutive equation proposed in Ref 2:

$$\sigma_T = k\varepsilon^n \quad \textbf{(Eq 4)}$$

where *k* is a constant known as the strength coefficient.

Equation 4 provides a good approximation for most steels, but is not very accurate for dual-phase steels and some aluminum alloys. For these materials, two or three *n* values may need to be calculated for the low, intermediate, and high strain regions.

When Eq 4 is an accurate representation of material behavior, $n = \ln (1 + e_u)$, where e_u is the uniform elongation, or elongation at maximum load in a tensile test. By definition, $\ln (1 + e_u)$ is identical to ε_u which is the true strain at uniform elongation.

Most steels with yield strengths below 345 MPa (50 ksi) and many aluminum alloys have *n* values ranging from 0.2 to 0.3. For many higher yield strength steels, *n* is given by the relationship (Ref 3):

$$n \simeq \frac{70}{\text{(yield strength in MPa)}} \quad \textbf{(Eq 5)}$$

A high *n* value leads to a large difference between yield strength and ultimate tensile strength (engineering stress at maximum load in a tensile test). The ratio of these properties therefore provides another measure of formability.

The *m* value, or strain rate sensitivity, is defined by:

$$m = \frac{d \ln \sigma_T}{d \ln \dot{\epsilon}} \quad \textbf{(Eq 6)}$$

where $\dot{\epsilon}$ is the strain rate, $d\varepsilon/dt$. This implies a relationship of the form:

$$\sigma_T = f(\varepsilon) \cdot \dot{e}^{\,m}$$

or

$$\sigma_T = k\,\varepsilon^n \cdot \dot{e}^{\,m} \quad \textbf{(Eq 7)}$$

where Eq 7 incorporates Eq 4 between stress and strain.

A positive strain rate sensitivity indicates that the flow stress increases with the rate of deformation. This has two consequences. First, higher stresses are required to form parts at higher rates. Second, at a given forming rate, the material resists further deformation in regions that are being strained more rapidly than adjacent regions by increasing the flow stress in these regions. This helps to distribute the strain more uniformly.

The need for higher stresses in a forming operation is usually not a major consideration, but the ability to distribute strains can be crucial. This becomes particularly important in the post-uniform elongation region, where necking and high strain concentrations occur. An approximately linear relationship has been reported between the *m* value and the post-uniform elongation for a variety of steels and nonferrous alloys (Ref 4). As *m* increases from -0.01 to +0.06, the post-uniform elongation increases from 2 to 40%.

Metals in the superplastic range have high *m* values of 0.2 to 0.7, which are one to two orders of magnitude higher than typical values for steel. At ambient temperatures, some metals, such as aluminum alloys and brass, have low or slightly negative *m* values, which explains their low post-uniform elongation.

High *n* and *m* values lead to good formability in stretching operations, but have little effect on drawability. In a drawing operation, metal in the flange must be drawn in without causing fracture in the wall. In this case, high *n* and *m* values strengthen the wall, which is beneficial, but they also strengthen the flange and make it harder to draw in, which is detrimental.

The *r* value, or plastic strain ratio, relates to drawability and is known as the anisotropy factor. This is defined as the ratio of the true width strain to the true thickness strain in the uniform elongation region of a tensile test:

$$r = \frac{\epsilon_w}{\epsilon_t} = \frac{\ln\left(\frac{w}{w_o}\right)}{\ln\left(\frac{t}{t_o}\right)} \quad \textbf{(Eq 8)}$$

The *r* value is a measure of the ability of a material to resist thinning. In drawing, material in the flange is stretched in one direction (radially) and compressed in the perpendicular direction (circumferentially). A high *r* value indicates a material with good drawing properties.

The *r* value frequently changes with direction in the sheet. In a cylindrical cup drawing operation, this variation leads to a cup with a wall that varies in height, a phenomenon known as earing (Fig. 3). It is therefore common to measure the average *r* value, or average normal anisotropy, r_m, and the planar anisotropy, Δr.

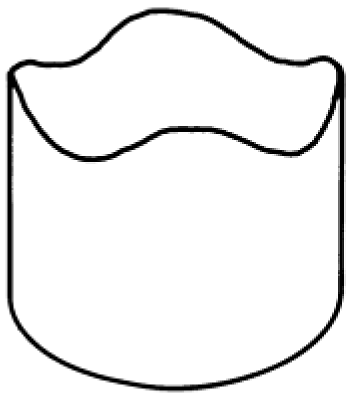

Fig. 3 Drawn cup with ears in the directions of high *r* value.

The property r_m is defined as $(r_0 + 2r_{45} + r_{90})/4$, where the subscripts refer to the angle between the tensile specimen axis and the rolling direction. The value Δr is defined as $(r_0 - 2r_{45} + r_{90})/2$. It is a measure of the variation of *r* with direction in the plane of a sheet. The value r_m determines the average depth (that is, the wall height) of the deepest draw possible. The value Δr determines the extent of earing. A combination of a high r_m value and a low Δr value provides optimal drawability.

Hot-rolled low-carbon steels have r_m values ranging from 0.8 to 1.0; cold-rolled rimmed steels range from 1.0 to 1.4, and cold-rolled aluminum-killed (deoxidized) steels range from 1.4 to 2.0. Interstitial-free steels have values ranging from 1.8 to 2.5, and aluminum alloys range from 0.6 to 0.8. The theoretical maximum r_m value for a ferritic steel is 3.0; a measured value of 2.8 has been reported (Ref 5).

Maximum Strain Levels: The Forming Limit Diagram

Each type of steel, aluminum, brass, or other sheet metal can be deformed only to a certain level before local thinning (necking) and fracture occur. This level depends principally on the combination of strains imposed, that is, the ratio of major and minor strains. The lowest level occurs at or near plane strain, that is, when the minor strain is zero.

This information was first represented graphically as the forming limit diagram, which is a graph of the major strain at the onset of necking for all values of the minor strain that can be realized (Ref 6, 7). Figure 4 shows a typical forming limit diagram for steel. The diagram is used in combination with strain measurements, usually obtained from circle grids, to determine how close to failure (necking) a forming operation is or whether a particular failure is due to inferior work material or to a poor die condition (Ref 8).

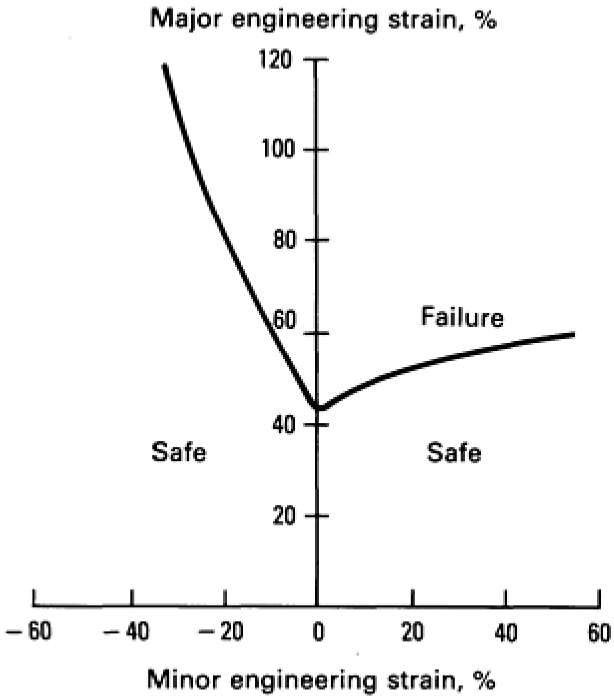

Fig. 4 Typical forming limit diagram for steel.

For most low-carbon steels, the forming limit diagram has the same shape as the one shown in Fig. 4, but the vertical position of the curve depends on the sheet thickness and the *n* value. The intercept of the curve with the vertical axis, which represents plane strain and is also the minimum point on the curve, has a value equal to *n* in the (extrapolated) zero thickness limit. The intercept increases linearly with thickness to a thickness of about 3 mm (0.12 in.).

The rate of increase is proportional to the *n* value up to $n = 0.2$, as shown in Fig. 5. Beyond these limits, further increases in thickness and *n* value have little effect on the position of the curve. The level of the forming limits also increases with the *m* value (Ref 4).

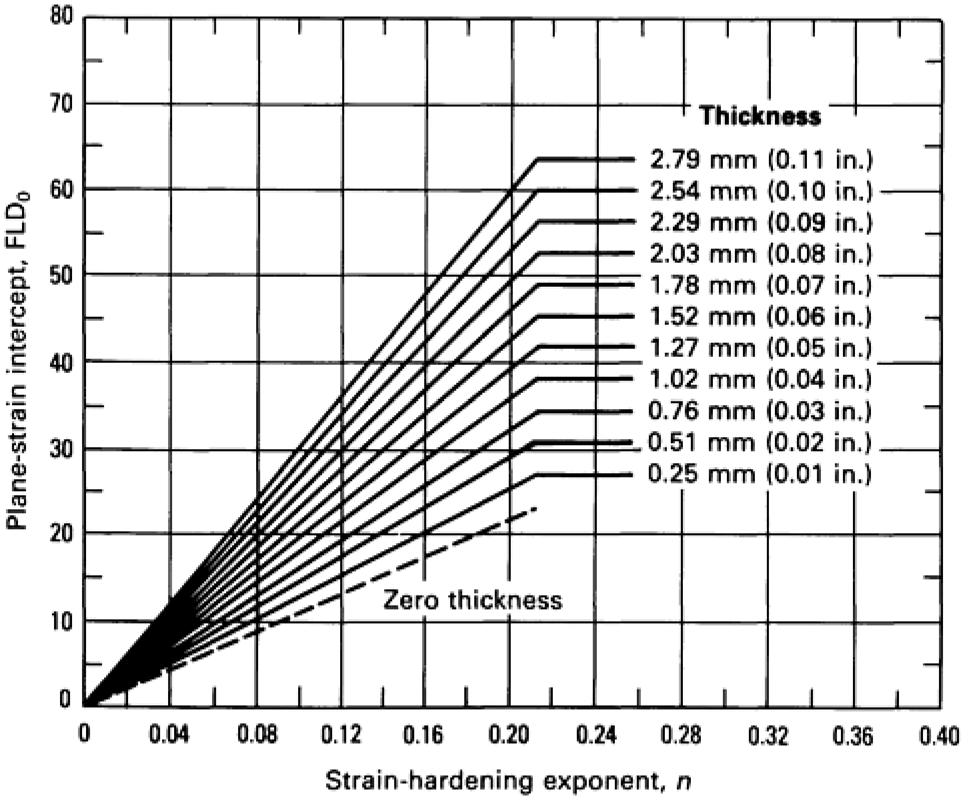

Fig. 5 Effect of thickness and *n* value on the plane-strain intercept of a forming limit diagram. Source: Ref 9.

The shape of the curve for aluminum alloys, brass, and other materials differs from that in Fig. 4 and varies from alloy to alloy within a system. The position of the curve also varies and rises with an increase in the thickness, *n* value, or *m* value, but at rates that are generally not the same as those for low-carbon steel.

The forming limit diagram is also dependent on the strain path. The standard diagram is based on an approximately uniform strain path. Diagrams generated by uniaxial straining followed by biaxial straining, or the reverse, differ considerably from the standard diagram. Therefore, the effect of the strain path must be taken into account when using the diagram to analyze a forming problem.

Material Properties and Wrinkling

The effect of material properties on the formation of buckles or wrinkles is the subject of extensive research. In drawing operations, there is general agreement, based primarily on experiments with conical and cylindrical cups, that a high r_m value and a low Δr value reduce buckling in both flanges and walls (Ref 10, 11, 12). In addition to the above correlations, a low flow-stress-to-elastic-modulus ratio (σ_F/E) decreases wall wrinkling (Ref 13). The *n* value has an indirect effect. When the binder force is kept constant, the *n* value has no effect. However, high *n* values enable higher binder forces to be used, which reduces buckling.

In stretching operations, the situation appears to be different. A close correlation between the formation of buckles at low strain levels and the yield-strength-to-tensile-strength ratio (YS/TS) has been reported, as well as an inverse correlation with the low strain *n* value and an absence of correlation with the r_m value and uniform elongation (Ref 14). Some of the differences between these results may be attributed to the fact that the experiments with cups involved high strains and high compressive stresses, while the stretching experiments were conducted at low strain and low compressive stress levels. In both situations, the problem becomes significantly more severe as the sheet thickness decreases.

Material Properties and Shear Fracture

Shear fractures due to in-plane shear stresses are more prevalent in high-strength cold-worked materials, particularly when internal defects such as inclusions are present. Typical strain combinations that cause shear fracture are shown on the forming limit diagram in Fig. 6. For this material, Fig. 6 shows that, at high strain levels in the regions close to $\varepsilon_2 = \pm\varepsilon_1$, failure occurs by shearing before the initiation of necking.

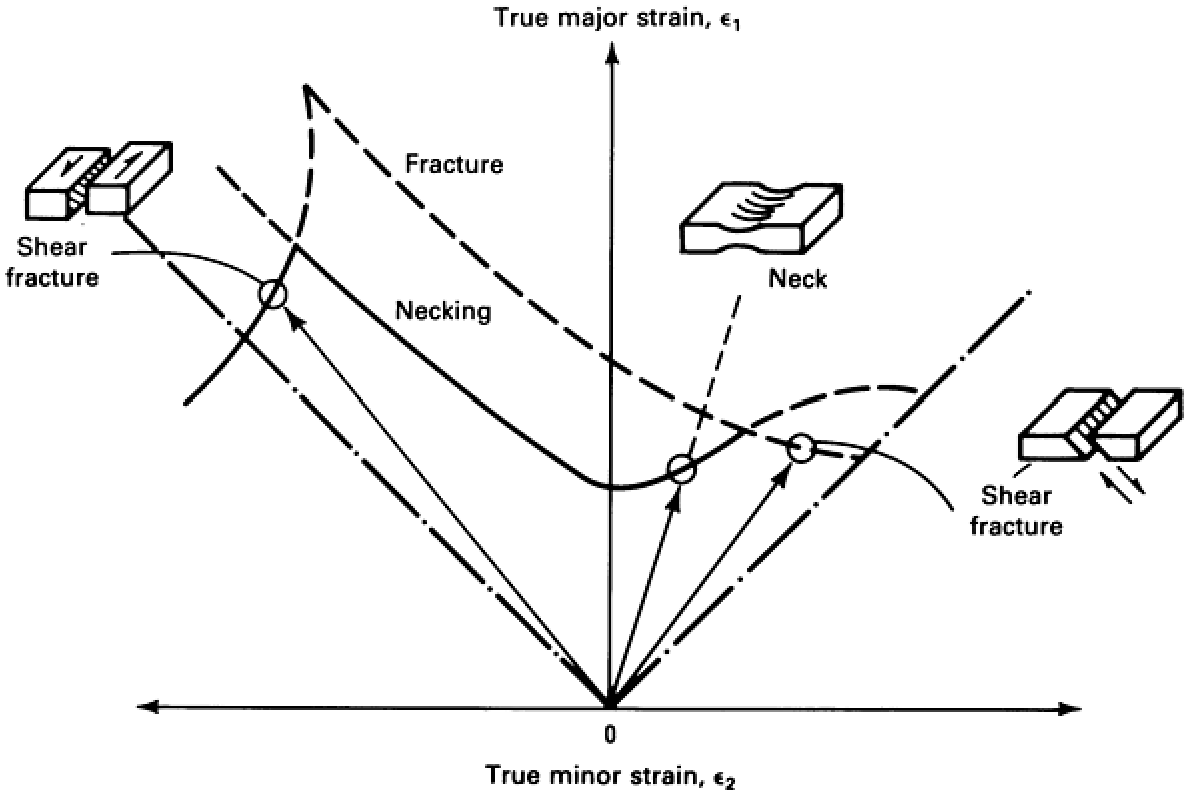

Fig. 6 Forming limit diagram including shear fracture. Source: Ref 15.

The position and shape of the shear fracture curve depends on the material, its temper, and the type and degree of prestrain or cold work (Ref 15, 16, 17). Limited data are available on shear fracture.

Material Properties and Springback

Material properties that control the amount of springback that occurs after a forming operation are:

- Elastic modulus, E
- Yield stress, σ_y
- Slope of the true stress/strain curve, or tangent modulus, $d\sigma_T/d\varepsilon$

Springback is best described by means of three examples involving a rectangular beam: elastic bending below the yield stress, simple bending with the yield stress exceeded in the outer layers of the beam, and combined stretching and bending. In an actual part, springback is determined by the complex interaction of the residual internal elastic stresses, subject to the constraints of the part geometry.

Elastic Bending Below the Yield Stress. Tensile elastic stresses are generated on the outside of the bend. These stresses decrease linearly from a maximum at the surface to zero at the center (neutral axis). They then become compressive and increase linearly to a maximum at the inner surface. Upon removal of the externally applied bending forces, the internal elastic forces cause the beam to unbend as they decrease to zero throughout the cross section (Fig. 7a).

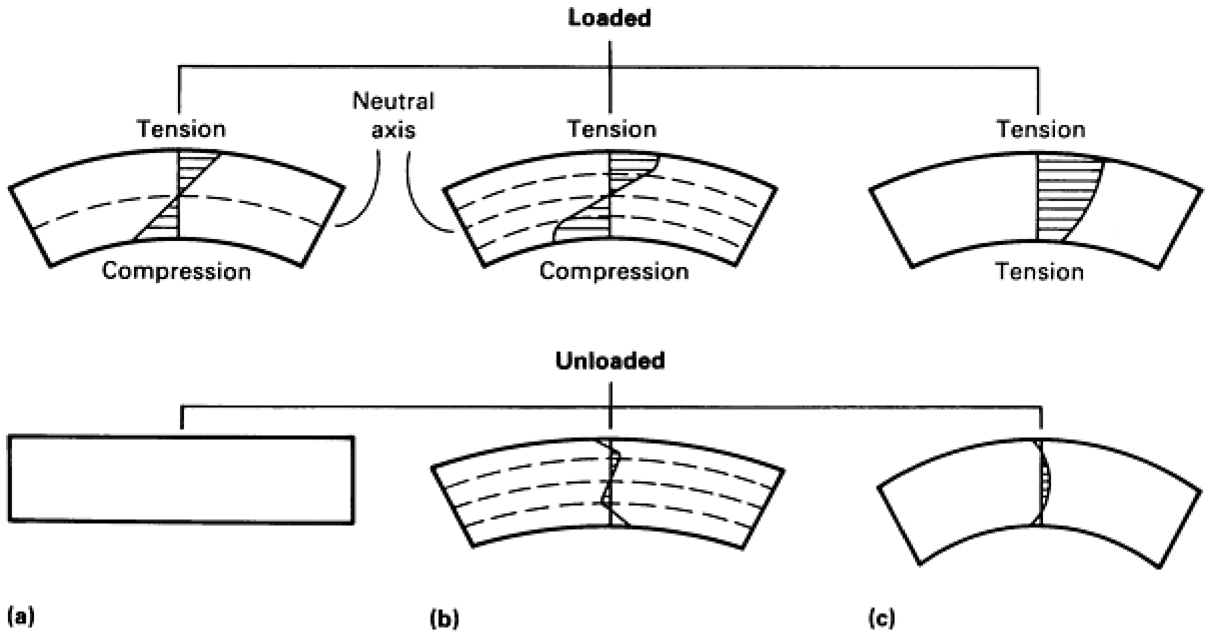

Fig. 7 Springback of a beam in simple bending. (a) Elastic bending. (b) Elastic and plastic bending. (c) Bending and stretching.

The maximum amount of elastic deflection that can be produced without entering the plastic range is proportional to the yield stress divided by the elastic modulus. The strain at the yield point is equal to σ_y/E ($E = \sigma/\varepsilon$). The springback moment for a given deflection is therefore proportional to the elastic modulus ($\sigma = E\varepsilon$).

Simple Bending. In this example, the yield stress is exceeded in the outer layers of the beam. The outer layers deform plastically, and their stored elastic stresses continue to increase, but at a much lower rate that is proportional to the slope of the true stress-strain curve, or tangent modulus, $d\sigma_T/d\varepsilon$, instead of the elastic modulus. Figure 7(b) illustrates this condition for a beam bent so that 50% of its volume is in the plastic range.

Upon removal of the externally applied bending forces, the stored elastic stresses cause the beam to unbend until their combined bending moment is zero. This produces compressive stresses at the outer surface and tensile stresses at the inner surface.

The springback in this case is less than for a material whose yield strength is not exceeded at the same strain level. This can result from either a higher yield stress or a lower elastic modulus. It is also apparent that higher values of the tangent modulus cause greater springback when the yield strength is exceeded.

In actual conditions, the neutral axis moves inward upon bending because the outer part of the beam is stretched and becomes thinner and because the inner part is compressed and becomes thicker. This effect is analyzed in detail in Ref 18.

Combined Stretching and Bending. In this case, the entire beam can be plastically deformed in tension by as little as 0.5% stretching. However, a stress gradient still exists from the outer to the inner surface (Fig. 7c). Upon removing the external forces the internal elastic stresses recover.

This causes unbending, but to a lesser extent than in the previous cases. As the level of stretching is increased, the amount of springback decreases because the tangent modulus and therefore the stress gradient through the beam decrease at higher strains. The yield strength ceases to be a factor in springback once all regions are plastically deformed in tension.

In the bending of wide sheets, the metal is deformed in plane strain, and the plane-strain properties (elastic modulus, yield stress, and tangent modulus) should be used. The effects of a low elastic modulus and a high yield stress and tangent modulus in increasing springback have been experienced in forming operations. Springback is more severe with aluminum alloys than with low-carbon steel (1 to 3 modulus ratio). High-strength steels exhibit more springback than low-carbon steels (~2 to 1 yield strength ratio), and dual-phase steels spring back more than high-strength steels of the same yield strength (higher tangent modulus).

The effect of stretching in reducing springback to very low levels has also been reported (Ref 19). Springback is also greatly influenced by geometrical factors, and it increases as the bend angle and ratio of bend radius to sheet thickness increase.

Surface Quality

The previously mentioned conditions that lead to undesirable surface textures can be minimized or prevented. The formation of orange peel in heavily deformed regions can be minimized by using a fine-grain material. The development of Lüders lines in rimmed steels can be prevented by temper rolling to 0.25 to 1.25% extension or by flex rolling, which produces mobile dislocations for a limited period of time, until they are trapped by nitrogen atoms. This also reduces elongation slightly. This problem is becoming less common with the increased use of continuous casting, which requires killed steels. These steels have less free nitrogen to interact with the dislocations and do not develop Lüders lines. Similar treatments can be applied to aluminum-magnesium alloys to prevent this defect.

Formability Testing of Sheet Metals

Brian Taylor, General Motors Corporation

Effect of Temperature on Formability

A change in the overall temperature alters the properties of the material, which thus affects formability. In addition, local temperature differences within a deforming blank lead to local differences in properties that affect formability.

At high temperatures, above one-half of the melting point on the absolute temperature scale, extremely fine-grain aluminum, copper, magnesium, nickel, stainless steel, steel, titanium, zinc, and other alloys become superplastic. Superplasticity is characterized by extremely high elongation, ranging from several hundred to more than 1000%, but only at low strain rates (usually below about $10^{-2}/s^{-1}$) at high temperatures.

The requirements of high temperatures and low forming rates have limited superplastic forming to low-volume production. In the aerospace industry, titanium is formed in this manner. The process is particularly attractive for zinc alloys because they require comparatively low temperatures (~270 °C, or ~520 °F).

At intermediate elevated temperatures, steels and many other alloys have less ductility than at room temperature (Ref 20, 21). Aluminum and magnesium alloys are exceptions and have minimum ductility near room temperature. Alloys of these metals have been formed commercially at slightly elevated temperatures (~250 °C, or ~480 °F). The strain rate sensitivity (*m* value) and post-uniform elongation for aluminum-magnesium alloys have been found to increase significantly in this temperature range (Ref 22).

Low-temperature forming has potential advantages for some materials, based on their tensile properties, but practical problems have limited application. Local increases in temperature occur during forming because of the surface friction and internal heating produced by the deformation. Generally, this is detrimental because it lowers the flow stress in the area of greatest strain and tends to localize deformation.

A method of improving drawability by creating local temperature differences has been developed and is being used commercially (Ref 23). It involves water cooling the punch in a deep-drawing operation. This lowers the temperature of the blank where it contacts the punch, which is the principal failure zone, and increases the local flow stress. Heating the die in order to lower the flow stress in the deformation zone at the top of the draw wall has also been found to be beneficial. The combination of these procedures has produced an increase of over 20% in the drawability of an austenitic stainless steel.

Types of Formability Tests

Formability tests are of two basic types: intrinsic and simulative. Intrinsic tests measure the basic characteristic properties of materials that can be related to their formability. Simulative tests subject the material to deformation that closely resembles the deformation that occurs in a particular forming operation.

Intrinsic tests provide comprehensive information that is insensitive to the thickness and surface condition of the material. The most important and extensively used intrinsic test is the uniaxial tensile test, which provides the values of many material properties for a wide range of forming operations. Other commercially important intrinsic tests are the plane-strain tensile test, the Marciniak stretching and sheet torsion tests, the hydraulic bulge test, the Miyauchi shear test, and hardness tests.

Simulative tests provide limited and specific information that is usually sensitive to thickness, surface condition, lubrication, and geometry and type of tooling. This information usually relates to only one type of forming operation. Many simulative tests, such as the Olsen and Swift cup test, have been extensively used for many years with good correlation to production in specific cases. Several simulative tests are described later in this article.

Formability Testing of Sheet Metals

Brian Taylor, General Motors Corporation

Uniaxial Tensile Testing

The most widely used intrinsic test of sheet metal formability is the uniaxial tensile test. A specimen such as that illustrated in Fig. 8 is used; its sides are accurately parallel over the gage length, which is usually 50.8 mm (2.00 in.) long and 12.7 mm (0.50 in.) wide. The specimen is gripped at each end and stretched at a constant rate in a tensile machine until it fractures, as described in ASTM E 8. The applied load and extension are measured by means of a load cell and strain gage extensometer.

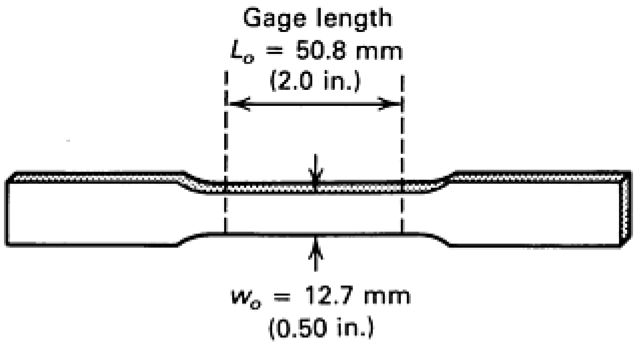

Fig. 8 Sheet tensile test specimen.

The load extension data can be plotted directly. However, data are usually converted into engineering (conventional) stress, σ_E (load/original cross section), and engineering strain, *e* (elongation/original length), or to true stress, σ_T (load/instantaneous cross section), and true strain, ε(natural logarithm of strained length/original length).

In addition, for formability testing, it is common practice to measure the width of the specimen during the test. This is done either intermittently by interrupting the test at preselected elongations to make measurements manually or continuously by means of width extensometers. From these measurements, the plastic strain ratio (anisotropy factor), or *r* value, can be determined.

During the rolling process used to produce metals in sheet form and the subsequent annealing, the grains and any inclusions present become elongated in the rolling direction, and a preferred crystallographic orientation develops. This causes a variation of properties with direction. Therefore, it is common practice to test specimens cut parallel to the rolling direction and at 45 and 90° to this direction. These are known as longitudinal, diagonal, and transverse specimens, respectively. This also enables the values of r_m and Δr to be calculated. Because the mechanical properties and elongation tend to be lower in the transverse direction, tests in this direction are often used as the basis for specifications.

The rate at which the test is performed can have a significant effect on the end results. Two methods are commonly used to determine this effect. In the first method, replicate samples are tested at different rates, and the results are influenced by variations between the samples. In the second method, the test rate is alternated between two levels. This approach avoids the problem of variation between samples, but it cannot be used at very high rates and is complicated by transients, which occur each time the rate is changed. The strain rate sensitivity, or *m* value, can be calculated from these tests.

Figure 9 shows a typical engineering stress-strain curve and the corresponding true stress-strain curve for a material that has a smooth transition between the very low strain (elastic) and the higher strain (plastic) regions of the curve. When the load is removed in the elastic region, the sample returns to its original dimensions. When this is done in the plastic region, the sample retains permanent deformation.

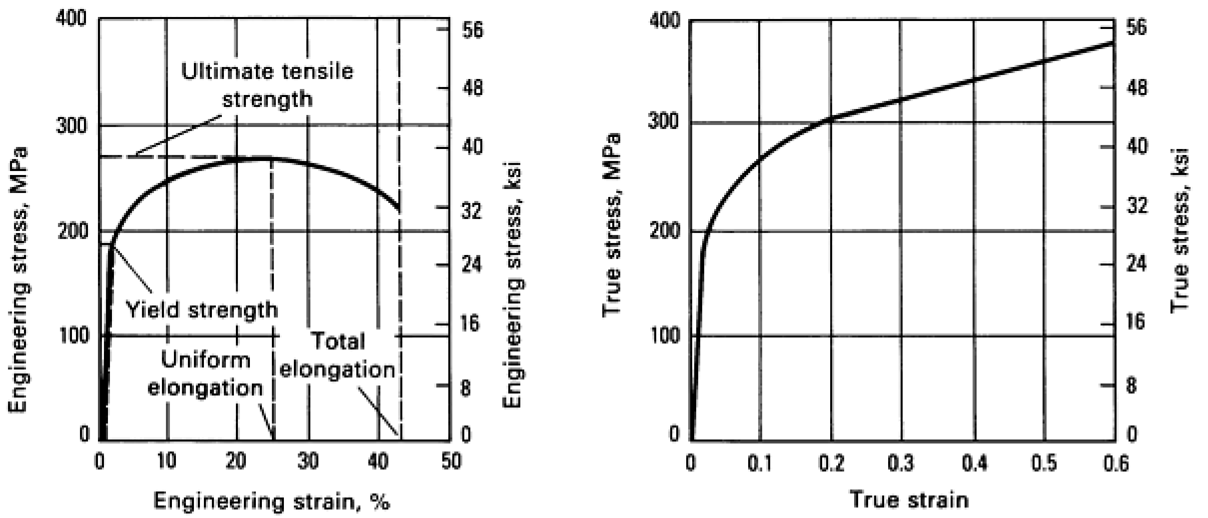

Fig. 9 Typical engineering and true stress-strain curves.

In the tensile test, the load increases to a maximum value and then decreases prior to fracture. The decrease is due to the localization of the deformation, which causes a reduction in cross section. This reduction has a greater effect than the opposing increase in flow stress due to strain hardening.

Some materials such as aged rimmed steels do not have a smooth transition between the elastic and plastic regions of the stress-strain curve. The load they can support decreases at the beginning of the plastic region and remains approximately constant for up to about 7% elongation. Subsequently, the load increases to a maximum and then decreases again at high elongations. This type of stress-strain curve is shown in Fig. 10. With the increasing use of continuous casting, which requires killed steels (steels deoxidized by small additions of aluminum, for example), rimmed steels are becoming less common.

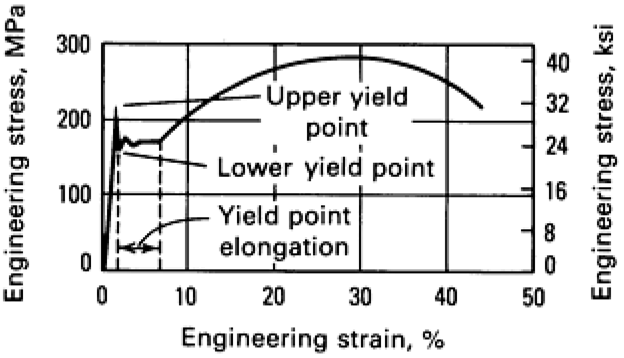

Fig. 10 Engineering stress-strain curve for rimmed steel.

Test Procedure

For accurate and reproducible results, uniaxial tensile testing must be performed in a carefully controlled manner. The main steps in the procedure are discussed in detail in the Section "Tension Testing" in *Mechanical Testing*, Volume 8 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.* These procedures are summarized below.

Specimen Preparation. The surfaces of the specimen should be free from scratches or other damage that can act as stress raisers and cause early failure. The edges should be smooth and free from irregularities. Care should be taken not to cold work the edges, or to ensure that any cold work introduced is removed in a subsequent operation, because this changes mechanical properties and lowers ductility.

It is common practice to mill and grind the edges, but other procedures such as fine milling, nibbling, and laser cutting are also used. When a new method is used, initial tests should be performed to compare the results with those obtained by conventional methods.

The width of a nominally 12.7 mm (0.50 in.) wide specimen should be measured to the nearest 0.025 mm (0.001 in.), and the thickness for specimens in the range of 0.5 to 2.5 mm (0.02 to 0.1 in.) should be measured to the nearest 0.0025 mm (0.0001 in.). If this is impractical because of surface roughness, the thickness should be measured to the nearest 0.025 mm (0.001 in.).

The tensile test is sensitive to variations in the width of the specimen, which should be accurately controlled. For a specimen 12.7 mm (0.50 in.) wide, the width of the reduced section should not deviate by more than ±0.25 mm (±0.01 in.) from the nominal value and should not differ by more than ±0.05 mm (±0.002 in.) from end to end.

Some investigators intentionally taper the reduced section slightly toward the center to increase the probability that fracture will occur within the gage length. In this case, the center should not be narrower than the ends by more than 0.10 mm (0.004 in.).

Alignment of Specimens. The specimen should be accurately aligned with the centerline of the grips. The effect of small displacements (10% of the specimen width) of one or both ends from the centerline has been calculated (Ref 24). It has been determined that the latter case is the more serious, but both strongly affect the strain in the outermost fibers. It has also been concluded that the calculated stress-strain curve is not significantly affected at strains above 0.3%.

Measurement of Load and Elongation. The applied load is measured by means of a load cell in the test machine, for which the usual calibration procedures must be followed (ASTM E 4). Elongation is usually determined by using a clip-on strain gage extensometer (ASTM E 83). In addition, small scratches are often scribed across the specimen at the ends of the gage length so that the total elongation can be determined from the broken specimen.

Circle grids are sometimes etched or printed on the specimen. These can be used to measure the strain distribution and width strain as well as the overall strain. This can be done continuously by means of a video camera and data processing system if required. Optical extensometers are used for some applications, particularly high-speed testing. These units require well-illuminated boundaries that are clearly delineated by means of high-contrast coatings, such as black-and-white paint.

An approximate measure of elongation can be obtained from the crosshead travel. This involves errors due to elongation of the specimen outside the gage length and elastic strain in the grips, which can be compensated for to some extent. This method is used when the specimen is inaccessible, such as in nonambient testing.

The signals from the load cell and extensometer can be plotted on a chart recorder or processed by a data processing system to the required form, such as plots of stress versus strain or tables of mechanical and forming properties.

Measurement of Width and Thickness. In addition to the initial measurements of specimen width and thickness, which are required to calculate the stress, measurements can be made at intervals during the test to determine the *r* value (ASTM E 517) and to determine the reduction in area and true strain. The *r* value is measured at a specified strain level between the yield point and the uniform elongation (for example, at 15% elongation). It can be measured by stopping the test at this strain level and then measuring the width accurately (±0.013 mm, or ±0.0005 in.) at a minimum of three equally spaced points in the gage length (for a 50.8 mm, or 2.0 in., gage length). In practice, the thickness is calculated from the specimen width and length, assuming no change in volume.

Alternatively, width measurements can be made during the test using width extensometers, although this is a more complicated procedure. Attempts are underway to develop combined width and length extensometers to simplify this method.

Reduction in area is the ratio $(A_o - A)/A_o$, where A is the instantaneous cross-sectional area and A_o is the original cross-sectional area. It is used to calculate the true strain in the region of post-uniform elongation. A large reduction in area at fracture correlates with a small minimum bend radius, a high *m* value, and high energy absorption. To calculate the reduction in area, the width and thickness must be measured in the narrowest part of the necked region.

Effect of Gage Length on Elongation. In post-uniform elongation, part of the specimen is elongated uniformly, and the remainder is narrowed into a necked region of higher strain level. A change in the gage length alters the ratio of these two regions and has a significant effect on the total elongation measurement. This phenomenon is discussed in detail in Ref 25.

To obtain results that are comparable for different gage lengths, the ratio of the square root of the cross-sectional area to the length, $\sqrt{A}/L$, should be the same. When comparing samples of different thickness, this implies that the gage length or the width should be adjusted to maintain this ratio.

Rate of Testing. Most tensile tests are performed on screw-driven or hydraulic testing machines at strain rates of 10^{-5} to 10^{-2} s^{-1}. The strain rate is defined as the increase in length per unit length per second. These tests are known as low strain rate or static tests.

Most high-volume production forming operations are performed at considerably higher strain rates--in the range of 1 to 10^2 s^{-1}. To determine the tensile properties in this range, dynamic test machines, which operate at rates of 10^{-1} to 10^2 s^{-1}, are used (Ref 25). As mentioned previously, steels have higher tensile properties and lower elongations at high strain rates. The properties of aluminum alloys have little sensitivity to the strain rate.

Material Properties

The stress-strain curve determined by uniaxial tension testing provides values of many formability-related material properties. Several of these properties and methods for measurement are discussed below. Table 1 lists typical values of properties measured in tensile tests on thin (0.5 to 1.0 mm, or 0.02 to 0.04 in.) sheet materials.

Table 1 Typical tensile properties of selected sheet metals

Material	Young's modulus, E		Yield strength		Tensile strength		Uniform elongation, %	Total elongation, %	Strain-hardening exponent, n	Average normal anisotropy, r_m	Planar anisotropy, Δr	Strain rate sensitivity, m
	GPa	10^6 psi	MPa	ksi	MPa	ksi

Young's Modulus. The initial slope of the stress-strain curve, that is, the ratio of the stress to the strain in the elastic region before any plastic deformation has occurred, is the Young's modulus, *E*, of the material. This property affects springback and shape distortion at low strains. For accurate measurement of Young's modulus, a low strain rate and a high data acquisition rate should be used in the elastic region (below about 0.5% elongation), and a very stiff tension-testing machine should be used if strain is inferred from crosshead displacement.

Yield Strength. The stress at which the stress-strain curve deviates in elongation from the initial elastic slope by a specified amount, commonly 0.2%, is known as the yield strength (YS). The yield strength determines the load necessary to initiate deformation in a forming operation, which is usually a high percentage (40 to 90%) of the maximum load required.

For accurate measurement of yield strength, a rate of loading of less than 690 MPa/min (100 ksi/min) is specified. Beyond this point, the strain rate should not exceed 0.08 s^{-1}. Some materials elongate without an increase in load, or at a decreased load, at the transition between the elastic and plastic regions. The point at which this initiates is known as the yield point.

With a decrease in load, the material has an upper yield point and a lower yield point. The upper yield point is difficult to measure reproducibly. The lower yield stress usually fluctuates, and the minimum value is used.

The elongation that occurs after yielding before the load starts to increase monotonically is known as the yield point elongation. Yield point elongation leads to nonuniform deformation at low strains in forming operations. If it exceeds about 1.5%, irregular surface markings known as Lüders lines or stretcher strains may occur to an extent that is unacceptable in visible parts.

Tensile Strength. The maximum stress observed in the test is known as the tensile strength (TS), or ultimate tensile strength. Tensile strength determines the maximum load that can be usefully applied in a forming operation.

Uniform Elongation. The engineering strain at the maximum engineering stress is known as the uniform elongation, e_u. Prior to this point, the sample deforms uniformly. Subsequently, deformation concentrates--initially in a fairly large region known as a diffuse neck, and ultimately in a localized region of sharply reduced cross section known as a local neck. Deformation continues to concentrate in this region until fracture occurs.

Total Elongation. Elongation at the point of fracture is known as total elongation, e_T. It has been extensively used as an approximate indication of sheet metal formability. However, no single property is a reliable indicator of formability under all conditions.

Reduction in area, $(A_o - A)/A_o$, is calculated from measurements of actual specimen width and thickness in the narrowest part of the necked region. The true strain, which cannot be determined from length measurements in the post-uniform elongation region, is also calculated from these values.

The true strain in the necked region is equal to ln (dL/dL_o), where dL is a small element of length in this region, whose original length was dL_o. Equating the original and final volumes of this element of length gives:

$$V_o = A_o dL_o = V = AdL$$

or

$$\epsilon = \ln\left(\frac{dL}{dL_o}\right) = \ln\left(\frac{A_o}{A}\right) \quad \textbf{(Eq 9)}$$

The relationship between the reduction in area at fracture and the minimum bend radius is as follows (Ref 25). For values of reduction in area at fracture, q, below 0.2, the ratio of the minimum bend radius, R_m, to sheet thickness, t, is given by:

$$\frac{R_m}{t} = \frac{1}{2q} - 1 \quad \textbf{(Eq 10)}$$

For values of q greater than 0.2:

$$\frac{R_m}{t} = \frac{(1 - q)^2}{(2q - q^2)} \quad \textbf{(Eq 11)}$$

Strain-Hardening Exponent. The n value, $d \ln \sigma_T / d \ln\varepsilon$, is given by the slope of a graph of the logarithm of the true stress versus the logarithm of the true strain in the region of uniform elongation. For materials that closely follow the Holloman constitutive equation (Eq 4), an approximate n value can be obtained from two points on the stress-strain curve by the Nelson-Winlock procedure (Ref 26). The two points commonly used are at 10% strain and at the maximum load. The ratio of the loads or stresses at these two points is calculated, and the n value and uniform elongation can then be determined from a table or graph. The accuracy of the n value determined in this way is ±0.02.

The n value can be determined more accurately by linear regression analysis, as in ASTM E 646. For some materials, n is not constant, and initial (low strain), terminal (high strain), and sometimes intermediate n values are determined. The initial n value relates to the low deformation region, in which springback is often a problem. The terminal n value relates to the high deformation region, in which fracture may occur.

Plastic Strain Ratio. The r value, or anisotropy factor, is defined as the ratio of the true width strain to the true thickness strain in a tensile test. Generally, its value depends on the elongation at which it is measured. It is usually measured at 10, 15, or 20% elongation.

The r value is calculated from the measured width and length as:

$$\epsilon_w = \ln\left(\frac{w}{w_o}\right)$$
$$\epsilon_t = \ln\left(\frac{t}{t_o}\right) = \ln\left(\frac{L_o w_o}{L w}\right) \quad \textbf{(Eq 12)}$$

where constancy of volume ($Lwt = L_o w_o t_o$) has been used and:

$$r = \frac{\epsilon_w}{\epsilon_t} = \frac{\ln\left(\frac{w}{w_o}\right)}{\ln\left(\frac{L_o w_o}{L w}\right)} \quad \textbf{(Eq 13)}$$

The average r value, or normal anisotropy (r_m), and the planar anisotropy, or Δr value, can be calculated from the values of r in different directions using Eq 1, 2, 8, and 12.

Strain Rate Sensitivity. The m value, $d \ln \sigma_T / d \ln \dot{e}$, is determined either from duplicate tensile tests performed at different strain rates or from a single test in which the rate is alternated between two levels during the test. These methods are shown schematically in Fig. 11. The m value can be determined at various strain levels in the region of uniform elongation:

$$m = \frac{\ln\left(\frac{\sigma_1}{\sigma_2}\right)}{\ln\left(\frac{\dot{\epsilon}_1}{\dot{\epsilon}_2}\right)} \quad \textbf{(Eq 14)}$$

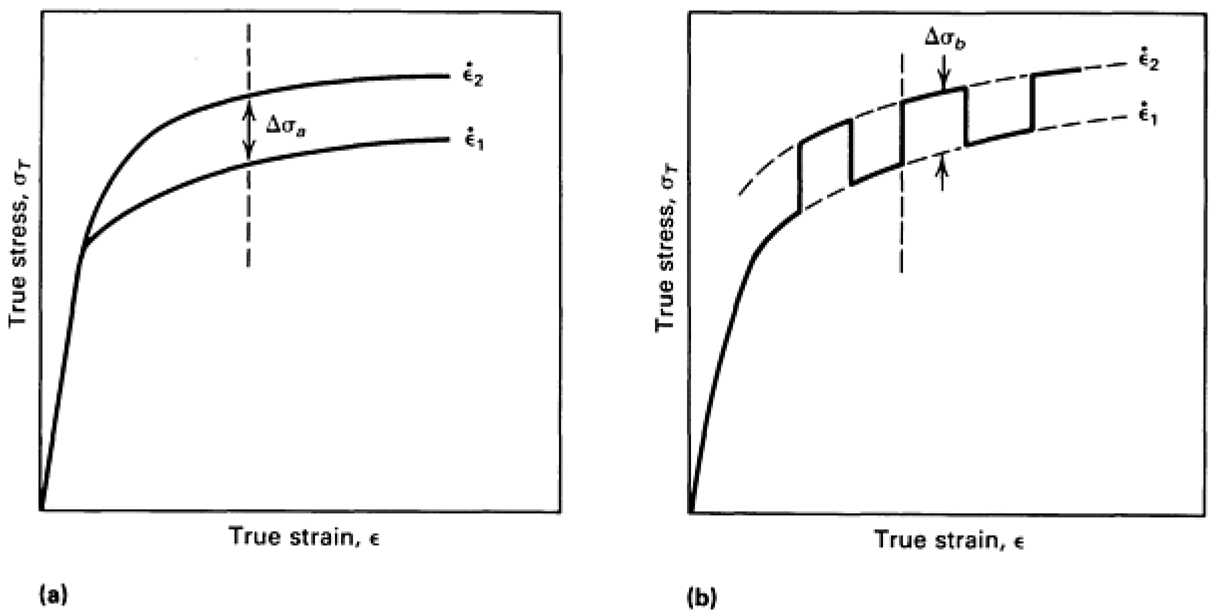

Fig. 11 Methods for determining strain-rate sensitivity (*m* value). (a) Duplicate test method. (b) Changing rate method.

In some materials, *m* is insensitive to strain (Ref 4, 27). In other materials, however, *m* is sensitive to strain and strain rate (Ref 28). In many materials, *m* increases and *n* decreases with an increase in temperature (Ref 29), sometimes to the extent that superplastic properties develop.

Determining *n* and *r* Values

The time and facilities required for sample preparation and for performing the uniaxial tensile test make it difficult to use for on-line process control. The following simplified tests for determining *n* and *r* are more suitable for this purpose. The circle arc elongation test and the rapid-*n* test utilize tensile specimens with two sections that differ in width by about 5% to determine *n* values. Fracture almost always occurs in the narrow section, but the final measurements are made on the wide section, which elongates uniformly. The *r* value can be obtained from these tests, but for ferritic steels, the Modul-*r* test is faster and easier to perform. This test actually measures the elastic modulus of the specimen and uses an empirically determined correlation between the modulus and the *r* value.

The circle arc elongation test does not require measurement of the applied loads (Ref 30). It uses a rectangular tensile specimen with a reduced width section produced by milling a pair of small circular arc notches on opposite sides. The gage length is marked in the full-width section, and the specimen is pulled to fracture, which usually occurs in the narrow section. The uniform elongation is measured in the full-width section. The value is slightly lower than that obtained in the conventional tensile test and gives a slightly lower *n* value. However, it is suitable for production control. The *r* value can be determined by the additional measurement of the change in width in the full-width section.

The rapid-*n* test provides rapid and fairly accurate measurements of yield and tensile strengths, elongation, and *n* and *r* values (Ref 31). It requires relatively simple equipment and can be performed in less than 5 min, including specimen preparation. The test is suitable for sheet metals whose properties are represented accurately by the Holloman equation, $\sigma_T = k\varepsilon^n$. It has been successfully used on low-carbon and stainless steels and on a variety of nonferrous alloys.

The test specimen, which is punched directly from the sheet sample, has the dimensions shown in Fig. 12. Generally, 25 mm (1.0 in.) gage lengths are marked on both the wide and narrow sections, and the specimen is strained to fracture in a manual or motorized load frame or in a tension-testing machine. The yield load is measured if there is discontinuous yielding, and the maximum load is measured. Yield and tensile strengths are calculated from the measured loads and the initial dimensions of the narrow section. If the yielding is continuous, the yield strength can be calculated from the tensile strength and *n* value, as indicated below.

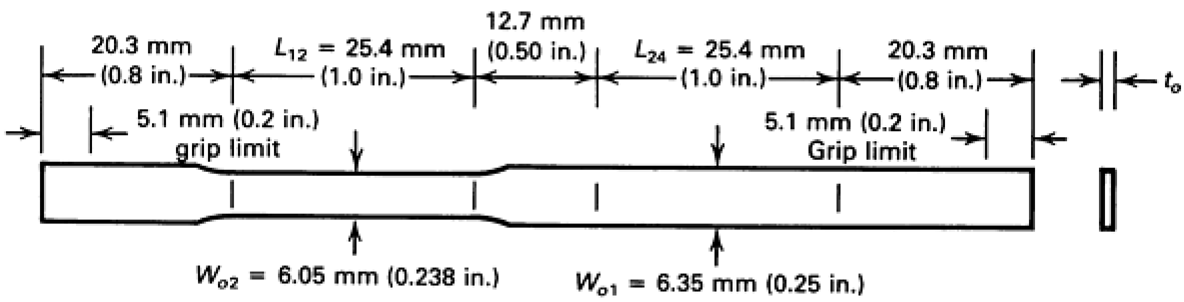

Fig. 12 Rapid-*n* test specimen. Source: Ref 31.

An empirically determined correction is applied to compensate for the effect of the sheared edges of the specimens. For steel, this correction reduces the measured yield and tensile strengths by 13.6 MPa/mm (50.0 ksi/in.) of initial sample thickness. The *n* value is calculated from:

$$n = \frac{\ln\left(\dfrac{w_{o2}t_o}{w_{f1}t_f}\right) - n}{\ln\left[\dfrac{\ln\left(w_{o1}t_o/w_{f1}t_f\right)}{n}\right]} \qquad \textbf{(Eq 15)}$$

where w_{o1} and w_{o2} are the initial widths of the wide and narrow sections, respectively; w_f is the final width of the wide section; and t_o and t_f are the initial and final thicknesses of the wide section, respectively. Equation 15 can be solved iteratively in four steps, or by means of a simple computer program, beginning with a trial value of 0.24 for *n*.

For materials that do not have a discontinuous yield point, the yield strength can be calculated as:

$$\text{YS} = \text{TS}\left(\frac{\text{C}}{n}\right)^n \quad \textbf{(Eq 16)}$$

where TS is the tensile strength and C is a constant. For low-carbon steels, C $\simeq$0.02. For other materials, C must be determined empirically. The *r* value can be computed from the initial and final dimensions of the wide section as described previously.

The Modul-*r* test measures the elastic modulus (Young's modulus) of low-carbon steel samples by determining their resonant frequencies by exciting them using an oscillating magnetic field (Ref 32). The elastic modulus is directly proportional to the square of the resonant frequency, and simple empirical relationships exist between the directionally averaged elastic modulus and the r_m value and between the planar variation of the modulus and the Δr value.

This test uses a flat 102 × 6.35 mm (4.0 × 0.25 in.) punched specimen and a specially designed, commercially available magnetostrictive oscillator. The specimen is placed inside drive and pickup coils in the oscillator. An alternating current passed through the drive coil produces an alternating magnetic field, which causes magnetostrictive oscillations in the sample. The oscillations induce an alternating current in the pickup coil. This current is used to change the frequency of the current in the drive coil to maximize the amplitude of the oscillations, that is, to obtain the resonant frequency, which is displayed digitally.

The relationships used to determine r_m and Δr from the resonant frequency, *f*, are:

$$E = 4\rho L^2 f^2 \quad \textbf{(Eq 17)}$$

$$r = \frac{4822.6}{(E_m - 267.7)^2} - 0.564 \quad \textbf{(Eq 18)}$$

$$\Delta r = 0.031 - 0.0468\,\Delta E \quad \textbf{(Eq 19)}$$

where E is the elastic modulus in gigapascals; ρ and L are the density and length of the specimen, respectively; and E_m and ΔE are defined analogously to r_m and Δr.

This test provides a more reproducible measure of r_m and Δr than the conventional tensile-testing method and is less sensitive to differences between operators. It can be performed in 5 min, including specimen preparation. When alloy steels or ferritic stainless steels are tested, a different correlation between the modulus and *r* value must be used. This must be determined experimentally. When the test is used on coated products, the coating must be removed chemically prior to testing.

Formability Testing of Sheet Metals

Brian Taylor, General Motors Corporation

Plane-Strain Tensile Testing

In conventional uniaxial tensile testing, the sample is strained in the region of drawing; that is, the minor or width strain is negative. The test does not provide information on the response of sheet materials in the plane-strain state, in which the minor strain is zero. However, it can be modified to produce this strain state in part of the sample. This modification involves the use of a very wide, short sample or the use of knife-edges to prevent transverse (width) strain in part of the sample.

Wide Sample Methods. Increasing the width of the sample and decreasing the gage length changes the strain state from one with a large negative minor strain component toward the plane-strain state, in which the minor strain component is zero. In the rectangular sheet tension test, samples with length-to-width ratios of 1 to 1, 1 to 2, and 1 to 4 are used to approach the plane-strain conditions (Ref 33). Gage lengths are constrained further by reinforcements welded onto each side of the sample at both ends, thus making the samples three layers thick except in the gage length.

The minimum minor strain obtained with the 1 to 4 length-to-width ratio is -0.05 times the major strain, which is close to the plane-strain condition of zero minor strain. The in-plane strains are measured by means of grid markings on the samples, and through-thickness deformations can be observed by holographic interferometry.

A similar approach was used in testing many wide specimen designs to determine the effect of edge profile and length-to-width ratio on strain state (Ref 34, 35, 36). The specimen geometry that yielded the highest center strain at failure with a large region of plane strain is shown in Fig. 13. The plane-strain region, which is arbitrarily taken as the region where $|e_2/e_1|$ is less than 0.2, occupies about 80% of the specimen width. The outer part of the specimen deforms in a similar manner to a standard tensile test specimen.

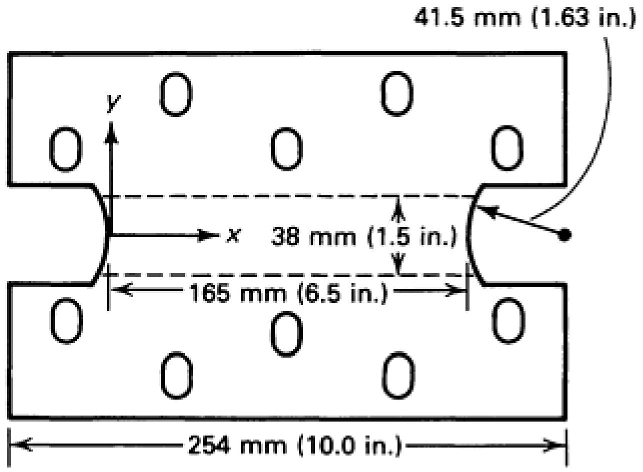

Fig. 13 Plane-strain tensile test specimen. Source: Ref 36.

Special grips were developed that exert a high clamping force at the inner contact lines. This minimizes distortion and slip-page in these regions, giving the test well-defined boundary conditions. The results of both types of wide specimen tensile tests described above correlated well with stress-strain predictions obtained by finite-element modeling using material properties obtained in the standard tensile test (Ref 34, 37).

Width Constraint Method. In the width constraint method, a rectangular sample is used that has a central gage section reduced in width by circular notches (Ref 38). The gage section is clamped between two pairs of opposing parallel knife-edges (stingers) aligned with the sample axis. The knife-edges prevent transverse (width) strain in this region. The sample is pulled to fracture in a tension-testing machine, and the plane-strain limit (necking) and fracture strains are determined from thickness measurements made on the fractured sample. This procedure is described in detail in Ref 38. The use of a spring-loaded clamp around the knife-edges makes adjustment of the clamp during testing unnecessary.

Formability Testing of Sheet Metals

Brian Taylor, General Motors Corporation

Biaxial Stretch Testing

Two tests that determine the properties of sheet metals in biaxial stretching without involving surface friction effects are the Marciniak biaxial stretching test (Ref 39) and the hydraulic bulge test (Ref 40). The Marciniak test subjects the sample to in-plane biaxial stretching, but does not determine the stresses. In the hydraulic bulge test, the stresses can be determined, but the sample is deformed into a dome, which involves out-of-plane stresses and strains.

Marciniak Biaxial Stretching Test. A disk of the test material is stretched over a flat-bottomed punch of cylindrical or elliptical cross section. This creates uniform in-plane biaxial strain in the center of the sample, with a strain ratio that is determined by the ratio of the major and minor diameters of the punch. Most testing has been performed with a cylindrical punch, which produces balanced biaxial stretching.

The center of the punch is hollowed out to eliminate friction in this area, and a spacer is placed between the sample and the punch. The spacer is a disk of material similar to that under test--with the same diameter, but with a hole at the center. The experimental arrangement is shown in Fig. 14. As the disk and spacer are stretched over the punch, the hole in the spacer enlarges, and the central part of the test sample is deformed in uniform in-plane biaxial stretching.

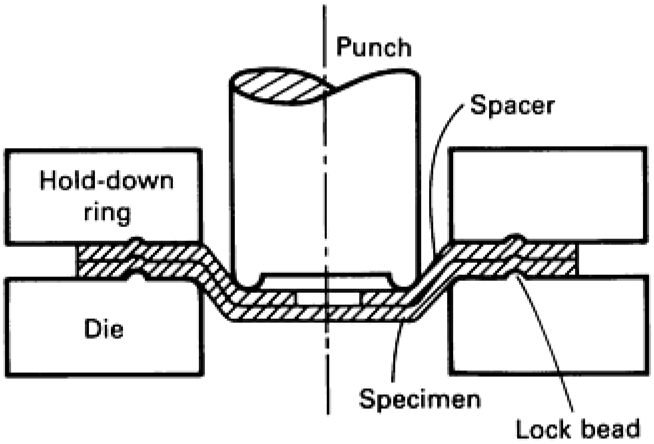

Fig. 14 Schematic of Marciniak biaxial stretching test.

The function of the spacer is to reverse the direction of the surface friction experienced by the sample. In the absence of the spacer, the surface friction opposes the movement of the sample over the punch and reduces the maximum strain level attainable. The spacer deforms more easily than the test sample because of the hole in the center, and it exerts a frictional force on the sample directed outward over the punch radius.

For the material to stretch freely, the punch and die radii must be adequate for the thickness of the material under test. A ratio of spacer hole diameter to punch diameter of 1 to 3 has been successfully used. The strains can be measured by using grid circles, squares, or other suitable markings. The test has the following applications:

- Determination of the limiting strains of materials in uniform in-plane biaxial stretching without surface friction
- Application of a carefully controlled level of uniform in-plane biaxial strain to samples with large areas to be used in other tests--for example, tests to determine the effect of different strain paths on the limiting strain levels
- Detection of defects, such as inclusions, by straining a sample of large area to a uniformly high level. Defects will cause early localized fracture, usually parallel to the rolling direction

Hydraulic Bulge Test. The periphery of a sheet metal sample is clamped between circular or elliptical die rings, and hydraulic pressure is applied on one side of the sample to deform it into a dome, as shown in Fig. 15. The edge of the sample is prevented from slipping by a lock bead placed in the die rings. This consists of a ridge with small radii on one ring and a matching groove on the other.

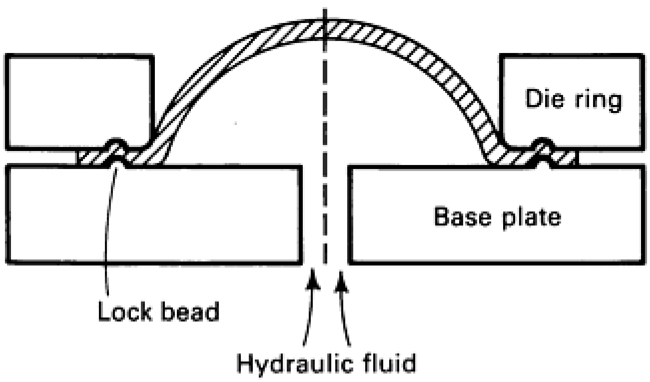

Fig. 15 Schematic of hydraulic bulge test.

With circular die rings, the center of the dome has been found to be nearly spherical (Ref 40). The stress and strain states in this region can be determined from the curvature and extension and the fluid pressure. A biaxial test extensometer has been developed that measures the extension and curvature by means of a spherometer and an extensometer that are in direct contact with the dome (Ref 41).

More recently, a system for controlling the strain rate in this test has been developed (Ref 42) because significantly different test results have been obtained (Ref 43) under conditions of constant strain rate and constant fluid flow. The system uses feedback from the extensometer signal to operate a servo-valve, which controls the flow of hydraulic oil to the bulge. This system was used to determine the strain rate sensitivity of aluminum alloys to a much higher strain level than is possible in the tensile test.

A computerized system is available that uses electronic vision to measure the principal strains and closed-loop feedback to control the strain rate (Ref 44). This system monitors the relative positions of the centers of three closely spaced white dots painted on a black background at the center of the sample. Initially, the dots form a right-angled isosceles triangle. The principal strains are computed from the change in the spacings of the dots and changes in the angle they subtend. This information is recorded and also used to maintain a constant strain rate by controlling the hydraulic pressure. Strains can be computed only once per second, which limits the maximum controllable strain rate.

A camera is mounted so that it maintains a constant distance from the top of the dome and the dots, except for the effect of the curvature of the dome, which is negligible. The stress state is determined by measuring the curvature of the dome with a contacting spherometer and by measuring the hydraulic pressure with a strain gage pressure transducer.

For thin samples, bending stresses can be neglected, and the radial (meridional) stress, σ_r, is given by:

$$\sigma_r = \frac{pR}{2t} \quad \textbf{(Eq 20)}$$

where p is the hydraulic pressure, R is the radius of curvature, and t is the instantaneous thickness. The thickness is calculated from the measured strains using constancy of volume. At the top of the dome, the sample is in balanced biaxial stretching, and the circumferential stress, σ_c, is equal to the radial stress.

For convenience, it is customary to express the results of hydraulic bulge tests in terms of the true thickness stress and strain. This is done by theoretically superimposing a hydrostatic compressive stress that does not influence deformation and that has in-plane components equal to the actual radial and circumferential tensile stresses. This converts the stress state to a simple uniaxial thickness compressive stress, as shown in Fig. 16.

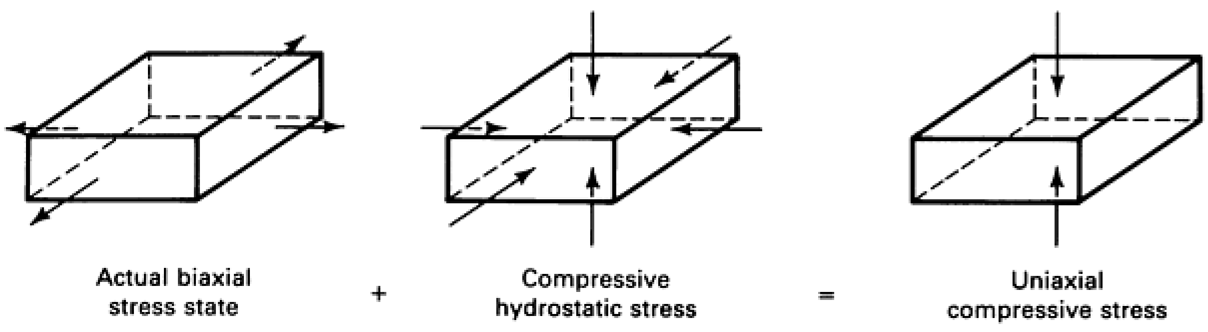

Fig. 16 Addition of compressive hydrostatic stress to biaxial tensile stress.

The true thickness strain, ε_t, can be obtained from the radial strain, ε_r, and circumferential strain, ε_c, by using the constancy of volume condition:

$$\varepsilon_t = - \varepsilon_r - \varepsilon_c \qquad \textbf{(Eq 21)}$$

This enables the results to be represented by a true compressive stress-strain curve in the thickness direction. The hydraulic bulge test has the following applications:

- Intrinsic material characterization in biaxial stretching, which is a very common strain state in production stampings
- Testing to much higher strain levels than those achievable in tensile testing (in some cases, by as much as a factor of ten), particularly for heavily cold-worked materials
- Checking the validity of plasticity theories that attempt to predict the yielding behavior of metals in all stress states from properties measured in uniaxial and plane-strain tensile testing

Formability Testing of Sheet Metals

Brian Taylor, General Motors Corporation

Shear Testing

Two tests have been developed to determine the properties of sheet metals subjected to planar shear deformation: the Marciniak in-plane sheet torsion test (Ref 45) and the Miyauchi shear test (Ref 46).

Marciniak In-Plane Sheet Torsion Test. A flat 50 mm (1.97 in.) square sample is effectively divided into three zones: an inner circular zone, which is clamped; a ring-shaped middle zone, which surrounds the inner zone and is free to deform; and an outer ring-shaped zone, which is clamped. The inner zone is rotated in its plane relative to the outer zone, which deforms the middle zone in shear. The sample is deformed to fracture, and the angular rotations at two radii in the middle zone are measured by means of calibrated drums that rotate with the sheet. This is shown schematically in Fig. 17.

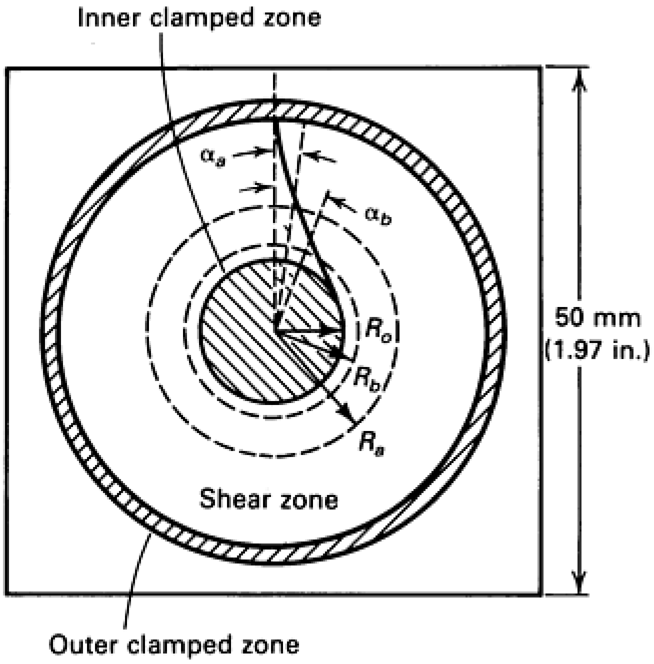

Fig. 17 Deformed Marciniak in-plane torsion test specimen.

For materials that follow the power law shear strain-hardening relationship:

$$\tau = C\gamma^n \quad \textbf{(Eq 22)}$$

where τ is the shear stress, C is a constant, and γ is the shear strain; it can be shown that (Ref 45):

$$n = \frac{2 \log \left(\frac{R_a}{R_b}\right)}{\log \left(\frac{\alpha_a}{\alpha_b}\right)} \quad \textbf{(Eq 23)}$$

where α_a and α_b are the angular displacements at radii R_a and R_b.

Shear fracture occurs where the shear stress is greatest--at the inner radius, R_o, of the deforming ring. The shear fracture strain, γ_f, is given by:

$$\gamma_f = \frac{2\alpha_a \left(\frac{R_a}{R_o}\right)^{2/n}}{n} \quad \textbf{(Eq 24)}$$

This test enables the forming properties of sheet metals to be determined at much higher strain levels than is possible in the uniaxial tensile test and in a different strain state, that is, in shear.

The Miyauchi shear test determines the properties of sheet metals in planar shear deformation by means of a modified tensile technique (Ref 46). The test uses flat, rectangular specimens whose ends are divided into three equal sections by parallel longitudinal slits, as shown in Fig. 18(a).

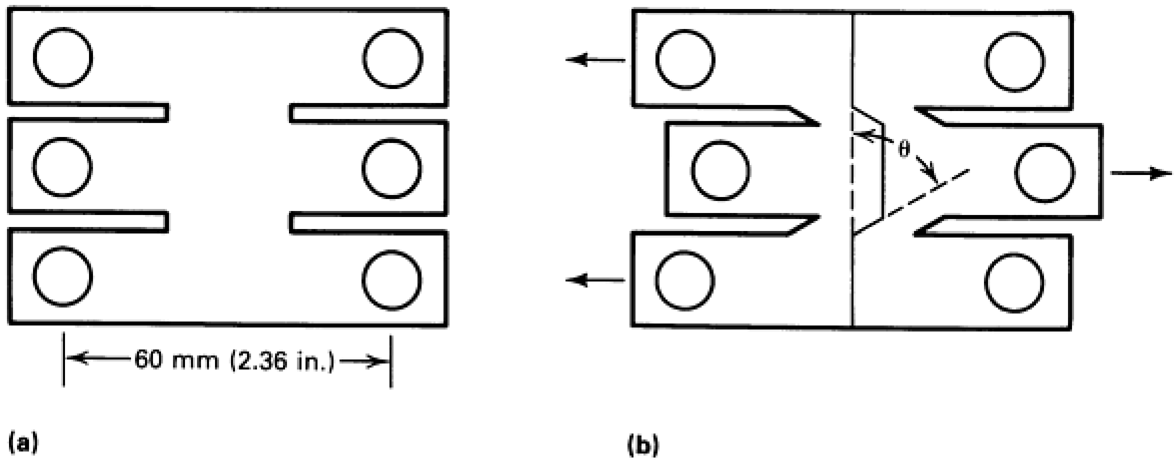

Fig. 18 Miyauchi shear test specimen. (a) Undeformed. (b) Deformed. Source: Ref 46.

The specimen is clamped in a fixture that prevents out-of-plane deformation. The inner and outer sections are then pulled in opposite directions in a tensile machine. This produces a shear stress in the regions between the inner and outer sections and deforms the specimen, as shown in Fig. 18(b). The deformation in these regions is uniform, except at the ends.

The shear strain, γ, is the tangent of angle θ, which is the change in direction of lines scribed across the specimen as they pass through the shear zone, as shown in Fig. 18(b). The strain can also be determined from the displacement of the inner section once a relationship has been established between the displacement and θ, which must be done for each type of sheet metal tested. Shear stress-strain curves are given in Ref 46 for three different steels. These curves show differences in the strain dependence of the work-hardening coefficient from that in the tensile test.

Brian Taylor, General Motors Corporation

Hardness Testing

Hardness, or the resistance to indentation by a concentrated load applied by a suitable indenter, has been used in many stamping plants as a measure of formability. Generally, formability decreases with increasing hardness, but the fine-scale correlation between these properties has not been reliable. The test can be used effectively to monitor changes in a particular grade of material caused by changes in processing that may affect formability.

For steels, hardness measurements correlate well with yield strength values (Ref 47). Therefore, hardness testing is useful in quality control to ensure that the material in use is the specified grade and has the required strength level.

The Rockwell hardness test (ASTM E 18), which is described in detail in the article "Rockwell Hardness Testing" in *Mechanical Testing*, Volume 8 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*, is typically used to determine the hardness of such materials. The load and indenter must be selected for the gage and hardness range of the material according to the test specification to ensure that the indentation is the appropriate size. If the indentation is too deep in a sheet sample, the reading will be artificially high because of the influence of the supporting anvil. This becomes a more serious consideration with the use of thinner gage sheet metal in many industries. For thicker and harder materials, the Rockwell B scale is commonly used, and for thinner or softer materials, the Rockwell 30T superficial scale is used.

Hardness readings are influenced by the degree of flatness and surface conditions. In addition, the presence of cold-worked surface layers can cause unrepresentatively high hardness readings that suggest a lower formability level than actually exists.

Formability Testing of Sheet Metals

Brian Taylor, General Motors Corporation

Simulative Tests

For many forming operations, tests that simulate the operation are more useful and relevant than fundamental intrinsic property measurement tests. These tests subject the work material to deformation that closely approximates the production operation, including the effects of factors not present in the intrinsic tests, such as bending and unbending and friction between the work materials and die surfaces. Because these additional factors are present, simulative tests tend to be less reproducible than intrinsic tests and must be performed under carefully controlled conditions to minimize variability in the results.

Simulative tests can be classified on the basis of the predominant forming operation involved: bending, stretching, drawing, and stretch-drawing. In addition, tests have been developed to measure wrinkling and the springback that occurs after bending or another forming operation.

Bending Tests

Two types of bending tests relate to sheet metal forming: simple bending and stretch-bending tests. Simple bending tests are useful in predicting how the sheet metal will perform when bent without tension, as in a hemming operation. Stretch-bending tests relate to the response to combined bending and stretching, as when sheet metal is pulled over a punch or die radius.

Simple bending tests can be performed in various ways (ASTM E 290). The simplest method for thin sheet material is to clamp a specimen and a bending die in a vise, as shown in Fig. 19, and to bend the specimen over the die manually or with a nonmetallic mallet.

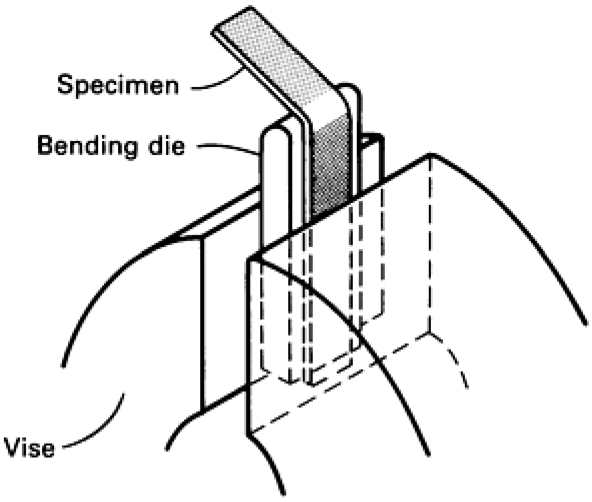

Fig. 19 Schematic of simple bending test.

If the specimen bends through 180° without fracturing or cracking, the experiment is repeated using a bending die of smaller radius. A modified test is performed for highly ductile metals that have extremely small bend radii. The specimen is initially bent at its midpoint, through less than 90°, over a small radius. The test is then completed by pressing the ends of the specimen together between flat platens without a bending die placed between the platens.

The ratio of specimen width to thickness should be greater than 8 to 1, and sheared edges should be machined, filed, or sanded to remove the heavily cold-worked metal present. The orientation of the specimen with respect to the rolling direction may be important because it affects the resistance of the specimen to fracture. Specimens cut perpendicular to the rolling direction usually require a larger bend radius and therefore provide a more conservative measure of this property.

For low-carbon sheet steels, the minimum bend radius is usually not a limiting factor. For high-strength steels and aluminum alloys, it sometimes is, and methods such as rope hemming, which increase the bend radius, have been developed to prevent cracking during the hemming of these materials.

Stretch-Bending Tests. A rectangular strip of sheet metal is clamped at its ends in lock beads and deformed in the center by a punch, as shown in Fig. 20. There are two types of stretch-bending tests: the hemispherical test, in which a hemispherical-tipped punch and a concentric circular lock bead are used, and the angular test, in which a wedge-shaped punch and straight parallel lock beads are used. The hemispherical test involves a range of strain states. The angular test produces the plane-strain state.

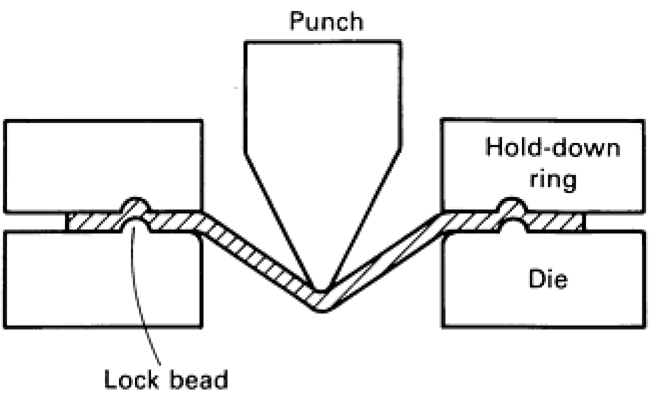

Fig. 20 Schematic of stretch-bending test.

The punch travel between initial contact and specimen fracture is measured. The conditions are chosen so that fracture occurs in the region of punch contact. When fracture occurs in the unsupported region, which tends to happen with narrow thin-gage specimens and large punch radii, the test effectively becomes a tensile test.

The results of several hemispherical and angular stretch-bending tests on three types of steels and an aluminum alloy have been reported (Ref 48). For the hemispherical test, the effects of variations in punch tip radii ranging from 3.2 to 51 mm (0.13 to 2.0 in.), in sheet thicknesses ranging from 0.5 to 3.3 mm (0.02 to 0.13 in.), and in specimen widths ranging from 25 to 203 mm (1.0 to 8.0 in.) were investigated in the dry and lubricated conditions. The tests showed that the height at fracture increased with increasing punch radius and sheet thickness and with the use of lubricants. It decreased with increasing specimen width in the range of 102 to 203 mm (4.0 to 8.0 in.), in which fracture occurred in the region of punch contact. The ranking of two of the steels was found to be dependent on specimen thickness.

Fewer conditions were investigated in the angular test. The results for a 76 mm (3.0 in.) wide specimen and punch radii ranging from 1.6 to 6.4 mm (0.06 to 0.25 in.) showed much greater heights than for the same conditions in the hemispherical test. Increases in height with increasing punch radius were also evident, but in contrast to the hemispherical case, a decrease with increasing thickness was observed. Preliminary correlation between the results of these tests and production experience is reported to be fairly good.

Data from the angular stretch-bending test have been analyzed and indicate that fracture occurs at a constant limit strain that is independent of sheet thickness and punch radius (Ref 49). Stretch-bending tests are useful for material selection and for predicting the effects of material substitution and gage reduction in many forming operations.

Stretching Tests

Historically, ball punch tests, such as the Olsen cup test and Erichsen cup test, have been used to determine the properties of sheet metals in stretching. These tests stretch a specimen over a hardened steel ball and measure the height of the cup produced. More recently, tests that stretch the specimen over a much larger hemispherical dome have been developed, including the limiting dome height test, which uses specimens of different widths to control the strain ratio at fracture.

Many forming operations involve stretching an edge of a part or a cutout (hole) in a part. For example, when a concavely contoured edge is flanged, the metal is stretched. The ability of the material to undergo this type of forming operation can be measured by the hole expansion test. In this test, a cylindrical, hemispherical, or conical punch is pushed through a circular hole of smaller diameter in the specimen. This initially increases the diameter of the hole and then forms a rim of stretched metal. The edge ductility of the material is indicated by the amount of hole expansion that occurs without edge cracking.

Ball Punch Tests. The Olsen and Erichsen cup tests are similar, differing principally in the dimensions of the tooling used. The Olsen test (ASTM E 643) uses a 22.2 mm (0.875 in.) diam hardened steel ball and a die with a 25.4 mm (1.0 in.) internal diameter (28.6 mm, or 1.125 in., for gages over 1.5 mm, or 0.06 in.) and a 0.81 mm (0.032 in.) die profile radius, as shown in Fig. 21. The Erichsen test, which is extensively used in Europe, uses a 20 mm (0.79 in.) diam ball and a die with a 27 mm (1.06 in.) internal diameter and a 0.75 mm (0.03 in.) die profile radius.

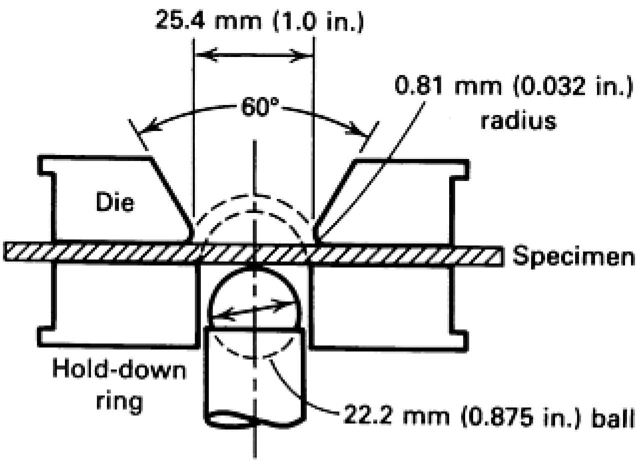

Fig. 21 Schematic of Olsen cup test.

In both tests, the cup height at fracture is used as the measure of stretchability. The preferred criterion for determining this point is the maximum load. When this cannot be determined, the onset of a visible neck or fracture can be used, but this yields a slightly different value. The cup height measured by means of a visible fracture is 0.3 to 0.5 mm (0.012 to 0.020 in.) greater than the height measured at the maximum load.

These tests, as indicators of stretchability, should correlate with the *n* value, but the correlation is not satisfactory. Improved correlations with the total elongation (Ref 50) and reduction in area (Ref 51) have been reported. Some investigators have reported poor reproducibility of results in the Olsen and Erichsen tests and poor correlation with production experience (Ref 52, 53). Satisfactory reproducibility and correlation in specific cases have been reported when experimental conditions were carefully controlled (Ref 50).

The variability in tests has been attributed to the small size of the penetrator, uncontrolled drawing-in of the flange, and inconsistent lubrication (Ref 52, 53). The small size of the penetrator leads to excessive bending, particularly in thicker sheet, and is generally unrepresentative of production conditions. Drawing-in can be controlled somewhat by standardizing the specimen size and by using a high (~71 kN, or ~8 tonf) clamping force. Even greater control can be achieved by using lock beads or serrated dies (dies with concentric circular ridges of triangular cross section that dig into the specimen and prevent slippage).

Consistent lubrication can be achieved by using oiled polyethylene between the specimen and penetrator. The problems with the Olsen and Erichsen tests have led to the development of stretching tests that use a much larger diameter punch and a lock bead to prevent drawing-in.

Hemispherical dome tests using 50.8, 76.2, and 101.6 mm (2.0, 3.0, and 4.0 in.) punches have been reported (Ref 52, 53). A 100 mm (3.94 in.) test is the most widely used. Typical tooling designed for this test is shown in Fig. 22. The lock bead, in combination with a hold-down force of about 222 kN (25 tonf), completely prevents drawing-in of the flanges.

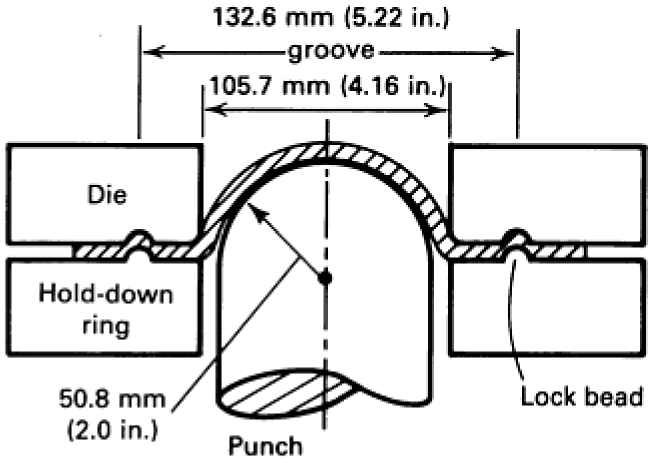

Fig. 22 Tooling for the 101.6 mm (4.0 in.) hemispherical dome test. Source: Ref 52.

The specimens fracture circumferentially at a distance (for lightly lubricated low-carbon steel) of 35 to 40 mm (1.38 to 1.57 in.) from the pole, at which point the radial strain peaks sharply. The circumferential strain varies gradually from a maximum of 10 to 20% at the pole to zero at the lock bead.

The hemispherical dome test yields more reproducible results than the Olsen and Erichsen cup tests. For low-carbon steels, the dome height, which is measured at the point of maximum load, increases linearly with the *n* value. For a wide range of material (including brasses, aluminum alloys, and zinc), optimal correlation is found between the dome height and the total elongation, which incorporates the effects of strain rate hardening and limiting strains.

Overall, the use of lubrication in hemispherical dome tests is beneficial. A thin layer of a standard lubricant, applied in a consistent manner, reduces scatter in test results, simulates production conditions more closely, reduces damage to the tooling, and simplifies specimen preparation. The improved sensitivity obtained in the dry condition is negated by the increased scatter in the results.

The use of lubrication makes the strain ratio at fracture more biaxial. This is undesirable for production simulation, because most production failures occur in the region of plane strain, that is, in a less biaxial manner. To control the strain ratio at fracture, specimens of different widths were used (Ref 54). This technique has been developed further into the limiting dome height test (Ref 55, 56).

Limiting Dome Height (LDH) Test. Specimens of various widths are held in a circular lock bead and stretched over a 100 mm (3.94 in.) dome using tooling of the type shown in Fig. 22. In principle, this test can be used to duplicate a large range of production failure strain states and to select the most suitable material for each particular operation. In practice, most production failures occur close to plane strain, which is generally the strain state at the minimum on a plot of dome height versus specimen width. Consequently, attention has concentrated on this minimum value.

When testing a new material, initial tests should be performed to determine the specimen width that yields the minimum dome height, or LDH value, and the corresponding minor strain. Once this has been established, tests can be conducted at this width only. For low-carbon steels, the minimum dome height occurs at a width of approximately 124 mm (4.9 in.). This can also be used as an approximation for other materials. Increments in test specimen width of ±3 mm (±0.12 in.) are sufficiently close.

It has been found that, for specimens lubricated lightly with a wash oil, the dome height increases with decreasing hold-down force below about 250 kN (28 tonf). This is attributed to the drawing-in of the flange. Therefore, a hold-down force of at least 250 kN (28 tonf) should be used. The limiting dome height is taken as the height at which the maximum load occurs.

Preliminary tests have shown a correlation between the limiting dome height test and production stamping performance (Ref 57). Some problems have been encountered with test reproducibility over a period of time and among different test facilities. Numerous attempts have been made to determine a correlation between the limiting dome height test and mechanical and forming property measurements. The dome height depends on the ability of the material to distribute strain and on the limiting strain level and would therefore be expected to correlate with the total elongation. Correlation for a range of different materials has been reported (Ref 58).

The specimens used in the limiting dome height test can be sheared or blanked from the sheet sample, and the test can be performed rapidly on equipment that automatically measures the dome height at the maximum punch load. The test has considerable potential for production control and research applications.

Hole Expansion Test. A flat sheet specimen with a circular hole in the center is clamped between annular die plates and deformed by a punch, which expands and ultimately cracks the edge of the hole. Flat-bottomed hemispherical and conical punches have been used, and in some cases die plates have been equipped with lock beads to prevent drawing-in of the flange. The punch should be well lubricated and should have a large profile radius. A spacer can be used between the punch and the sample, as in the Marciniak test. Figure 23 illustrates the hole expansion test using a flat-bottomed punch.

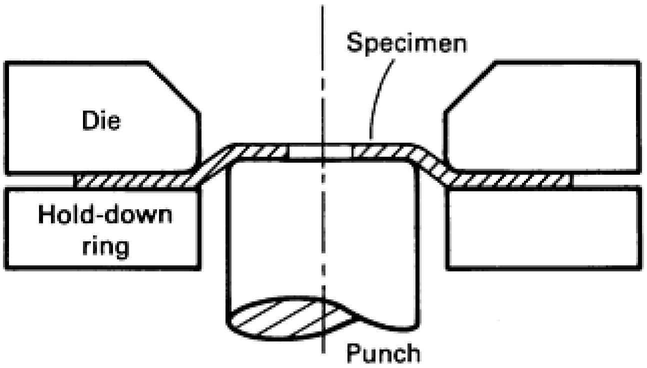

Fig. 23 Schematic of the hole expansion test with a flat-bottomed punch.

The test is terminated when a visible crack is observed, and the hole expansion is expressed as the percentage of increase in hole diameter:

$$\text{Hole expansion (\%)} = \frac{100(D_f - D_o)}{D_o} \quad \textbf{(Eq 25)}$$

where D_o and D_f are the initial and final hole diameters, respectively.

The results of several hole expansion tests on eight different types of steel are reported in Ref 59. Square specimens measuring 203 mm (8.0 in.) on each side with a 25 mm (1.0 in.) diam punched hole, a 101.6 mm (4.0 in.) diam hemispherical punch, and die plates with a 2 mm (0.08 in.) radius lock bead were used. The measured hole expansion ranged from 24 to 82% for steels with yield strengths ranging from 253 to 537 MPa (36.7 to 77.9 ksi).

In most cases, removing the burr and cold-worked metal from the edge of the punched hole increased the hole expansion considerably. The hole expansion also increased with increasing total elongation and r_m value and decreased with increasing tensile strength (which was anticipated, because total elongation decreases with increasing tensile strength). Inclusions were observed in crack locations, and inclusion shape control improved hole expansion performance.

Drawing Test

Swift Cup Test. The most commonly used test for deep drawability is the Swift cup test. Circular blanks of various diameters are clamped in a die ring and deep drawn into cups by a flat-bottomed cylindrical punch. The standard tooling for this test is shown in Fig. 24. Drawability is expressed as either the limiting draw ratio (LDR) or the percentage of reduction. The limiting draw ratio is the ratio of the diameter, *D*, of the largest blank that can be successfully drawn to the diameter, *d*, of the punch:

$$\text{LDR} = \frac{\text{maximum blank diameter}}{\text{punch diameter}} = \frac{D}{d} \quad \textbf{(Eq 26)}$$

Percentage of reduction is defined as:

$$\text{Percentage of reduction} = \frac{100(D - d)}{D} (\%) \quad \textbf{(Eq 27)}$$

Cup height, *h*, is approximately (Ref 60):

$$h = \frac{(D^2 - d^2)}{4d} \quad \textbf{(Eq 28)}$$

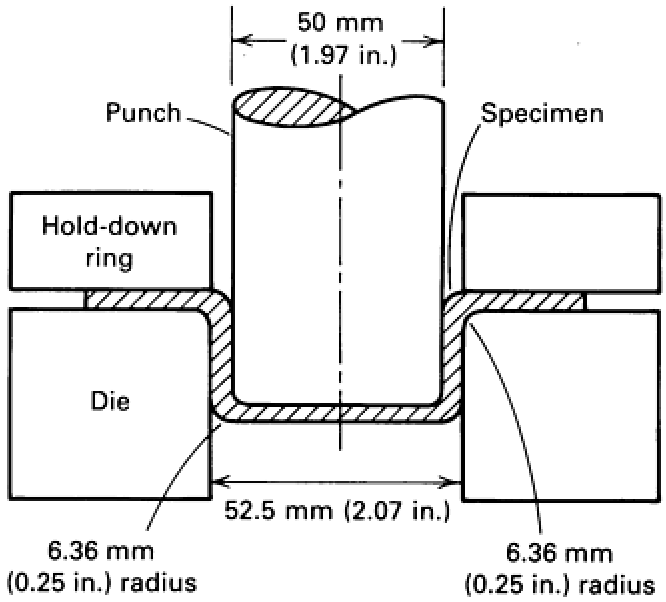

Fig. 24 Standard tooling for the Swift flat-bottomed cup test.

An alternative method for determining the limiting draw ratio uses blanks of a single diameter, which is less than the critical diameter in the standard test (Ref 61). The blanks are drawn to the maximum load, which usually takes place before 50% of the draw has occurred. The clamping force is then increased to prevent further drawing-in of the flange, and the load is increased to the point of fracture. The limiting blank diameter (LBD) is defined by:

$$\text{LBD} = \left[\frac{\text{Fracture load} \cdot (\text{blank diameter} - \text{die diameter})}{\text{Maximum drawing load}}\right] + \text{Die diameter} \quad \textbf{(Eq 29)}$$

The limiting draw ratio is given by:

$$\text{LDR} = \frac{\text{LBD}}{\text{Punch diameter}} \quad \textbf{(Eq 30)}$$

This method has been shown to correlate well with the standard test for a range of materials of widely different drawability (Ref 61).

The limiting draw ratio increases with normal anisotropy (r_m) and thickness, particularly at the low ends of the ranges for these variables, but is not sensitive to the *n* value (Ref 62). The limiting draw ratio also increases as the punch profile radius increases up to about eight times the sheet metal thickness, as the die profile radius increases up to about 12 times the metal thickness, and as the punch speed increases. The height of the ears formed in this test is proportional to the Δr value.

Too low a blankholder force may cause wrinkling, and too high a blankholder force may cause fracture at the punch profile radius. The die rings should be well lubricated, but the punch should not be lubricated. By not lubricating the punch, the amount of stretching that occurs over the punch profile radius and the tendency for splitting to occur at this location are reduced.

Stretch-Drawing Tests

Many forming operations involve stretching and drawing; for example, square cups have drawn corners and stretched sides. The ratio of stretching to drawing in an actual part can be measured by a shape analysis technique (Ref 63). A line is drawn from a reference point (for example, the center of the blank) to the edge of the blank, through the critical forming area. After forming, the ratio of the increases in length of this line inside and outside the initial die contact line is taken as the ratio of stretching to drawing. Two tests are commonly used for stretch-drawing: the Swift round-bottomed cup test and the Fukui conical cup test.

The Swift round-bottomed cup test resembles the Swift flat-bottomed cup test described above. However, the top of the punch is hemispherical, which causes stretching in the center of the specimen in addition to the drawing-in of the flange to produce the wall of the cup.

This test was used to evaluate 50 different steels with a 50 mm (1.97 in.) diam punch and 127 mm (5.0 in.) diam specimens and with a 65 mm (2.56 in.) diam punch and 165 mm (6.5 in.) diam specimens (Ref 64). Hold-down forces of 490 and 981 N (110 and 220 lbf), respectively, were used at a test speed of 1 mm/s (0.04 in./s). Both sides of the specimens were lubricated with thin polyethylene sheet.

The end point of the test is determined by observing fracture visually or by detecting a drop in the punch load. Multiple regression analysis of the test results showed that the cup height at fracture increased linearly with increases in the r_m value, n value, and metal thickness.

To determine the correlation between performance of the steels in the stretch-drawing test and in actual parts production, 4 automotive stampings were made, using 12 different steels for each. The Stampings had stretch-to-draw ratios ranging from approximately 1 to 5 to 2 to 1, and minor-to-major strain ratios in critical areas ranging from -0.3 to +0.45. The correlation coefficients between the test and stamping results had an average value of 0.92 and ranged from 0.89 to 0.94 (a value of 1.00 indicates perfect correlation). In another trial on a stamping with a stretch-to-draw ratio of 4.5 to 1, the test results did not correlate. These tests indicate that for parts that involve both stretching and drawing, without excessive stretching, the Swift flat-bottomed cup test is useful as a quality control tool.

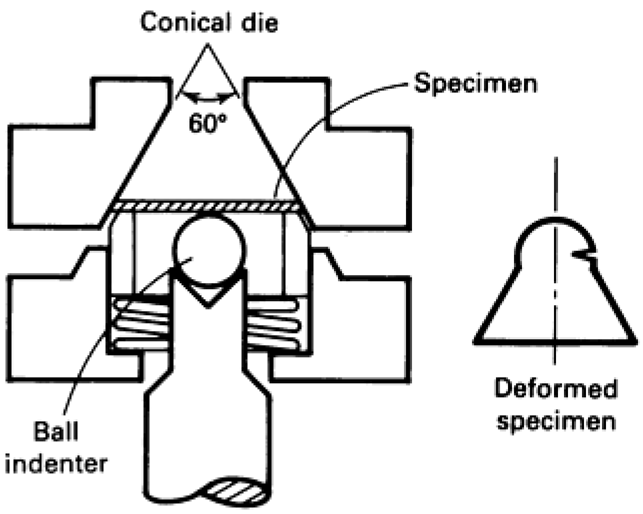

Fig. 25 Schematic of the Fukui conical cup test. Source: Ref 62.

Fukui Conical Cup Test. In the Fukui conical cup test, circular specimens punched from a sample of sheet metal are deformed into conical cups by means of a 12.5 to 27 mm (0.5 to 1.1 in.) diam ball and tooling of the type shown in Fig. 25 (Ref 62, 65, JIS Z 2249). The ball size depends on the sheet thickness. The specimens are lubricated on the die side only. Lubrication on the punch side leads to tilting of the specimens. Specimens are centered and held in place by the hold-down ring and deformed to fracture by the punch.

The diameter of the base of the conical cup formed is measured and divided by the diameter of the original specimen to give the Fukui conical cup value. The end point of the test is not critical, because the diameter of the cone does not change after fracture. A constant punch travel is usually used. When the test material has a high level of planar anisotropy (a high Δr value), the conical cup is asymmetric, and an average diameter must be determined. A high correlation between the Fukui conical cup value and the product of the average n value and the average r value has been reported for low-carbon steels (Ref 62).

An alternative method has been developed for performing this test (Ref 50). The punch travel between the initial contact with the specimen and the onset of a drop in the punch load, which coincides with the formation of a visible neck, is measured and used instead of the ratio of the diameters. This value, known as the formability index, correlates with the uniform elongation and therefore with the *n* value for low-carbon steels.

Wrinkling and Buckling Tests

Two principal types of tests are used for wrinkling and buckling: the conical cup wrinkling test and the Yoshida buckling test. The conical cup wrinkling test is similar to the Swift flat-bottomed cup test, but uses a punch that is much smaller than the die opening. Consequently, the cup wall is conical and is not in contact with the punch. Under some conditions, wrinkles form in the cup wall. In the Yoshida buckling test, a flat, square specimen is stretched slightly in the diagonal direction, and the height of the buckle that is formed is measured (Ref 66).

Conical Cup Wrinkling Test. A circular blank is clamped between annular dies and deformed by a flat-bottomed punch with a diameter that is typically about 75% of the internal diameter of the die. This procedure is illustrated in Fig. 26. At very low levels of hold-down force, wrinkling occurs in the flange. At higher levels, flange wrinkling is suppressed, but wrinkling occurs in the unsupported wall. This is caused by compressive stresses in the circumferential direction (hoop stresses) that are due to the local reduction in diameter as drawing progresses. For example, with a 75 mm (2.96 in.) diam punch and a 100 mm (3.94 in.) diam die, the top of the wall has a diameter of 100 mm (3.94 in.). If the cup depth is doubled, the original top of the wall becomes the new midpoint and must decrease in diameter to 87.5 mm (3.44 in.).

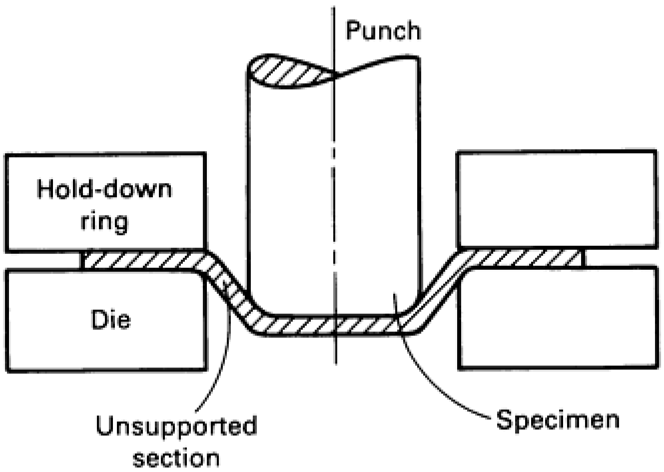

Fig. 26 Schematic of the conical cup wrinkling test.

At high levels of blankholder force, the tensile stresses in the radial direction in the wall prevent the formation of wrinkles, and fracture at the punch or die radius becomes the limiting factor. The maximum cup height occurs at the intersection of the wall wrinkling and fracture limits, as shown in Fig. 27.

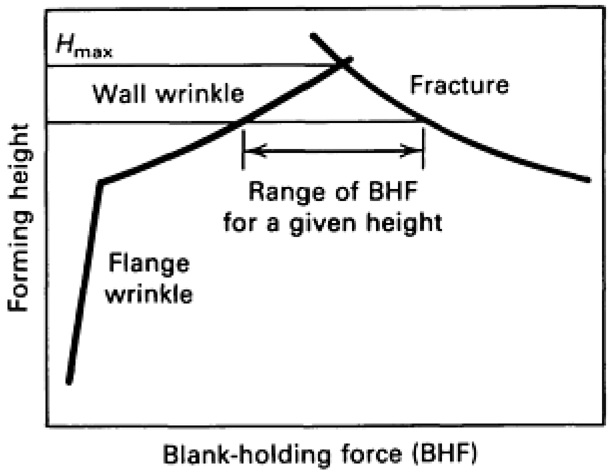

Fig. 27 Wrinkling and fracture limits in conical cup drawing. Source: Ref 67.

The results of experiments on several types of steel with different thicknesses and tooling of various dimensions have been reported in Ref 13 and 68. Wrinkling occurred in the unsupported wall when the true compressive hoop strain exceeded a certain value for each level of the tensile radial strain for all tooling geometries and forming conditions. The critical wrinkling strains were plotted on the forming limit diagram, as shown in Fig. 28.

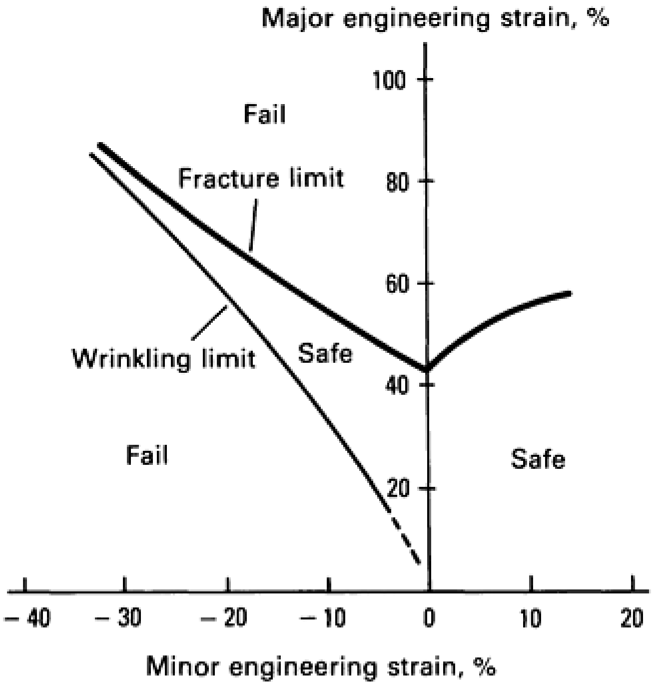

Fig. 28 Combined forming and wrinkling limit diagram. Source: Ref 68.

Attaining the critical wrinkling strain is strongly influenced by the dimensions of the specimen and tooling, lubrication, and the hold-down force. Changes in these variables that reduce the radial stress (that is, an increase in the die radius, improved lubrication, or a reduction in the blank diameter or the hold-down force) increase the tendency toward wrinkle formation.

Material properties that affect wrinkling in the conical cup test are the r_m, Δr, and n values and the ratio of the flow stress to the elastic modulus. A high r_m value and low Δr value reduce wrinkling, which initiates in the directions of lowest r

value. A high *n* value enables the hold-down force to be increased, which increases the radial force and reduces wrinkling. A low flow-stress-to-elastic-modulus ratio also reduces wrinkling.

Yoshida Buckling Test. A flat, square specimen is gripped at opposite corners and pulled in tension in the diagonal direction, as shown in Fig. 29 (Ref 66, 67). The standard specimen is 100 mm (3.94 in.) square with 41 mm (1.6 in.) wide grips and a gage length of 75 mm (2.95 in.). The buckle height is measured over a 25.4 mm (1.0 in.) width at the center of the specimen.

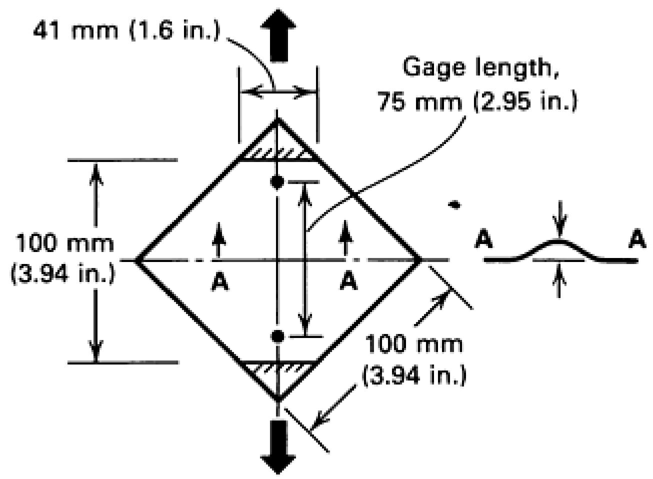

Fig. 29 Schematic of the Yoshida buckling test. Source: Ref 67.

Nonuniform stresses are generated in the specimen, and these stresses cause a buckle to form in the center along the direction of loading. The height of the buckle at a given elongation, for example, 2%, is used as the measure of buckling.

Several investigations have been conducted on the correlation between buckle height and test material properties. The Yoshida buckling test and a conical cone wrinkling test (using a hemispherical punch) were performed on several ferrous and nonferrous materials in different tempers (Ref 69). A direct correlation for both tests between the buckling or wrinkling height and the yield strength, an inverse correlation with the work-hardening exponent, and a lack of correlation with the normal anisotropy were reported. The Yoshida test was not successful for aluminum, because the specimens fractured before buckling.

The Yoshida test was performed on 31 steels of different types and thicknesses, and correlations between the slope of the buckle height versus elongation curve, which is easier to determine than the height at a particular elongation, and the yield strength and the ratio of yield strength to tensile strength were obtained (Ref 14). An inverse correlation with the instantaneous (2%) strain-hardening exponent and a lack of correlation with the uniform elongation and normal anisotropy were also noted.

Springback Tests

Springback tests that bend a specimen about a mandrel and determine the change in the angle of bending upon removal of the bending load have been used as indicators of yield strength. This test was developed with a 12.5 mm (0.5 in.) radius mandrel, as shown in Fig. 30, for use as a quality control tool with sheet materials with thicknesses ranging from 0.15 to 0.38 mm (0.006 to 0.015 in.) (Ref 70). Previously, hardness measurements had been used for this purpose, but they were found to be insufficiently accurate for hard thin-gage steels and aluminum alloys, and they did not provide any information on anisotropy.

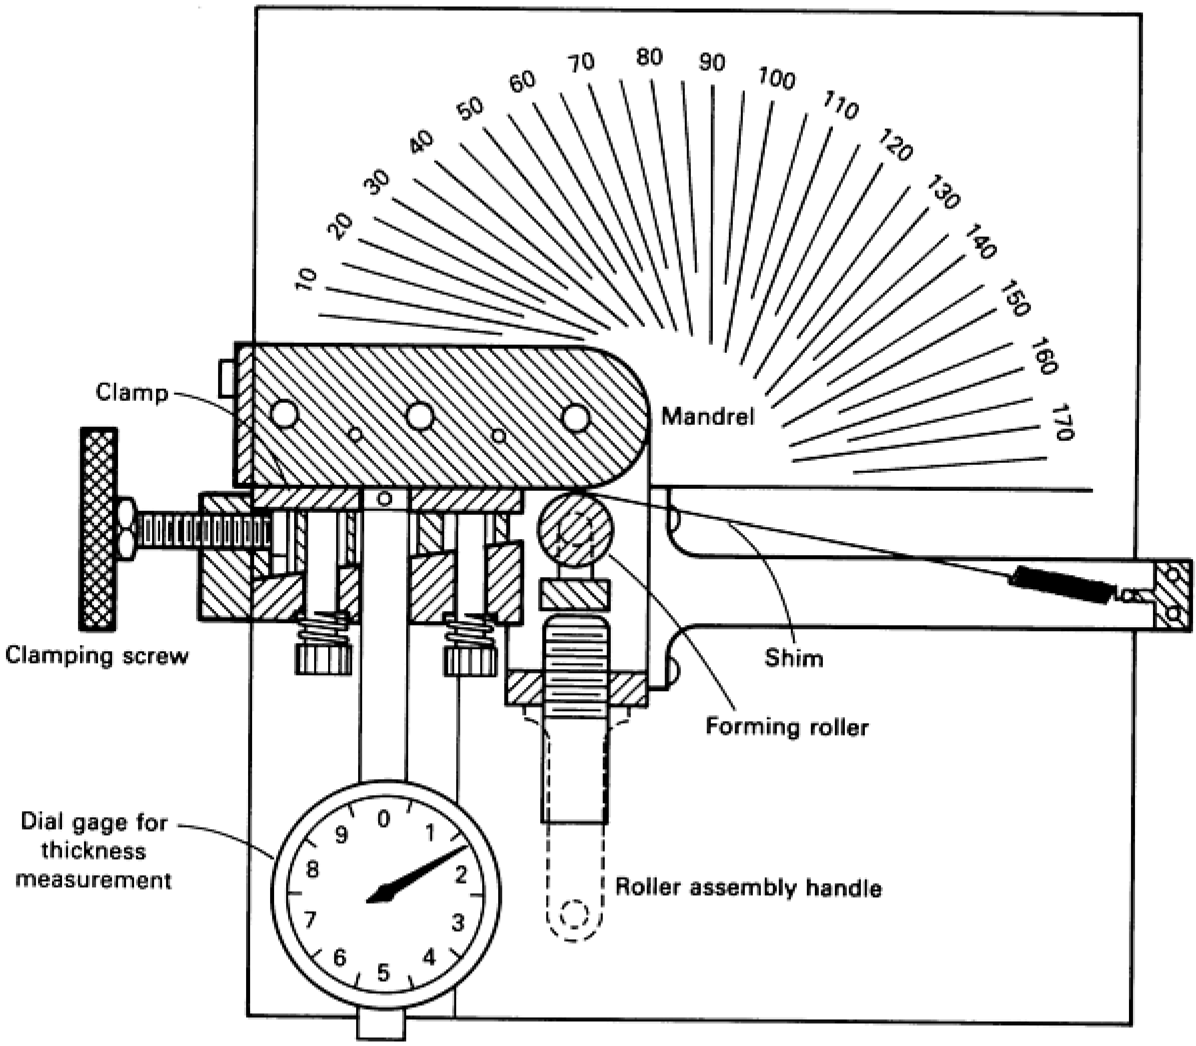

Fig. 30 Springback tester for determining yield strength. Source: Ref 70.

In the test, specimens are bent through 180° and released, and the angle of springback is read on the scale. The yield stress can then be determined from the springback angle and material thickness by means of a previously determined nomograph. Springback depends on the elastic modulus, which necessitates different nomographs for materials with different moduli. The test is most accurate in the range of springback angles of 60 to 120° and should be modified by changing the mandrel radius if the angle is less than 30° or greater than 150°.

The nomograph was calculated assuming an elastic/perfectly plastic stress-strain relationship, which is the same in tension and compression (that is, zero strain hardening and no Bauschinger effect). This calculation has been refined by using an average of the experimentally determined tensile and compressive stress-strain curves, including strain hardening (Ref 71). This improves the average ratio of the yield strength predicted using springback measurements to the tensile test yield strength from 0.80 to 0.91.

More recently, a similar test was developed that uses a larger-radius mandrel (19 mm, or 0.75 in.) (Ref 72). Twenty steels with thicknesses ranging from 0.56 to 2.36 mm (0.022 to 0.093 in.) and with tensile strengths ranging from 293 to 710 MPa (41.6 to 103.5 ksi) were tested. The measured springback correlated better with the forming strength, which is the average of the yield and tensile strengths, than with the individual strength values. For the same forming strength, steels with high (>1.5%) levels of yield point elongation develop less springback than those without. In these cases, the tangent modulus is almost zero in the region of yield point elongation.

Springback after a 90° flanging operation has been measured as a function of material flow stress, thickness, degree of cold work, and die radius and clearance for a low-carbon steel, two high-strength low-alloy steels, and a dual-phase steel

(Ref 73). Springback increased with increases in flow stress as well as die radius and clearance and with a decrease in material thickness.

For minimum springback, the ratio of the thickness to the die radius should be greater than 0.4, beyond which a further increase has little effect. The springback developed by the dual-phase steel increased more rapidly with the level of cold work than that developed by the high-strength steels, as anticipated from its higher strain-hardening exponent.

Springback after the combined effects of bending and stretching has been investigated using a tensile machine and a three-point bending fixture (Ref 19). Tests were performed on four thin-gage (~0.4 mm, or ~0.016 in.) low-carbon steels in various tempers with yield strengths ranging from 155 to 670 MPa (22.5 to 97.0 ksi). For applied tensile stresses that are below the yield strength of the material, the springback decreased linearly with the tensile stress to the same extent whether the stress was applied during or after bending.

For tensile stresses above the yield strength, tension during bending decreased the springback to a level that was independent of the initial yield strength and thickness. Stretching after bending, which deforms the entire cross section plastically in tension, decreases the springback progressively to extremely low levels.

Correlation Between Simulative Tests and Material Properties

Quantitative correlations between the results of simulative tests and select tensile properties have been determined for the Olsen cup, Swift flat-bottomed cup, and Fukui conical cup tests (Ref 50) and for the Swift round-bottomed cup test (Ref 64). In the first correlation, 48 materials were tested, including aluminum-killed, rimmed, and stainless steels and aluminum alloys in various tempers (Ref 50). Tensile properties included the directionally averaged percentage of total elongation, $\bar{e}_T$, to indicate the stretchability, and the normal anisotropy, r_m, to indicate drawability. The following relationships and correlation coefficients were obtained:

Test parameter	Relationship	Correlation coefficient
Olsen cup height/punch diameter	$0.217 + 0.00474\bar{e}_T + 0.00392r_m$	0.925
Limiting draw ratio (Swift)	$1.93 + 0.00216\bar{e}_T + 0.226r_m$	0.835
Formability index (Fukui)	$0.525 + 0.0134\bar{e}_T + 0.207r_m$	0.757

The Olsen test involves a much greater ratio of stretching to drawing than the Fukui test, which in turn involves a much greater ratio than the Swift flat-bottomed cup test.

In the second correlation, 50 different steels were tested (Ref 64), and the results were correlated with the average n and r values and thickness, t, as follows:

$$\frac{\text{Swift round-bottomed cup height}}{\text{Blank diameter}} = 0.0830t + 0.679\bar{n} + 0.0594r_m - 0.036 \quad \textbf{(Eq 31)}$$

Formability Testing of Sheet Metals

Brian Taylor, General Motors Corporation

Determination of Forming Limit Diagrams

Forming limit diagrams indicate the limiting strains that sheet metals can sustain over a range of major-to-minor strain ratios. Two main types of laboratory tests are used to determine these limiting strains. The first type of test involves stretching test specimens over a punch or by means of hydraulic pressure--for example, the hemispherical punch method. This produces some out-of-plane deformation and, when a punch is used, surface friction effects. The second test produces only in-plane deformation and does not involve any contact with the sample within the gage length.

The first type of test has been used much more extensively (Ref 6, 74, 75, 76) than the second and provides slightly different results (Ref 33, 77). Good correlation has been obtained between forming limit diagrams determined in the laboratory and production experience.

The hemispherical punch method for determining forming limit diagrams uses circle-gridded strips of the test material ranging in width from 25.4 to 203 mm (1.0 to 8.0 in.) that are clamped in a die ring and stretched to incipient fracture by a 102 mm (4.0 in.) diam steel punch (Ref 74, 76). The narrowest strip fractures at a minor-to-major strain ratio of about -0.5, which is comparable to that obtained in a tensile test. As the strip width is increased, the strain ratio increases to a slightly positive value for a full-width specimen. Further increases in the ratio to a maximum value of +11.0 (balanced biaxial stretching) are achieved by using progressively improved punch lubrication (oiled polyethylene, oiled neoprene) and by increasing thicknesses of polyurethane rubber.

The strains are measured in and around regions of visible necking and fracture. The forming limit curve is drawn above the strains measured outside the necked regions and below those measured in the necked and fractured regions, as shown in Fig. 31.

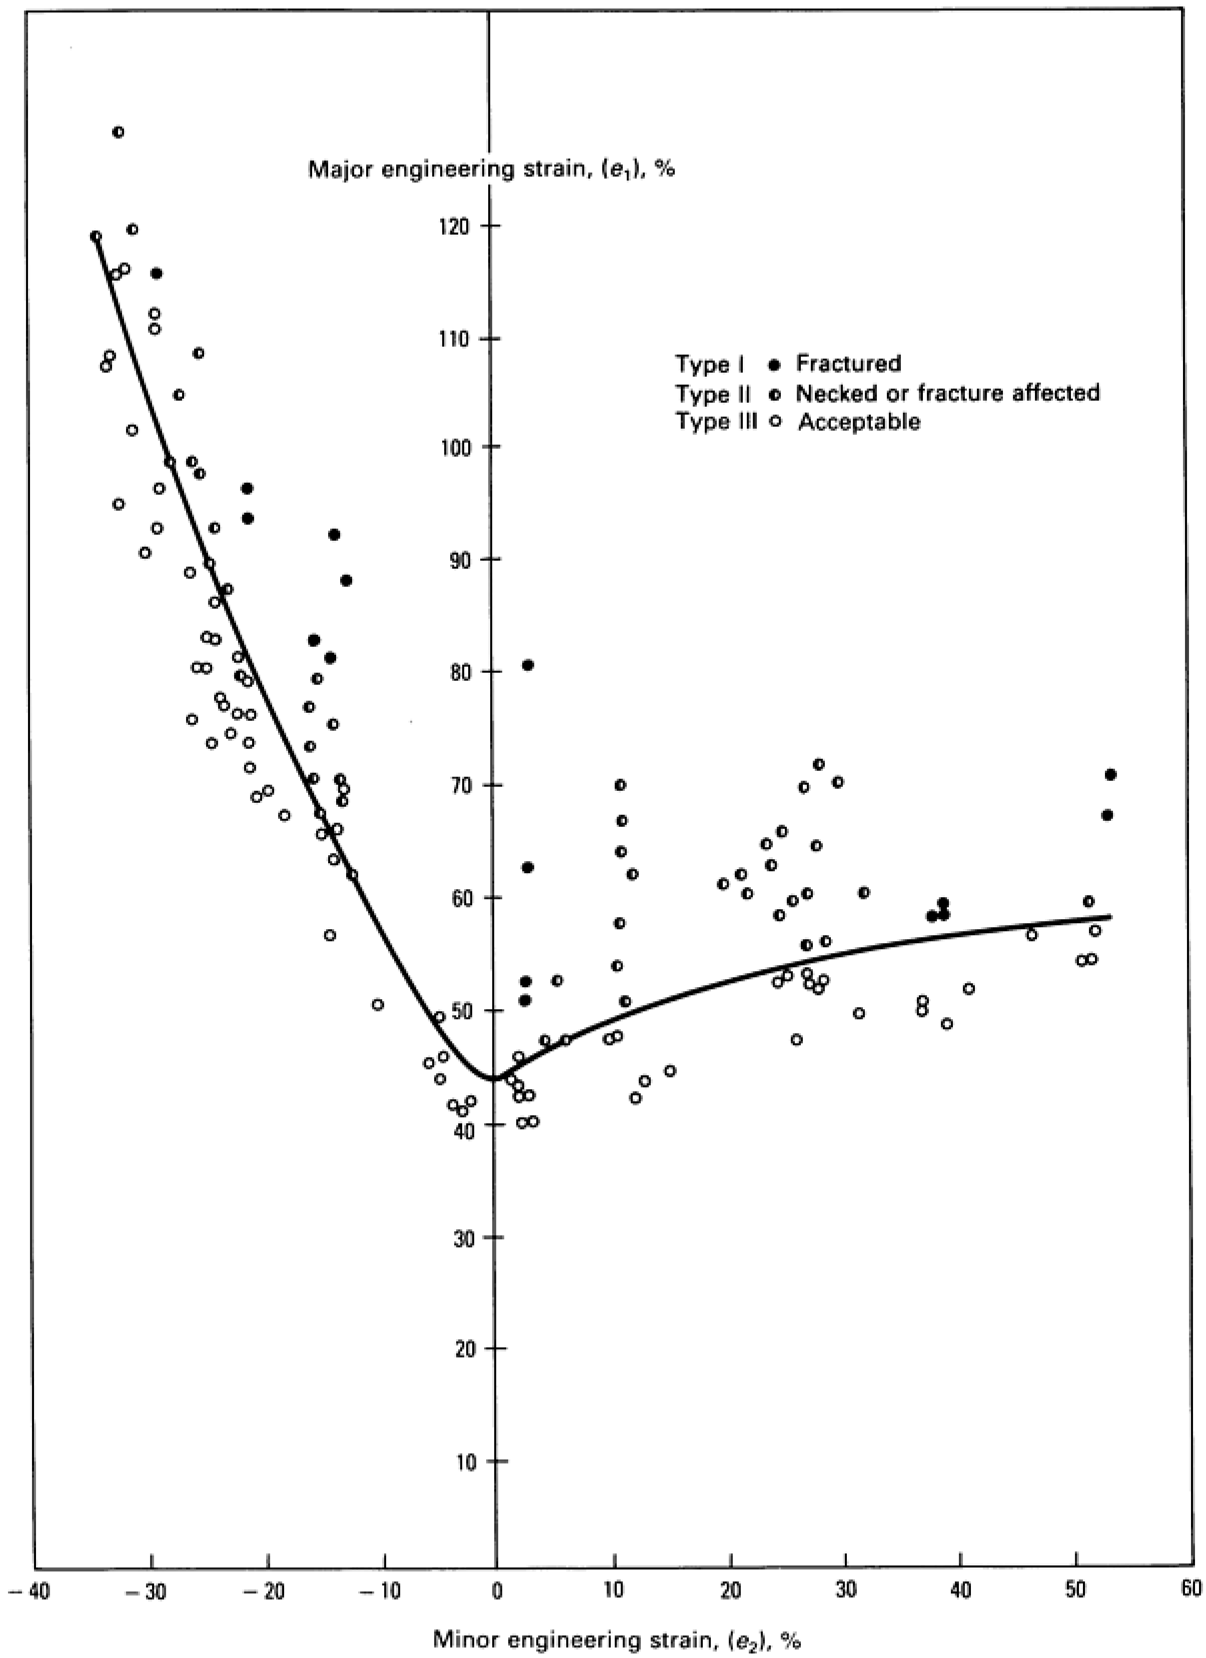

Fig. 31 Strain measurements and forming limit diagram for aluminum-killed steel. Source: Ref 76.

In-plane determination of the forming limit diagram can be achieved by using the uniaxial tensile test, rectangular sheet tension test, or Marciniak biaxial stretching test with elliptical and circular punches, as described earlier in this article. The forming limit curve can be determined over the full range of strain ratios, without introducing any out-of-plane deformation. A comparison of the in-plane and punch methods showed close agreement for negative strain ratios and slightly higher values in the punch test at plane strain and for positive strain ratios (Ref 33).

Formability Testing of Sheet Metals

Brian Taylor, General Motors Corporation

Circle Grid Analysis

Circle grid analysis is a useful technique for ensuring that a die is adequately prepared for production and for diagnosing the causes of necking and splitting failures in production (Ref 78). The forming limit diagram for the type and gage of work material selected must first be obtained. Arrays of small diameter (2.5 mm, or 0.1 in.) evenly spaced circles are printed or etched on several blanks in the critical strain regions, preferably in the same location on each blank. Some of the blanks are formed into parts, and the major and minor axes of the deformed circles are measured in the critical locations. The critical strain regions of the part are identified by visual observation of necking or splitting, or by previous experience with similar parts. The local strains are then calculated from the measured dimensions and plotted on the forming limit diagram.

If the maximum strains measured are close to or above the forming limit strains, problems with the tooling, lubrication, blank size or positioning, or press variables are indicated, whether or not necking or splitting actually occurs. Fluctuations that occur in operating conditions and in the properties of the work material over a production run will eventually cause failure if the material is strained to its full capacity. In this case, some of these variables should be changed until the circle grid strain measurements fall below the material limits by a given safety factor, such as 10%.

If the maximum strains measured are significantly below the limit strains and necking or splitting occurs, the batch of work material is substandard. The material used in die tryout must have typical, or slightly lower, forming properties than the production material. The use of superior material may indicate an adequate forming safety margin that will disappear when a more typical or lower formability material is used. It is good practice to form a few gridded blanks of a standard (nonaging) reference material periodically during a production run to determine the trends in the maximum strains. If the strains are approaching the maximum limits, corrective measures can be taken before any actual failures occur.

Circle Grids. Many types of circle grid patterns have been used, such as square arrays of contacting or closely spaced non-contacting circles and arrays of overlapping circles. The contacting and overlapping circles provide improved coverage, but are more difficult to measure manually and, at this time, cannot be measured automatically.

With small, closely spaced circles, it is possible to determine strain gradients accurately, provided the circles are not too small for accurate measurement. Circles with 2.5 mm (0.1 in.) diameters have been found to be a good size. Both open and solid circles have been successfully used, and automatic systems have been developed for measuring both types.

Applying Circle Grids to the Blanks. The circle grids can be applied to the blanks by a printing or photographic technique or by electrochemical etching. Printed and photographically applied circles are easily damaged and tend to rub off in areas contacted by the dies. This has led to general acceptance of etched circles.

In the electrochemical etching process, an electric stencil with the required grid pattern is placed on the blank and covered with a felt pad soaked in an etching solution. An electrode is placed on the pad, and a low-voltage (up to 14 V) current is passed between the electrode and the blank for a short time, usually less than 1 min. This produces a lightly etched and oxidized pattern on the surface of the blank. The stencils, etching solutions, and power supplies for this process are commercially available. Different metals require different solutions, levels and types of voltage, and etching times.

Measuring Strains From Deformed Circles. Deformed circles can be measured manually by means of dividers and a ruler, graduated transparent tapes, or a low-power microscope with a graduated stage. Automatic systems, known as grid circle analyzers, have also been developed for measuring the dimensions of the circles and calculating and displaying the major and minor strains (Ref 79, 80). These systems are now commercially available.

In regions of high curvature, the most accurate method of measurement is use of the transparent tape because it follows the contour of the part and measures the arc length, while the other methods measure the chord length. The tapes have a pair of diverging lines graduated to give direct readings of the strain, as shown in Fig. 32.

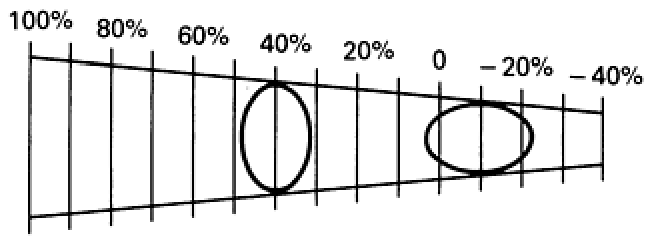

Fig. 32 Transparent tape measurement of deformed circles. Source: Ref 78.

Grid circle analyzers use a solid-state digital array camera with a built-in light source, a minicomputer, keyboard, CRT display, and printer. An image of a given deformed circle is displayed on the CRT, and a least squares curve fitting program selects the most suitable ellipse, which is displayed simultaneously. The major and minor strains, computed from the equation for the ellipse and the diameter of the original circle, are displayed on the screen and printed. A typical layout for the equipment is shown in Fig. 33.

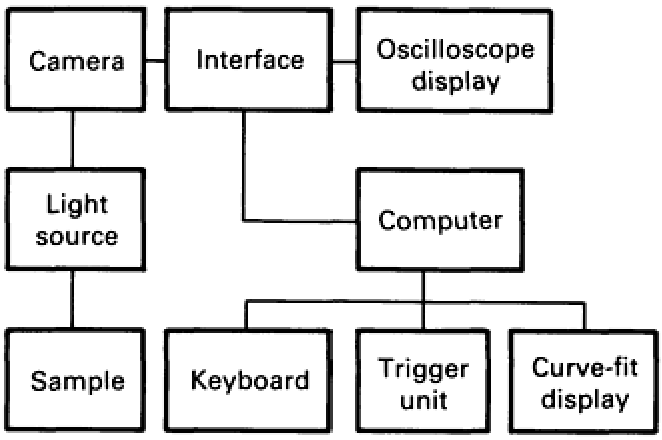

Fig. 33 Layout of a grid circle analyzer. Source: Ref 79.

Drawbead Forces

It is common practice in production stamping operations to control the movement of the edges of the blank into the die cavity by means of drawbeads placed in the blankholder. These consist of a semicylindrical ridge in the upper part of the blankholder and a corresponding groove with rounded shoulders in the lower part, or a similar but opposite configuration. The drawbeads cause the periphery of the blank to bend and straighten three times as it passes through each bead, as shown in Fig. 34.

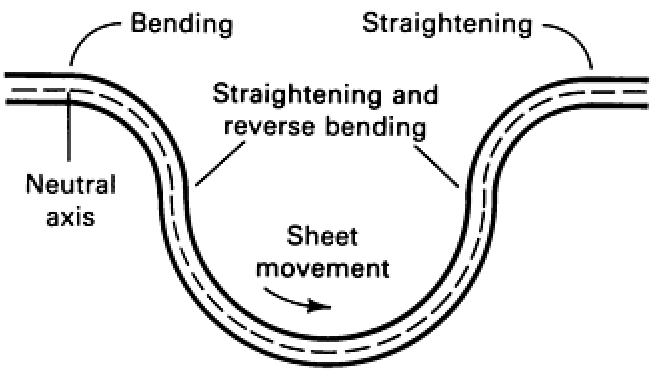

Fig. 34 Repeated bending and straightening of a blank edge in a drawbead.

The repeated bending and straightening produces a restraining force in addition to that caused by surface friction. A method has been devised for measuring the restraining force due to deformation independently of the effects of friction, using a drawbead simulator with low-friction rollers instead of a fixed bead and groove (Ref 81, 82). A second drawbead simulator with nonrotating parts can be used to measure the combined effects of friction and deformation. Figure 35 shows both types of simulators.

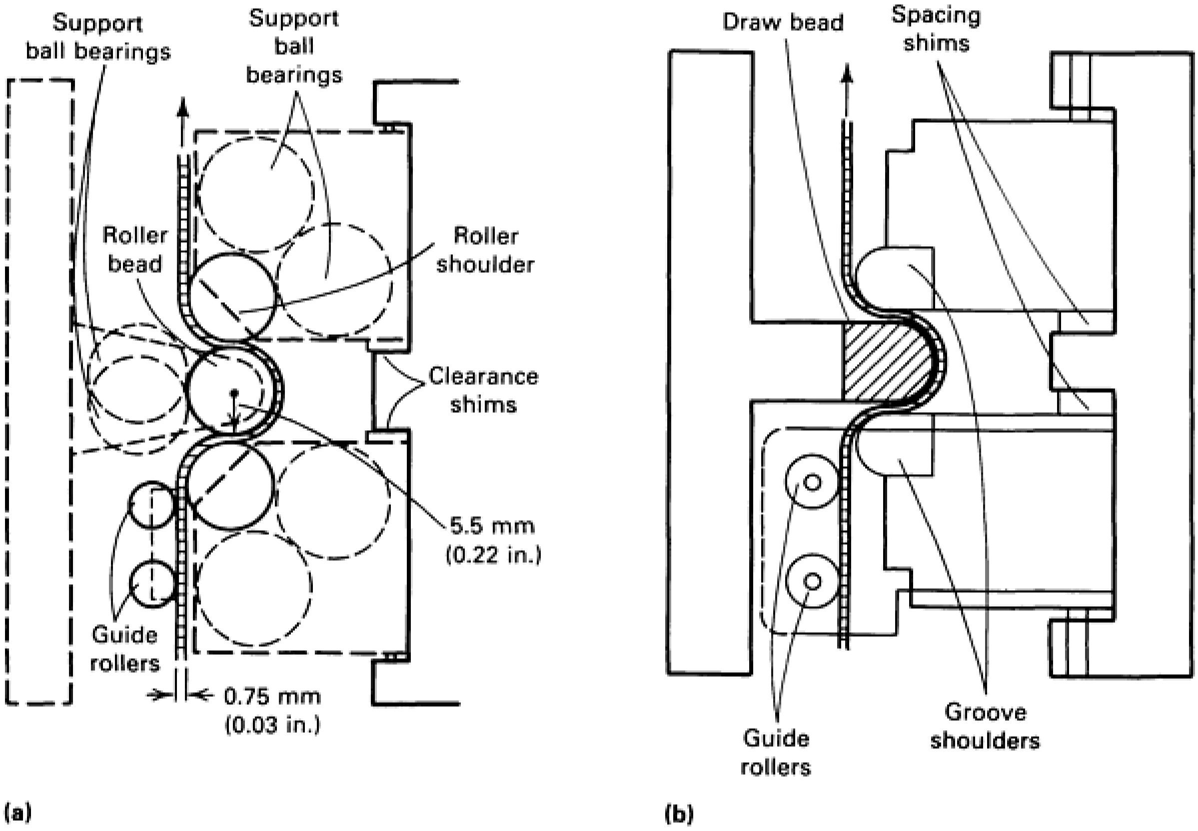

Fig. 35 Drawbead simulators. (a) Frictionless simulator. (b) Standard simulator. Source: Ref 82.

Strips of 0.75 to 1.00 mm (0.03 to 0.04 in.) thick and 50 mm (1.97 in.) wide rimmed and aluminum-killed steels and two aluminum alloys were tested using simulators and a universal testing machine. The contribution from deformation to the total restraining force depended on the lubricant used and ranged from an average of 60% with poor lubrication to 85% with very good lubrication. The required clamping forces, surface strains in the workpiece at various locations in the drawbead simulators, effect of drawbead radius, and effect of rate of testing were also investigated.

Lubricants

The use of lubricants is essential in most forming operations (see the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume). An effective lubricant provides the following advantages:

- Reduction or elimination of direct sheet metal to die contact and the associated wear and galling

- Control of friction
- More uniform distribution of strain and therefore an increase in the overall level of deformation
- Reduction of heating

Lubricants must meet many requirements to be used in a production operation, such as:

- Suitable viscosity over the ranges of temperatures and pressures encountered
- Chemical and physical compatibility with work and die materials
- Ease of application, removal, and disposal
- Compatibility with welding operations, sealants, and paint systems

No single lubricant is optimal for all types and rates of forming and all combinations of work and die materials. Rankings of lubricants change considerably for different types of operations and material combinations; this necessitates evaluation on an individual basis. Differences in the performance of lubricants are to be anticipated in view of the differences in surface composition, roughness, and texture of work and die materials and the different strain paths and rates of different forming operations. For example, some stretching operations involve local increases in area in excess of 100%, but in many drawing operations, a negligible or negative change in area occurs. In addition, the rate at which the work material slides over the dies varies widely.

A simple test for evaluating lubricants measures the frictional force exerted on a lubricated strip of sheet metal when it is pulled between two rectangular blocks of die material. The force used between the blocks and the test rate can be varied. The number of strips that can be tested before the onset of galling provides an additional measure of the effectiveness of the lubricant. However, this test does not include some of the important aspects of actual forming operations, such as plastic deformation of the work material, the ranges of sliding speeds and rates of straining involved, die geometry (which influences the amount of residual lubricant in various locations as the operation progresses), and the heating that occurs in high-volume production operations.

The drawbead simulator described earlier is more realistic and has been used to measure friction forces with various lubricants (Ref 81, 82). Under most of the conditions tested, friction was described by Coulomb's law, which states that the friction force, F, is directly proportional to the normal force, N, between the contacting surfaces:

$$F = \mu N \quad \textbf{(Eq 32)}$$

where μ is the coefficient of friction. Coulomb's law did not apply at the highest contact pressure tested. The value of the coefficient of friction for mill oil, a poor lubricant, was found to be 0.17; for the best lubricant tested--a soap-based lubricant--it was 0.06.

In addition, simulative tests can be used as lubricant evaluation tests. The production operation should be characterized in terms of the principal types of forming operations involved and their relative severities, and the appropriate simulative test selected. The Swift flat-bottomed cup test has been extensively used for the evaluation of lubricants for deep drawing, and the Swift round-bottomed and Fukui conical cup tests have been used for stretch-drawing operations. The 100 mm (3.94 in.) hemispherical dome test can be used for stretching operations.

The various regimes of lubrication--that is, thick film, thin film, mixed, and boundary lubrication--and their characteristics are reviewed in Ref 83, which also discusses the limited validity of Coulomb's law, methods for lubricant evaluation, and some of the current limitations in this area.

Introduction

Virginia Mouch, Electronic Data Systems Corporation

COMPUTER-AIDED DESIGN AND MANUFACTURE (CAD/CAM) typically involves the use of graphic displays, which allow the interactive creation and modification of geometric shapes, but CAD/CAM is not limited to this technique. In its broadest definition, CAD/CAM can be the application of any software program--batch or interactive--that facilitates product design and manufacture.

There are two principal advantages of applying CAD to the design of dies for sheet metal stamping. First is the generation of computer surface data for downstream CAM applications to generate numerically controlled (NC) cutter paths and to eliminate the need for die models. Second is the reduction of downstream die tryout time and the reduction of die construction aids by producing more geometrically accurate data. These advantages can result in both time and cost savings. This article will discuss the application of CAD/CAM to the diemaking process, first in general terms and then in a specific case study.

CAD/CAM as Applied to Diemaking

Diemaking, whether manual or computerized, is currently an art, not a science. The methods of approaching the problem may be as numerous as the number of people doing the job. Once these methods are known, it is easier to select the best system package. Most currently available CAD/CAM systems are generic; few systems have specific software tools tailored to the designing of dies. However, with some attention to several key issues, these generic systems can be successfully applied to the design and manufacture of dies. Some of the key issues involved in moving from a manual process to a computerized one are identified below. Flow charts for manual and computer-aided die processing are shown in Fig. 1.*

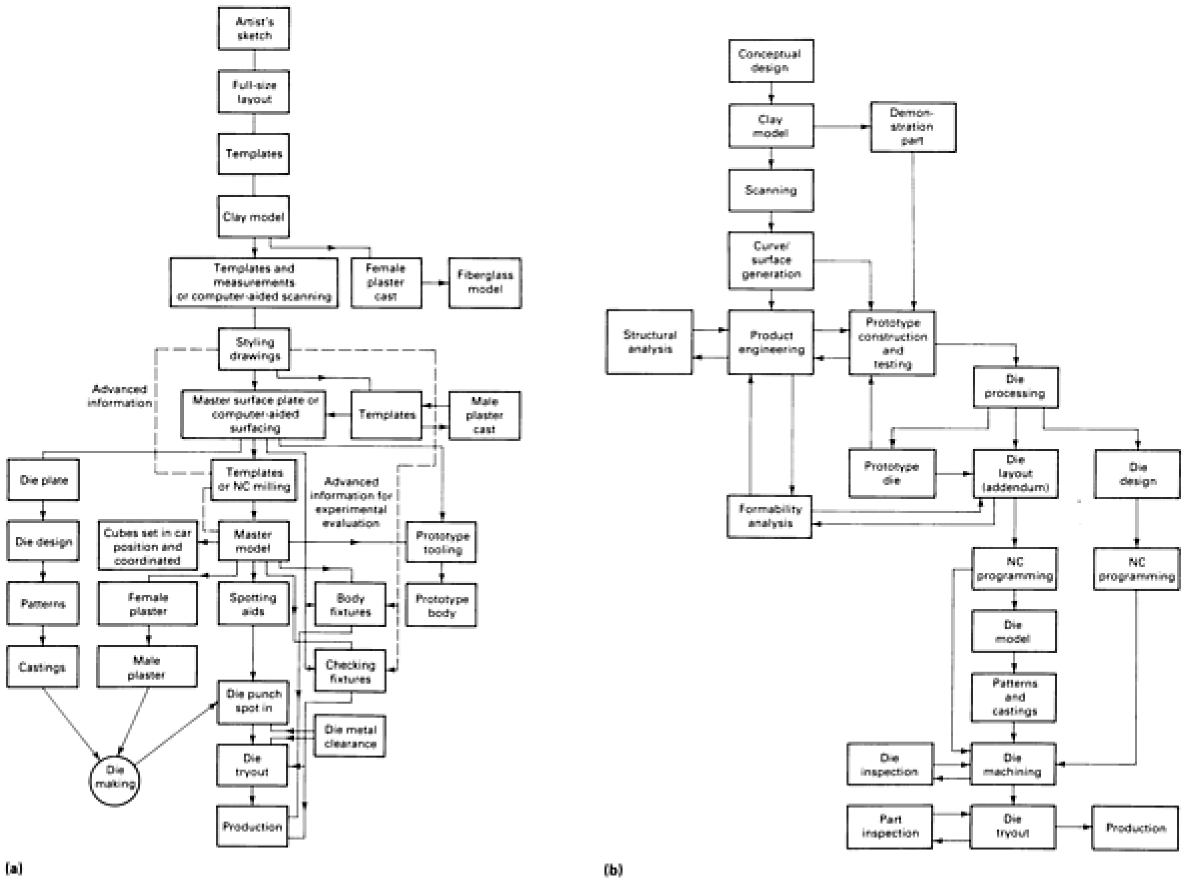

Fig. 1 Comparison of manual and computer-aided diemaking operations illustrating the steps eliminated using CAD/CAM. (a) Traditional manual die processing. Source: Ref 1. (b) Die processing using CAD/CAM.

Establishing the Form of the Master Product Data. It is imperative that the master product data (the computer model, drawings, and physical model) be established and that the CAD system have the capability of accepting this information in the form identified. These master product data represent the starting point for development of the die. All personnel involved in the tooling process must know where to obtain the master product data. Depending on its form, they may need to perform additional operations to make use of it. For example, prior to computerization, a physical model may have been the master. When CAD/CAM systems are used to produce the tooling and the physical model is still the master, it becomes necessary to incorporate scanning devices and data translation software to make use of the master data in the CAD/CAM system.

Determining the Mathematical Representation Required for the Computer Model of the Die. Computer-aided design and manufacture systems can present a number of different mathematical methods of representing or storing data. This can be in the form of traditional two-dimensional drawings, three-dimensional lines, arcs, points, or more complex three-dimensional surface representations.

If NC cutter path generation is to be done by a CAM system, then a surface representation for most of the product and die will make the process more efficient. Surface creation and modification will then be a critical feature of the CAD system selected. Wireframe capabilities will also be needed for designing the mechanical components of the die. Depending on the CAM system selected, the mechanical components may or may not require surfacing.

Determining the Form and Use of the CAD Die Data. In a typical manufacturing operation, several different departments may need these data in order to generate NC cutter paths, to develop castings, to produce prototype models, and to schedule construction. The CAD-developed die data may need to be transmitted through drawings or mathematical models to a CAM system.

In a noncomputerized environment, a drawing is the standard output for those sectors of an organization concerned with die construction. Depending on the extent of computerization, this may be sufficient. However, if NC machines are to be programmed offline using an automatic part-programming system, then the most efficient form of the output is an electronic mathematical representation of the tool. If these needs are many and varied, they must be identified, and the data translation tools included in the CAD/CAM package(s) must be selected.

Determining How CAD and CAM Will be Linked. In the previous paragraphs, an assumption was made that the same system need not be used to design the product, to design the tool, and to manufacture the tool. However, if CAD and CAM systems will be used, the method for establishing the electronic mathematical model between the two systems must be analyzed.

Again, in a noncomputerized environment, this link may consist of passing a drawing from one person to the next. Ideally, it is most efficient for moving data between processes if the systems are the same. However, there may be trade-offs in accomplishing this total integration. It may be difficult to find one CAD/CAM system that meets all of the functional requirements. Before branching off into different systems, the cost of data movement and translation should be analyzed.

Determining the Type of CAM System Required. This issue gets closer to the shop floor. The sophistication required of the NC cutter path generation software will depend on the NC machines to be programmed (that is, three axis or five axis). In addition, postprocessors must be acquired for each NC machine. Numerically controlled cutter paths can be postprocessed directly on the CAM system or downloaded to another system.

Determining the Method of Downloading Posted Machine Data to the NC Machines. A number of methods are available, ranging from paper tape to floppy disk to direct numerical control (DNC) (direct communication link from a host computer to the NC machine controller). In determining which method is appropriate for a given installation, the anticipated volume of NC data to be downloaded versus the cost of the link should be considered.

* The flow chart shown in Fig. 1(b) represents one point of view of the application of CAD/CAM to the product life cycle. It is intended to be a generic description of the cycle. The diagram may vary from organization to organization based on the amount of time computer assists have been used and the degree of success achieved in phasing out manual methods. The figure attempts to show that computer assists are being added to the process but some manual assists, in reality, have not been phased out. Several processes in the cycle can be phased out. These include wood/plaster master models, checking fixtures and spotting aids. There are also several processes that can be added to the cycle. These include formability analysis, die inspection and part inspection.

CAD / CAM System Selection

The processes and data flow should be analyzed before any system is purchased. In addition, an analysis of future processes and data flow is needed to assess what, if any, organizational or procedural changes will be required. This future analysis also facilitates the selection of the CAD/CAM systems and the peripheral equipment, such as printers and plotters. These analyses can be done by in-house personnel, outside independent consultants, or companies that provide such services along with their systems.

The application of CAD/CAM technology to the diemaking process is ongoing. Key to its success are careful analysis and planning, quality training, and commitment from all levels of the organization. The process must be considered in terms of the application of CAD/CAM as well as the interface with the shop floor. The following sections provide more specific details on some of the issues discussed in this introduction.

Equipment, Advantages, and Applications of CAD / CAM for Diemaking

Lee Spruit, Autodie Corporation

The advent of CAD/CAM has transformed the manufacture of dies for automotive sheet forming from what was once essentially a manual process that involved making expensive models and trial and error for arriving at a die design into a highly accurate and automated process that is augmented by the use of computers. Many of the steps taken in traditional die design can be eliminated (see Fig. 1), resulting in much shorter lead times. Die quality is also improved through the use of computer-aided manufacture, and as a data base of standard die designs is developed, a cost savings can be realized.

Computer-Aided Design

Computer-aided design has been defined as the technique by which geometrical descriptions of three-dimensional objects can be created and stored in the form of mathematical models in a computer system; once created, the models can then be displayed, manipulated, and analyzed in a number of ways on a CRT (Ref 2).

This Section will describe typical CAD equipment and processes used for sheet forming die design. Figure 2 shows a flow chart of the operations described in this Section.

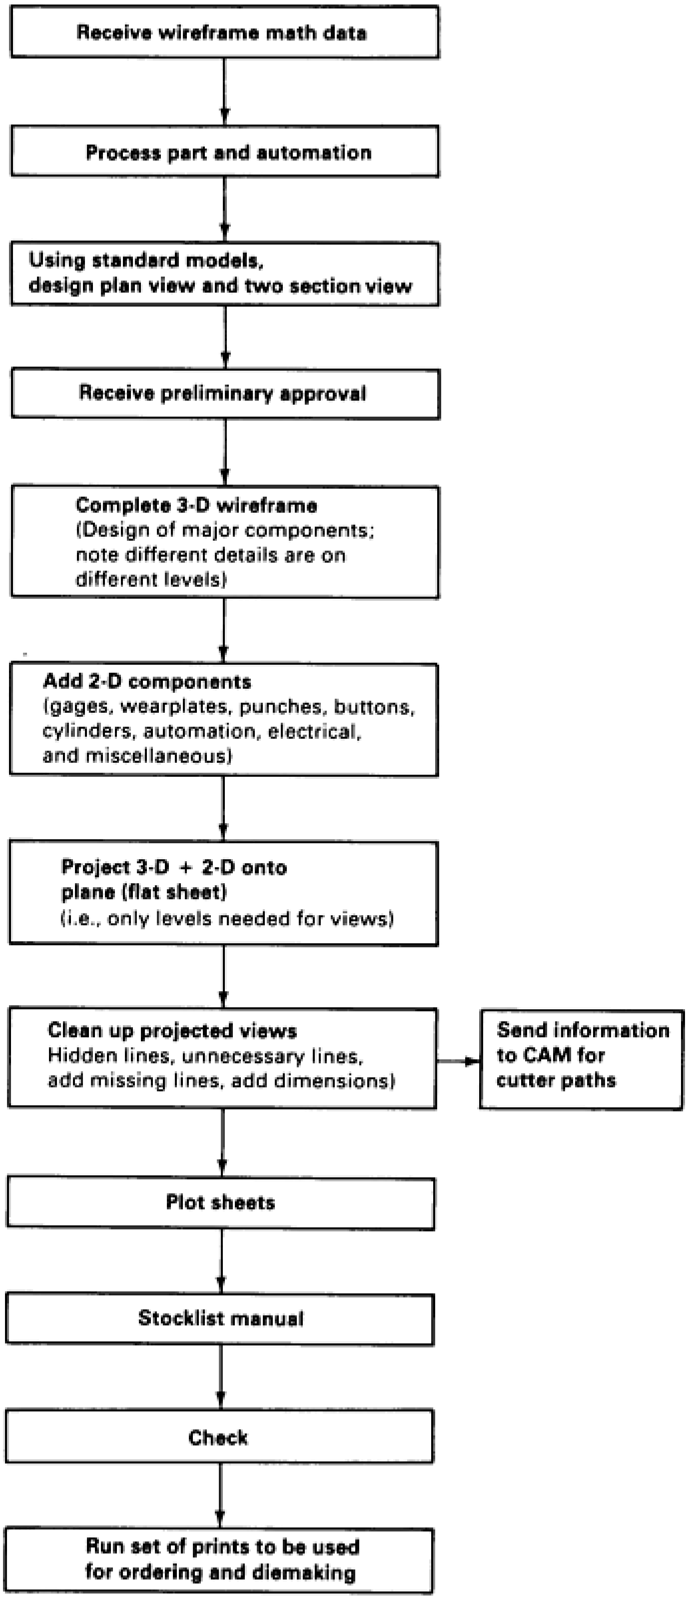

Fig. 2 Flow chart of die design and processing. See also Fig. 1. Courtesy of Autodie Corporation.

Equipment

Hardware. Central to a CAD system is a series of individual workstations, each of which may be equipped with its own processing unit or may operate through a central computer on a time-sharing basis. Even when each workstation has its own processing unit, they are usually linked to all of the other workstations at the facility. This avoids the system slowdown that may be encountered during peak computing periods when using a central computer and prevents the idling of an entire department in the event that the main computer "crashes" (fails or "goes down").

Each workstation must be equipped with memory capacity to handle the size of the data files used. A typical workstation may have 8 megabytes of random-access memory. Additional memory capacity is supplied by a disk drive. Peripheral equipment may include magnetic-tape readers, telephone modems for communication with other computers, and a printing device for output.

Software used for CAD/CAM applications is often available from workstation suppliers. One function of the software is to maintain, update, and store a constantly expanding parts library. This data base will continue to provide the key to the increasing cost-effectiveness of computer-aided design for diemaking. As tooling for new parts is required, it can be patterned after designs for existing tooling rather than created from the beginning, as is usually done in manual operations. However, to realize this economy, standard details for tooling components must be adopted and shared. When this is accomplished, there will ideally be almost no original design work undertaken; all new tooling will come from an assembly of standard die components.

Costs and Advantages Associated With CAD

Costs. Unquestionably, the cost of a tool designed with CAD will be higher than one designed by the traditional method. Some shops have estimated this increase in cost to be approximately 20% or more. In addition, although die design has traditionally represented about 10% of total die cost, with CAD, the current percentage is closer to 15%. However, these figures are transitory and deceptive.

Computer-aided design requires a significant financial commitment to the purchase of computers and associated equipment and software. Modifications to the plant are also often necessary to accommodate all of the sensitive equipment. Even when the commitment has been made to spend hundreds of thousands of dollars to purchase the system, skilled operators will then be needed to handle it. Aside from the training costs for these operators, efficiency will suffer while the designers become familiar with the power of the new techniques. Beyond all of this, there are the financial and time costs associated with building a library of parts and standard die components. In all, any firm deciding to enter this technology should allot approximately 1 year of relative inefficiency to setting up the entire system.

As discussed later in this Section, the primary advantages of CAD are its tie-in to CAM and the smooth, efficient machining of dies that results. Therefore, the cost of machining the die is reduced, and this in turn raises the percentage of total cost represented by the design function, even if absolute design costs were to remain constant. Nevertheless, die design costs may eventually fall below the levels associated with traditional design.

Advantages. Although the costs of implementing computer-aided design are readily apparent, the advantages are far less so and are often unquantifiable. In fact, most of the advantages accrue downstream in the manufacturing process, rather than directly in the design function. These advantages include DNC part programming, better scheduling, reduced number of setups, and faster machining times. These will be covered more fully in the discussion "Computer-Aided Manufacture" in this section.

Within the design phase itself, most advantages derive from enhanced productivity in terms of speed and accuracy. Depending on the specific task, productivity can typically increase from three to ten times for particular functions. As mentioned above, standardized components help tremendously in raising this figure; other factors include the complexity of the part, the degree of part symmetry, and its similarity to previously designed components. Another element of productivity gain is found in the reaction time to any changes in input, which may range from days to literally moments.

As important as productivity increases may be, perhaps the greatest contribution of CAD is in design accuracy. On one hand, there is dimensional control that is often well above that attainable by manual drafting. A designer can precisely scale and view the work from any perspective, rotating the design on the screen at will. Further, with this three-dimensional capability, when an alteration is made to a design in one dimension, the computer automatically makes the equivalent change in the remaining views, thus preserving continuity and minimizing the possibility of errors. These features lead to vastly improved comprehension by the designers, because they are not required to assemble a series of two-dimensional drawings into a mental three-dimensional image. On the other hand, CAD systems provide the opportunity to avoid errors in drafting and documentation because the computer maintains records and continuity. In addition, computer tolerances are much closer than those of a drafter; inconsistencies that may be difficult to detect on paper are immediately obvious to the system.

Advantages also result from the maintenance of a single, unified data base. No longer are engineering changes circulated about haphazardly from a variety of sources, often in ignorance of other changes being proposed. Instead, all changes are made directly into one data base for all users to access. Historical data can also easily be filed for reference.

When to Use CAD

Not all die design work is currently suitable for CAD; even if CAD is capable of handling the design work, it is not always economically feasible to do so. As noted previously, it is often more expensive to design a die with CAD than manually. However, economies can be achieved for large families of similar parts, for which a library can be maintained and accessed often. Poor candidates for CAD are unique items, or those requiring a sizable amount of individual attention, for which library entries do not exist and will not be useful in the future. Ideal candidates are repeat commodities. In the automotive industry, these include hood inner and outer panels, roofs, fenders, doors, and quarter panels.

Even where CAD is used, only 80 to 90% of the designing is done on-screen. Functions still frequently done manually include such tasks as double checking and detailing[**] the designs. Computer detailing requires exorbitant amounts of computer memory, but it is a relatively simple task to perform manually. Thus, there are not enough advantages to justify performing this operation on the computer. This may change, however, as newer and more powerful software and hardware become available.

To use CAD, it is necessary to obtain three-dimensional wireframe diagrams (Fig. 3) of the finished part from the customer. Not all parts are available as wireframes; perhaps 95% of all new outer-skin prints in the automotive industry have such diagrams available. However, virtually 100% of all new automotive parts can be found in the computer. Surface data are not required for CAD, although they are necessary for CAM.

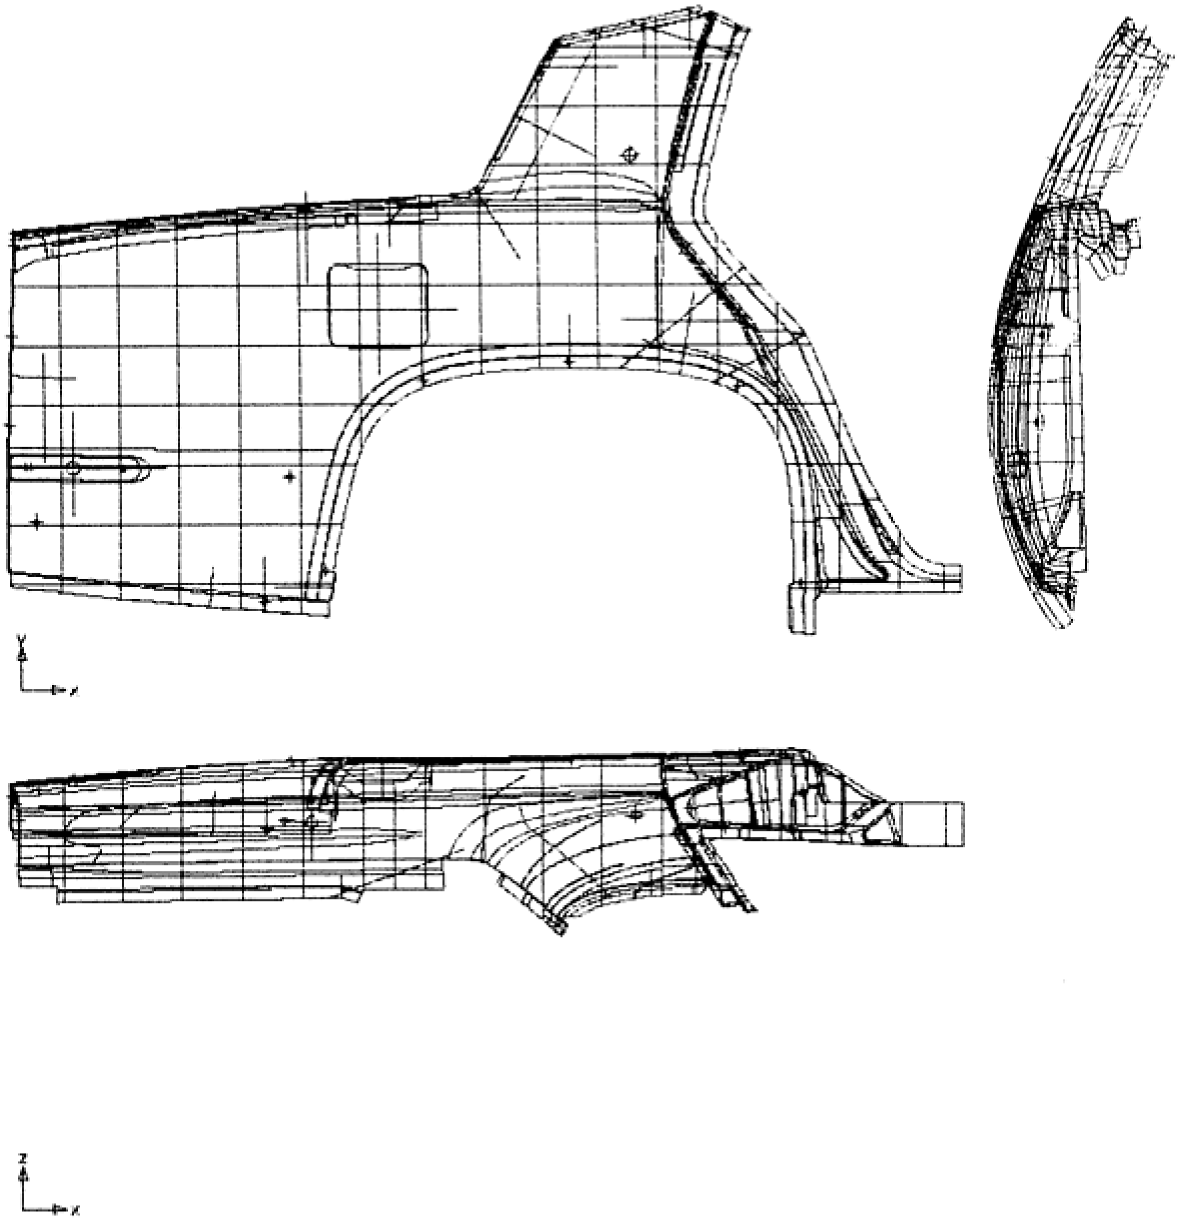

Fig. 3 Wireframe (three-dimensional representation) of an automobile rear quarter panel. Courtesy of Autodie Corporation.

Drawing dies require the development of draw-die binder surfaces, the areas used to restrain and clamp the sheet metal blank during forming (Ref 3). Two methods can be used to generate the binder geometry:

- Creating the geometry on the CRT
- Digitizing the geometry off an actual binder development

In the latter method, a prototype model is NC cut and a binder surface is created. A prototype die is built, tried out, and altered to make an acceptable panel. The proven binder is then digitized and entered into the computer. The design then represents a proven development. The digitized data are passed on to the cutter path programs, where cutter paths are generated. Binder geometries are often complex shapes where the contours cannot be visualized on a CRT, and far less time and money are spent using the digitizing approach. However, digitizing requires some means of obtaining data from the prototype and uploading it to the design computer; a computer-controlled coordinate-measuring machine is often used for this purpose.

Die Design Using CAD

Obtaining and Storing Data. The designing of sheet forming dies for automotive stampings usually begins with a telephone link to the data center of the automaker. Using the direct link, the die designer can obtain the data necessary to generate a wireframe of the panel (Fig. 3). Once obtained from the computer of the automaker, the data can be used immediately or stored on magnetic disk or tape for later reference.

For design work, the wireframe must be in three dimensions. Two-and-one-half dimensions fail to depict sufficient detail in the third dimension to allow proper design of the entire surface. In addition, when changes are made in one dimension, the computer is unable to calculate the resulting changes in the remaining dimensions.

When the design is being manipulated on the workstation, the data for the part may require 25 to 30% of the memory. The operating system occupies about 20%, and the graphics package used may take up another 30%. This leaves about 25 to 30% of available memory capacity. As much as one-half of the data obtained from the automaker are unnecessary for die design and may be purged.

Laying Up the Design. In the design process, models are summoned from the library and compared to the current workpiece. The designer enlarges or reduces the size of the details of the standard model to fit the new part. Guide pins, wear plates, air cylinders, air headers, and other die details are included in the standard model. With the full three dimensions available, the panel and die representation can be rotated in any direction for a better view of the part. Because the model is still in a wireframe format, sections initially appear as a series of unconnected dots. The points are connected by the designer. Currently, there is no automatic routine for connecting the points. Because the computer does not know which points to connect, a skilled designer is needed. In laying up the design, hidden lines also must be indicated by the designer. This is done by altering line fonts on each view or section that contains hidden design features.

Creating Views and Detailing. To create a view, the three-dimensional wireframe is dissected in a manner that allows viewing of specific areas within the die. A three-dimensional image seen on the workstation screen is projected onto a flat plane. At this time, the designer can remove hidden lines and otherwise enhance the projection (for example, add dimensions, finish marks, and so on) to suit his needs. When this process is completed, the depiction is transferred to the plotter. The resulting drawing(s) are then used for manual detailing and checking and filing for future reference. The final drawing is used as a medium to convey the information from the computer to the shop floor.

** Detailing refers to the process of looking at the overall design and subsequently breaking the design down into individual elements for construction.

Computer-Aided Manufacture

Computer-aided manufacture is defined as the use of computers (or, in this case, stand-alone workstations) for partial or complete control of the manufacturing processes; in practice, the term is usually applied only to computer-based developments or NC technology (Ref 2).

Equipment

Hardware. The equipment used for the computer-aided manufacture of sheet forming dies can be divided into two categories. First are the workstations used to generate cutter paths for NC machines on the shop floor; these were described in the discussion "Computer-Aided Design" in this section. The second category is the machine tools themselves, which are described below.

Software. To establish the cutter paths on outer sheet metal panels, it is necessary to work from a surface model--the full mathematical equivalent of what the part should be. The main reason for this requirement is to ensure compatibility between the male punch and the female shoe of the die. As with CAD, two-and-one-half dimensions are insufficient. The CAM worker must have three dimension to see the details on all surfaces in order to predict cutter behavior, to check for potential gouging, to avoid interference, and to generate accurate cutter paths.

As part of its own processes, each automaker develops its own surface models for all of its new exterior panels. Die manufacturers may not have the capability to develop such models and usually use data supplied by the automaker. However, this can be done only if the software used by the automaker is compatible with that of the die manufacturer. A common graphics software exchange package is Interactive Graphic Exchange Software (IGES), which was developed by the National Bureau of Standards. Although wireframe data do not require this intermediary, surface model data (as well as solid model data) do. Not all of the software used by automakers and CAD/CAM suppliers is IGES compatible, and not all of the characters are recognized by all systems. A direct data translator for coupling two different systems together is a faster and more accurate means of communication. This is desirable when data transfer will be frequent, but the translator must be modified whenever software changes are made.

In cases where surface data are not available, the die manufacturer must generate such models in-house. This is done by interpolating points between the wires in a wireframe model. At times, additional section cuts are required to define the surface fully. However, it is preferable to avoid this method of developing surface data when possible because it often duplicates work already performed by the automaker and represents a potential source for errors and/or misinterpretations.

There are several different methods by which the automobile companies generate their own surface models, and all of them involve best-curve interpolation from wire-frames. Among the techniques used are the Gordon method, the Coons patch method, and the Chebychev method. In some European installations, surfaces are generated directly from original equations, primarily employing the B-splines, or Bezier, method.

Patches

To handle a surface model efficiently, it is usually necessary to break the panel representation into a series of patches. A patch is a region on the surface over which a smooth flow for a cutter path can be generated. If a given panel were to be almost featureless, permitting long, uninterrupted strokes by the machine tool, only one surface patch encompassing the entire part would be necessary. In practice, even the simplest panel requires a number of patches.

The borders of such patches are determined by the surface geometries involved. A border is created wherever there are sharp changes in geometry requiring significant changes in cutter path. Each patch is treated independently; even when the die is actually being machined, the tool will work on one surface patch completely before moving on to another. The boundaries are common, and there is no overlapping of sections.

The number of patches required for a die is a function of its size and geometric complexity. A roof panel, because of its comparative simplicity, may be divided into only about 10 patches; a quarter panel, into around 40; and a floor pan, with all of its convolutions, as many as 100. To handle the entire panel as one model would require data files of enormous proportions that would be virtually unmanageable with a stand-alone computer. This occurs when it occasionally becomes necessary to combine adjacent patches on the computer. This practice usually requires a good deal of integration effort by the CAM programmer and up to seven times the computer space needed by the two former patches separately. In theory, such combining would help reduce the potential for error in matching adjacent patches; however, the amount of additional effort required is seldom justified by the marginal benefit. Newer software packages, however, will soon facilitate the machining of multiple patches.

Cutter Path Generation

Not all CAM work must be run from three-dimensional surface models. Relatively straightforward work such as milling, profiling, and trim and pierce operations, in which only two-dimensional descriptions are required, typically runs off of wireframe product data or computer-aided die design data. Complex surface machining dictates the use of three-dimensional surface models.

In addition, although it is a simple procedure in the design phase to take the mirror image of a right-hand part to create its left-hand complement, and vice versa, the same is not true for cutter path generation. When the machine tool is reversible, surfaces can be mirrored, but a conventional cut on one hand is a climb cut on the other.

Postprocessing

During this phase of CAM, the computer takes the cutter path data created at the workstation and translates it into the appropriate NC machine language. Generally, each type of NC machine tool has its own language; therefore, a routine for making the data readable to one tool would be different from that required for another. After the translation is complete, a computer may generate a paper tape containing the machine instructions, or it may download them directly through an electronic link to the tool. Direct loading of data is preferred; paper tape is very slow to make and to read in and is bulky and confusing to distribute.

Computer Requirements

The raw wireframe data for a part taken from the computers of the automaker typically require 1 to 2 megabytes of space (in the case of a roof panel, the figure may be about 1.1 megabytes). In contrast, the surface model may take 2.5 to 4 megabytes of space (for a roof panel, approximately 2.8 megabytes). As with the CAD process, much of the data found in the files of the automotive company are unnecessary for CAM cutter path generation and are purged.

The size of the NC files sent to the machine tools may range from 1 to 10 megabytes, again depending on part complexity and the number of patches required. Therefore, the file for any one panel may require up to 30% of the operating storage space of the workstation.

NC Machine Tools

Controls. It is not necessary to have a different type of controller for each machine tool. For example, one die manufacturer maintains only three types of controllers for 29 NC machine tools. This is in keeping with a prime rule for the shop--keep it simple. This low number of controls yields flexibility in the choice of tool to be used. In addition, not all jobs must be programmed using numerical control. Some tasks are simpler to program manually; numerical control should be used when the computer can do the programming more accurately and efficiently.

The presence of cutter offsets in the control must be ensured. This is to compensate for cutter size due to grinding, as well as the changing to different cutter sizes other than those programmed.

On-board machine memory may use paper tape or disk drives. In the case of disk drives, downloading is done directly from the computer. The time required to load a program may range from 4 to 30 min, depending on the hardware used. In addition, some machine tool manufacturers are developing routines to allow data downloading while the machine is already operating, thus saving more time. If paper tape were used to load programs, loading would be up to approximately 30 times slower.

Machine Tools. A wide variety of machines can be used with numerical control. Care should be taken in selecting machines to be sure that they are able to meet the demands of the jobs typically undertaken. Features such as accuracy, number of axes, and size of the workpiece that can be handled should be considered to ensure that the tool is suitable for the intended application.

Cutting Tools. Carbide tools are often used in the machining of sheet forming dies. An advantage of NC machines is their rigidity, which permits the use of carbide tools. Older machines, without proper holders, could cause shattering of the carbide tools. The use of carbide tools allows higher speeds and much faster metal removal than other tool materials.

Maintenance. Periodic preventive maintenance is critical to the sustained accuracy and repeatability of the machine tool. Although such a process may appear costly on a short-term basis, it will more than pay for itself over the longer term in the form of greatly reduced downtime and consistent superior-quality products that require minimal subsequent hand work. A rigid maintenance schedule must be established at the outset and followed closely throughout the lifetime of the tool. Air filters in the control cabinets must be changed regularly because of the sensitive nature of the electronics and the magnetic properties of the dust.

Costs and Advantages Associated With CAM

Costs. As with CAD, there are significant initial investment costs that are necessary in order to take advantage of CAM. There is no question that NC machine tools are considerably more expensive to purchase than their conventional counterparts; even retrofitting is an expensive process. In addition, there is the cost of training skilled tool operators capable of programming the machines on the shop floor, as well as the higher wages associated with these increased skills.

Advantages. Again, like CAD, the benefits derived from the use of CAM are difficult, and sometimes impossible, to quantify. Some stem from the reduction in man-hours required for machining; even more come from the greater accuracy and product quality achieved from the use of the system. Among the specific advantages are:

- Time savings from the reduction of multiple setups
- Greater productivity in the cutting process itself (due primarily to the elimination of drag imposed by the tracer on the model surface; improvements of up to 50% may be achieved)
- Elimination of inaccuracies in models due to warpage
- Accurate cutter paths for profiling from computer data instead of from templates
- Less subsequent handwork required
- Reduction in tryout time due to reduced part errors
- More productive use of employees

Computer-aided manufacturing allows the machine to perform the routine functions, thus enabling the diemaker to concentrate on more complex tasks. The main theme of the above list of advantages is the avoidance of errors, and this is what makes the quantification of benefits associated with the use of CAM so difficult. It is difficult to place a value on errors and slowdowns that never occur.

In addition, the use of true CAM is impossible without CAD. Computer-aided design inputs the data that allow the cutter paths to be generated by computer. Without CAD, CAM must create all of its own data, slowing the overall process. Although CAD and CAM operations are described separately in this Section, the system is more appropriately viewed as a whole.

When to Use CAM

Two-And-One-Half Dimensional Work. Some aspects of die manufacture are relatively straightforward, requiring only two-dimensional representations for cutter path generation. In the case of casting millwork (flat surfaces that require simple mill cutting), it remains easier to input much of the data manually, particularly for straight areas. Operators can use their experience and judgment to determine cutter paths quickly; therefore, it is not economical to use CAM for this process. However, for angled millwork, the operator would have to perform excessive calculations and programming. With CAD/CAM, the process is effortless and accurate. The overall is a net reduction in design and manufacturing time.

Computer-aided manufacturing is also useful for the machining of standard die components. These components are used quite frequently; therefore, much duplication of effort can be avoided. Profiles are also done completely on CAM. For trim and flange operations, CAM is a must. On pierce dies, CAM is useful for cutting die buttons, keys, and clearances in die pads. This is examined in more detail below.

Three-Dimensional Work. To program three-dimensional surfaces, data must be available in wireframe; surface data are more desirable, but are not always available. If a surface model does not exist, it must be created. The more complex the part geometry, the greater the number of patches required, and the longer it takes to create the surface. If surfaces are available, a small amount of trimming of the surface patches is required in order to eliminate patch extension and/or overlap. Outer surface parts have relatively simple geometries with critical surface and dimensional requirements, and CAM is a must with or without supplied surfaces. Existing CAD/CAM systems can handle the data and create excellent cutter paths in a timely, efficient manner. On inner parts, where surfaces are complex with multiple patches, the effectiveness of cutting the shape by CAM is questionable because of the current limitations of surface mathematics. The surface is seldom supplied. The task of creating a surface on a panel such as a hood inner is an 8-week program before cutter paths can start to be generated. If the programming for CAM takes too long or creates gouges, the net effect is lost time and money. A directive cannot be set that all machining be programmed and cut using CAM. Because CAD/CAM is an emerging technology that does certain items well, it should be used only for those applicable items, such as outer panels, hoods, and fenders. Applications can be expanded as new software allows.

Machining With CAM

To ensure precise alignment of all machining work and subsequent addition of die components, a reference system should be used to locate the centerlines of a die. An example of such a system would be two reference holes, which are located precisely on centerline or an exact distance from centerline. These holes form a precise centerline down the length of the casting. All points for future work are then referred to in terms of distance traversed along the centerline and distance away from the centerline.

The location of the panel must be called out in relationship to the centerline of the die. Holes are put into the die post shape as an aid for roughing or spotting. Kellering heights are also called out for all duplicating. All tips must be called out in degrees.

Two-And-One-Half Dimensional Work. As described above, much casting millwork is more efficiently performed by using manual, rather than CAM, programming procedures. However, flange and trim die profiles are often suitable for CAM programming, specifically on the male and female dies and the die pad. The position of the trim line is generally the key in deciding whether to use mathematical data or to develop data. If the trim line is in part-print (final) position, there are no difficulties, and the cutter paths are programmed directly from mathematical data; however, if the trim line is in a laid-out position, problems often occur. In such a situation, the radius in the drawn panel cannot be adequately simulated; therefore, the locating of a trim line will be developed incorrectly. Because of this, trim dies often require a trial-and-error manual process, in which a stamping is laser trimmed (with the trim line used recorded) and put through the flanging process. Errors in the resulting part are noted, the trim line is adjusted, and the procedure is repeated until a satisfactory panel results. Once a satisfactory development is determined, the final development is programmed for an NC machine and the male die, female die, and pad are cut, thus eliminating the welding of trim lines.

Three-Dimensional Work. The first step in cutting a surface is to rough cut the finished part shape using tracers to a roughing aid. The roughing aid is used to speed the process; acceptable CAM roughing routines are currently unavailable. On large dies, casting within 13 mm ($\frac{1}{2}$ in.) of the final shape is impractical. A roughing aid is inexpensive and quick. The NC cutter paths are used for the semifinish and finish cuts of the surface.

To maintain part shape integrity through the line of dies, a spotter is made off the draw die. This spotter is fitted against all subsequent line dies to ensure proper feature alignment. When this process of spotting has been completed, the dies are ready for tryout.

Flow of Information

To maximize the efficiency of die production, a series of decisions must be made and communicated to the shop floor. At the same time, the shop floor operators must have a channel of communication back to the planners to allow their expertise to influence these decisions. The sequence of decisions should follow a distinct pattern:

- Determination of what can be CAM machined and what should be programmed
- Setting the location of coordinating and reference holes to ensure that all personnel are working off the same center line
- Creation and storage of machining data ahead of time, including cutter paths, cutter specifications, and other relevant information
- Establishment of a distribution manuscript to die leaders that shows and describes the workpiece, the tools required, the work to be performed, and the machine file (Fig. 4)
- Downloading of programs to machine tools
- Completion and shipment of die(s)
- Disposal of CAM routines. Because every die is unique, there is no value in maintaining a library of CAM

routines

The Future of CAD/CAM

The evolution of CAD/CAM has been rapid, and it is accelerating. Within the next 5 years, CAD and CAM will merge to become CAE (computer-aided engineering). This has already been achieved on a small scale. The trend toward more extensive libraries filled with standardized components will also aid this trend. The unfortunate side to this development is that reinvestment in ever-more-advanced equipment and software will be required to keep pace with the competition; however, the benefits of such reinvestment will continue to outweigh the costs.

Although reinvestment in equipment is an obvious fact of life, the reinvestment in personnel must not be overlooked. Shop-floor workers and programmers must be given the ability and knowledge to understand the process as it evolves. At the very minimum, they should participate in training programs on a continual basis to stay current with the latest developments.

Introduction

ALTHOUGH SHEET METAL FORMING is a widely used processing method representing an industry with large production volumes, an integrated engineering approach was not adopted by the metal forming industry until the 1960s when the concept of the forming limit diagram (FLD) was introduced by S.P. Keeler (Ref 1) and G.M. Goodwin (Ref 2). The forming limits, which represent the relationship between limiting major and minor strains in the plane of the deformed sheet, however, remained a diagnostic tool rather than a predictive method. For example, when a sheet metal part fails by localized necking and fracture during manufacturing, a common practice is to either redesign the part or change the processing method so that the strains in the critical region do not exceed the forming limit.

Predicting such a failure in the formed sheet metal part, however, is a difficult task, largely because of the complex boundary and metal-die interfacial conditions and the difficulty of describing quantitatively the nonuniform deformation behavior of metals. It was not until the 1970s that important advances were made in the development of localized plasticity theory that could be used in the modeling of neck initiation and growth behavior. Some of these advances include constitutive and plasticity relations by J.W. Hutchinson and K.W. Neale (Ref 3), bifurcation and imperfection growth analysis methods by A. Needleman and J.R. Rice (Ref 4), and a variety of numerical schemes for elastic-plastic analysis using finite-element analysis methods (Ref 5). The most frequently used method for predicting the limiting strain, however, is based on the idea that necking develops from local regions of initial non-uniformity, as suggested by Z. Marciniak and K. Kuczynski (Ref 6). A number of authors have extended the idea of initial flaw, and an entire FLD was predicted by J.D. Hutchinson and K.W. Neale (Ref 3, 7), D. Lee and F. Zaverl (Ref 8), and Z. Lu and D. Lee (Ref 9).

The purpose of this article is to review various modeling and simulation methods that are available for the sheet metal forming processes and to outline an integrated process analysis method that may be used to predict the success or failure of the formed sheet metal part at the design stage. After reviewing various analysis methods, three sample cases will be examined to illustrate some of the critical points in modeling. Some of the new approaches are outlined to convey the underlying idea that an interdisciplinary approach can be developed to analyze a manufacturing process at a computer terminal.

Process Modeling and Simulation for Sheet Forming

D. Lee, S.A. Majlessi, and J. H. Vogel, Department of Mechanical Engineering, Rensselaer Polytechnic Institute

Generalized Approach

One of the important objectives of process modeling is to predict whether or not a particular sheet metal part can be formed successfully. In order to accomplish that objective, several data bases and analysis programs are required. A diagram illustrating the main elements, which may consist of an analysis program, a computer-aided design (CAD) program, and the computer terminal, is shown in Fig. 1. The analysis program consists of constitutive relations, an FLD analysis program, and a finite-element analysis program; some of the details of these elements will be covered in the following sections. The CAD program contains all the information necessary for a full geometric description of the parts that may be obtained from the engineering drawings. In addition, the material data base as well as details of loading condition are specified. Brief descriptions of each of the three elements that make up the analysis program are outlined below.

Plasticity and Constitutive Relations. Assuming an anisotropic, inelastic material dependent on deformation rate under a general state of stress, the inelastic strain rate, $\dot{\epsilon}_i$, may be expressed in terms of the flow potential, or the yield function f and the scalar multiplier λ(Ref 11, 12):

$$\dot{\epsilon}_i = \dot{\lambda} \left[\frac{\delta f}{\delta \sigma_i}\right]_{\dot{\lambda}} \quad \textbf{(Eq 1)}$$

where f is a generalized yield function such as that given in Ref 13, and the scalar multiplier $\dot{\lambda}$ is equal to (3/2) ($\dot{\bar{\epsilon}}/\bar{\sigma}$) where $\dot{\bar{\epsilon}}$ and $\bar{\sigma}$ represent equivalent strain rate and equivalent stress, respectively. For example, the yield function f can be written in terms of the distortion matrix M_{ij}, which describes the variation of the flow stress with orientation, or:

$$f = M_{ij}\sigma_i\sigma_j \quad \textbf{(Eq 2)}$$

where σ_i and σ_j denote the stress vectors corresponding to the appropriate tensor counterparts, σ_{ij}. Therefore, it follows that the equivalent stress, $\bar{\sigma}$, can be expressed as $\bar{\sigma} = (M_{ij}\ \sigma_i\sigma_j)^{1/2}$. For the case of a plane stress loading condition ($\sigma_3 = 0$) and materials with planar isotropy ($M_{11} = M_{22}$), it can be shown that the well-known anisotropy parameter R is related to M_{33} by $R = (2/M_{33}) - 1$.

In order to describe the strain hardening and strain rate hardening behavior of materials, the equivalent strain rate, $\dot{\bar{\epsilon}}$, may be expressed in terms of the equivalent stress, $\bar{\sigma}$, or:

$$\dot{\bar{\epsilon}} = \dot{\epsilon}_0 \left[\frac{\bar{\sigma}}{k}\right]^{1/m} \quad \textbf{(Eq 3)}$$

where m is known as the strain rate sensitivity of flow stress; the effective flow stress k and the reference strain rate $\dot{\epsilon}_0$ are defined below. The effect of temperature can be readily incorporated into Eq 3 by including an exponential function as an Arrhenius-type expression (Ref 12).

The effective flow stress k and its dependence on $\bar{\epsilon}$ can be determined from a uniaxial tension test at a reference strain rate ϵ_0. It has been demonstrated that a number of experimental data could be represented most accurately by the well-known Swift-type equation (Ref 14):

$$k = k_0\ (\epsilon_0 + \bar{\epsilon})^n \quad \textbf{(Eq 4)}$$

where k_0 and ϵ_0 are material constants and n is the well-known strain hardening exponent. Equations 3 and 4 can now be combined to express the equivalent stress $\bar{\sigma}$ in terms of variations in $\bar{\epsilon}$ and $\dot{\bar{\epsilon}}$ (Ref 12, 15, 16).

Prediction of Forming Limit Diagrams (FLDs). The detailed method of computing the limiting and elongation FLDs has been recently outlined (Ref 8, 9). Specifically, there are several methods that can be used to compute the FLDs. One method is to treat the onset of failure as the condition that leads to plastic instability (Ref 14, 17, 18); the second approach incorporates J_2 deformation theory into a classical bifurcation analysis (Ref 4, 7, 19). Finally, the approach based on the idea that necking develops from local regions of initial nonuniformity has been widely used in recent years to establish FLDs (Ref 3, 6, 7, 8, 9).

Extending the idea of initial nonuniformity to start the neck growth process, it is possible to formulate an analytical model that predicts the development of nonuniform flow in sheet metals under various plane-stress loading conditions (Ref 8, 9). Specifically, the specimen is assumed to have an initial geometric nonuniformity in the form of a band of reduced section. When the initial minimum thickness at the reduced section and the thickness at the uniform section are designated by $h)_0^0$ and $h)_1^0$, respectively, the nonuniformity index, η, is given by η= 1 - $h)_0^0/h)_1^0$]. A uniform strain rate state is then imposed on the specimen containing the initial nonuniformity. The growth of initial nonuniformity is described by simultaneously integrating a series of equations at different but prescribed locations in the neck. A rate-dependent flow theory of plasticity was used, and the computation of the detailed neck growth was repeated over a wide range of proportional loading conditions to establish the limiting strain FLDs. In addition to η, the input material parameters that are required for the calculation of FLD are *m, n,* ε_0, and M_{33}.

A computed limiting strain FLD and experimental data (Ref 15, 20, 21, 22) are compared for aluminum-killed steel in Fig. 2. The η value of 0.008 was obtained from the measurement of sheet thickness variations. Because the limiting strain refers to the ultimate level of strain in the uniform section while the neck growth has taken place, it is safe to conclude that the material has failed when the state of limiting strain is reached. An additional lower bound is also shown in Fig. 2 by the dashed lines which separate safe from marginal regions, taken from an appliance business practice (Ref 23). An added advantage of specifying such a lower bound is that it incorporates the empirical relationship that accounts for the effects associated with sheet thickness and material properties at the onset of necking (Ref 24).

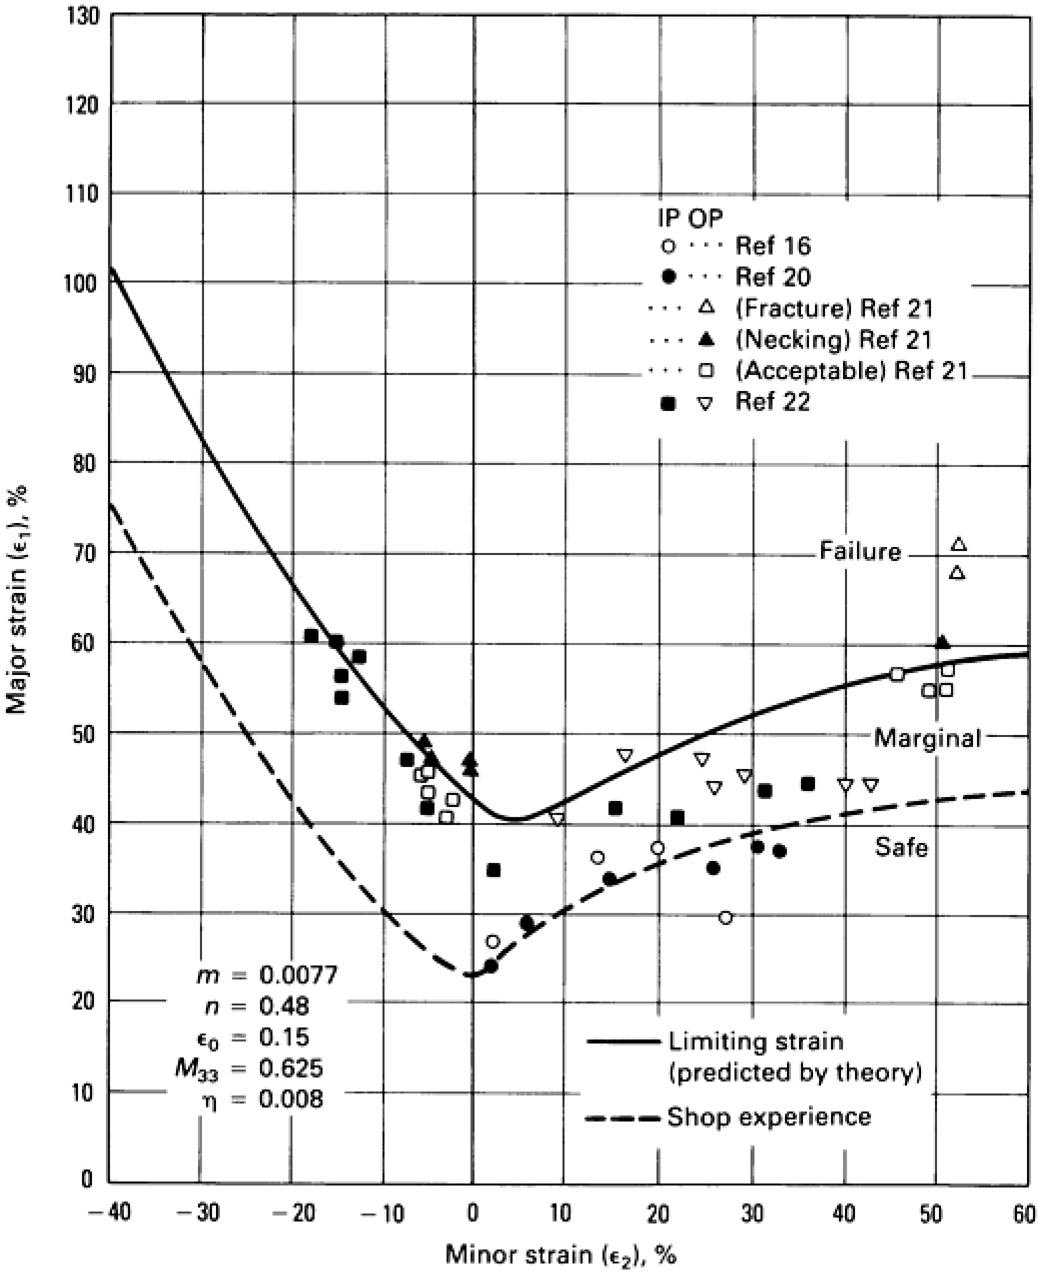

Fig. 2 Comparison of calculated limiting strain forming limit diagrams (FLDs) for aluminum-killed steel with experimental data. Experimental data are distinguished between those tested under the in-plane (IP) and the out-of-plane (OP) loading conditions.

Integrated Systems Approach. A method of processing and controlling the flow of information is outlined in Fig. 3 in the form of a simplified flow diagram. All the critical decision points are also indicated in the diagram. Briefly, the finite element analysis program obtains the necessary input material data, geometry of the part, and boundary conditions of loading, and thereby computes the stress and strain distributions on the formed part. Branching to the right side of the diagram, the necessary material parameters are read again from the material data base, and the theoretical limiting FLD is computed for the particular material. Because necking may occur below the limiting strain region, a boundary depicting the safe and marginal regions obtained from the shop experience is also specified on the computed FLD. Finally, the computed major and minor strains in the formed part are plotted directly on the composite FLD. If all the computed strains in the formed part fall in the safe zone, the program terminates with a sign that indicates that the particular part could be formed without any difficulty. On the other hand, if the computed strain levels are in the failure zone, the program requests that the material, geometry, or the details of loading condition be changed. The entire routine may be repeated until a satisfactory or safe condition is achieved.

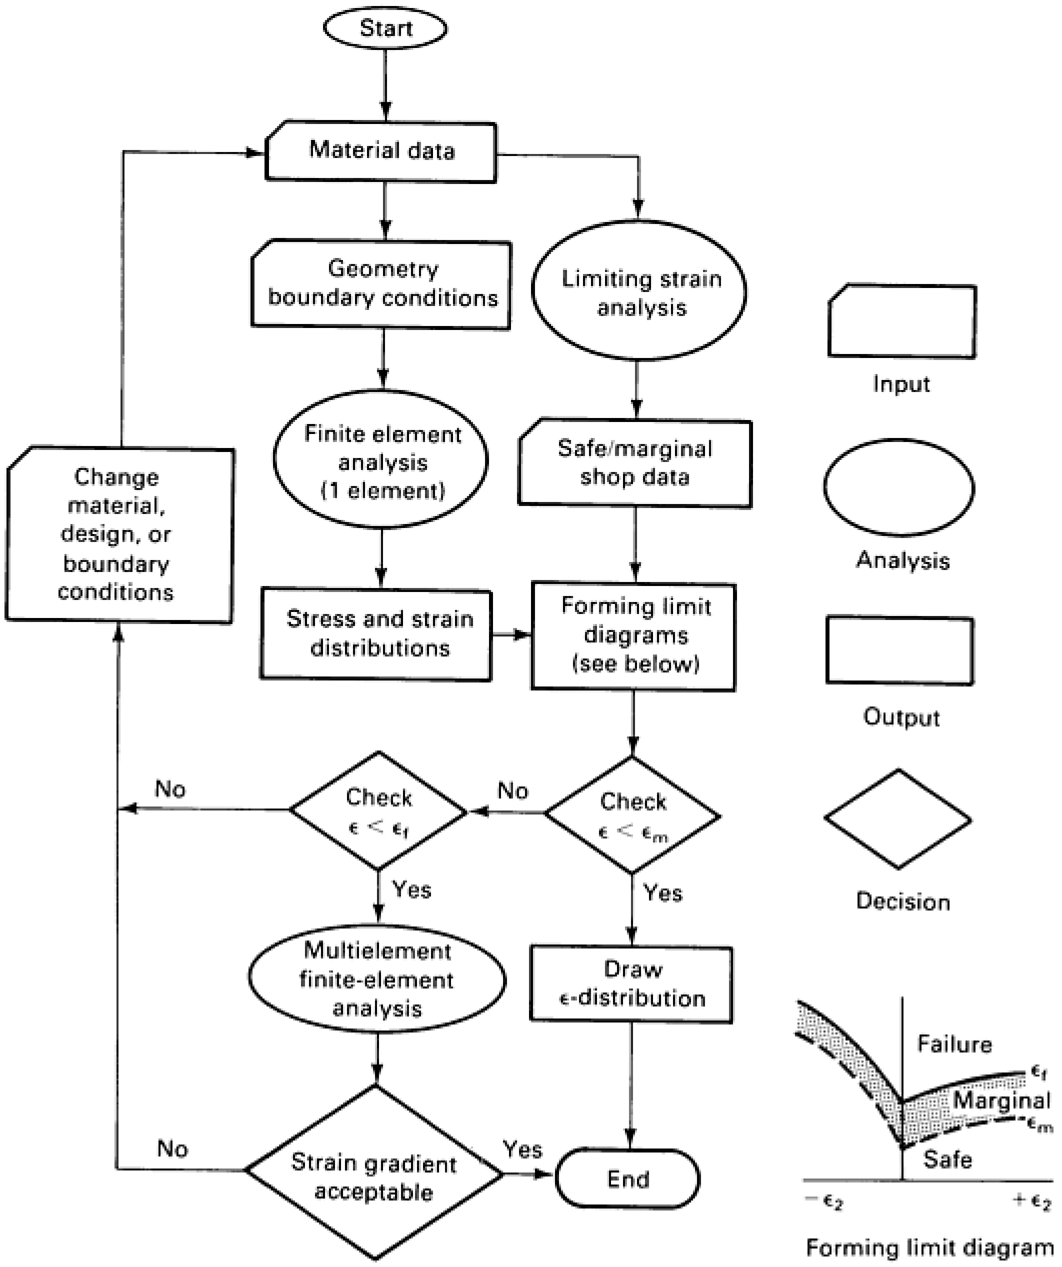

Fig. 3 Flow diagram illustrating various points of input, analysis, output, and decision for the formability analysis.

Because one of the main objectives of computer-aided analysis is to identify critical design and processing parameters while being cost effective, the use of a full-scale finite-element analysis method must be exercised with caution. For example, a typical three-dimensional finite-element mesh generation, analysis, and post-processing of the output for a structural analysis may easily require many days of effort.

Analytical Methods

Two different types of analytical methods will be examined in this section, one dealing with simple and empirical methods, and the other discussing more elaborate analytical methods for representative sheet metal forming processes. Application of these methods should be based on trade-offs between computation time and accuracy. It should also be pointed out that the following section does not include all the analytical methods that are available for sheet forming processes.

Simple and Empirical Methods

Sheet shearing is a process of separating adjacent parts of a sheet through controlled fracture. This is accomplished by placing the sheet between two edges of the shearing tools--in the case of blanking, a punch and a die. The quality of the cut surface is largely influenced by the clearance between the two shearing edges. Based on experience, the clearance is taken between 2 and 7% of the sheet thickness. The smaller clearance is used with a more ductile material. Because the process is largely localized shear over a very narrow zone where strain hardening takes place, a good approximation of shearing force, $\boldsymbol{P}_s$, is obtained from the following empirical equation (Ref 25):

$$\boldsymbol{P}_s = 0.7\ (\text{UTS}) \cdot h \cdot l \qquad \textbf{(Eq 5)}$$

where UTS stands for the ultimate stress, h is the sheet thickness, and l is the length of cut. When the shearing edges are parallel, the entire length of the contour must be taken into consideration.

Shearing is practiced in a number of other processes. When shearing is accomplished between rotary blades, the process is referred to as slitting; cutting along a straight line is simply shearing. A contoured part, such as a circular or more complex shape, is cut between the punch and die in a press, and the process is called blanking. The economy of the process depends on the proper physical arrangement of the parts to minimize scrap losses. Essentially, the same process is also used to remove unwanted parts of a sheet, such as punching of a hole.

Sheet Bending. One of the main characteristics of the sheet bending process is stretching (tensile elongation) imposed on the outer surface and compression of the inner surface (Fig. 4). There is only one line (the neutral line) that retains its original length. For a given sheet thickness, the tensile strain increases with decreasing bend radius. A structural weakening of the bent part occurs when elongation in the outer fiber exceeds the uniform elongation of the material, ϵ_u, in the tensile test. Referring to Fig. 4, the engineering strain e_t is equal to:

$$e_t = -y/\rho \qquad \textbf{(Eq 6)}$$

where y equals $\frac{1}{2}$ the sheet thickness, t, and ρ is bend radius $R + \frac{1}{2}t$. By substituting and rearranging,

$$e_t = \frac{1}{\left(\frac{2R}{t+1}\right)} \qquad \textbf{(Eq 7)}$$

The minimum permissible radius (or more generally, radius-to-thickness ratio) is related to the outer fiber strain, as shown by Eq 7. For example, as the bend radius to sheet thickness ratio, R/t, increases, the strain in the outer surface decreases. In order to develop a simple relationship between the geometry and material properties to achieve a maximum strain on the outer surface, it is assumed that the true strain at cracking is equal to fracture strain ϵ_f, that the material is isotropic and homogeneous, and that the plane strain condition is valid, that is, that width is relatively large compared to thickness.

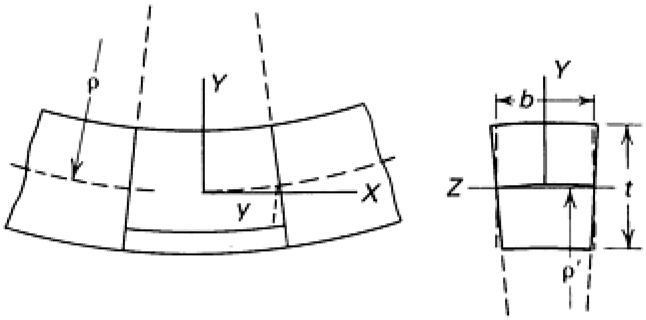

Fig. 4 A simple bending geometry.

The true strain at fracture in tension, ϵ_f, is equal to:

$$\epsilon_f = \ln(A_0/A_f) \qquad \textbf{(Eq 8)}$$

where A_0 and A_f are the initial and final areas. The reduction in area, r, is defined as l - (A_f/A_0). Therefore, $\epsilon_f = \ln(1/(1 - r))$. Because the maximum surface strain, ϵ_s, is equal to ln (e_t + 1), substituting the expression for e_t, gives:

$$\epsilon_s = \ln\left[\frac{R+t}{\frac{R+t}{2}}\right] \qquad \textbf{(Eq 9)}$$

Combining the two equations above and setting $\epsilon_f = \epsilon_s$, the final expression is:

$$\frac{R}{t} = \frac{1}{2r} - 1 \qquad \textbf{(Eq 10)}$$

Failure may take place by either nonuniform deformation (thinning) or by splitting the outside surface layer, which depends on ϵ_f.

Sheet Drawing. Although cup drawing may appear to be a simple operation, a thorough analysis of the forming process is rather difficult (Ref 26). A simple analysis method was, however, outlined by E. Siebel (Ref 27). From the equilibrium condition in the radial direction, the required drawing load and its variations along the punch stroke were determined analytically. The following equation for calculating the drawing load, F_d, has been proposed (Ref 27):

$$F_d = \pi d_m S_0 \left[\exp\left(\frac{\mu\pi}{2}\right) \cdot 1.1\sigma_{f,m} \ln\left(\frac{d}{d_m}\right) + \mu(d - d_m)P_{bh}/S_0 + \sigma_{f,m}\,(S_0/2r_d)\right] \qquad \textbf{(Eq 11)}$$

where d_m is the mean wall diameter, d is the instantaneous outside radius of the flange, S_0 is the blank thickness, r_d is the die radius, $\sigma_{f,m}$ is the mean value of flow stress of the blank material, μ is the coefficient of friction between flange and die or blankholder, and P_{bh} is the blankholder pressure. In Eq 11, the first term represents the ideal deformation load including the load increase due to friction at the die radius, the second term is the component produced by friction between the flange and die or blankholder, and the last term is the load necessary for bending the sheet around the die radius.

A typical load-stroke diagram for deep drawing, shown in Fig. 5, indicates that the flow stress increases continuously with punch displacement as the flange diameter becomes smaller (Ref 26). It has been suggested that the maximum drawing load is nearly independent of the workpiece material and the drawing ratio and occurs when $d = 0.77d_0$ (Ref 27), where d_0 is the initial blank diameter.

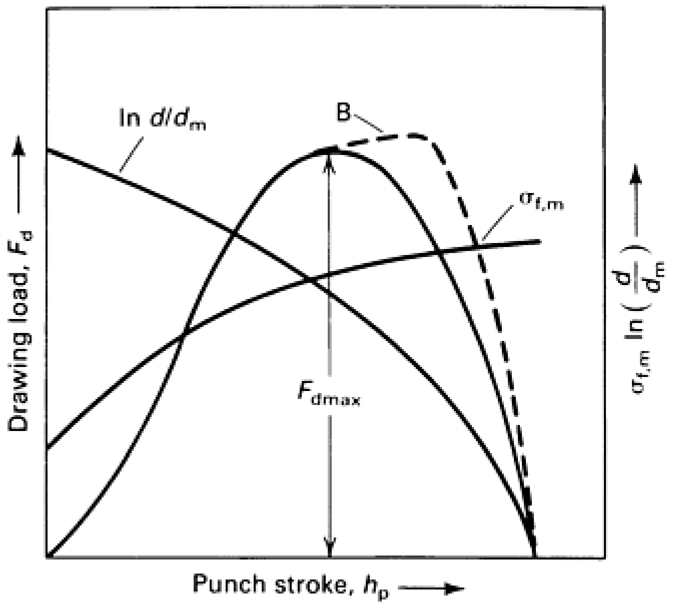

Fig. 5 Typical load-stroke diagram for the drawing process. The portion of the curve labeled B indicates the load distribution for narrow clearances or ironing at the end of the draw. Maximum drawing load F_{dmax} occurs when diameter $d \cong 0.77d_0$, where d_0 is the initial blank diameter.

In general, buckling cannot occur as long as the blank is clamped rigidly between the blankholder and die. During cup formation, the sheet thickness in the flange does not remain constant but may increase toward the outside edge; the center portion near the die radius becomes thinner than the initial thickness, S_0 in the early stages of the draw. Because the distance between the blankholder and die is determined by the largest flange thickness, there will be a gap between the blankholder and sheet near the die radius. This gap may create an opportunity for the initiation of wrinkles. Thin sheets (d_0/S_0 > 25 to 40) are especially sensitive to wrinkle formation because their moment of inertia in buckling is relatively small. The pressure necessary to avoid wrinkling depends on the material properties, the relative sheet thickness, and the drawing ratio. Earlier work by E. Siebel and H. Beisswänger showed that the required blankholder pressure could be estimated from the following empirical equation (Ref 27):

$$P_{bh} = 10^3 c[(\beta - 1)^3 + 0.005\,(d_0/S_0)]S_u \qquad \textbf{(Eq 12)}$$

where the factor c ranges from 2 to 3; β is the drawing ratio, which is defined as the ratio of the initial blank diameter d_0 to the inside diameter of the finished cup d_1; and S_u is the ultimate tensile strength of the material.

The flange-wrinkling behavior of sheet materials in deep-drawing operations was further analyzed by B.W. Senior (Ref 28) and J.M. Alexander (Ref 29). Their expression for the blankholder pressure is given as:

$$P_{bh} = \frac{E_0 t^3 \gamma (b^4 n^4 - 7.464 a^4)}{30.54 a^3 b^3} \qquad \textbf{(Eq 13)}$$

where the buckling modulus E_0 is equal to $4E\rho/(E^{1/2} + \rho^{1/2})^2$, E is the elastic modulus, ρ is the tangent modulus, t is the sheet thickness, γ is the wrinkle amplitude, b is the flange width, n is the number of wrinkles, and a is the mean radius of the flange. Equation 13 shows that blankholder pressure increases with the flange width in a complicated fashion.

Qualitatively, it is conceivable that proper control of the blankholder pressure may reduce fracture and wrinkles in simple drawing operations while reducing the punch load at the same time. In fact, possible ranges of the variation of minimum and maximum allowable blankholder pressure along the drawing depth were estimated by E. Doege and N. Sommer (Ref 30); the blankholder motion was also controlled by a cam mechanism to achieve greater drawing ratios by E.I. Odell (Ref 31).

Analytical Methods

Sheet forming operations may be roughly grouped into two types for the purpose of developing analytical models. One class includes both drawing and stretch forming, where the variations in stress and strain through the thickness of the sheet are usually neglected if any sort of closed-form solution is to be obtained. Within this class, drawing is one extreme, in which the sheet experiences tension in one principal direction and compression in the other; the other extreme is biaxial tension, which occurs in stretch forming. The other class of sheet forming operations is made up of those cases where bending is dominant. In bending, through-the-thickness variations in stress and strain must be taken into account.

Often a given forming operation will involve both bending and stretching/drawing. To include both, it may be necessary to divide the problem into parts, solving the bending and stretching/drawing problems separately and combining the results. A general solution of the combined problem will usually require a numerical procedure such as the finite-element method. In this section, the assumptions and equations used to develop a closed-form solution will be illustrated for both types of operations, using a simple example of each, and some of the techniques developed for extending these solutions to more difficult problems will be outlined.

The general approach to developing a model for a process involves several steps. The first step is to classify the problem according to whether a bending or stretching/drawing type of solution is applicable, and then to express the appropriate strains in terms of the geometry. This involves making simplifying assumptions about either the geometry or the strain distribution; constancy of volume is also usually assumed.

The second step is to choose a constitutive model, relating the stresses in the material to the strains. A constitutive or material model may consist of a definition of effective stress and effective strain and/or strain rate and the relationship between them, plus a flow rule that further relates the individual components of stress to the components of strain.

The next step is to write an equation of equilibrium, usually a force balance obtained by equating the forces applied by the tooling to the stresses in the material required to support these loads. In sheet forming, the effects of inertia and gravity are usually neglected in this force balance. In order to solve the resulting equations and obtain a useful solution, it is often necessary to refine the model, changing some of the assumptions or introducing some additional ones; therefore, the whole process is usually somewhat iterative.

Bending Analysis. As a first example, consider the bending of a flat plate to a prescribed radius. As a bending problem it is clear that the variations in both stress and strain through the thickness of the sheet are important. In order to relate the strains in the sheet to the bending geometry, it is convenient to make several assumptions. First of all, plane strain conditions are assumed to exist throughout the sheet, because the width of the sheet along the axis of the bend will not change significantly. While this assumption is not valid near the edges of the sheet, it is a good assumption as long as the width of the bend is much greater than the thickness of the sheet ($w/t \gg 1$).

Second, the neutral axis is assumed to remain in the center of the sheet, meaning that the midplane of the sheet does not change in length. The error introduced by this approximation is greater with tighter bends, but it is often reasonable for practical bend radii. Another assumption is that planar cross sections of the sheet remain planar and do not warp during the bend.

With the above assumptions in mind, the strains in the sheet may be related to the bend geometry. Referring to Fig. 6, let L_0, be the arc length at the midplane of the sheet, and let r_0, be the radius of curvature of the midplane. Before bending, all planes parallel to the surface of the sheet had the same length as the midplane ($L_0 = r_0\theta$), while the length of a plane in the bent configuration is given by $L = r\theta$. The engineering strain is:

$$e_\theta = \frac{\Delta L}{L_0} = \frac{r\theta - r_0\theta}{r_0\theta} = \frac{z}{r_0} \quad \textbf{(Eq 14)}$$

where $z = r - r_0$. This is not identical to the true strain, but for the strains encountered in most bends the two strains are nearly equal. Because e_w, has been assumed to be zero (that is, plane strain conditions exist throughout the sheet), assuming volume constancy gives $e_t = -e\theta$.

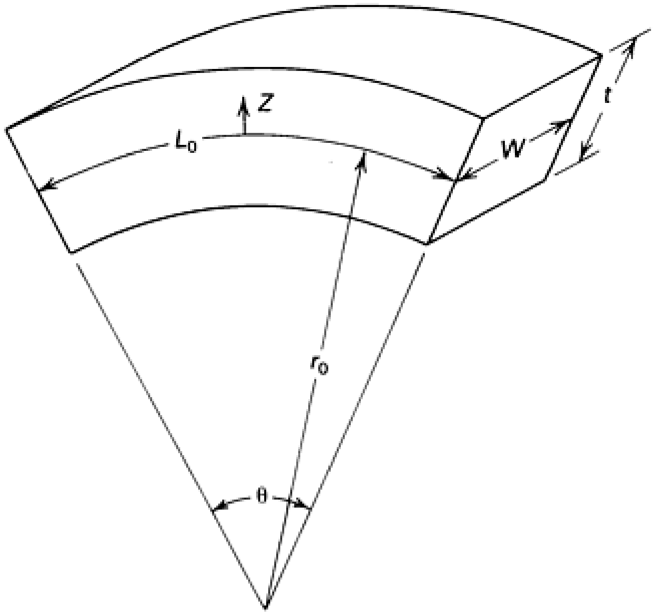

Fig. 6 Geometry definitions for bending analysis.

In order to find the stress distribution, it is necessary to have a material model. For simplicity, assume that the material is elastic-perfectly plastic (no work hardening), and that the stress-strain behavior is the same in tension or compression. While no material is exactly described by this model, in many cases it will give good results if the plastic flow stress chosen for the model is somewhere between the actual yield strength of the material and its ultimate strength.

With this model, the material toward the outside of the bend will be at some uniform value in tension, and the material at the inner part of the bend will be at the same uniform value in compression; the central part of the sheet will be elastic (see Fig. 7). Using both the von Mises yield criterion

$$(\sigma\theta - \sigma_t)^2 + (\sigma_t - \sigma_w)^2 + (\sigma_w - \sigma\theta)^2 = 2Y^2 \quad \textbf{(Eq 15)}$$

where Y is the plastic flow stress, and the plastic flow rule

$$\frac{\delta e_\theta - \delta e_t}{\sigma_\theta - \sigma_t} = \frac{\delta e_t - \delta e_w}{\sigma_t - \sigma_w} = \frac{\delta e_w - \delta e_\theta}{\sigma_w - \sigma_\theta} \quad \textbf{(Eq 16)}$$

the plastic stress level may be determined. In the plastic flow equation, δe refers to an increment of plastic strain, but in bending, these relationships also hold for the total strain because the ratio of the strains does not change during the bend. Using the results obtained for the strains, the stresses are computed to be:

$$\sigma\theta = \sqrt{4/3}\,Y$$
$$\sigma_w = \sqrt{1/3}\,Y \quad \textbf{(Eq 17)}$$
$$\sigma_t = 0$$

While it has not been stated what kind of tooling is being used to make this bend, the bending moment required can be computed. To do this, the contribution of the product of stress, area, and distance from the neutral axis is integrated to give the bending moment, *M*, about the neutral axis of the sheet:

$$M = \int_{-t/2}^{t/2} w\sigma_\theta z dz \qquad \textbf{(Eq 18)}$$

While this integral can be evaluated for the assumptions stated so far, it can be simplified a great deal by neglecting the elastic part of the material near the center of the sheet. For many practical ratios of sheet thickness to bend radius, this does not introduce much error. Making this assumption, and using the values for plastic flow stress just calculated, the following result is obtained:

$$M = \frac{wt^2 Y}{2\sqrt{3}} \qquad \textbf{(Eq 19)}$$

At this point the springback may be computed by noting that the applied bending moment goes to zero upon unloading, and therefore the internal moment must also go to zero. The (elastic) strains can be computed from the new geometry. Letting ***r***' be the new radius of curvature of the midplane after unloading:

$$\Delta e_\theta = \frac{z}{r_0} - \frac{z}{r'} \qquad \textbf{(Eq 20)}$$

Because the unloading is elastic, the appropriate material model for this part of the problem is Hooke's law, and solving for the stress in the θ direction,

$$\Delta\sigma_\theta = \frac{E\Delta e_\theta}{1 - \nu^2} = E' \, \Delta e_\theta \qquad \textbf{(Eq 21)}$$

where *E* is Young's modulus and *E*' = *E*/(1 - ν^2) is called the plane strain or bending modulus.

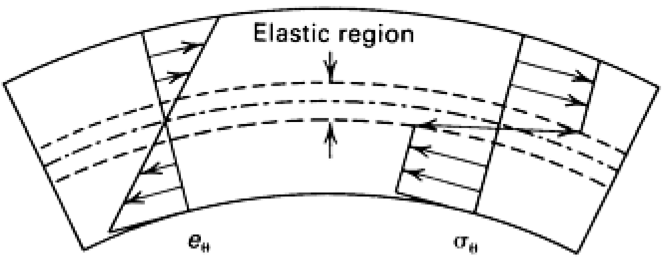

Fig. 7 Stresses and strains in bending.

The equilibrium condition here is that the change in the internal moment during unloading must be equal to the change in the external moment. The change in the internal bending moment is obtained from the following integral, which may be evaluated by using Eq 20 and 21:

$$\int_{-t/2}^{t/2} w\Delta\sigma_\theta z dz = \frac{wt^3 E'}{12}\left[\frac{1}{r_0} - \frac{1}{r'}\right] \qquad \textbf{(Eq 22)}$$

Because the change in the external moment is equal to the original applied moment (Eq 19), the equilibrium equation is:

$$\frac{wt^3E'}{12}\left[\frac{1}{r_0}-\frac{1}{r'}\right]=\frac{wt^2Y}{2\sqrt{3}} \quad \textbf{(Eq 23)}$$

Solving for *r'*, the radius of curvature of the midplane after springback:

$$\frac{1}{r'}=\frac{1}{r_0}-\frac{6Y}{\sqrt{3}E't} \quad \textbf{(Eq 24)}$$

This result is useful in predicting springback in simple bending. However, the assumptions made in deriving this expression must be kept in mind when applying it, principally that the ratio of sheet thickness to bend radius must be neither too small nor too large, and that the only load applied by the tooling is the bending moment. For instance, if the sheet is bent while in tension, or if a significant compressive stress is applied across the thickness of the sheet (due to contact with the die), the springback will be reduced. These conditions must be incorporated into the derivation if a solution for either of these cases is desired.

There are other examples of closed-form analytical solutions of sheet bending processes. For example, R. Hill (Ref 32) formulated the theory of plane strain bending for rigid-perfectly plastic materials. F. Proksa (Ref 33) used Hill's suggested displacement equations in developing a theory for plane strain bending of rigid-linear hardening materials. Extensive work has also been done by B.W. Shaffer and his collaborators (Ref 34, 35, 36).

If the process is more complicated than one of simple bending, or if a more accurate solution is desired, it may be necessary to use a numerical approach to solve the equations. For example, in air bending, considerably more springback will occur upon unloading than is predicted by Eq 24 because of the elastic unbending of the unsupported portion of the sheet. An analysis of this process (Ref 37) considers the springback to be due to both the portion of the sheet in contact with the punch and the free section of the sheet. These contributions are combined with the actual shape of the material response curve to compute the springback, using an iterative-solution procedure.

Other numerical solutions of the bending process have also been developed. For example, K.H. Wolter (Ref 38) and H. Verguts and R. Sowerby (Ref 39) took the deformation history of individual fibers into account. In a later study, further improvements were made by P. Dadras and S.A. Majlessi (Ref 40, 41).

Drawing Analysis. The analysis of sheet drawing or stretching is different in some respects, as described earlier, and an analysis of the cup-drawing process provides a good example. The following analysis is similar to work by R. Whitely (Ref 42) and shows the effect of anisotropy on the limiting drawing ratio.

The geometry of cup drawing is clearly more complex than can be represented by radial drawing alone, but an analysis of the flange, or radial drawing portion of the cup can yield useful results. To simplify the analysis, it is assumed that the thickness change may be neglected, or $\epsilon_t = 0$ (see Fig. 8).

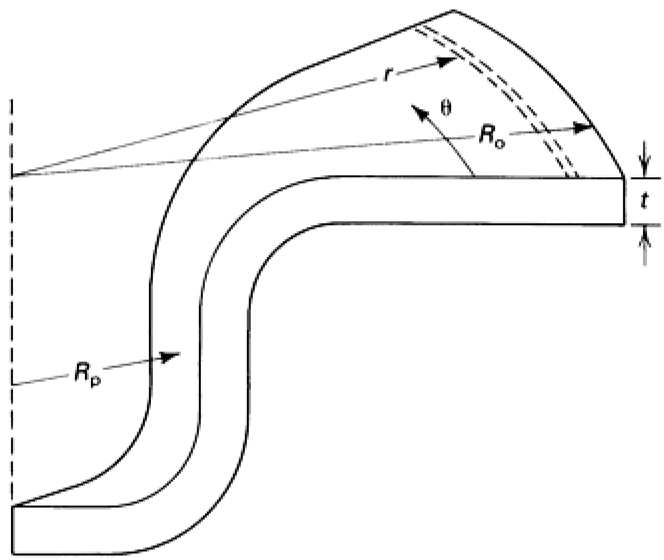

Fig. 8 Geometry definitions for drawing analysis.

The circumferential strain, $\epsilon\theta$, is related to the change in circumference at any radius by:

$$\epsilon_\theta = \ln\left[\frac{2\pi r}{2\pi R}\right] = \ln\left[\frac{r}{R}\right] \qquad \textbf{(Eq 25)}$$

where r is the radius of any element of material and R is the initial radius of that element. Based on the assumption of volume constancy with $\epsilon_t = 0$, the radial strain is given by $\epsilon_r = -\epsilon\theta$.

To relate the stresses to the strains, a rigid-perfectly plastic material model is assumed. To further simplify the analysis, the Tresca yield criterion is chosen, so that the difference between largest and smallest principal stress is assumed to be a constant at any point in the sheet. In the flange, shear stresses induced by friction are neglected, and the coordinate stresses are taken to be the principal stresses. The radial stress, σ_r, is therefore the (algebraically) largest principal stress, and the compressive circumferential stress, $\sigma\theta$, is the smallest. Therefore:

$$\sigma_r - \sigma\theta = Y_f \qquad \textbf{(Eq 26)}$$

where Y_f is the flow strength of the material in the flange under the condition that $\epsilon_t = 0$.

For the equilibrium equation, consider a small element of material in the flange between the radii r and $r + dr$ (see Fig. 9). Because in practice the flange is slightly thicker at the outer edge than anywhere else, it is assumed that any blankholder load is concentrated there. As a result, $\sigma_t = 0$ throughout the flange. Balancing the forces acting on this element in the r direction:

$$\sigma_r|_r tr\theta + 2\sigma\theta\, tdr \sin(\theta/2) = \sigma_r|_{r+dr} t(r + dr)\theta \qquad \textbf{(Eq 27)}$$

where $\sigma_r|_r$ is equal to σ_r evaluated at radius r. For small angles, sin (θ) ~θ, or:

$$\sigma_r|_r tr\theta + \sigma\theta\, tdr\theta = \sigma_r|_{r+dr} t(r + dr)\theta \qquad \textbf{(Eq 28)}$$

Rearranging and dividing through by r, t, and θ:

$$\frac{\sigma_r|_{r+dr} - \sigma_r|_r}{dr} = \frac{\sigma_\theta - \sigma_r|_{r+dr}}{r} \qquad \textbf{(Eq 29)}$$

Taking the limit as $dr \rightarrow 0$, the equilibrium equation at a point becomes:

$$\frac{\delta\sigma_r}{\delta r} = \frac{\sigma_\theta - \sigma_r}{r} = -\frac{Y_f}{r} \qquad \textbf{(Eq 30)}$$

Because of the assumption of a rigid-perfectly plastic material, the equilibrium equation turns out such that the stresses may be computed without reference to the strain distribution. Integrating Eq 30:

$$\sigma_r(r) = C - Y_f \ln(r) \qquad \textbf{(Eq 31)}$$

where C is an integration constant. Because $\sigma_r(R_0)$ is known, where R_0 is the radius of the outer edge of the flange, $C = Y_f \ln(R_0) + \sigma_r(R_0)$. This gives:

$$\sigma_r(r) = \sigma_r(R_0) + Y_f \ln\left(\frac{R_0}{r}\right) \qquad \textbf{(Eq 32)}$$

For the case of no blankholder, $\sigma_r(R_0) = 0$, or:

$$\sigma_r(r) = Y_f \ln\left(\frac{R_0}{r}\right) \qquad \textbf{(Eq 33)}$$

Now if the effects of bending and friction over the draw ring are neglected, the radial stress that must be supported by the cup wall to draw successfully may be computed from Eq 33:

$$\sigma_r(R_p) = Y_f \ln\left(\frac{R_0}{R_p}\right) \qquad \textbf{(Eq 34)}$$

where R_p is the punch radius. The draw will fail if $\sigma_r - \sigma\theta \geq Y_w$, the flow stress in the wall. The flow in the wall is characterized by $\epsilon\theta = 0$, so that for an anisotropic material, Y_w will be different from Y_f. Taking $\sigma\theta = 0$ at the top of the cup wall, the drawing limit is reached when:

$$Y_w = Y_f \ln\left(\frac{R_0}{R_p}\right) \qquad \textbf{(Eq 35)}$$

This gives the limit drawing ratio as:

$$\frac{R_0}{R_p} = \exp\left[\frac{Y_w}{Y_f}\right] \qquad \textbf{(Eq 36)}$$

This equation predicts a limiting drawing ratio for an isotropic material to be ln(1), or approximately 2.72, but in fact this is quite high. Actual values obtained experimentally are closer to 2.1 or 2.2 (Ref 43). The main reason for the discrepancy is the fact that frictional forces and bending were neglected in the equilibrium equation.

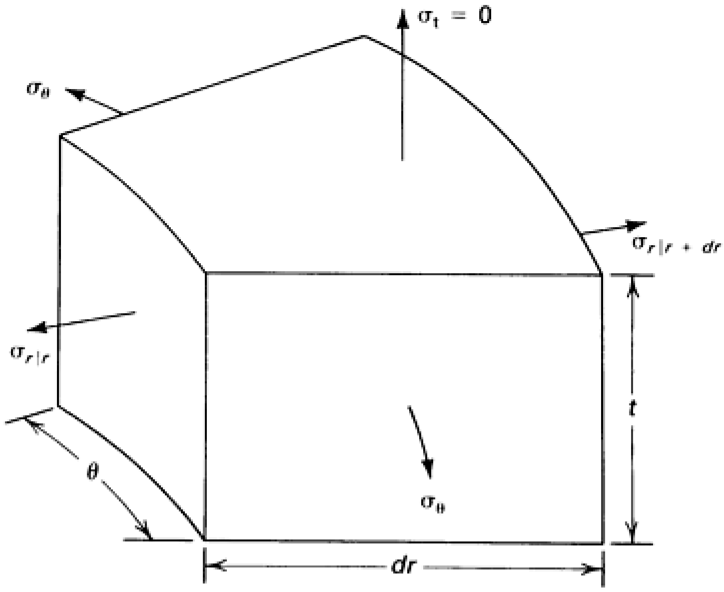

Fig. 9 Flange element for equilibrium equation in drawing.

This analysis may be continued, relating the ratio of flow strengths to the *R* value of the material, and an efficiency factor may be introduced to account for frictional losses and to give a better correlation with experimental results. The resulting theory, while not perfect, does demonstrate the strong dependence of the limiting drawing ratio on material anisotropy.

For a more accurate analysis, a closed-form solution has not yet been obtained. However, a very good solution requiring a computer program and an iterative solution procedure was developed by D.M. Woo (Ref 44, 45) following the same basic steps outlined here, but with much less restrictive assumptions regarding material behavior, friction, and geometry of the sheet. Using the Von Mises yield criterion and a rigidpower law hardening material model, the force equilibrium equations derived above are integrated by approximating the variation of stress and strain (including thickness strain) to be linear across each element. In this manner, the stress and strain distribution for the entire sheet was obtained for each small advance of the punch into the material, with the incremental strains at each stage being added to find the total strain. Many other researchers have since adopted and expanded the resulting finite-difference solution (Ref 46, 47, 48).

Process Modeling and Simulation for Sheet Forming

D. Lee, S.A. Majlessi, and J. H. Vogel, Department of Mechanical Engineering, Rensselaer Polytechnic Institute

Finite-Element Analysis Methods

With recent advances in high-speed computers, there has been a marked progress in the development and application of numerical methods for mechanics-related problems. Among these techniques, the finite-element analysis method has been widely used in the treatment of diverse classes of problems in this field. In particular, material forming processes, because of their complexity and large number of process variables, are ideally suited for the application of the finite-element analysis technique. A systematic survey of the developments and applications of the technique in the field of material processing has been given by A.S. Wifi (Ref 49). In another review paper, S. Kobayashi (Ref 50) has outlined the important role of the finite-element method in metal forming modeling work.

Although early development of the finite-element method was primarily concerned with linear problems, the method has been extended to nonlinear problems by the initial strain method (Ref 51, 52) and by the tangent modulus method (Ref 53, 54). The actual application of this technique to metal forming problems was made in the 1960s by P.V. Marcal *et al.* (Ref 55), Y. Yamada *et al.* (Ref 56), and O.C. Zienkiewicz *et al.* (Ref 57); additional applications were made in later years by employing the small-strain analysis method (Ref 58, 59, 60, 61, 62, 63, 64, 65).

Metal forming operations, however, inherently involve large strains and therefore different formulations were needed for proper analyses of these processes. During the 1970s two basic approaches for treating large deformation were developed. One of these was the rigid-plastic formulation (Ref 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77) where it is assumed that the elastic strains are small compared to plastic strains, and therefore can be ignored. In these analyses, a material model that obeyed the von Mises yield criterion and the associated flow rule were used. The incompressibility constraint was treated by either a Lagrange multiplier (Ref 66) or a penalty function (Ref 78, 79).

The rigid-plastic formulation, however, does not account for elastic unloading; therefore, such phenomena as springback and development of residual stresses cannot be treated by the model. Development of the second approach, elastic-plastic large-deformation finite-element analyses, has been accomplished partially as a result (Ref 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91). The classic paper of H.D. Hibbitt *et al.* (Ref 80) introduced one of the first large-strain finite-element formulations, in which a total Lagrangian formulation (TLF) was employed. In this formulation, the initial undeformed configuration of the material is chosen to be the reference state. A.S. Wifi (Ref 81) developed a complete finite-element program and analyzed the axisymmetric stretch-forming and deep-drawing processes, using the incremental TLF. N.M. Wang and B. Budiansky also employed a TLF-based nonlinear membrane theory and simulated the axisymmetric hemispherical punch stretching of sheet metals (Ref 91).

An alternative approach called the updated Lagrangian formulation (ULF), in which the current configuration of the deforming material is considered to be the reference state, was also developed and extensively used (Ref 83, 92, 93). Some of the key papers discussing the development of finite-element analysis using ULF for large elastic-plastic deformation are those of R.M. McMeeking and J.R. Rice (Ref 92) and E.H. Lee (Ref 93). The formulation of initial displacement matrix (the undeformed configuration of the material) is not required in the ULF method.

The basis of the finite-element analysis technique, using the variational approach, is to formulate a functional based on the specific constitutive relations. This functional is usually a statement of the potential energy of the deforming continuum. The finite-element equations are then formulated by the condition that the first variation of the functional should vanish. E.P. Popov *et al.* (Ref 94) employed the shell theory and developed a finite-element program to analyze sheet bending problems. Using this theory gives satisfactory results only when the deformation is moderate and the ratio of thickness to bending radius is small. For analysis of large-strain bending processes, V. Cupka *et al.* (Ref 95) employed the finite-element formulation developed by H.D. Hibbitt *et al.* (Ref 80) and solved a three-point bending problem with counterpressure at the bottom of a sheet. S.-I. Oh and S. Kobayashi (Ref 96) developed two finite-element analysis programs, using formulations suitable for rigid-plastic and elasto-plastic material behavior. It was shown that the results of the two analyses agreed very well with each other. In a recent effort, A. Makinouchi (Ref 97) formulated an elaborate constitutive equation assuming a varying Young's modulus, and developed a finite-element program using a ULF approach. As an example, the essence of that work is outlined in Example 1 of the following section.

Example 1: Finite-Element Analysis of Sheet Bending and Hemming.

An elastic-plastic incremental finite-element analysis program was developed for sheet bending and hemming processes of metals under plane strain conditions (Ref 97). A constitutive equation within the framework of finite deformation was also developed. The derivation of the constitutive equation follows the decomposition of the deformation gradient F as proposed by E.H. Lee (Ref 98):

$$F = V^e F^p \quad \textbf{(Eq 37)}$$

where V^e and F^p are elastic and plastic deformation gradients, respectively. The velocity gradient L in the current configuration, x, and the plastic velocity gradient L^p in the plastically deformed configuration, α, are given by:

$$L = \dot{F}F^{-1}\ 2L^p = \dot{F}^p F^{p-1} \quad \textbf{(Eq 38)}$$

The rate of deformation tensor D, which is the symmetric part of L, is expressed as:

$$D = \frac{1}{2}(L + L^T) = \frac{1}{2}V^{e^{-1}}(V^e \dot{V}^e + \dot{V}^e V^e + V^e V^e L^p + L^{p^T} V^e V^e)V^{e^{-1}} \quad \textbf{(Eq 39)}$$

where T stands for transposed. A measure of elastic strain ^{e} is introduced with respect to the plastically deformed configuration α, and is defined as follows:

$$\epsilon^e = \frac{1}{2}\left\{\frac{\delta u^e}{\delta\alpha} + \left[\frac{\delta u^e}{\delta\alpha}\right]^T\right\} \quad \textbf{(Eq 40)}$$

where u^e is the elastic displacement from the plastically deformed configuration to the current configuration, x. Using the above definitions, it can be shown that:

$$V^e = I + \ ^e \qquad \textbf{(Eq 41)}$$

where I is the unity tensor. Substituting the material time derivative of Eq 41 into Eq 39, we obtain:

$$D = \frac{1}{2}(2\dot{\epsilon}^e - \epsilon^e\dot{\epsilon}^e - \dot{\epsilon}^e\epsilon^e - 2W^p\epsilon^e + 2\epsilon^e W^p + 2D^p) \qquad \textbf{(Eq 42)}$$

where D^p is the plastic rate of deformation tensor, $D^p = (L^p + L^{p^T})/2$, and W^p is the plastic spin tensor $W^p = (L^p = L^{p^T})/2$. Because the analysis is concerned with small elastic strains, the elastic strain rate $\dot{\epsilon}^e$ can be neglected compared to plastic rate of deformation D^p; thus Eq 42 reduces to:

$$D = \dot{\epsilon}^e - W^p\ ^e + \ ^e W^p + D^p \qquad \textbf{(Eq 43)}$$

It is important to note that the first three terms in Eq 43 have the form of a Jaumann rate (Ref 92) of $\ ^e$. Therefore:

D = **MATH OMITTED**$^e + D^p$ **(Eq 44)**

where **MATH OMITTED**^{e} is the Jaumann rate of $\ ^e$. The above relationship is the rate form of the elastic-plastic decomposition for cases with small-elastic but finite-plastic deformation, and replaces the following well-known relationship:

$$D = D^e + D^p \qquad \textbf{(Eq 45)}$$

In one finite-element analysis program, R. Hill's variational principle (Ref 99) and the updated Lagrangian formulation has been employed. Hill's variational principle is expressed in the form:

$$\int_v [(\tau_{ij} - 2\sigma_{ik}D_{kj})\delta D_{ij} + \sigma_{jk}L_{ik}\delta L_{ij}]dV = \int_s t_i \delta v_i ds \qquad \textbf{(Eq 46)}$$

Constant-strain triangular elements were used in the calculations. In order to verify the theory, a number of experiments using mild steel and high-strength steel sheet were carried out. The stress-plastic strain relation obtained from the tensile tests is expressed by a Swift-type equation:

$$\overline{\sigma} = C(\ _0 + \overline{\epsilon}^p)^n \qquad \textbf{(Eq 47)}$$

It has been shown that the evolution of the elastic modulus can also be presented by a similar relation:

$$E = E_0\,(1.0 + 100\overline{\epsilon}^p)^m \qquad \textbf{(Eq 48)}$$

Figure 10 shows a comparison between computed and measured springback angle. Two computed results are shown for each material. One is obtained by using a constant Young's modulus E_0, and the other by using the variable Young's modulus E. As shown in Fig. 10, a closer agreement with the experimental data is achieved when a variable elastic modulus is used. Figure 11(a) illustrates the computed effective strain and the longitudinal stress profile at a 45° bent angle. In Fig. 11(b), the distribution of longitudinal stress σ_{ll}, normal stress σ_{nn}, lateral stress σ_{zz}, and shear stress σ_{ln} are depicted for the bent angle of 45°.

Sheet Stretching

Punch stretching can be characterized as a nonsteady metal-forming process because of the presence of the moving boundary that separates the sheet in contact with the punch head from the unsupported region of the sheet. Because of its complexity, a detailed analysis of the stretching process can only be made by numerical methods such as finite-difference (Ref 100, 101, 102) and finite-element techniques (Ref 91, 103, 104, 105, 106).

N.M. Wang and B. Budiansky (Ref 91) assumed that the sheet metal is rate insensitive, elasto-plastic, and exhibits normal anisotropy. Using a convected coordinate system, the variational principle was formulated and the resulting equations from finite-element discretization were solved. S. Kobayashi and his collaborators have also analyzed the sheet stretching process in rate-sensitive and rate-insensitive materials. The common assumption in those analyses is that the elastic strains are small compared to plastic strains and therefore can be ignored. The following example is presented to illustrate some of the important parts of this type of finite-element formulation.

Example 2: Finite-Element Analysis of Punch Stretching of Rate-Sensitive Materials.

In Ref 105, a finite-element program has been developed to analyze the axisymmetric punch stretching of rate-sensitive materials. A rigid-viscoplastic material model with normal anisotropy has been assumed. The finite-element model was based on the following variational formulation:

$$\delta\Phi = \int_V [\bar{\sigma}\delta(d\bar{E}) + H\, d\bar{E}\, \delta\,(d\bar{E})]dV - \int_{S_F} F \cdot \delta u\, dS = 0 \qquad \text{(Eq 49)}$$

where $\overline{\sigma}$ is the effective stress, $d\overline{E}$ is the incremental effective logarithmic strain, and H is the slope of the stress-strain curve. The second integral represents the variation of the work done by the traction F. In developing Eq 49, it was assumed that the principal axes of true strain rates maintain the same direction in each element and that the ratio of the principal strain rate components remain constant during each time increment. The following constitutive equations for a rate-sensitive material with normal anisotropy have been employed:

$$\bar{\sigma} = Y\left[+\frac{1}{\gamma}\left(\frac{d\bar{E}}{dt}\right)_{\mathrm{m}}\right] \qquad \text{(Eq 50)}$$

where Y is the yield stress and γ and m are material parameters. Following R. Hill's theory of anisotropy (Ref 32), effective stress and increment of effective strain are defined as:

$$\bar{\sigma} = \sqrt{\sigma_\theta^2 - \frac{2R}{1+R}\sigma_\theta\sigma_\phi + \sigma_\phi^2} \qquad \text{(Eq 51)}$$

and

$$d\bar{E} = \frac{1+R}{\sqrt{1+2R}}\sqrt{dE_\phi^2 + \frac{2R}{1+R}dE_\phi dE_\theta + dE_\theta^2} \qquad \text{(Eq 52)}$$

The incremental-strain components are defined as follows:

$$dE_\theta = \frac{d\hat{E}}{\bar{\sigma}}\left[\sigma_\theta - \frac{R}{1 + R^\sigma \phi}\right] \quad \textbf{(Eq 53)}$$

and

$$dE_\phi = \frac{d\hat{E}}{\bar{\sigma}}\left[\sigma_\phi - \frac{R}{1 + R^\sigma \theta}\right] \quad \textbf{(Eq 54)}$$

The sheet geometry is divided into a number of conical frustums, and the functional Φ is expressed within each element in terms of the nodal values associated with the particular element. The condition that the first variation of the functional vanishes provides the stiffness equations. These equations are nonlinear and are solved by the Newton-Raphson iterative scheme.

For verification purposes, a number of aluminum-killed steel specimens were stretched, and the results were compared with the predicted values of the finite-element program. Figure 12 shows the computed radial, $\varepsilon\phi$, and hoop, $\varepsilon\theta$, strain distributions for two coefficients of friction (μ = 0.25 and μ= 0.4) at the punch-sheet interface. The agreement with the measured strains is generally good. In order to examine the sensitivity of the material to strain rate, four separate computations were carried out with different punch speeds. In one case, a rate-insensitive material model was used. The computed load versus punch travel is depicted in Fig. 13.

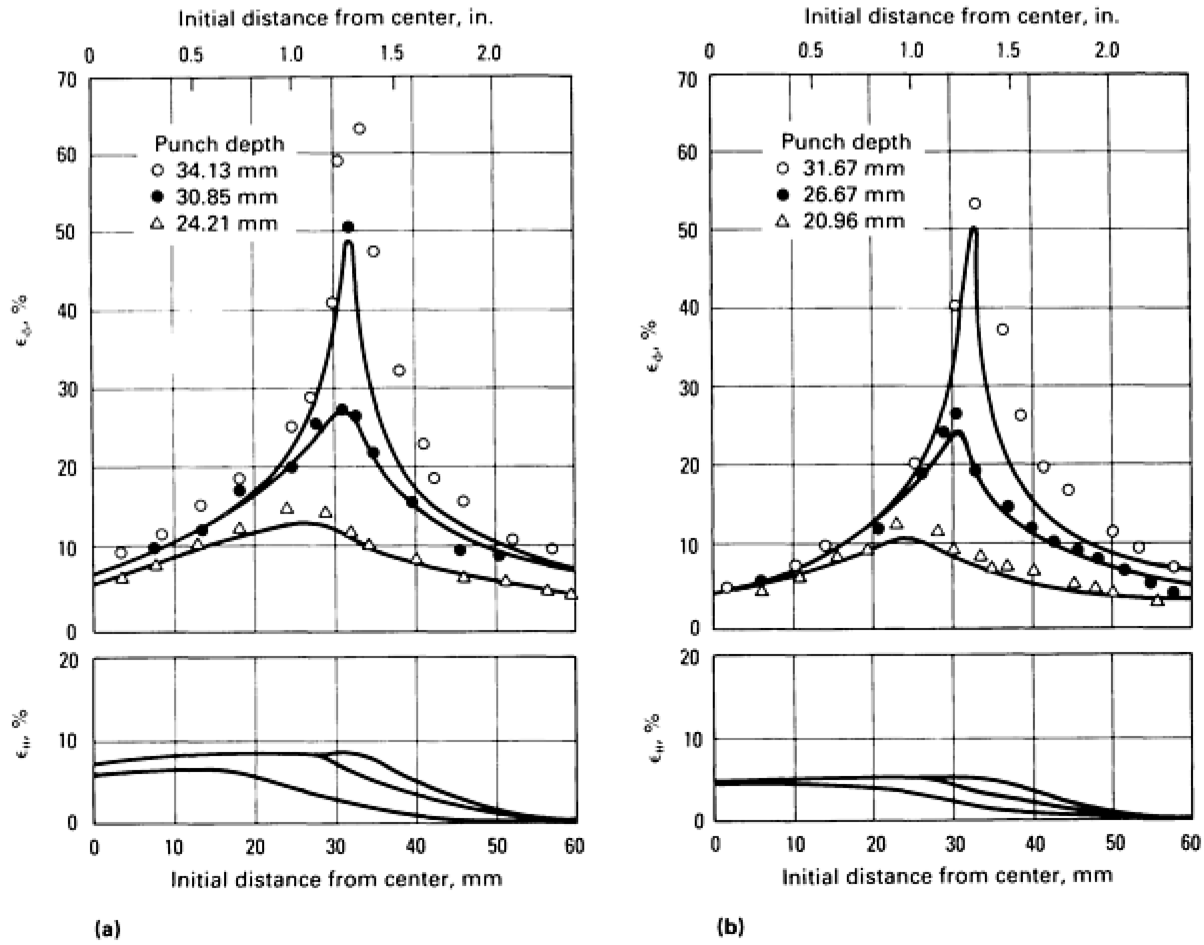

Fig. 12 Comparison of computed and measured strain distribution at several punch depths for two coefficients of friction. (a) μ= 0.25. (b) μ= 0.4 Source: Ref 105.

Deep Drawing

Several finite-element analysis programs using different formulations have been proposed to study the deep-drawing process. The majority of these analyses employed a rigid-plastic material model and the incremental theory of plasticity to analyze axisymmetric geometries. The process of nonaxisymmetric sheet metal forming has also been examined by several authors. C.H. Toh and S. Kobayashi (Ref 107, 108, 109) used a rigid-plastic finite-element analysis method based on the membrane theory to model deep drawing of nonaxisymmetric geometries. Y.J. Kim and D.Y. Yang (Ref 110) also developed an incremental rigid-plastic finite-element analysis method to analyze a hydrostatic-bulging process of rectangular sheet diaphragms.

As an alternative approach, S. Levy *et al.* applied the deformation theory of plasticity and developed a finite-element analysis program to approximate a cup-drawing process of an elastic-plastic material. It was shown that considerable savings in computational time was achieved by using the deformation theory (Ref 111). D. Lee and coworkers (Ref 10, 112, 113) further improved this approach to account for the anisotropic behavior of materials, and demonstrated that a computer software system based on the above approach can be applied to simulate actual sheet metal forming processes. A subsequent refinement of the analysis has also been made, with improved analytical and numerical methods (Ref 114). The basic approach has also been used by R.W. Logan and W.F. Hosford (Ref 115) to analyze necking and wall wrinkling in sheet metal stretching/drawing. They included a scheme for updating the reference state to the current configuration in the analysis, and reported an excellent computational efficiency over the stepwise incremental formulation.

Although a number of general-purpose finite-element codes have been developed lately for analyzing nonlinear problems (Ref 116, 117), they are not suitable for modeling sheet metal forming processes. Moreover, the prohibitive length of computation time has prevented the use of such programs as an interactive tool at the design stage. The main advantage of the membrane-type elements and deformation theory of plasticity is the simplicity. With such a simplified method, solutions may be obtained quickly, and yet they are within an acceptable range of engineering approximations.

Example 3: Using Final Part Configuration to Compute Size of the Undeformed Blank.

In Ref 114, a number of isoparametric elements were specified on the prescribed final configuration of an axisymmetric part, and the shape and size of the undeformed blank sheet were computed. It is shown that considerable savings in computer time can be achieved by using deformation theory.

The computational scheme is composed of first defining the locations of the nodal points in the undeformed configuration (trial nodal points), and then improving these locations by applying a Newton-Raphson iterative scheme. The principle of minimum potential energy is employed in the following manner. The potential energy of deformation ψ is decomposed into two parts:

$$\psi = \psi_x + \psi_u \qquad \textbf{(Eq 55)}$$

The first term, ψ_x, is the energy associated with the deformation of the trial nodes from the initial to the final configurations, and is given by:

$$\Psi_X = \int_V \left(\int_0^{\epsilon_f} \sigma d\epsilon \right) dV - \int_S T_X \, w_X dS \qquad \textbf{(Eq 56)}$$

The volume integral in the above equation refers to the strain energy where ϵ_x, is the strain due to deformation of the trial nodes from their beginning to end positions. The surface integral represents the work of traction forces. For a given final configuration, ψ_x, holds a constant value once the trial nodal positions are assumed.

The second term in Eq 55, ψ_u, is the increment of potential energy due to the small displacements, u_i, of the trial nodal points in the initial configuration, and is given by:

$$\Psi_u = \int_V \left(\int_{\epsilon_X}^{\epsilon_f} \sigma \, d\epsilon \right) dV - \int_S T_u w_u \, dS \qquad \textbf{(Eq 57)}$$

where ε_f, denotes the final strain. It has been shown that the surface integral of Eq 57 represents the frictional work only. Because ψ_u is a function of the small increments, u_i, the correct values of u_i can be determined by minimization of ψ_u:

$$\frac{\partial \Psi_u}{\partial (u)} = 0 \qquad \textbf{(Eq 58)}$$

Because of the nonlinear nature of the problem, the correct values of the initial nodal positions have to be determined through several iterations.

In Fig. 14, the computed strain distributions in radial and hoop directions are shown for a hypothetical cup model. In order to verify the model, several experiments have been conducted for axisymmetric cups made of drawing quality steel sheet. As shown in Fig. 15, the measured strain values agree well with the computed results, although there are some discrepancies in the punch profile region where the description of friction is not well defined.

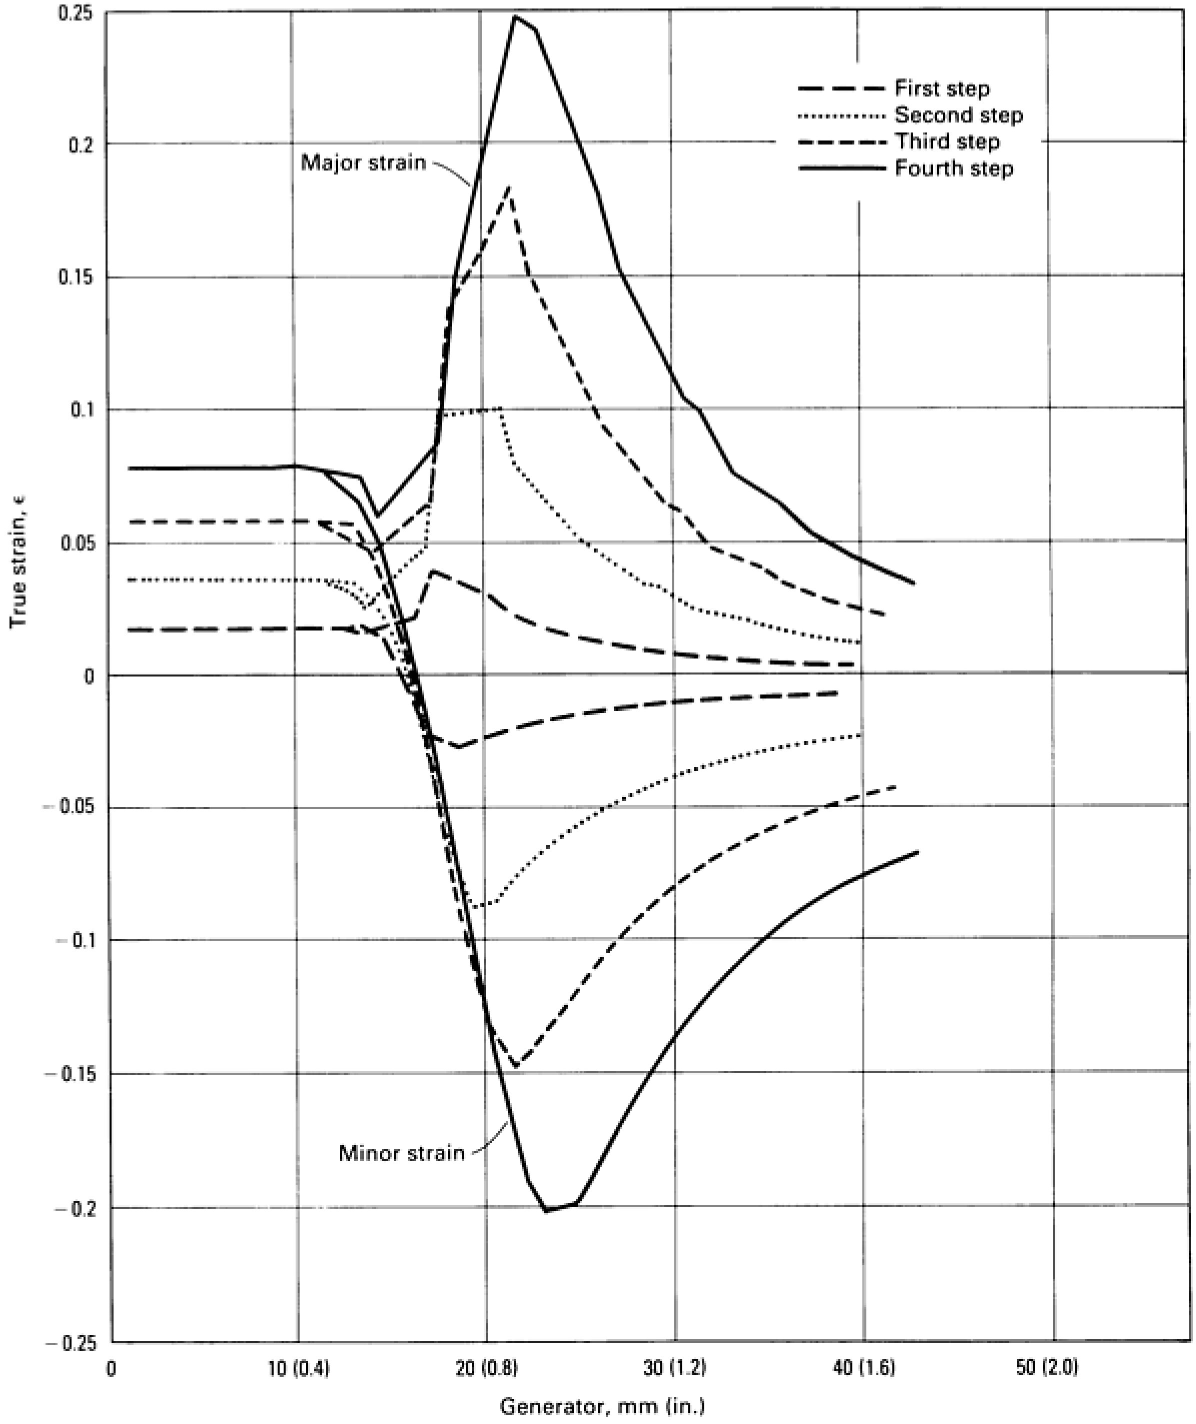

Fig. 14 Strain distributions at the end of each step of a four-step forming process for a steel cup.

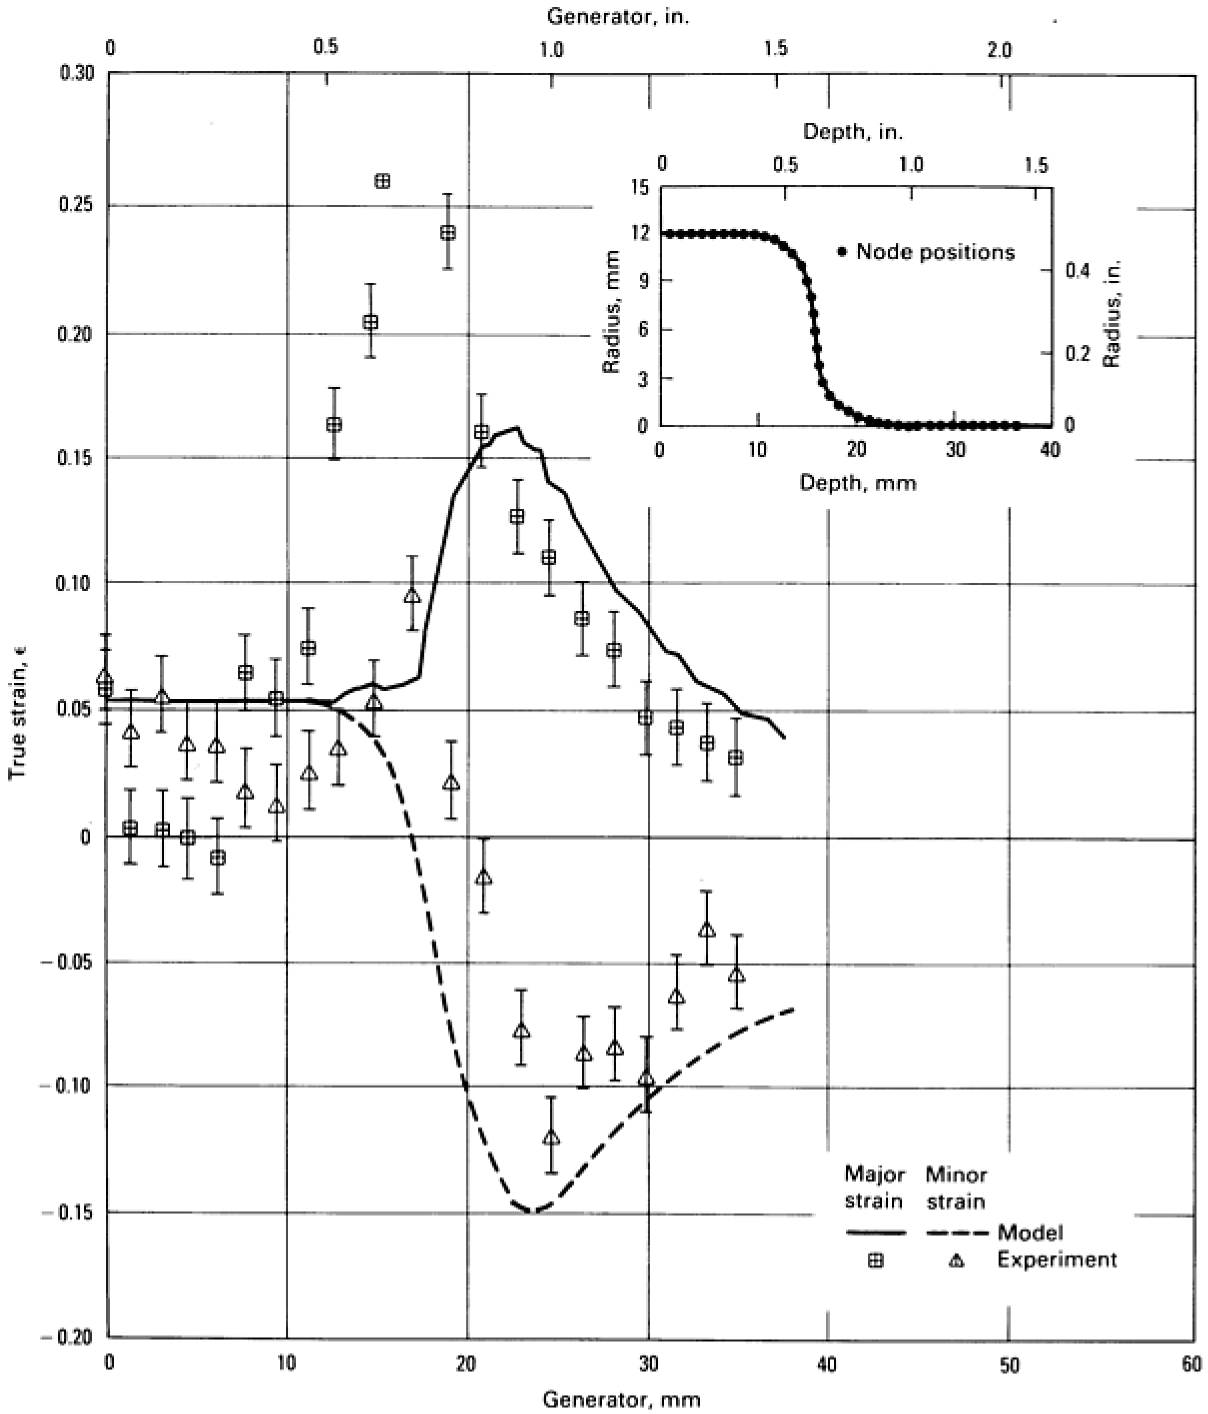

Fig. 15 Comparison of the computed strains along the final generator with experimental data of 11.10 mm (0.437 in.) deep cup made without lubrication. Inset shows the cup geometry. Source: Ref 114.

Process Modeling and Simulation for Sheet Forming

D. Lee, S.A. Majlessi, and J. H. Vogel, Department of Mechanical Engineering, Rensselaer Polytechnic Institute

Case Studies

This section will examine a total of three cases in order to illustrate different possibilities that occur under these sheet forming conditions. All the cases represent actual forming for which experiments have been conducted to verify the predictions.

In the cup forming, the frictional boundary condition was changed while the geometry was kept the same. In the vent-forming case, a portion of the three-dimensional part was approximated as an axisymmetric geometry. The box forming process was analyzed using three-dimensional sheet forming analysis.

Example 4: Cup Forming.

A photograph of the formed cup and the corresponding finite-element representation of the cup geometry are shown in Fig. 16. Details of the imposed frictional boundary conditions are that the measured coefficient of friction (0.14) was used in cup 1, and an exceedingly low coefficient of friction (0.02) was applied to cup 2 as a hypothetical case. Appropriate normal loads were also specified, and the relative motion of the sheet metal with respect to the die surface was accounted for by the sign of friction coefficient. Selection of specific nodal points for the application of the normal force has been found to be not critical; the normal force may be distributed over the appropriate nodal points.

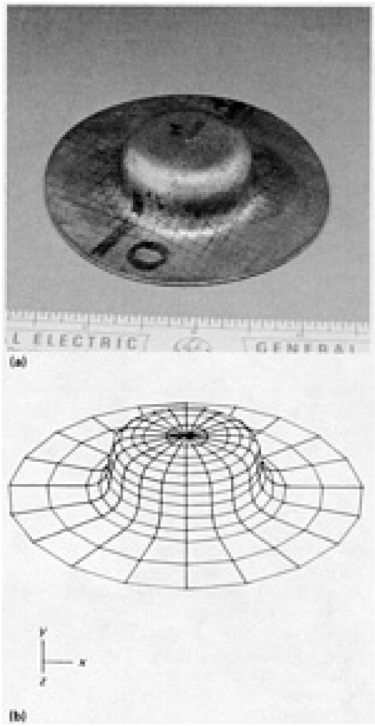

Fig. 16 (a) Photograph of the formed part. (b) A finite-element model for cup.

Given the material properties, the geometry file, and the loading boundary conditions, the next step in the flow diagram (Fig. 3) is to compute the strain distributions when the cups have been formed. A parallel analysis starting from the material data base yields a computed limiting strain FLD. The required inputs were strain rate sensitivity m, strain hardening coefficient n, offset strain ε_0, anisotropy index M_{33}, and the initial inhomogeneity index, η. Superimposing the safe/marginal shop FLD on the computed limiting FLD gives all the information that is necessary to establish a base for FLD criteria.

All the necessary information to make a decision is in place; the strain distributions for the particular formed part will be compared against the failure criteria, that is, the composite FLD, as shown in Fig. 17. The computed radial (major) and hoop (minor) engineering strains at each nodal point are identified in the composite FLD by the corresponding nodal point numbers. The resulting display gives the information necessary to proceed with the next step: Strain levels in some of the nodal points in cup 1 exceed the safe/marginal boundary, while with cup 2 it is entirely safe to proceed.

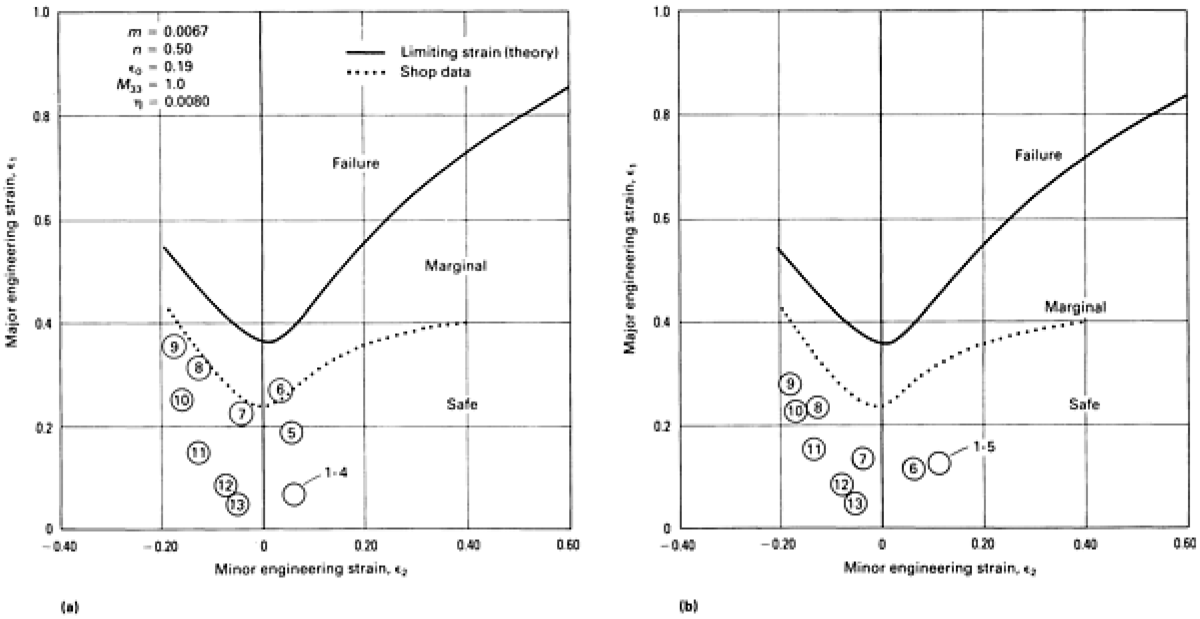

Fig. 17 Comparisons of theoretical and practical limiting strains at each node point for (a) cup 1 and (b) cup 2.

Example 5: Vent Forming.

The same procedure used for cup forming will be followed for the vent forming analysis. Photographs of the formed vent 1 part and the finite-element geometry model corresponding to the round section of the formed part are shown in Fig. 18. An obvious difference between the two is the side flange, which is not axisymmetric in the formed part. The effect of assuming a circular flange section in the analysis will be discussed when the analytical result is compared with the experimental data.

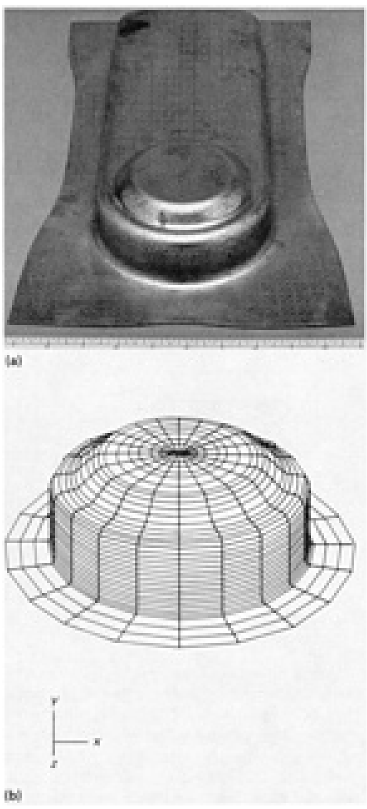

Fig. 18 (a) Photograph of the formed part and (b) finite element model for the circular section in (a) for vent.

Following the same procedure used in the cup analysis, the computed results are compared with the safe/marginal/failure FLD criteria shown in Fig. 19. Vent 1 can be formed without any difficulty. Laboratory forming of vent 1 did not cause any necking, which is consistent with the finite-element analysis results.

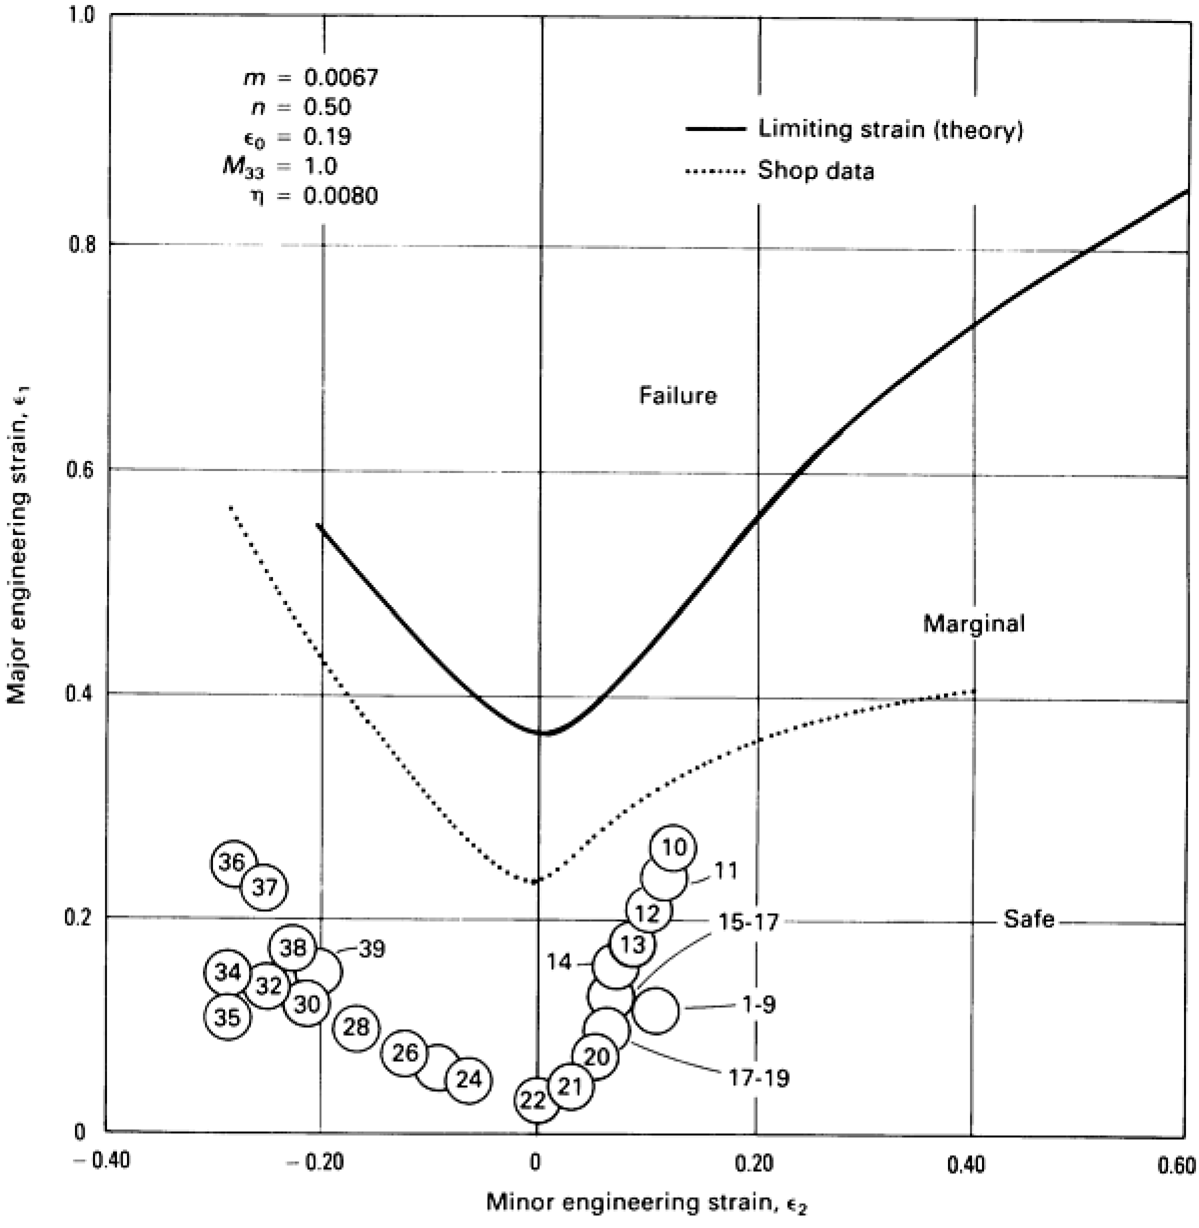

Fig. 19 Comparisons of theoretical and practical major and minor strains at each node point for vent 1.

Example 6: Square Box Forming.

The three-dimensional square-box forming process was modeled following an analytical procedure similar to that used in Examples 4 and 5. Here again, two assumptions were made: First, the plane stress condition is valid, and, second, the deformation theory of plasticity is applicable. The unknowns, then, are the initial location of the element nodal coordinates as well as the blank shape. These unknowns are computed by applying the principle of minimum potential energy. The basic mathematical approach is summarized in Ref 118.

A summary of the details of square-box geometry and loading boundary conditions include:

- Material: aluminum-killed steel
- Stress-stain curve: $\sigma= 739\ \varepsilon^{0.3}$ MPa
- Punch size: 40 × 40 mm (1.6 × 1.6 in.)
- Die size: 42.5 × 42.5 mm (1.7 × 1.7 in.)
- Punch radius: 5 mm (0.2 in.)
- Die radius: 5 mm (0.2 in.)
- Corner radius: 3.2 mm (0.125 in.)
- Blank size (undeformed): 110 × 110 mm (4.3 × 4.3 in.)
- Coefficient of friction: 0.2 at the punch and 0.04 at the die
- Blank holding pressure: 500 kgf (1100 lbf)

The deformed sheet domain used in the square-cup simulation is shown in Fig. 20. Eight noded isoparametric membrane-type elements were used. The solution was converged within 25 iterations to increments of nodal displacements of <25 μm (0.001 in.). Figures 21 and 22 show the major strain distributions across the diagonal and transverse generators of the square cup, respectively. The experimental results obtained by T.R. Thomson (Ref 119) were also included for comparison. Although a considerable discrepancy of the results is seen under the flat punch profile, good correlation between the predicted finite-element model and the experimental results is observed. In particular, the experimental and predicted results match most closely at the critical areas of the punch and die profile radii where the highest strains are observed.

Statistical Analysis of Forming Processes

Stuart Keeler, The Budd Company Technical Center

Introduction

STATISTICS are becoming important tools in the operation of press shops, providing numerical process analysis capabilities that far exceed the more traditional recording of simple breakage rates. The most common use of statistics in the press shop is the area of statistical process control (SPC). Though utilized in many formats, SPC is simply the use of statistical techniques such as control charts to analyze a process or its output and thus enable appropriate actions to be taken to achieve and maintain a state of statistical control. The use of statistical process control instead of traditional quality control methods such as inspection/sorting is beneficial in a number of ways. Statistical process control:

- Decreases scrap, rework, and inspection costs by controlling the process
- Decreases operating costs by optimizing the frequency of tool adjustments and tool changes
- Maximizes productivity by identifying and eliminating the causes of out-of-control conditions
- Allows the establishment of a predictable and consistent level of quality
- Eliminates or reduces the need for receiving inspection by the purchaser because it produces a more reliable, trouble-free product, resulting in increased customer satisfaction

The use of statistics in analysis of the forming process, however, goes well beyond SPC. The whole area of design of experiments (DOE) is becoming important as the interactions within the forming process are detailed and studied. This article will discuss the role of statistics in sheet metal forming operations both in terms of different statistical process control techniques and design of experiments. Information on the statistical analysis of mechanical testing is available in the Section "Statistics and Data Analysis" in *Mechanical Testing*, Volume 8 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

Stuart Keeler, The Budd Company Technical Center

The Forming Process

A wide range of forming processes are currently in use. Although the details of these processes differ significantly, most forming processes share certain characteristics. Each forming process, however simple, can be viewed as a system. For sheet metal forming, one common breakdown of the system consists of the following components:

- Material
- Lubricant
- Tooling
- Press

Each of these major components can be further broken down into subcomponents.

The components of forming systems are highly interactive. A change in one component can produce significant changes in the effects of other components. Not only are the changes within a single component difficult to trace and understand, but the interaction of the components makes the task even more difficult. Small changes made in one or more components of the system can cause very large changes in the output of the system (the finished part). These synergistic changes may not be predictable or even possible to anticipate.

Ideally, the forming system should be a continuous process. For many processes, the system appears to be continuous. The tools are inserted into the designated press and remain there for the production life cycle of the part, which often spans several years. Changes made during the production life cycle may in fact create major disruptions in the continuous nature of the process. These changes can include engineering modifications, tooling replacement, routine maintenance, process improvements, and other seemingly minor modifications to the process.

Many forming processes are conducted on a batch basis, typically with large volumes. Tooling is inserted into a press, a specific number of pieces are made, and the tooling is removed from the press. This type of process is often considered to be an interrupted or segmented form of a continuous process. In reality, however, a new forming system is created each time the tooling is inserted into the press. This is evidenced by the extended period of trial-and-error adjustments necessary to the tooling before the production of satisfactory parts can begin.

Statistical Analysis of Forming Processes

Stuart Keeler, The Budd Company Technical Center

The Statistical Approach

Statistical process control programs are becoming commonplace in industry. An entire science has been developed to deal with the problem of defining, analyzing, correcting, and controlling production processes (Ref 1, 2, 3, 4, 5). By providing data on the capabilities and output of a process, statistical methods provide a rational, rather than an emotional, basis for problem solving and decision making. Other benefits of statistical process control have been listed in the introduction to this article.

As a system, the forming process is amenable to system analysis and the techniques of system control. Various statistical techniques, many of which have their origins in quality control practices, can be applied to the forming process. In this article, these statistical techniques are divided into two broad categories: historical tracking and statistical deformation control (process design).

Statistical Analysis of Forming Processes

Stuart Keeler, The Budd Company Technical Center

Historical Tracking

Historical tracking is a long-term process of measuring, recording, and analyzing one or more specific characteristics of a process. This record then becomes the basis upon which the current state of the process can be assessed and the future state of the process predicted. Numerous statistical techniques are applicable to historical tracking (Ref 1, 2, 3, 4, 5); one is the control chart and another is statistical deformation control.

Control Charting

The heart of many SPC systems is the control chart. The control chart is a method of monitoring process output through the measurement of a selected characteristic and the analysis of its performance over time. Because the output from one process is often the input to the next process, the physical location of the measurement can be at either end of the transfer link. For example, the output from a blanking press--the blanks--becomes the input to the next stage, which is the press itself.

A control chart can be a very powerful statistical tool. Information from the control chart can be used to inform the operator when to adjust the process and, perhaps more important, when not to adjust the process. This places the operator in control of the process, based on statistically valid numbers instead of trial and error.

For example, the operator is given a machine capable of producing the required parts and is then given the means to measure the characteristics of output (the finished parts) in real time. Thus, the operator knows the quality of the part coming off the machine on a real time basis. In addition, the operator has control limits for the process. These control limits tell the operator when to adjust the process and when not to adjust the process, which permits the operator to prevent rather than detect defects. Such a system for the control of steel sheet thickness is described in the following example.

Example 1: Constructing a Control Chart for Steel Thickness Measurements.

Uniformity of blank thickness is often stated to be important for high productivity in sheet metal forming operations, although published information on this subject is limited (Ref 6, 7). Once the tooling is set for a specific sheet thickness, adjustments to the tooling cannot be readily made. A control chart can be constructed to statistically monitor variations in the incoming steel.

For each coil of steel received, five blanks are sampled at specific locations along the length of the coil, such as the head, quarter, center, quarter, and tail locations. Examples of such measurements are given below.

The values of $\overline{X}$ (the average thickness) and R (the range of thicknesses) are plotted on the respective graphs. After sufficient measurements are made, the $\overline{\overline{X}}$-value and the upper and lower control limits (UCL and LCL) can be calculated and plotted on the same diagram.

The control chart shown in Fig. 1 indicates that the thickness of the steel being processed is stable. A process is said to be in a state of statistical control if it is operating without special causes of variation (Ref 4). It will exhibit random variation within calculated control limits and will have predictability; that is, measurements taken in the future are expected to be within the same control limits. However, no prediction can be made about where any individual measurement will lie within these control limits.

Fig. 1 Raw data (in millimeters; 1 in. = 25.4 mm) obtained from steel thickness measurements and the resulting $\overline{X}$ -*R* control charts. Upper and lower control limits can be calculated and the mean determined when sufficient data have been collected.

Unfortunately, the control limits shown in Fig. 1 are rather wide and would require frequent tooling adjustments. This means that a normal distribution of thicknesses within the control chart would be expected. However, this expected range is too large for the tooling and would necessitate tooling adjustments to accommodate changes in thickness between the extremes of the range. Therefore, it is necessary to work with the steel supplier to reduce the range of the control limits to an engineering specification window acceptable to the tooling.

Control limits are important in statistical process control because they define the amount of variation in a process due solely to chance causes. If the process is operating within these limits (Fig. 2a), it is considered to be stable. If the process is operating outside these limits (Fig. 2b), it is unstable.

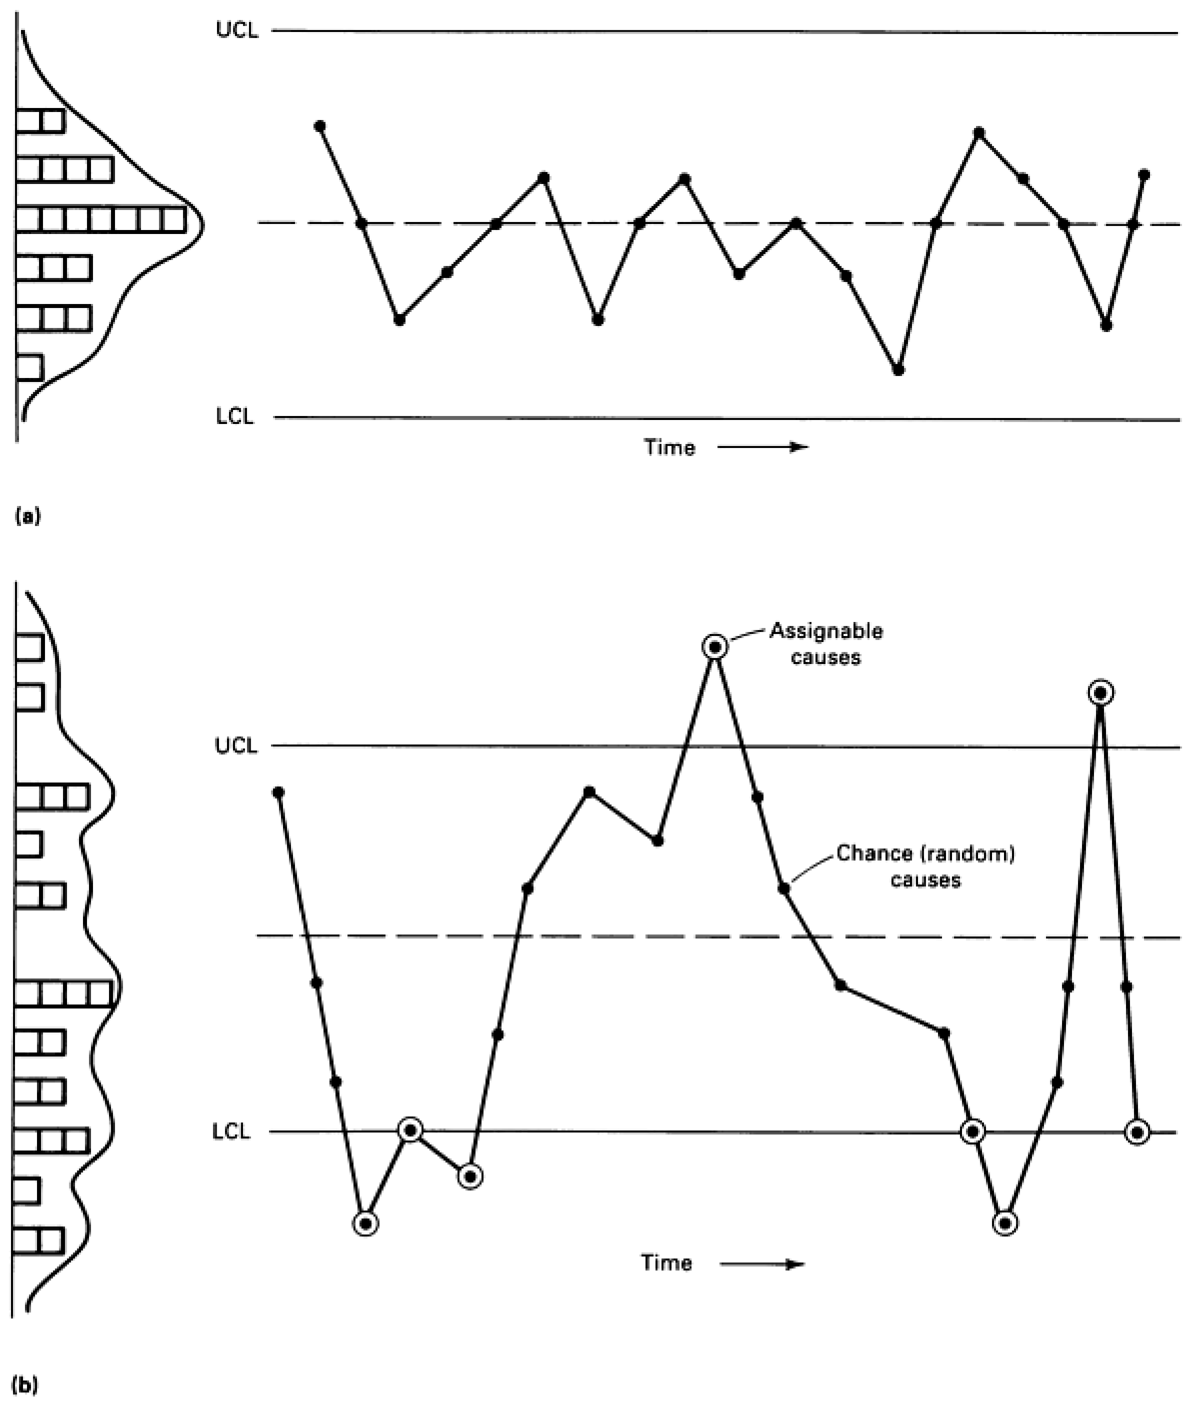

Fig. 2 Distribution curves (histograms; left) and control charts illustrating processes that are in control (within control limits) (a) and out of control (outside of control limits) (b). Variation outside of assigned control limits is always the result of some assignable cause, as shown in (b).

The control chart represents the best that the operator of a given process can do with the process as it exists. If this is unacceptable, then the basic process must be changed. Engineering and management, not the operator, are required to implement these process changes because this may require new equipment, new tools, new processing sequences, additional stages, or even a new part design.

If the process is operating within its control limits (statistical control), then the capability of the system to meet specifications can be assessed. If the system is out of control, then changes to the process must be made to make the process stable before the capabilities can be assessed.

Control charts are most effective when monitored over an extended period of time. Thus, changes in the process can be detected, often before rejects begin to occur. Two general types of changes in the process might be encountered. One is the central sample tendency $\overline{X}$, which is monitored to detect a shift in the location of the distribution (Fig. 3). A location change would imply that the normal distribution remains the same but that the average is displaced. An example in forming might be the angle of a bend. The variation from bend to bend would remain acceptable, but the average angle of all bends would have changed. Some factors that may affect the $\overline{X}$ -value are gradual deterioration of the equipment, worker fatigue, accumulation of waste products (such as excess lubricant or flaked metallic coatings), and environment.

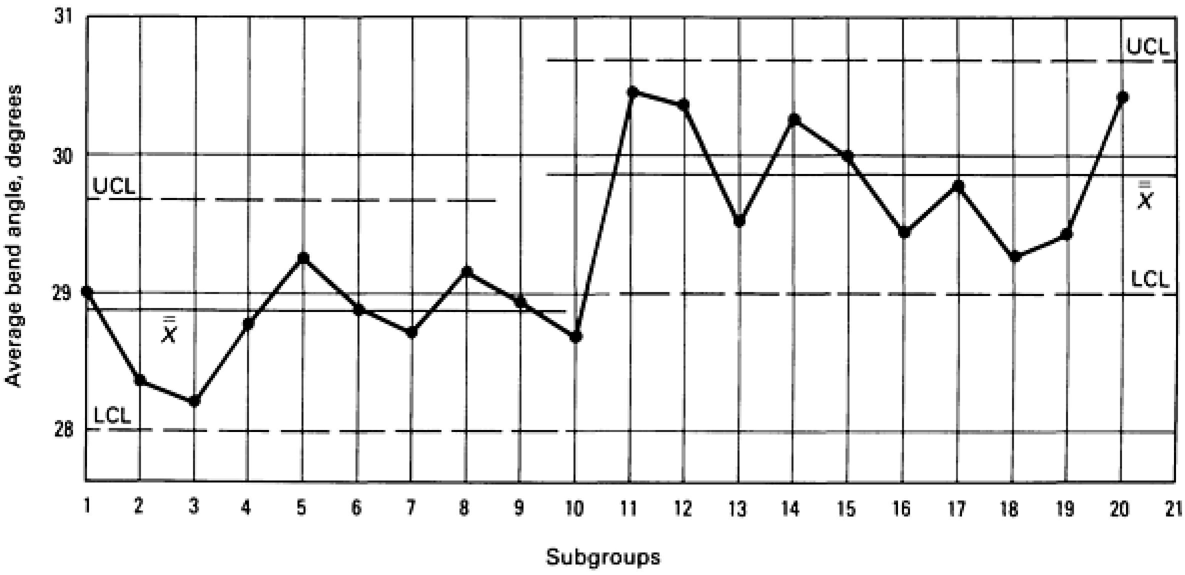

Fig. 3 Shifting of a control chart (upper and lower control limits and mean) due to a change in processing. Values of *R* remain the some. See also Fig. 4.

Another type of process change is a change in the sample range or the variation from one sample to another (Fig. 4). This range change is observed as a change in the width of the normal curve for a given area under the curve. This means increased variability. For the bending example shown in Fig. 3, the average bend angle would remain the same, but large differences would be detected among samples from the same lot or even consecutive samples. Some factors that may affect the *R* chart are changes in operator skill, worker fatigue, change in the mix of components feeding an assembly line, and gradual change in quality of the incoming material.

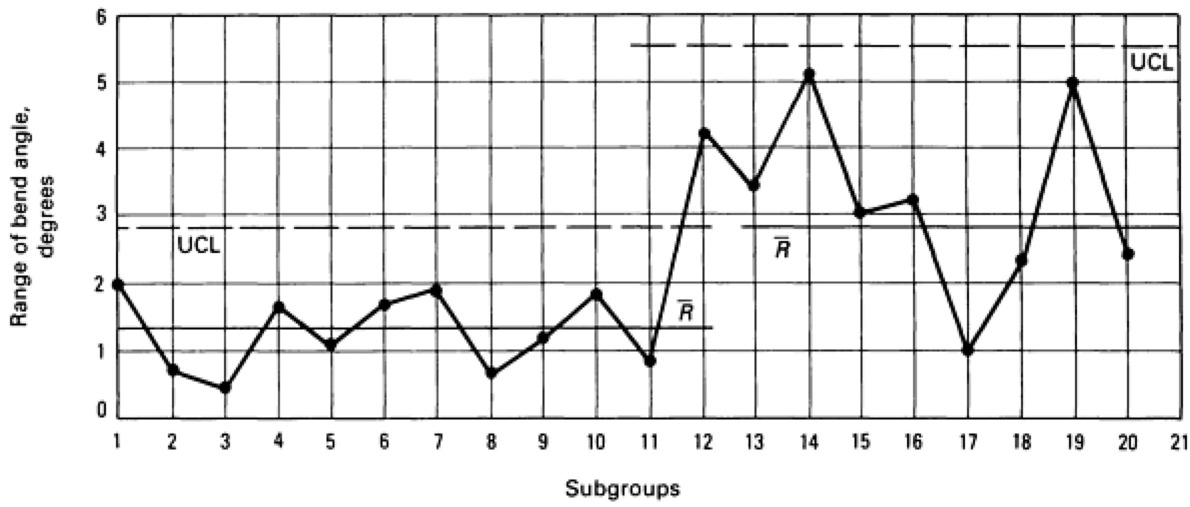

Fig. 4 Increase in the range of values within a subset (increase in *R*). Values of $\overline{X}$ remain the same. See Fig. 3.

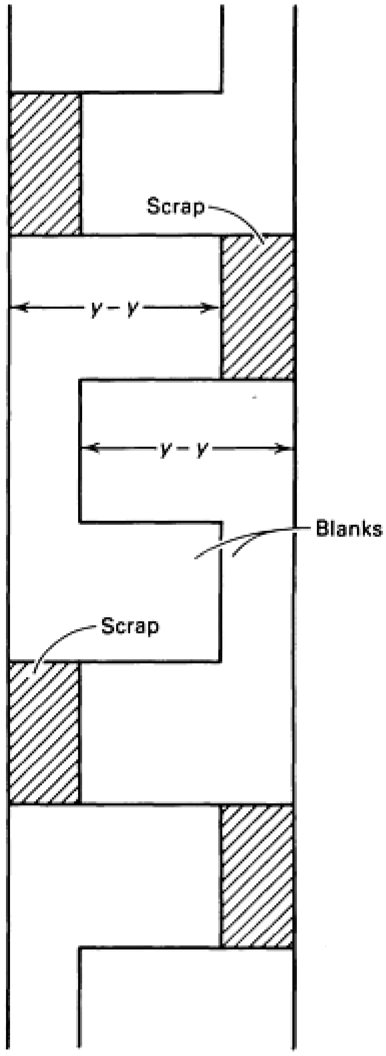
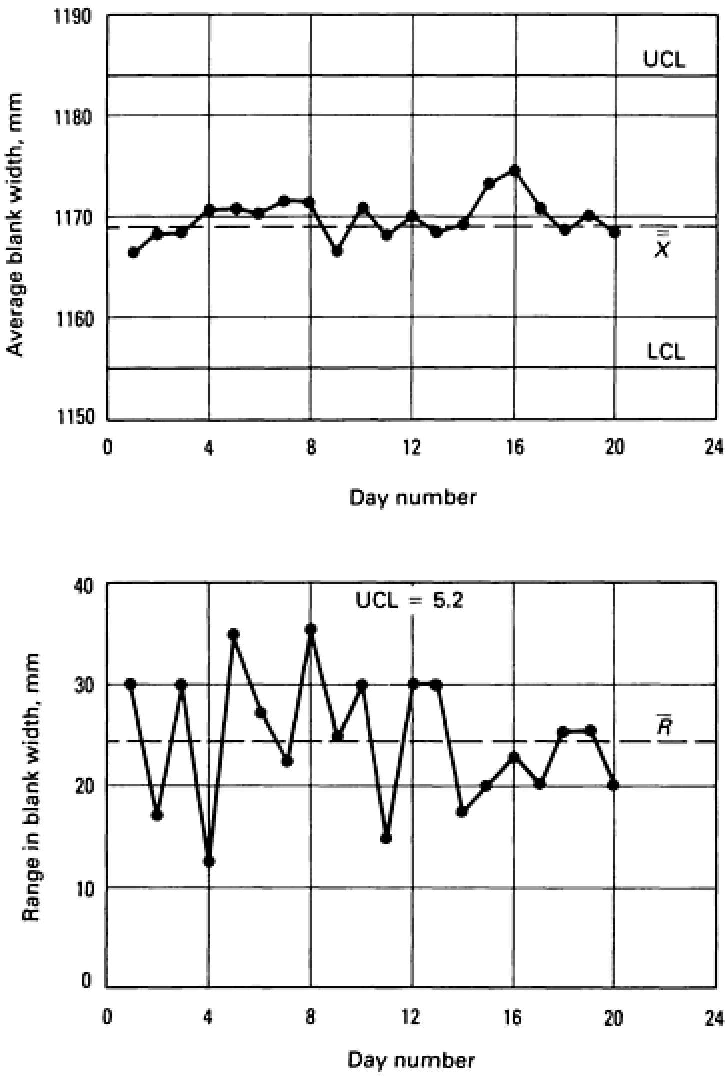
The two key concepts that emerge from control charts are control and capability. The term control defines the stability of the process, which in turn means that the process is predictable. It does not necessarily mean that the process is acceptable with regard to the specification. This is in contrast to the term capable; this term means that the process has the capability to meet specifications.

Example 2: Solving a Problem of Fender Blank Size Variation.

Two fender blanks were generated with each stroke of a blanking punch (Fig. 5a). Measurements of the critical dimension *y*-*y* on each blank showed large variations in *R*-values, but $\overline{X}$ -values were quite constant (Fig. 5b). Further analysis revealed that plots of only the right-side blanks and only the left-side blanks had different characteristics (Fig. 6). These data showed a reduced variation in *R* but a larger variation in the $\overline{X}$ -values. Interestingly, the $\overline{X}$ -values of the right- and left-side blanks changed simultaneously but in opposite directions.



(a)



(b)

Fig. 5 (a) Schematic showing nesting of blanks for an automobile fender. Dimension *y*-*y* was monitored for the SPC study reported in Example 2. (b) $\overline{X}$ -*R* control charts for both right side and left side fender blanks taken as a single population. See also Fig. 6.

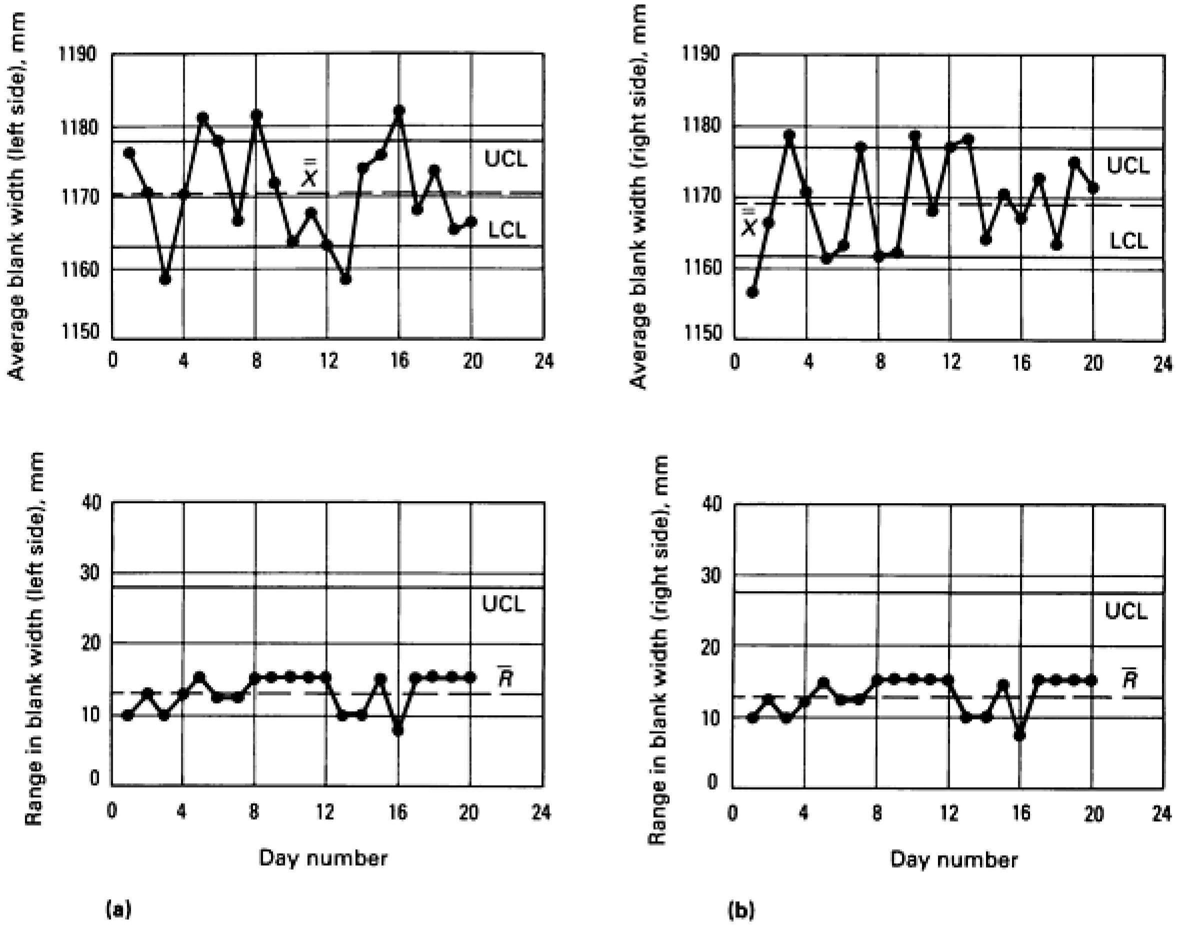


Fig. 6 $\overline{X}$ **-*R* control charts for left-side fender blanks (a) and right-side fender blanks (b) taken as separate populations.**

Further observation of the blanking process revealed frequent tandem adjustment of both the right- and left-side guides in response to changes in the width of the coil of steel. Even if the coil of steel did not change in width, movement of the right and left guides would cause one blank to increase in width while the other blank would decrease in width. This would cause the range to increase equal to twice the amount of the guide shift.

The first process change made was to weld the left-side guide into correct position. This meant that the left-side blank had the correct width regardless of the width of the coil. As a result, all blank width variations were associated with the right-side blank, and these variations could be related to the variations in the width of the coils of steel. These control charts could be given to the steel supplier as a performance review of the as-supplied coil width variations.

Problem Solving Using Control Charts. Control charts are only signals to operators and management of the operating conditions of the process. Personnel must respond to these signals and identify the sources of the variations. Control charts are useful in many problem-solving situations (Ref 4); they can:

- Assist in distinguishing between special and common causes of variation
- Help determine whether unacceptable variations can be improved by the personnel immediately involved in the process (such as tightening a loose tool holder) or whether they are due to the system and can be corrected only by management
- Identify trends in the process average
- Highlight increased process variability

The opportunities are limitless for using control charts as a key SPC tool. Data collection is the easiest aspect of the process. Finding the cause of a problem will often require some difficult detective work, and elimination of the problem may be a major task. For example, recording the scheduled times for a shuttle bus is easy. Determining the real cause of deviation from the schedule may be difficult; periodic high traffic density may be due to maintenance being performed on an adjacent street. To make the shuttle bus immune to delays and to improve trip time consistency would require a major study and perhaps drastic modifications to the traffic control system.

Statistical Deformation Control

Each of the four components of a forming system--material, lubricant, tooling, and press--can be tracked using the SPC techniques described above. Typical measurements could include:

- Material thickness, coil/blank dimensions, and properties
- Lubricant composition, viscosity, and application thickness
- Tooling pressures, surface treatment, and dimensional accuracy
- Press speed, stroke, and ram pressures

Many of these measurements are charted in an attempt to reduce process variability and to improve product quality.

However, the components of forming systems are complex, interactive, and synergistic; reliable models are not available for predicting the output of the forming system based solely on the system inputs. Therefore, monitoring of the final output of the system is required. Dimensional checking of the final product can be easily accomplished, but monitoring forming severity is more difficult.

Numbers representing the percentage of scrap or the percentage of breakage are traditionally recorded to represent the status of the forming system. These numbers are inadequate measures of forming severity. For example, many stamping processes result in high levels of strain but not breakage. Therefore, the current behavior--no breakage--gives no indication that breakage may be imminent; some measure of performance must be sought that permits a broader range of conditions. Once breakage begins, the stamping process is out of control. General global straining ceases as the tear develops and opens; other forming modes become active. In addition, the percentage of breakage averages the forming severity over a large number of stampings instead of determining the forming severity at a preselected location in each individual stamping. For these cases, percentage of breakage does not accurately define the various levels of severity.

One means of evaluating forming severity used in many sheet metal press shops is circle grid analysis and forming limit diagrams; these are described in Ref 8, 9, 10, and 11. The actual amount of deformation that the sheet has experienced is determined from the deformed circles (Fig. 7). The forming limit diagram shows the maximum amount of deformation a stamping can undergo before failure. Forming severity can be defined as the maximum allowable deformation minus the actual deformation. This forms the basis for monitoring and controlling stamping performance.

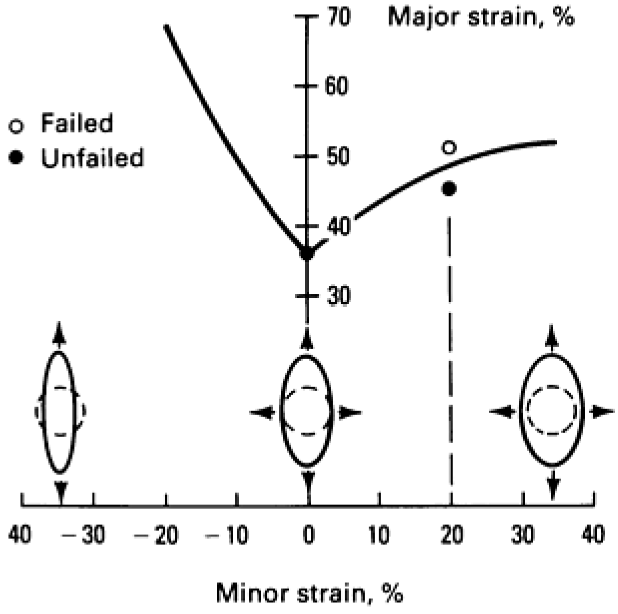

Fig. 7 Forming limit diagram showing strain states where forming is safe (below curve) and where stampings will begin to fail from localized necking during forming (above curve). The strain values are determined from deformed circle grids placed on the blank before forming.

The process of pregridding the blank before deformation and measuring the deformed circles presents logistical problems if it is used for routine analyses of a large number of stampings over an extended period of time. These problems include removing blanks from the material lifts for pregridding, the time required for gridding, careful reapplication of lubrication to duplicate production levels, reinsertion of blanks into the production cycle without stopping production, proper lighting for grid reading, the time required for accurate reading, and disposal of gridded blanks after analysis. Therefore, only one or two stampings are commonly gridded to provide a single analysis (with respect to time) of the severity of the stamping. No information can be deduced about the change of the forming system with time, nor can the single stamping be characterized with respect to the dynamic changes of the system.

Dynamic changes, however, can be analyzed with statistical process control. A critical variable is measured at specified intervals and plotted as a function of time to generate a control chart. From this control chart, using SPC analysis techniques, the current status of the system can be identified relative to its historical performance. The dynamic variability of the system can be defined, and determinations can be made as to whether the system is in control, out of control, or changing.

Statistical deformation control (SDC) combines the best features of circle grid analysis, forming limit diagrams, and statistical process control (Ref 12). The deformation severity of the stamping under investigation becomes the critical variable that is tracked by statistical process control. To simplify the press shop procedures further, the amount of deformation experienced by the stamping is defined by the ratio of final thickness t_f to initial thickness t_0. The thickness ratio is determined from ultrasonic measurements of sheet metal thickness in the most critical zone of the stamping. The ultrasonic measurements are rapid, the blanks do not have to be pregridded, and the stampings are not damaged by a grid and therefore need not be scrapped after the measurement is made.

Like most analytical tools, statistical deformation control does not involve a single, invariant procedure. Several levels of complexity are possible, and each level contributes an increased degree of understanding of the forming system. These levels are:

- *Level 1:* generating a standard control chart
- *Level 2:* assigning a deformation severity value
- *Level 3:* separating material variability from process variability
- *Level 4:* determining sensitivity of the forming system to individual inputs

Again, like most analytical tools, statistical deformation control is flexible and should be applied only at the level necessary to solve the problem. Therefore, routine applications of statistical deformation control to a system that is in control will be at the level of the basic control chart.

All levels of statistical deformation control require a preliminary stamping analysis. Measurement of deformation at the critical location is a key element of statistical deformation control. Therefore, an early circle grid analysis of the stamping in question is required to identify the location, mode, and severity of strain in the most critical zone within the stamping. Repetitive ultrasonic measurement of many stampings over an extended period of time requires a template to be made for the ultrasonic probe; the simplest template is a section of an identical stamping with a hole drilled for the head of the probe.

Template holes are drilled for the most critical location and for an area of the stamping that is undeformed. The latter measurement is required to determine the initial thickness of the stamping in order to generate the final-thickness-to-initial-thickness ratio without the inconvenience of premeasuring the blank thickness. The ability to measure critical and initial metal thicknesses on the formed stamping means that random stampings can be selected for evaluation after production.

SDC Level 1: Control Charting. Standard control-charting procedures are used. A typical application would require the removal of five stampings in sequence at the end of the press line. Measurements of the thickness in the critical zone and an undeformed zone would be made, and the thickness ratio calculated. These five ratio values would then be converted into the traditional $\overline{X}$ -R values and plotted on the control chart. Control chart analysis procedures are used to calculate upper and lower control limits and other SPC data.

The control chart is monitored to determine the viability of the forming system and to initiate corrective actions when such actions are mandated (Ref 4). The importance of these analyses is the predictive capability, which can provide early warning of impending forming process failures. Therefore, statistical deformation control can be used to show an increase in the forming severity for a press line for which breakage is not yet a problem, as in the following example.

Example 3: Tracking a Sheet Metal Forming System by Monitoring Metal Thinning.

An appliance stamping for a range top was selected for study, using sheet metal thinning as a measure of stamping severity. Measurements were conveniently made with an ultrasonic thickness gage, which permitted measured stampings to be returned to the production line without loss of the stampings. Because breakage was not a problem with this stamping, measurements were made only twice a week. The results of the measurements are shown in Fig. 8.

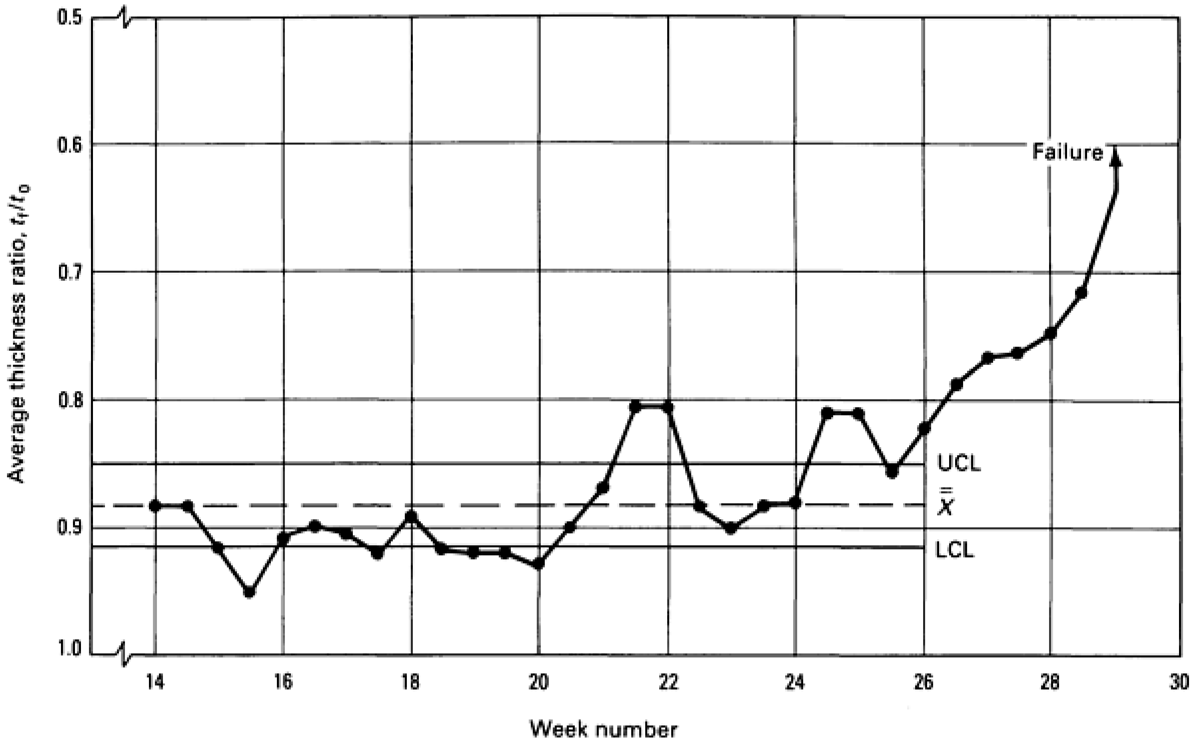

Fig. 8 Control chart of average thickness ratio t_f/t_0 for a stamping. Note the increase in forming severity (reduced thickness ratio) beginning at week 21 and the continuous decrease in thickness ratio beginning at week 25.

The stamping was shown to be out of control. However, because the amount of metal thinning did not cause breakage, the stamping was not on the list of problem stampings. After 6 months of good performance, the amount of metal thinning began to increase. Eventually, excessive production breakage of the stampings began to occur. Because this was a test of the SDC procedure, no attempts were made to determine the cause of the increased thinning or to correct the cause. This would have disrupted the test and would have changed the data base. However, the test did show that the stampings that were not breaking could be statistically tracked over extended periods of time in order to detect changes in severity that would lead to production problems if left uncorrected. The absence of breakage in a forming process does not necessarily indicate that the process is in control.

SDC Level 2: Severity Assignment. A unique feature of statistical deformation control for formability analysis is that each control chart can be subdivided and calibrated according to forming severity for each type of stamping made in the press shop. This severity assignment is independent of whether the process is in or out of control. The severity ranges are assigned based on the thickness forming limit diagram (Ref 12). The following example shows how a process can be in control and producing good stampings and yet have an insufficient safety factor for good long-term reliability.

Example 4: Assigning a Severity Rating for Stampings With Only Sporadic Breakage.

Sporadic breakage was occurring in an automotive stamping. The question was asked whether this breakage was the result of random events not typical of the normal system or whether the system was in fact critical and the breakage was a normal by-product of statistical swings in severity. To determine this, metal-thinning readings were made for several weeks (Fig. 9). The control chart showed that the system was in control.

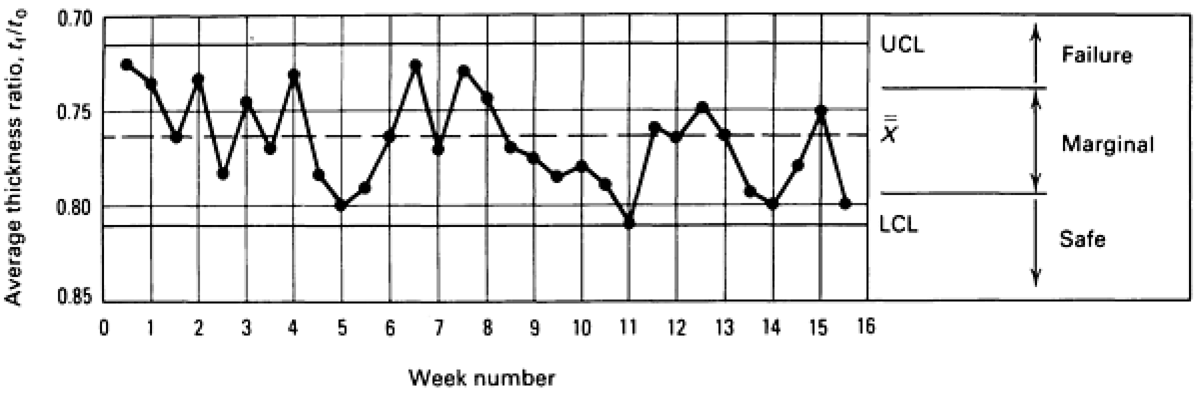

Fig. 9 Severity zones added to average thickness ratio control chart in a Level 2 SDC analysis.

Additional information was gained, however, when deformation severity zones were added to the control chart (Ref 12). The severity zones showed that $\bar{X}$ was in the marginal zone and that some proportion of the control chart fell in the breakage zone. This meant that the sporadic breakage was normal for the system as established and could be expected to continue as long as the process was maintained as currently designed. However, the process was in control and therefore amenable to a process change that would lower the upper control limit from the failure zone into the marginal zone.

Specifications, Control Limits, and Forming Severity. An important point of understanding is the differences among engineering specifications, control limits, and forming severity. For example, a stamping is designed to have a maximum metal thinning of 42% in order to meet in-service performance requirements. The control limits indicate whether the process is in statistical control. The state of being in statistical control means that all special causes of variation have been eliminated and that only common (random) causes remain. Special causes are intermittent sources of variation that are unpredictable or unstable; sometimes called unassignable causes, these variations are signaled by points beyond the control limits. An example of a special cause would be inserting the wrong material into the forming process. On the other hand, common causes of variation are always present and indicate the random variation inherent in the process itself. An example of this would be excess gap in the punch guidance system. Forming severity is the proximity of a given stamping to breakage. This forming limit is independent of future in-service performance requirements or part-by-part variation over time.

Example 5: Comparing Engineering Specifications and Forming Severities to Control Charts.

Engineering specifications, control limits, and forming severity for a control arm are illustrated in Fig. 10. The allowable maximum metal thinning specified by the part print (engineering specification) is rather high. In fact, the engineering specification is in the failure zone of Fig. 10. This means that the stamping would fail before attaining the maximum thinning allowed by the engineering specification. Therefore, the practical thinning limit of the process is established by forming severity rather than engineering specifications.

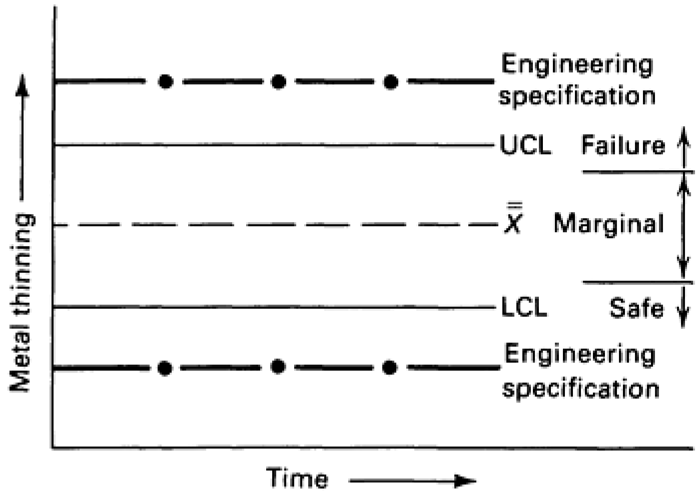

Fig. 10 Schematic control chart showing the differences among engineering specifications, control limits, and severity zones.

The control chart and its attendant control limits reflect the current operating status of the forming process. In Fig. 10, the operating status of the control arm is shown to be in control but with a certain portion of the control chart in the failure zone. This means that some quantity of pieces will break in the forming process. Changes in the forming process, such as modifying the lubricant or reducing the die radii, could narrow the control limits shown in Fig. 10, but would not change the position of the engineering specification or the severity limits. The initial assessment of forming severity and the tracking of the severity through the production life cycle of the stamping--and especially through tooling modifications--are important aspects of statistical deformation control.

SDC Level 3: Material Versus Process Variability. Statistical process control or statistical deformation control can easily identify a forming system that is out of control. Determining the cause of the variability is a more difficult problem. An important first step for most press shops is to separate variability in incoming material from process variability (for example, lubricant, tooling, press, and other in-house variables).

Statistical deformation control provides a method of separating this variability. First, a list of reference material is set aside. This reference material would typically be production material that has average, but consistent, properties. Ideally, this would be verified by evaluating the mechanical properties and surface characteristics of the top and bottom sheets.

Each time a control chart measurement is made with production material, an equal number of identified reference blanks are also formed, and the severity is measured. Two charts of severity versus time are maintained; one for the production material and one for the reference material (Fig. 11). Comparison of Fig. 11(a) and 11(b) indicates whether the system variability is due to the production material or the process.

Time

(b)

Fig. 11 Schematic control charts showing the effects of materials variables (a) and process variables (b). The identical variations in forming severity for both production and reference steel in (b) indicate that the fluctuation in severity is caused by process variables.

In Fig. 11(a), the forming severity of the production steel is varying, while the forming severity of the reference steel is relatively constant. This indicates that the process parameters are producing a stamping of constant severity and that system variability is due to incoming material variability. The reverse is true in Fig. 11(b); the variability of the production material is identical to that of the reference material. This indicates that all variation in forming severity is due to process variables.

For most forming processes, the forming severities of both the production material and the reference material will vary, but will not be identical to each other. This indicates the common situation in which both the material and the process affect the output of the forming system. The variability must then be apportioned between material and process.

SDC Level 4: Input Sensitivity. Once the forming system variability has been identified as being either material or process related, a more detailed analysis can be conducted to minimize this variability. A key control factor is identified and changed to determine the improvement to the system variability (or conversely, system stability). Selection of the factor can be based on experience or experimental techniques, such as the Taguchi method (see the section "Taguchi Experiments" in this article).

There are at least two analysis possibilities. One is to process the new material according to the modified specification--for example, a new metal thickness. This new material parameter is then processed with the reference material and the severity data compared. The key is to run the reference material with the new material in order to isolate material variability from process variability.

A second technique would be to substitute the modified material (alternate parameter) for the reference material. Severity data are then collected for the regular production material and the modified material. The two severity curves can be compared to separate the process variability (Fig. 12) and to permit judgments about the relative performance of the two conditions. If sufficient data points (usually > 25) are collected, complete control chart information can be calculated.

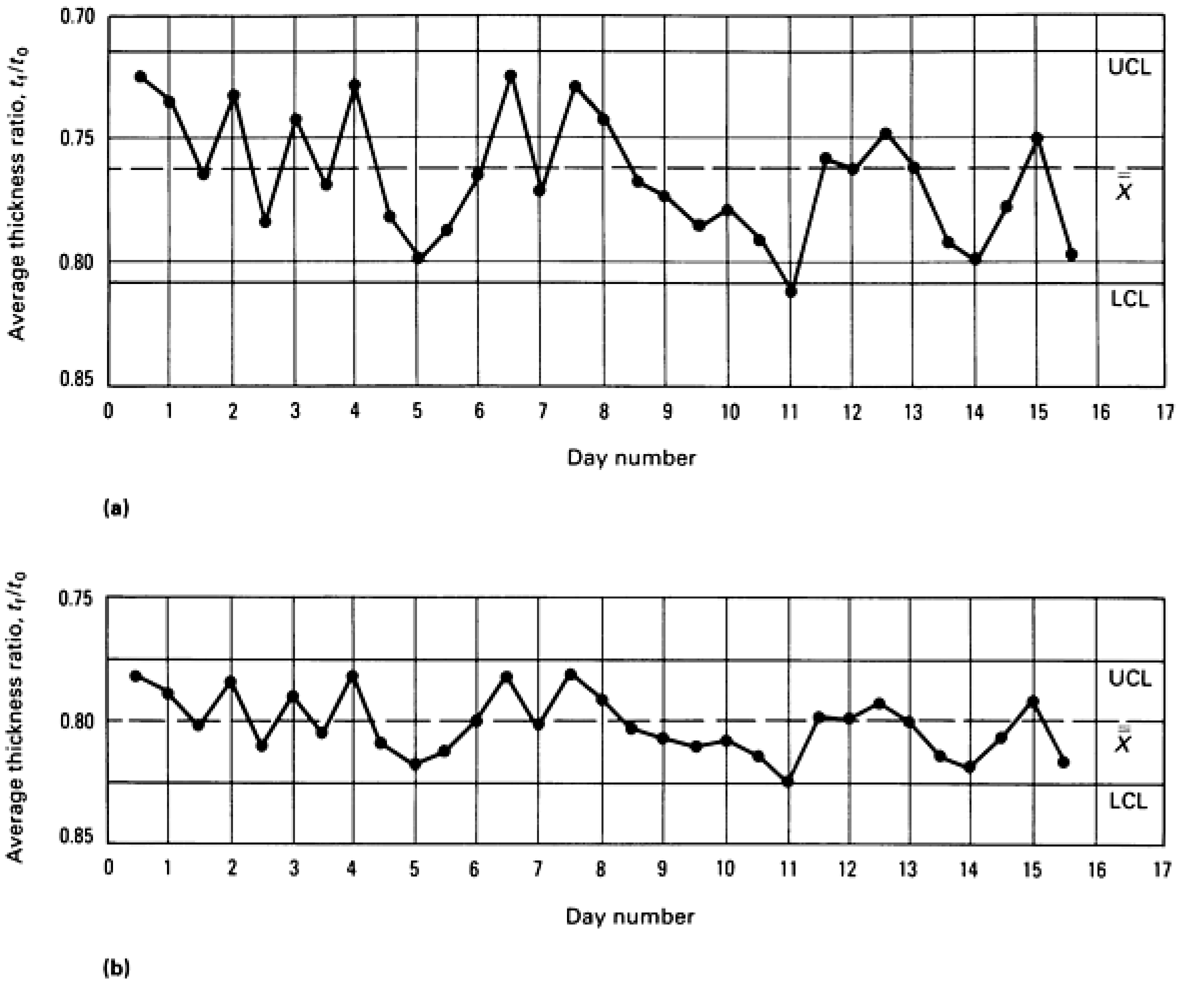

Fig. 12 Control charts showing original spread of process means (a) and second chart showing reduced spread of process means (b) after a change in the process.

The importance of statistical process control and statistical deformation control can be illustrated by describing two alternative methods of process control and analysis, both of which contain major flaws. One common method of process analysis is to produce a large quantity of output (in this case, sheet metal stampings) with condition A (the first level of the parameter under investigation, such as material properties, type of lubricant, press setting, and so on). The next step is to produce a large quantity of output with condition B (the second level of the parameter). The percentage of part breakage is then compared. A major problem exists if breakage is zero for both levels of the parameter under study. Even if the breakage is different for the two conditions, one cannot determine if the difference is due to the change from condition A to condition B, a change in the process itself, or normal statistical variation.

A second method of process analysis is to produce one stamping with condition A and one with condition B. The stampings are compared in some manner, such as degree of tearing or visual quality (Fig. 13). The argument is made that if two sequential stampings are produced, then the process is unchanged. However, statistical information is needed to compare the relative change of the two stampings with the normal expected statistical change between any two consecutive stampings without any intentional system changes.

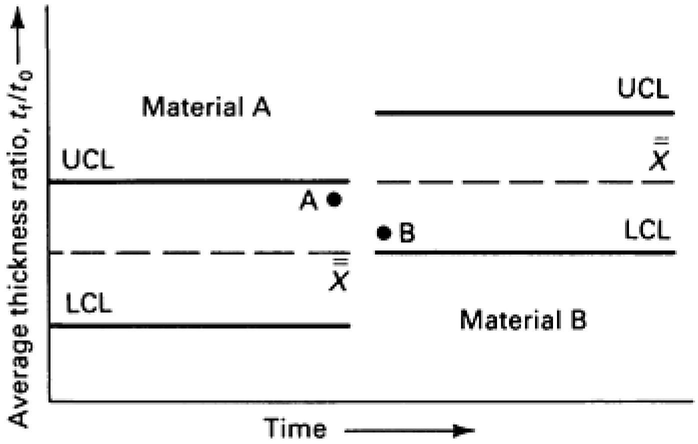

Fig. 13 Measurements from two points in time (values A and B) would suggest that material B has the lower forming severity. However, when full control charts are evaluated, material A has the lower severity.

If the forming system is unstable, then the system must first be stabilized before any changes are made and documented. The following example illustrates how statistical deformation control can be used to identify the sources of processing difficulties.

Example 6: SDC Analysis of an Outer Side Panel of a Truck Body.

The production of a truck outer side panel was marked with sporadic breakage problems. First, high breakage rates were recorded in area A of Fig. 14 for limited but specific lots of steel brought to the press. Mechanical-property evaluation of these high-breakage lots showed certain formability parameters to be equivalent to those measured in other lots of the same steel type that did not break. Second, certain extended runs of the part experienced more incidents of breakage than other runs.

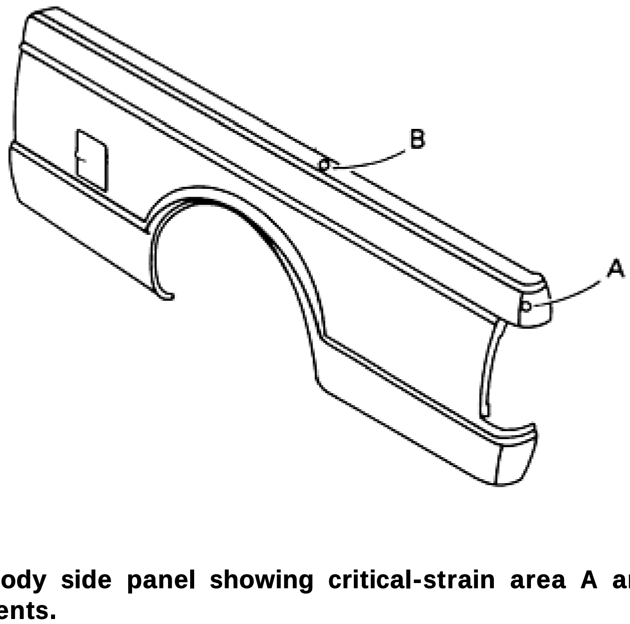

Fig. 14 Illustration of truck body side panel showing critical-strain area A and zero-strain area B used for ultrasonic thickness measurements.

Process Analysis. This problem was selected as a trial for statistical deformation control. The following six steps were utilized.

First, a circle grid analysis of the stamping was performed using a sheet of the current production material that was satisfactorily making the stamping (Ref 8, 9, 12). The most severe strain was located in area A of Fig. 14. Plotting this strain state on the forming limit diagram showed a safety margin of 8 strain%. This means that the stamping had marginal severity but would not be expected to fracture if the current conditions of the forming system were maintained.

Second, the circle grid analysis showed no strain in area B of Fig. 14. This location was designated as the as-received sheet thickness for purposes of the ultrasonic thickness measurements. This location was ideally suited to thickness measurement because it was at the same relative edge-center-edge location in the coil as the most severe strain location.

Third, a template was prepared for the stamping by cutting a section of another stamping to encompass the two locations. A hole was drilled at each location to accommodate the head of the ultrasonic probe.

Fourth, one lot of the production steel that was successfully making the stamping was set alongside the press as a reference lot. Blank edges were marked with yellow paint to identify at the end of the line all stampings made from this reference lot.

Fifth, at the halfway point of each lot of production steel brought to the press, five of the reference blanks were formed. Stampings from these blanks, plus the next five production stampings, were removed from the end of the production line for evaluation. Thickness ratio t_f/t_0 was determined for each stamping. The $\overline{X}$ and R values were calculated for both the production steel and the reference steel.

Sixth, concurrent plots of the $\overline{X}$ and R values for the production and the reference steel lots were maintained. Sections of the $\overline{X}$ plot are shown in Fig. 15. The mean, the upper control limit, and the lower control limit are not shown, because the solution to the problem was achieved before sufficient data points were collected for these statistical calculations.

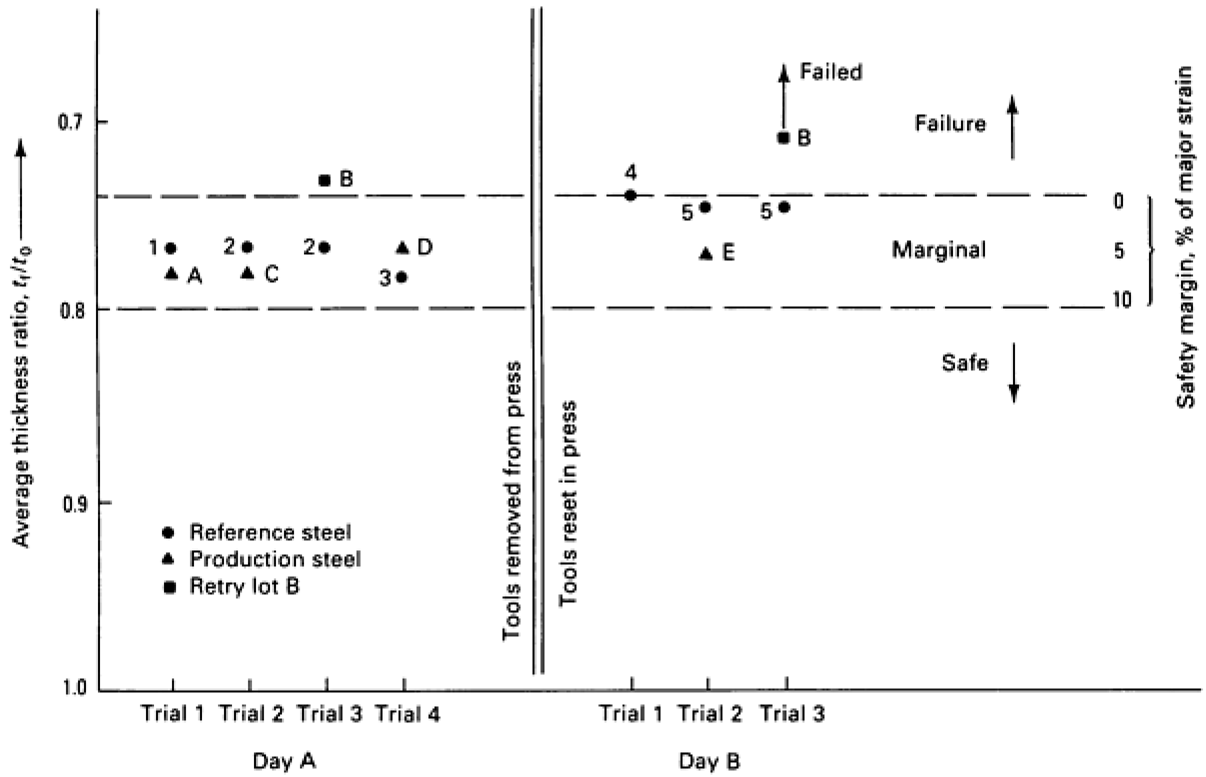

Fig. 15 Data for two days of measurements made on the truck body side panel shown in Fig. 14. See text for details.

Solution. The left-hand side of Fig. 15 verifies the initial circle grid evaluation that the stamping has some safety margin but that the safety margin is insufficient; the value of the thickness ratio is located in the bottom half of the marginal zone. In this case, it is possible to evaluate the severity of each reading as it is made; the quantity of data points needed to create a control chart is not required in order to determine the forming severity of each stamping.

Both the production steel and the reference steel appear to be maintaining not only a constant but also an equal forming severity. Neither the production steel nor the forming process provides indications of impending breakage.

One lot of steel that was previously rejected for high breakage rates (retry lot B, Fig. 15) was retried; a marked increase in forming severity to the failure zone was noted. The formability of sheet steel is an interaction of substrate properties and the lubricity of the steel/lubricant combination. However, this lot of steel had forming properties equal to or better than the production and reference steels noted in Fig. 15. Therefore, the lubricity of the steel surface was suspected; the steel was coated on the punch side of the sheet with a corrosion-resistant paint. To test the influence of the painted surface, several blanks were turned over so that the bare side of the sheet contacted the punch. These sheets were successfully formed into stampings without breakage. Although unacceptable for production in this reversed condition, these stampings verified that the substrate had sufficient formability to produce the stamping without breakage when the interface friction was correct.

It was recommended that the painted (punch) side of the blanks be sprayed with lubricant if breakage was encountered with a specific lot of steel. If breakage persisted with the additional lubricant, the lot was to be rejected for laboratory analysis of the substrate properties.

The right-hand side of Fig. 15 illustrates another problem. When the tooling was reset in the press for another run, extensive breakage was encountered with many of the lots of steel brought to the press. An SDC analysis of the stamping showed that the severity of the stamping for the reference steel had increased to zero safety margin, which meant that the tooling was not performing identically to the previous run. This indicated a different setting in the press or modifications made to the tooling during the period the tool was out of the press. Discussion with the tool and die staff revealed that the draw beads and binder surfaces of the tooling were reworked in an attempt to reduce low spots in the stamping. This reduced the flow of metal from the binder areas and increased the stretch component required over the punch, thus increasing the stamping severity. The increased severity was verified when samples of the previous problem lot B were inserted in the tooling. Long splits were encountered compared to the previously encountered slight necking condition. The recommended solution was to encourage additional metal flow from the binder area through reduced binder pressure until the reworked draw beads became reduced in effectiveness through normal wear.

Production steel E had a slightly increased severity as compared to production steels A, C, and D. However, production steel E had a lower severity than the reference steel; production steels A, B, and D had a severity comparable to that of the reference steel. Using the reference steel as a common base for comparing various production runs, steel E actually had better formability than steels A, B, D, and the reference steel for the specific stamping under investigation.

Continued collection and monitoring of data during the entire production run was recommended. This would require a number of reference lots. However, the SDC procedure allows for this transition by the interleaf forming (alternate blanks) of both reference steels to calibrate the new reference lot relative to the previous reference lot.

Statistical Analysis of Forming Processes

Stuart Keeler, The Budd Company Technical Center

Experimental Design

Forming operations span an extensive production life cycle, including design, prototyping, engineering changes, tryout, and production. During this entire cycle, a pervasive question is whether the process can be modified. Process optimization is the usual motivation for this modification. This optimization may mean lower cost, faster production rates, fewer rejects, better quality, and so on.

Some process simulation techniques may be available for determining the steps needed to optimize the process and the effectiveness of the various options. However, most of these simulation techniques are mathematically based and only approximate the system under evaluation (Ref 13, 14, 15). Therefore, most optimization studies are conducted on the system itself by selectively changing the system variables and measuring the effects of the changes.

These system studies are most effectively conducted with experimental design. Experimental designs are used to increase the efficiency of information acquisition.

Several forms of experimental design are available, and each has advantages and disadvantages. The types of experiments discussed in this article are single-variable studies, multi-variable studies, and Taguchi experiments. More information on the design and execution of such experiments is available in the article "Process Modeling and Simulation for Sheet Forming" in this Volume.

Single-Variable Studies

The most common experiment conducted with forming operations is the single-variable study. Although many variables are identified as affecting the process, only one of these variables is changed at a time.

Single-variable studies are widely used because they are easy to conduct and require a minimum number of experiments. First, one variable is changed, and then another, and so on, until all of the variables are at the second level. One such experimental design table is shown in Fig. 16. Here the (+) indicates the high level of the variable, and (-) indicates the low level of the variable. The following example outlines the procedure used in a typical single-variable experiment.

	Process variables						
Experiment number	Steel	Blank size	Lubricant	Die temperature	Blank position	Blankholder pressure	Ram speed
1	+A	+B	+C	+D	+E	+F	+G
2	−A	+B	+C	+D	+E	+F	+G
3	+A	−B	+C	+D	+E	+F	+G
4	+A	+B	−C	+D	+E	+F	+G
5	+A	+B	+C	−D	+E	+F	+G
6	+A	+B	+C	+D	−E	+F	+G
7	+A	+B	+C	+D	+E	−F	+G
8	+A	+B	+C	+D	+E	+F	−G
Level of variables (− / +)	A versus B	Large versus small	Yes versus no	Hot versus cold	Normal versus offset	High versus low	High versus low

Fig. 16 Layout of an experimental design for a single-variable investigation.

Example 7: Finding Improved Process Settings for the Production of an Automobile Inner Door.

High breakage rates were observed during the die tryout of an automotive inner door. A quality group met and identified seven key factors (controlling variables) that affect this particular forming process.

Two steels and a lubricant were obtained. First, the stamping was made with steel A; all other variables were kept at their existing conditions. The severity of the process was determined using the thickness ratio analysis described above. The stamping was then made using steel B.

Next followed the additional six changes indicated in Fig. 16. The thickness ratio was determined for each change. After all eight experiments were conducted, the level of each variable showing the greatest thickness ratio (least amount of metal thinning) was selected as the new standard operating procedure.

Problems With Single-Variable Studies. In this study, one variable was changed while all other variables were kept constant. The problem is that the conclusions obtained from this experiment are valid only if all other variables are kept identical to the experimental value. This type of experiment ignores synergistic effects among process variables. In the experiment described in Example 7, the effects of different materials (steels A and B) can be measured only if variable C (lubricant) is maintained at its high level (with lubricant). If variable C is at its low level (no lubricant), misleading results may be obtained. In this case, one cannot deduce what variable A does for all levels of the other variables. Therefore, some type of factorial experiment (orthogonal array) is required.

Multi-Variable Studies

Multi-variable studies are usually conducted using some form of an orthogonal array. The experimental layouts using these orthogonal arrays yield experimental results such that the effects of varying a given parameter can be separated from other effects. Figure 17 shows a complete orthogonal array, sometimes called a full factorial experiment, for seven variables. These orthogonal arrays have also been termed square games (Ref 16).

				A_1				A_2			
				B_1		B_2		B_1		B_2	
				C_1	C_2	C_1	C_2	C_1	C_2	C_1	C_2
D_1	E_1	F_1	G_1								
			G_2								
		F_2	G_1								
			G_2								
	E_2	F_1	G_1								
			G_2								
		F_2	G_1								
			G_2								
D_2	E_1	F_1	G_1								
			G_2								
		F_2	G_1								
			G_2								
	E_2	F_1	G_1								
			G_2								
		F_2	G_1								
			G_2								

Fig. 17 Layout of a full factorial (multi-variable) experimental design for a group of seven variables.

The term orthogonal means balanced, separable, or not mixed, and this indicates that each variable is evaluated equally for all other conditions. Therefore, for each of the two levels of any variable in the array in Fig. 17, there are 64 combinations of the other variables. For example, for level A_1 in Fig. 17, there are 64 possible combinations of variables B, C, D, E, F, and G. This also holds for level A_2. Therefore, any effect of level A_1 versus level A_2 is determined in the presence of both the high and low levels of all the other variables.

When the quantity of parameters is increased in these factorial experiments, the number of experiments required increases so rapidly that it may not be feasible to implement the experimental design. The full factorial experiment detailed above involves 128 experiments. Increasing the number of variables by 1 doubles the number of experiments required to 256.

The full factorial experiment provides the effect of all the single-variable effects plus all the interactions. If some of the interactions can be ignored or deemed unimportant, then the experiment can be redesigned as a partial factorial. A partial factorial has a reduced number of required experiments. The procedure used in one full factorial analysis is outlined in the following example.

Example 8: A Full Factorial Experiment for Finding Improved Process Settings for Stamping an Automobile Inner Door.

The same quality group that conducted the experiment described in Example 7 realized that the synergistic effects were not being evaluated with a single-variable experiment. The group decided to design a full factorial experiment in which all interactions would be active in the study and all interactions could be calculated from the data obtained.

The full orthogonal array shown in Fig. 17 was used. The same variable assignments used in Example 7 (see Fig. 16) were repeated in this study. Again, ultrasonic measurements of sheet thickness were used to determine the thinnest area (maximum metal thinning) for calculation of stamping severity. Analysis of the results showed that some of the interactions were very important and had to be considered in selecting the best operating levels of each parameter.

Taguchi Experiments

Conventional experimental design techniques were primarily developed for use in scientific research in order to determine cause-effect relationships (Ref 16). In science, there is generally only one law to explain a natural phenomenon; therefore, the primary experimental efforts are aimed at finding the law that explains the relationships being studied.

In technological fields, however, there are numerous ways to obtain a given product design objective. In forming a sheet metal stamping, there are various steel characteristics, die designs, die steels and surface treatments, lubricants, forming sequences, and other variables to be considered. Different combinations can be used to produce the same end design of stamping. A desirable goal is to find the combination that provides the most stable and reliable performance at the lowest manufacturing cost. This is the goal of the Taguchi experiments--to develop the most robust process possible (that is, the process that is least sensitive to the causes of variation).

In many cases, knowing the cause of a problem is insufficient for solving the problem. Removal of the cause of the problem may be too costly or even impossible. The Taguchi strategy then becomes one of finding countermeasures--not to eliminate the cause but to reduce the influence of the cause on the end product. Efforts are aimed at making the final product insensitive to all process variables. Taguchi techniques are oriented more toward cost effectiveness and marketing than are conventional experimental design techniques (Ref 16). This difference affects the nature of the parameters to be cited, the way in which the experiments are laid out, and the way in which the data are analyzed. In a sense, the Taguchi method of conducting experiments is formalized to such an extent that only minimal exchange of information is required among experimenters trained in this technique in order to achieve complete understanding of the experimental parameters, the experiments, the analysis of the data, and the results/conclusions.

Differences between the Taguchi approach to experimental design and the conventional approach are philosophical and methodological (Ref 16). Philosophically, the Taguchi approach is technological rather than theoretical, inductive rather than deductive, an engineering tool rather than scientific analysis. Taguchi emphasizes productivity enhancement and cost effectiveness with a rapid, formalized procedure--not statistical rigor. With regard to its methodology, the Taguchi approach emphasizes the application of orthogonal arrays, signal-to-noise ratios (in Taguchi analysis, the variables that affect a process are classified as signal, control, or noise factors), and newly developed analytical techniques (Ref 16).

One primary advantage of the special orthogonal arrays used by Taguchi is the capacity and flexibility of assigning numerous variables with a small number of experiments. An even more important advantage of the array is the reproducibility of the conclusions across many different process conditions. One criticism is that the Taguchi array is nothing more than a fractional factorial, which has long existed in conventional experimental design techniques. However, the Taguchi technique is one of philosophy and content, as explained above. The application is more versatile and sophisticated.

Further explanation of the Taguchi method or the experimentation/analysis procedures is beyond the scope of this article. Additional information is available in Ref 16 or from the American Supplier Institute (Dearborn, MI). The following example outlines the approach used in one Taguchi analysis.

Example 9: A Taguchi Design of Experiments for Finding Improved Process Settings for Stamping an Automobile Inner Door.

The same seven variables used in Examples 7 and 8 are used in this experiment. Selection of the proper experimental variables is extremely important in Taguchi experiments. The variables should be primary variables with little interaction. In studying stamping severity, for example, blankholder pressure (variable F) is not set by the tons of force shown on a load indicator, because the measured tons are highly interactive with all of the other variables of the system, such as blank thickness, metal strength, die temperature, and shims used. Instead, the blankholder pressure variable is controlled by the position of the nut (or turns of the screw) on the outer ram relative to the zero load reference position. The extra time spent identifying and selecting the important process variables is the key to the success of the Taguchi experiment.

Figure 18(a) shows the layout of the Taguchi experiment for the seven variables detailed in Example 7 (Fig. 16). The array is a standard array for up to seven controlling variables or factors. The eight experiments required for a full factorial analysis are shown in Fig. 18(b).

Factor	A	B	C	D	E	F	G	Results
No.	1	2	3	4	5	6	7	
1	1	1	1	1	1	1	1	y_1
2	1	1	1	2	2	2	2	y_2
3	1	2	2	1	1	2	2	y_3
4	1	2	2	2	2	1	1	y_4
5	2	1	2	1	2	1	2	y_5
6	2	1	2	2	1	2	1	y_6
7	2	2	1	1	2	2	1	y_7
8	2	2	1	2	1	1	2	y_8

(b)

Fig. 18 Layout of the Taguchi experimental design for seven variables.

There are eight rows representing eight experiments, numbered 1 through 8. The elements of the seven columns consist of 1s and 2s. There are four 1s and four 2s in every column. In any pair of columns, there are four possible 1, 2 combinations; namely 11, 12, 21, and 22. Because each of these four combinations occurs at an equal number of times in a given pair of columns, the two columns are balanced or orthogonal. Figure 18 shows that all column combinations have an equal number of 11, 12, 21, and 22 combinations; therefore, all interactions are within the experimental design. After the eight experiments are completed, the data are analyzed according to a prescribed procedure in order to determine the level of each variable that contributes to the most robust (most insensitive process) combination of processing variables.

- A
- **air bend die**
  - Angle-forming dies in which the metal is formed without striking the bottom of the die. Metal contact is made at only three points in the cross section: the nose of the male die and the two edges of a V-shaped die opening.
- **air-lift hammer**
  - A type of gravity-drop hammer in which the ram is raised for each stroke by an air cylinder. Because length of stroke can be controlled, ram velocity and therefore the energy delivered to the workpiece can be varied. See also drop hammer and gravity hammer .
- **angle of bite**
  - In the rolling of metals, the location where all of the force is transmitted through the rolls; the maximum attainable angle between the roll radius at the first contact and the line of roll centers. Operating angles less than the angle of bite are termed contact angles or rolling angles.
- **angularity**
  - The conformity to, or deviation from, specified angular dimensions in the cross section of a shape or bar.
- **anvil**
  - A large, heavy metal block that supports the frame structure and holds the stationary die of a forging hammer. Also, the metal block on which blacksmith forgings are made.
- **anvil cap**
  - Same as sow block .
- **automatic press**
  - A press with built-in electrical and pneumatic control in which the work is fed mechanically through the press in synchronism with the press action.
- **automatic press stop**
  - A machine-generated signal for stopping the action of a press, usually after a complete cycle, by disengaging the clutch mechanism and engaging the brake mechanism.
- **axial rolls**
  - In ring rolling , vertically displaceable, tapered rolls mounted in a horizontally displaceable frame opposite to, but on the same centerline as, the main roll and rolling mandrel. The axial rolls control ring height during rolling.
- B
- **backward extrusion**
  - Same as indirect extrusion . See extrusion .
- **bar**
  - (1) A section hot rolled from a billet to a form, such as round, hexagonal, octagonal, square, or rectangular, with sharp or rounded corners or edges and a cross-sectional area of less than 105 cm^2 (16 $in.^2$). (2) A solid section that is long in relationship to its cross-sectional dimensions, having a completely symmetrical cross section and a width or greatest distance between parallel faces of 9.5 mm ($\frac{3}{8}$ in.) or more.
- **barreling**
  - Convexity of the surfaces of cylindrical or conical bodies, often produced unintentionally during upsetting or as a natural consequence during compression testing. See also compression test .
- **bead**
  - A narrow ridge in a sheet metal workpiece or part, commonly formed for reinforcement.
- **beaded flange**
  - A flange reinforced by a low ridge, used mostly around a hole.
- **bed**
  - (1) Stationary platen of a press to which the lower die assembly is attached. (2) Stationary part of the shear frame that supports the material being sheared and the fixed blade.
- **bend or twist (defect)**
  - Distortion similar to warpage generally caused during forging or trimming operations. When the distortion is along the length of the part, it is termed bend; when across the width, it is termed twist. When bend or twist exceeds tolerances, it is considered a defect. Corrective action consists of hand straightening, machine straightening, or cold restriking.

- **bend angle**
  - The angle through which a bending operation is performed, that is, the supplementary angle to that formed by the two bend tangent lines or planes.
- **bending**
  - The straining of material, usually flat sheet or strip metal, by moving it around a straight axis lying in the neutral plane. Metal flow takes place within the plastic range of the metal, so that the bent part retains a permanent set after removal of the applied stress. The cross section of the bend inward from the neutral plane is in compression; the rest of the bend is in tension. See also bending stress .
- **bending brake or press brake**
  - A form of open-frame single-action press that is comparatively wide between the housings, with a bed designed for holding long, narrow forming edges or dies. Used for bending and forming strip, plate, and sheet (into boxes, panels, roof decks, and so on).
- **bending dies**
  - Dies used in presses for bending sheet metal or wire parts into various shapes. The work is done by the punch pushing the stock into cavities or depressions of similar shape in the die or by auxiliary attachments operated by the descending punch.
- **bending rolls**
  - Various types machinery equipped with two or more rolls to form curved sheet and sections.
- **bending stress**
  - A stress involving tensile and compressive forces, which are not uniformly distributed. Its maximum value depends on the amount of flexure that a given application can accommodate. Resistance to bending can be termed stiffness.
- **bend radius**
  - The inside radius of a bent section.
- **billet**
  - (1) A semifinished section that is hot rolled from a metal ingot , with a rectangular cross section usually ranging from 105 to 230 cm^2 (16 to 36 $in.^2$), the width being less than twice the thickness. Where the cross section exceeds 230 cm^2 (36 $in.^2$), the term bloom is properly but not universally used. Sizes smaller than 105 cm^2 (16 $in.^2$) are usually termed bars. (2) A solid semifinished round or square product that has been hot worked by forging, rolling, or extrusion. See also bar .
- **blank**
  - (1) In forming, a piece of sheet material, produced in cutting dies, that is usually subjected to further press operations. (2) A piece of stock from which a forging is made; often called a slug or multiple .
- **blankholder**
  - The part of a drawing or forming die that restrains the movement of the workpiece to avoid wrinkling or tearing of the metal.
- **blanking**
  - The operation of punching, cutting, or shearing a piece out of stock to a predetermined shape.
- **block**
  - A preliminary forging operation that roughly distributes metal preparatory for finish .
- **block and finish**
  - The forging operation in which a part to be forged is blocked and finished in one heat through the use of tooling having both a block impression and a finish impression in the same die block.
- **block, first, second, and finish**
  - The forging operation in which a part to be forged is passed in progressive order through three tools mounted in one forging machine; only one heat is involved for all three operations.
- **blocker dies**
  - Dies having generous contours, large radii, draft angles of 7° or more, and liberal finish allowances. See also finish allowance .
- **blocker-type forging**
  - A forging that approximates the general shape of the final part with relatively generous finish allowance and radii. Such forgings are sometimes specified to reduce die costs where only a small number of forgings are desired and the cost of machining each part to its final shape is not excessive.
- **blocking**

    - A forging operation often used to impart an intermediate shape to a forging, preparatory to forging of the final shape in the finishing impression of the dies. Blocking can ensure proper working of the material and can increase die life.
- **blocking impression**
    - The impression that gives a forging its approximate shape.
- **bloom**
    - A semifinished hot-rolled product, rectangular in cross section, produced on a blooming mill. See also billet . For steel, the width of a bloom is not more than twice the thickness, and the cross-sectional area is usually not less than about 230 cm^2 (36 $in.^2$). Steel blooms are sometimes made by forging.
- **blooming mill**
    - A primary rolling mill used to make blooms.
- **board hammer**
    - A type of forging hammer in which the upper die and ram are attached to "boards" that are raised to the striking position by power-driven rollers and let fall by gravity. See also drop hammer .
- **bolster plate**
    - A plate to which dies can be fastened; the assembly is secured to the top surface of a press bed. In press forging, such a plate may also be attached to the ram.
- **boss**
    - A relatively short, often cylindrical protrusion or projection on the surface of a forging.
- **bottom draft**
    - Slope or taper in the bottom of a forge depression that tends to assist metal flow toward the sides of depressed areas.
- **bottoming bending**
    - Press-brake bending process in which the upper die (punch) enters the lower die and coins or sets the material to eliminate springback .
- **bow**
    - The tendency of material to curl downward during shearing, particularly when shearing long narrow strips.
- **breakdown**
    - (1) An initial rolling or drawing operation, or a series of such operations, for reducing an ingot or extruded shape to desired size before the finish reduction. (2) A preliminary press-forging operation.
- **buckling**
    - A bulge, bend, kink, or other wavy condition of the workpiece caused by compressive stresses. See also compressive stress .
- **bulging**
    - The process of increasing the diameter of a cylindrical shell (usually to a spherical shape) or of expanding the outer walls of any shell or box shape whose walls were previously straight.
- **bulk forming**
    - Forming processes, such as extrusion, forging, rolling, and drawing, in which the input material is in billet, rod, or slab form and a considerable increase in surface-to-volume ratio in the formed part occurs under the action of largely compressive loading. Compare with sheet forming .
- **bull block**
    - A machine with a power-driven revolving drum for cold drawing wire through a drawing die as the wire winds around the drum.
- **bulldozer**
    - Slow-acting horizontal mechanical press with a large bed used for bending and straightening. The work is done between dies and can be performed hot or cold. The machine is closely allied to a forging machine.
- **burr**
    - A thin ridge or roughness left on forgings or sheet metal blanks by cutting operations such as slitting, shearing, trimming, blanking, or sawing.
- **buster**
    - A pair of shaped dies used to combine preliminary forging operations, such as edging and blocking, or to loosen scale.
- **C**
- **camber**

- The tendency of material being sheared from sheet to bend away from the sheet in the same plane.
- **cam press**
  - A mechanical press in which one or more of the slides are operated by cams; usually a double-action press in which the blankholder slide is operated by cams through which the dwell is obtained.
- **canning**
  - (1) A dished distortion in a flat or nearly flat sheet metal surface, sometimes referred to as oil canning. (2) Enclosing a highly reactive metal within a relatively inert material for the purpose of hot working without undue oxidation of the active metal.
- **chamfer**
  - (1) A beveled surface to eliminate an otherwise sharp corner. (2) A relieved angular cutting edge at a tooth corner.
- **check**
  - (1) A crack in a die impression corner, generally due to forging strains or pressure, localized at some relatively sharp corner. Die blocks too hard for the depth of the die impression have a tendency to check or develop cracks in impression corners. (2) One of a series of small cracks resulting from thermal fatigue of hot forging dies.
- **chord modulus**
  - The slope of the chord drawn between any two specific points on a stress-strain curve. See also modulus of elasticity .
- **circle grid**
  - A regular pattern of circles, often 2.5 mm (0.1 in.) in diameter, marked on a sheet metal blank.
- **circle-grid analysis**
  - The analysis of deformed circles to determine the severity with which a sheet metal blank has been deformed.
- **close-tolerance forging**
  - A forging held to unusually close dimensional tolerances so that little or no machining is required after forging. See also precision forging .
- **closed-die forging**
  - The shaping of hot metal completely within the walls or cavities of two dies that come together to enclose the workpiece on all sides. The impression for the forging can be entirely in either die or divided between the top and bottom dies. Impression-die forging, often used interchangeably with the term closed-die forging, refers to a closed-die operation in which the dies contain a provision for controlling the flow of excess material, or flash , that is generated. By contrast, in flashless forging, the material is deformed in a cavity that allows little or no escape of excess material.
- **closed dies**
  - Forging or forming impression dies designed to restrict the flow of metal to the cavity within the die set, as opposed to open dies, in which there is little or no restriction to lateral flow.
- **closed pass**
  - A pass of metal through rolls where the bottom roll has a groove deeper than the bar being rolled and the top roll has a collar fitting into the groove, thus producing the desired shape free from flash or fin .
- **cluster mill**
  - A rolling mill in which each of two small-diameter work rolls is supported by two or more backup rolls.
- **cogging**
  - The reducing operation in working an ingot into a billet with a forging hammer or a forging press.
- **coin straightening**
  - A combination coining and straightening operation performed in special cavity dies designed to impart a specific amount of working in specified areas of a forging to relieve the stresses developed during heat treatment.
- **coining**
  - (1) A closed-die squeezing operation in which all surfaces of a workpiece are confined or restrained, resulting in a well-defined imprint of the die on the work. (2) a restriking operation used to sharpen or change an existing radius or profile. Coining can be done while forgings are hot or cold and is usually performed on surfaces parallel to the parting line of the forging.
- **coining dies**

- Dies in which the coining or sizing operation is performed.

- **cold coined forging**
  - A forging that has been restruck cold in order to hold closer face distance tolerances, sharpen corners or outlines, reduce section thickness, flatten some particular surface, or, in nonheattreatable alloys, increase hardness.
- **cold forming**
  - See cold working
- **cold heading**
  - Working metal at room temperature such that the cross-sectional area of a portion or all of the stock is increased. See also heading and upsetting .
- **cold lap**
  - A flaw that results when a workpiece fails to fill the die cavity during the first forging. A seam is formed as subsequent dies force metal over this gap to leave a seam on the workpiece surface. See also cold shut .
- **cold-rolled sheet**
  - A mill product produced from a hot-rolled pickled coil that has been given substantial cold reduction at room temperature. The usual end product is characterized by improved surface, greater uniformity in thickness, and improved mechanical properties as compared with hot-rolled sheet.
- **cold shut**
  - (1) A fissure or lap on a forging surface that has been closed without fusion during the forging operation. (2) A folding back of metal onto its own surface during flow in the die cavity; a forging defect.
- **cold trimming**
  - The removal of flash or excess metal from a forging at room temperature in a trimming press.
- **cold working**
  - The plastic deformation of metal under conditions of temperature and strain rate that induce strain hardening . Usually, but not necessarily, conducted at room temperature. Also referred to as cold forming or cold forging. Contrast with hot working .
- **combination die**
  - See compound die .
- **compact (noun)**
  - The object produced by the compression of metal powder, generally while confined in a die.
- **compact (verb)**
  - The operation or process of producing a compact; sometimes called pressing.
- **compound die**
  - Any die designed to perform more than one operation on a part with one stroke of the press, such as blanking and piercing, in which all functions are performed simultaneously within the confines of the blank size being worked.
- **compressive strength**
  - The maximum compressive stress a material is capable of developing. With a brittle material that fails in compression by fracturing, the compressive strength has a definite value. In the case of ductile, malleable, or semi-viscous materials (which do not fail in compression by a shattering fracture), the value obtained for compressive strength is an arbitrary value dependent on the degree of distortion that is regarded as effective failure of the material.
- **compressive stress**
  - A stress that causes an elastic body to deform (shorten) in the direction of the applied load. Contrast with tensile stress .
- **compression test**
  - A method for assessing the ability of a material to withstand compressive loads.
- **contour forming**
  - See roll forming , stretch forming , tangent bending , and wiper forming .
- **counterblow forging equipment**
  - A category of forging equipment in which two opposed rams are activated simultaneously, striking repeated blows on the workpiece at a midway point. Action is vertical or horizontal.
- **coring**
  - (1) A central cavity at the butt end of a rod extrusion; sometimes called extrusion pipe . (2) A condition of variable composition between the center and surface of a unit of microstructure

(such as a dendrite, grain, or carbide particle); results from nonequilibrium solidification, which occurs over a range of temperature.

- **corrugating**
  - The forming of sheet metal into a series of straight, parallel alternate ridges and grooves with a rolling mill equipped with matched roller dies or a press brake equipped with specially shaped punch and die.
- **corrugations**
  - Transverse ripples caused by a variation in strip shape during hot or cold reduction.
- **counterblow equipment**
  - Equipment with two opposed rams that are activated simultaneously to strike repeated blows on the workpiece placed midway between them.
- **counterblow hammer**
  - A forging hammer in which both the ram and the anvil are driven simultaneously toward each other by air or steam pistons.
- **counterlock**
  - A jog in the mating surfaces of dies to prevent lateral die shift caused by side thrust during the forging of irregularly shaped pieces.
- **crank**
  - Forging shape generally in the form of a "U" with projections at more or less right angles to the upper terminals. Cranks shapes are designated by the number of throws (for example, two-throw crank).
- **crank press**
  - A mechanical press whose slides are actuated by a crankshaft.
- **crimping**
  - The forming of relatively small corrugations in order to set down and lock a seam, to create an arc in a strip of metal, or to reduce an existing arc or diameter. See also corrugating .
- **crown**
  - (1) The upper part (head) of a press frame. On hydraulic presses, the crown usually contains the cylinder; on mechanical presses, the crown contains the drive mechanism. See also hydraulic press and mechanical press . (2) A shape (crown) ground into a flat roll to ensure flatness of cold (and hot) rolled sheet and strip.
- **cup**
  - (1) A sheet metal part; the product of the first drawing operation. (2) Any cylindrical part or shell closed at one end.
- **cup fracture (cup-and-cone fracture)**
  - A mixed-mode fracture, often seen in tensile test specimens of a ductile material, in which the central portion undergoes plane-strain fracture and the surrounding region undergoes plane-stress fracture. One of the mating fracture surfaces looks like a miniature cup; it has a central depressed flat-face region surrounded by a shear lip. The other fracture surface looks like a miniature truncated cone.
- **cupping**
  - (1) The first step in deep drawing . (2) Fracture of severely worked rods or wire in which one end looks like a cup and the other a cone.
- **cupping test**
  - A mechanical test used to determine the ductility and stretching properties of sheet metal. It consists of measuring the maximum part depth that can be formed before fracture. The test is typically carried out by stretching the test piece clamped at its edges into a circular die using a punch with a hemispherical end. See also cup fracture , Erichsen test , and Olsen ductility test .
- **cutoff**
  - A pair of blades positioned in dies or equipment (or a section of the die milled to produce the same effect as inserted blades) used to separate the forging from the bar after forging operations are completed. Used only when forgings are produced from relatively long bars instead of from individual, precut multiples or blanks. See also blank and multiple .
- **D**
- **daylight**
  - The maximum clear distance between the pressing surfaces of a press when the surfaces are in the usable open position. Where a bolster plate is supplied, it is considered the pressing surface. See also shut height .
- **deep drawing**

- Characterized by the production of a parallel-wall cup from a flat blank of sheet metal. The blank may be circular, rectangular, or a more complex shape. The blank is drawn into the die cavity by the action of a punch. Deformation is restricted to the flange areas of the blank. No deformation occurs under the bottom of the punch--the area of the blank that was originally within the die opening. As the punch forms the cup, the amount of material in the flange decreases. Also called cup drawing or radial drawing.

- **deflection**
  - The amount of deviation from a straight line or plane when a force is applied to a press member. Generally used to specify the allowable bending of the bed, slide, or frame at rated capacity with a load of predetermined distribution.
- **deformation limit**
  - In drawing , the limit of deformation is reached when the load required to deform the flange becomes greater than the load-carrying capacity of the cup wall. The deformation limit (limiting drawing ratio, LDR) is defined as the ratio of the maximum blank diameter that can be drawn into a cup without failure, to the diameter of the punch.
- **Demarest process**
  - A fluid forming process in which cylindrical and conical sheet metal parts are formed by a modified rubber bulging punch. The punch, equipped with a hydraulic cell, is placed inside the workpiece, which in turn is placed inside the die. Hydraulic pressure expands the punch.
- **developed blank**
  - A sheet metal blank that yields a finished part without trimming or with the least amount of trimming.
- **die**
  - A tool, usually containing a cavity, that imparts shape to solid, molten, or powdered metal primarily because of the shape of the tool itself. Used in many press operations (including blanking, drawing, forging, and forming), in die casting, and in forming green powder metallurgy compacts. Die-casting and powder metallurgy dies are sometimes referred to as molds. See also forging dies .
- **die assembly**
  - The parts of a die stamp or press that hold the die and locate it for the punches.
- **die block**
  - A block, often made of heat-treated steel, into which desired impressions are machined or sunk and from which closed-die forgings or sheet metal stampings are produced using hammers or presses. In forging, die blocks are usually used in pairs, with part of the impression in one of the blocks and the rest of the impression in the other. In sheet metal forming, the female die is used in conjunction with a male punch. See also closed-die forging .
- **die cavity**
  - The machined recess that gives a forging or stamping its shape.
- **die check**
  - A crack in a die impression due to forging and thermal strains at relatively sharp corners. Upon forging, these cracks become filled with metal, producing sharp ragged edges on the part. Usual die wear is the gradual enlarging of the die impression due to erosion of the die material, generally occurring in areas subject to repeated high pressures during forging.
- **die clearance**
  - Clearance between a mated punch and die; commonly expressed as clearance per side. Also called clearance or punch-to-die clearance.
- **die closure**
  - A term frequently used to mean variations in the thickness of a forging.
- **die cushion**
  - A press accessory placed beneath or within a bolster plate or die block to provide an additional motion or pressure for stamping or forging operations; actuated by air, oil, rubber, springs, or a combination of these.
- **die forging**
  - A forging that is formed to the required shape and size through working in machined impressions in specially prepared dies.
- **die forming**
  - The shaping of solid or powdered metal by forcing it into or through the die cavity .
- **die height**
  - The distance between the fixed and the moving platen when the dies are closed.

- **die holder**
  - A plate or block, on which the die block is mounted, having holes or slots for fastening to the bolster plate or the bed of the press.
- **die impression**
  - The portion of the die surface that shapes a forging or sheet metal part.
- **die insert**
  - A relatively small die that contains part or all of the impression of a forging or sheet metal part and is fastened to the master die block .
- **die life**
  - The productive life of a die impression , usually expressed as the number of units produced before the impression has worn beyond permitted tolerances.
- **die line**
  - A line or scratch resulting from the use of a roughened tool or the drag of a foreign particle between tool and product.
- **die lubricant**
  - In forging or forming, a compound that is sprayed, swabbed, or otherwise applied on die surfaces or the workpiece during the forging or forming process to reduce friction. Lubricants also facilitate release of the part from the dies and provide thermal insulation. See also lubricant .
- **die match**
  - The alignment of the upper (moving) and lower (stationary) dies in a hammer or press. An allowance for misalignment (or mismatch) is included in forging tolerances.
- **die pad**
  - A movable plate or pad in a female die; usually used for part ejection by mechanical means, springs, or fluid cushions.
- **die proof (cast)**
  - a casting of a die impression made to confirm the accuracy of the impression.
- **die radius**
  - The radius on the exposed edge of a deep-drawing die, over which the sheet flows in forming drawn shells.
- **die set**
  - (1) The assembly of the upper and lower die shoes (punch and die holders), usually including the guide pins , guide pin bushings , and heel blocks . This assembly takes many forms, shapes, and sizes and is frequently purchased as a commercially available unit. (2) Two (or, for a mechanical upsetter, three) machined dies used together during the production of a die forging .
- **die shift**
  - The condition that occurs after the dies have been set up in a forging unit in which a portion of the impression of one die is not in perfect alignment with the corresponding portion of the other die. This results in a mismatch in the forging, a condition that must be held within the specified tolerance.
- **die shoes**
  - The upper and lower plates or castings that constitute a die set (punch and die holder). Also a plate or block upon which a die holder is mounted, functioning primarily as a base for the complete die assembly . This plate or block is bolted or clamped to the bolster plate or the face of the press slide .
- **die sinking**
  - The machining of the die impressions to produce forgings of required shapes and dimensions.
- **die space**
  - The maximum space (volume), or any part of the maximum space, within a press for mounting a die.
- **die stamping**
  - The general term for a sheet metal part that is formed, shaped, or cut by a die in a press in one or more operations.
- **direct (forward) extrusion**
  - See extrusion .
- **double-action mechanical press**
  - A press having two independent parallel movements by means of two slides, one moving within the other. The inner slide or plunger is usually operated by a crankshaft; the outer or blankholder slide, which dwells during the drawing operation, is usually operated by a toggle mechanism or by cams. See also slide .

- **dimpling**
  - (1) The stretching of a relatively small, shallow indentation into sheet metal. (2) In aircraft, the stretching of metal into a conical flange for a countersunk head rivet.
- **draft**
  - The amount of taper on the sides of the forging and on projections to facilitate removal from the dies; also, the corresponding taper on the sidewalls of the die impressions. In open-die forging , draft is the amount of relative movement of the dies toward each other through the metal in one application of power. See also draft angle .
- **draft angle**
  - The angle of taper, usually 5 to 7°, given to the sides of a forging and the sidewalls of the die impression. See also draft .
- **drawability**
  - A measure of the formability of a sheet metal subject to a drawing process. The term usually used to indicate the ability of a metal to be deep drawn. See also drawing and deep drawing .
- **draw bead**
  - An insert or riblike projection on the draw ring or hold-down surfaces that aids in controlling the rate of metal flow during deep draw operations. Draw beads are especially useful in controlling the rate of metal flow in irregularly-shaped stampings.
- **draw forming**
  - A method of curving bars, tubes, or rolled or extruded sections in which the stocks is bent around a rotating form block . Stock is bent by clamping it to the form block, then rotating the form block while the stock is pressed between the form block and a pressure die held against the periphery of the form block.
- **draw marks**
  - See scoring , galling , pickup , and die line .
- **draw plate**
  - A circular plate with a hole in the center contoured to fit a forming punch; used to support the blank during the forming cycle.
- **draw radius**
  - The radius at the edge of a die or punch over which sheet metal is drawn.
- **draw ring**
  - A ring-shaped die part (either the die ring itself or a separate ring) over which the inner edge of sheet metal is drawn by the punch.
- **draw stock**
  - The forging operation in which the length of a metal mass (stock) is increased at the expense of its cross section; no upset is involved. The operation includes converting ingot to pressed bar using "V," round, or flat dies.
- **drawing**
  - A term used for a variety of forming operations, such as deep drawing a sheet metal blank; redrawing a tubular part; and drawing rod, wire, and tube. The usual drawing process with regard to sheet metal working in a press is a method for producing a cuplike form from a sheet metal disk by holding it firmly between blankholding surfaces to prevent the formation of wrinkles while the punch travel produces the required shape.
- **drawing compound**
  - A substance applied to prevent pickup and scoring during deep drawing or pressing operations by preventing metal-to-metal contact of the workpiece and die. Also known as die lubricant .
- **drop forging**
  - The forging obtained by hammering metal in a pair of closed dies to produce the form in the finishing impression under a drop hammer ; forging method requiring special dies for each shape.
- **drop hammer**
  - A term generally applied to forging hammers in which energy for forging is provided by gravity, steam, or compressed air. See also air-lift hammer , board hammer , and steam hammer .
- **drop hammer forming**
  - A process for producing shapes by the progressive deformation of sheet metal in matched dies under the repetitive blows of a gravity-drop or power-drop hammer. The process is restricted to relatively shallow parts and thin sheet from approximately 0.6 to 1.6 mm (0.024 to 0.064 in.).
- **dummy block**
  - In extrusion , a thick unattached disk placed between the ram and the billet to prevent overheating of the ram.

- **dwell**
    - Portion of a press cycle during which the movement of a member is zero or at least insignificant. Usually refers to (1) the interval when the blankholder in a drawing operation is holding the blank while the punch is making the draw or (2) the interval between the completion of the forging stroke and the retraction of the ram.
- **E**
- **earing**
    - The formation of ears or scalloped edges around the top of a drawn shell, resulting from directional differences in the plastic-working properties of rolled metal with, across, and at angles to the direction of rolling.
- **eccentric**
    - The offset portion of the driveshaft that governs the stroke or distance the crosshead moves on a mechanical or manual shear.
- **eccentric gear**
    - A main press-drive gear with an eccentric(s) as an integral part. The unit rotates about a common shaft, with the eccentric transmitting the rotary motion of the gear into the vertical motion of the slide through a connection.
- **eccentric press**
    - A mechanical press in which an eccentric, instead of a crankshaft, is used to move the slide .
- **edger (edging impression)**
    - The portion of a die impression that distributes metal during forging into areas where it is most needed in order to facilitate filling the cavities of subsequent impressions to be used in the forging sequence. See also fuller (fullering impression) .
- **edging**
    - (1) In sheet metal forming, reducing the flange radius by retracting the forming punch a small amount after the stroke but before release of the pressure. (2) In rolling, the working of metal in which the axis of the roll is parallel to the thickness dimension. Also called edge rolling. (3) The forging operation of working a bar between contoured dies while turning it 90° between blows to produce a varying rectangular cross section.
- **effective draw**
    - The maximum limits of forming depth that can be achieved with a multiple-action press; sometimes called maximum draw or maximum depth of draw.
- **elastic limit**
    - The maximum stress a material can sustain without any permanent strain (deformation) remaining upon complete release of the stress. See also proportional limit .
- **elastic deformation**
    - A change in dimensions that is directly proportional to and in phase with an increase or decrease in applied force; deformation which is recoverable when the applied force is removed.
- **elasticity**
    - The property of a material by which the deformation caused by stress disappears upon removal of the stress. A perfectly elastic body completely recovers its original shape and dimensions after the release of stress.
- **electromagnetic forming**
    - A process for forming metal by the direct application of an intense, transient magnetic field. The workpiece is formed without mechanical contact by the passage of a pulse of electric current through a forming coil. Also known as magnetic pulse forming.
- **elongation**
    - A term used in mechanical testing to describe the amount of extension of a testpiece when stressed. See also elongation, percent .
- **elongation, percent**
    - The extension of a uniform section of a specimen expressed as a percentage of the original gage length:

$$\text{Elongation, \%} = \frac{(L_x - L_o)}{L_o} \cdot 100$$

    - where L_o is the original gage length and L_x is the final gage length.
- **embossing**

- A process for producing raised or sunken designs in sheet material by means of male and female dies, theoretically with no change in metal thickness. Examples are letters, ornamental pictures, and ribs for stiffening. Heavy embossing and coining are similar operations.
- **embossing die**
  - A die used for producing embossed designs.
- **ejector**
  - A mechanism for removing work or material from between the dies.
- **ejector rod**
  - A rod used to push out a formed piece.
- **Erichsen test**
  - A cupping test used to assess the ductility of sheet metal. The method consists of forcing a conical or hemispherical-ended plunger into the specimen and measuring the depth of the impression at fracture.
- **explosive forming**
  - The shaping of metal parts in which the forming pressure is generated by an explosive charge. See also high-energy-rate forming .
- **extrusion**
  - The conversion of an ingot or billet into lengths of uniform cross section by forcing metal to flow plastically through a die orifice. In forward (direct) extrusion, the die and ram are at opposite ends of the extrusion stock, and the product and ram travel in the same direction. Also, there is relative motion between the extrusion stock and the die. In backward (indirect) extrusion, the die is at the ram end of the stock and the product travels in the direction opposite that of the ram, either around the ram (as in the impact extrusion of cylinders such as cases for dry cell batteries) or up through the center of a hallow ram. See also hydrostatic extrusion and impact extrusion .
- **extrusion defect**
  - See extrusion pipe .
- **extrusion forging**
  - (1) Forcing metal into or through a die opening by restricting flow in other directions. (2) A part made by the operation.
- **extrusion billet**
  - A metal slug used as extrusion stock .
- **extrusion pipe**
  - A central oxide-lined discontinuity that occasionally occurs in the last 10 to 20% of an extruded bar. It is caused by the oxidized outer surface of the billet flowing around the end of the billet and into the center of the bar during the final stages of extrusion. Also called coring .
- **extrusion stock**
  - A rod, bar, or other section used to make extrusions.
- **eyeleting**
  - The displacing of material about an opening in sheet or plate so that a lip protruding above the surface is formed.
- **F**
- **fillet**
  - The concave intersection of two surfaces. In forging, the desired radius at the concave intersection of two surfaces is usually specified.
- **fin**
  - The thin projection formed on a forging by trimming or when metal is forced under pressure into hairline cracks or die interfaces.
- **finish**
  - (1) The surface appearance of a product. (2) The forging operation in which the part is forged into its final shape in the finish die. If only one finish operation is scheduled to be performed in the finish die, this operation will be identified simply as finish; first, second, or third finish designations are so termed when one or more finish operations are to be performed in the same finish die.
- **finish allowance**
  - The amount of excess metal surrounding the intended final shape; sometimes called clean-up allowance, forging envelope, or machining allowance.
- **finish trim**
  - Flash removal from a forging; usually performed by trimming, but sometimes by band sawing or similar techniques.

- **finishing dies**
  - The die set used in the last forging step.
- **finishing temperature**
  - The temperature at which hot working is completed.
- **finisher (finishing impression)**
  - The die impression that imparts the final shape to a forged part.
- **first block, second block, and finish**
  - The forging operation in which the part to be forged is passed in progressive order through three tools mounted in one forging machine; only one heat is involved for all three operations.
- **fishtail**
  - (1) In roll forging , the excess trailing end of a forging. Before being trimmed off, it is often used as a tong hold for a subsequent forging operation. (2) In hot rolling or extrusion, the imperfectly shaped trailing end of a bar or special section that must be cut off and discarded as mill scrap.
- **flame straightening**
  - The correction of distortion in metal structures by localized heating with a gas flame.
- **flange**
  - A projecting rim or edge of a part; usually narrow and of approximately constant width for stiffening or fastening.
- **flaring**
  - The forming of an outward acute-angle flange on a tubular part.
- **flash**
  - Metal in excess of that required to fill the blocking or finishing forging impression of a set of dies completely. Flash extends out from the body of the forging as a thin plate at the line where the dies meet and is subsequently removed by trimming. Because it cools faster than the body of the component during forging, flash can serve to restrict metal flow at the line where dies meet, thus ensuring complete filling of the impression. See also closed-die forging .
- **flash extension**
  - That portion of flash remaining on a forged part after trimming; usually included in the normal forging tolerances.
- **flash land**
  - Configuration in the blocking or finishing impression of forging dies designed to restrict or to encourage the growth of flash at the parting line, whichever may be required in a particular case to ensure complete filling of the impression.
- **flash line**
  - The line left on a forging after the flash has been trimmed off.
- **flash pan**
  - The machined-out portion of a forging die that permits the flow through of excess metal.
- **flat die forging**
  - See open-die forging .
- **flattening**
  - (1) A preliminary operation performed on forging stock to position the metal for a subsequent forging operation. (2) The removal of irregularities or distortion in sheets or plates by a method such as roller leveling or stretcher leveling .
- **flattening dies**
  - Dies used to flatten sheet metal hems; that is, dies that can flatten a bend by closing it. These dies consist of a top and bottom die with a flat surface that can close one section (flange) to another (hem, seam).
- **flex roll**
  - A movable roll designed to push up against a sheet as it passes through a roller leveler. The flex roll can be adjusted to deflect the sheet any amount up to the roll diameter.
- **flex rolling**
  - Passing sheets through a flex roll unit to minimize yield-point elongation in order to reduce the tendency for stretcher strains to appear during forming.
- **floating die**
  - (1) A die mounted in a die holder or a punch mounted in its holder such that a slight amount of motion compensates for tolerance in the die parts, the work, or the press. (2) A die mounted on heavy springs to allow vertical motion in some trimming, shearing, and forming operations.
- **floating plug**

    - In tube drawing, an unsupported mandrel that locates itself at the die inside the tube, causing a reduction in wall thickness while the die is reducing the outside diameter of the tube.
- **flop forging**
    - A forging in which the top and bottom die impressions are identical, permitting the forging to be turned upside down during the forging operation.
- **flow lines**
    - (1) Texture showing the direction of metal flow during hot or cold working. Flow lines can often be revealed by etching the surface or a section of a metal part. (2) In mechanical metallurgy, paths followed by minute volumes of metal during deformation.
- **flow through**
    - A forging defect caused by metal flow past the base of a rib with resulting rupture of the grain structure.
- **fluid-cell process**
    - A modification of the Guerin process for forming sheet metal, the fluid-cell process uses higher pressure and is primarily designed for forming slightly deeper parts, using a rubber pad as either the die or punch. A flexible hydraulic fluid cell forces an auxiliary rubber pad to follow the contour of the form block and exert a nearly uniform pressure at all points on the workpiece. See also fluid forming and rubber-pad forming .
- **fluid forming**
    - A modification of the Guerin process, fluid forming differs from the fluid-cell process in that the die cavity, called a pressure dome, is not completely filled with rubber, but with hydraulic fluid retained by a cup-shaped rubber diaphragm. See also rubber-pad forming .
- **flying shear**
    - A machine for cutting continuous rolled products to length that does not require a halt in rolling, but rather moves along the runout table at the same speed as the product while performing the cutting, and then returns to the starting point in time to cut the next piece.
- **foil**
    - Metal in sheet form less than 0.15 mm (0.006 in.) thick.
- **fold**
    - A forging defect caused by folding metal back onto its own surface during its flow in the die cavity.
- **follow die**
    - A progressive die consisting of two or more parts in a single holder; used with a separate lower die to perform more than one operation (such as piercing and blanking) on a part in two or more stations.
- **forgeability**
    - Term used to describe the relative ability of material to deform without fracture. Also describes the resistance to flow from deformation. See also formability .
- **forging**
    - The process of working metal to a desired shape by impact or pressure in hammers, forging machines (upsetters), presses, rolls, and related forming equipment. Forging hammers, counterblow equipment, and high-energy-rate forging machines apply impact to the workpiece, while most other types of forging equipment apply squeeze pressure in shaping the stock. Some metals can be forged at room temperature, but most are made more plastic for forging by heating. Specific forging processes defined in this Glossary include closed-die forging , high-energy-rate forging , hot upset forging , isothermal forging , open-die forging , powder forging , precision forging , radial forging , ring rolling , roll forging , rotary forging , and rotary swaging .
- **forging billet**
    - A wrong metal slug used as forging stock .
- **forging dies**
    - Forms for making forgings; they generally consist of a top and bottom die. The simplest will form a completed forging in a single impression; the most complex, consisting of several die inserts, may have a number of impressions for the progressive working of complicated shapes. Forging dies are usually in pairs, with part of the impression in one of the blocks and the rest of the impression in the other block.
- **forging envelope**
    - See finish allowance .
- **forging machine (upsetter or header)**

- A type of forging equipment, related to the mechanical press , in which the principal forming energy is applied horizontally to the workpiece, which is gripped and held by prior action of the dies.

- **forging plane**
  - In forging, the plane that includes the principal die face and is perpendicular to the direction of ram travel. When the parting surfaces of the dies are flat, the forging plane coincides with the parting line. Contrast with parting plane .
- **forging quality**
  - Term used to describe stock of sufficient quality to make it suitable for commercially satisfactory forgings.
- **forging rolls**
  - Power-driven rolls used in preforming bar or billet stock that have shaped contours and notches for introduction of the work.
- **forging stock**
  - A wrought rod, bar, or other section suitable for subsequent change in cross section by forging.
- **form block**
  - Tooling, usually the male part, used for forming sheet metal contours; generally used in rubber-pad forming .
- **form die**
  - A die used to change the shape of a sheet metal blank with minimal plastic flow.
- **form rolling**
  - Hot rolling to produce bars having contoured cross sections; not to be confused with the roll forming of sheet metal or with roll forging .
- **formability**
  - The ease with which a metal can be shaped through plastic deformation. Evaluation of the formability of a metal involves measurement of strength, ductility, and the amount of deformation required to cause fracture. The term workability is used interchangeably with formability; however, formability refers to the shaping of sheet metal, while workability refers to shaping materials by bulk forming . See also forgeability .
- **forming**
  - The plastic deformation of a billet or a blanked sheet between tools (dies) to obtain the final configuration. Metalforming processes are typically classified as bulk forming and sheet forming . Also referred to as metalworking.
- **forming limit diagram (FLD)**
  - A diagram in which the major strains at the onset of necking in sheet metal are plotted vertically and the corresponding minor strains are plotted horizontally. The onset-of-failure line divides all possible strain combinations into two zones; the safe zone (in which failure during forming is not expected) and the failure zone (in which failure during forming is expected).
- **forward extrusion**
  - Same as direct extrusion. See extrusion .
- **four-high mill**
  - A type of rolling mill, commonly used for flat-rolled mill products, in which two large-diameter backup rolls are employed to reinforce two smaller work rolls, which are in contact with the product. Either the work rolls or the backup rolls may be driven. Compare with two-high mill and cluster mill .
- **frame**
  - The main structure of a press.
- **Fuller (fullering impression)**
  - Portion of the die used in hammer forging primarily to reduce the cross section and lengthen a portion of the forging stock. The fullering impression is often used in conjunction with an edger (edging impression) .
- **G**
- **gage**
  - (1) The thickness of sheet or the diameter of wire. The various standards are arbitrary and differ with regard to ferrous and nonferrous products as well as sheet and wire. (2) An aid for visual inspection that enables an inspector to determine more reliably whether the size or contour of a formed part meets dimensional requirements.
- **galling**

- A condition whereby excessive friction between high spots results in localized welding with subsequent spalling and further roughening of the rubbing surface(s) of one or both of two mating parts.
- **gap-frame press**
  - A general classification of press in which the uprights or housings are made in the form of a letter C, thus making three sides of the die space accessible.
- **gibs**
  - Guides or shoes that ensure the proper parallelism, squareness, and sliding fit between press components such as the slide and the frame. They are usually adjustable to compensate for wear and to establish operating clearance.
- **gravity hammer**
  - A class of forging hammer in which energy for forging is obtained by the mass and velocity of a freely falling ram and the attached upper die. Examples are the board hammer and air-lift hammer .
- **green**
  - Unsintered (not sintered).
- **green compact**
  - An unsintered compact .
- **green strength**
  - (1) The ability of a green compact to maintain its size and shape during handling and storage prior to sintering . (2) The tensile or compressive strength of a green compact.
- **gripper dies**
  - The lateral or clamping dies used in a forging machine or mechanical upsetter.
- **Guerin process**
  - A rubber-pad forming process for forming sheet metal.
- **guide**
  - The parts of a drop hammer or press that guide the up-and-down motion of the ram in a true vertical direction.
- **guide pin bushings**
  - Bushings, pressed into a die shoe, that allow the guide pins to enter in order to maintain punch-to-die alignment.
- **guide pins**
  - Hardened, ground pins or posts that maintain alignment between punch and die during die fabrication, setup, operation, and storage. If the press slide in out of alignment, the guide pins cannot make the necessary correction unless heel plates are engaged before the pins enter the bushings. See also heel block .
- **gutter**
  - A depression around the periphery of a forging die impression outside the flash pan that allows space for the excess metal; surrounds the finishing impression and provides room for the excess metal used to ensure a sound forging. A shallow impression outside the parting line.
- **H**
- **hammer forging**
  - Forging in which the work is deformed by repeated blows. Compare with press forging .
- **hammering**
  - The working of metal sheet into a desired shape over a form or on a high-speed hammer and a similar anvil to produce the required dishing or thinning.
- **hammer**
  - A machine that applies a sharp blow to the work area through the fall of a ram onto an anvil. The ram can be driven by gravity or power. See also gravity hammer and power-driven hammer .
- **hand forge (smith forge)**
  - A forging operation in which forming is accomplished on dies that are generally flat. The piece is shaped roughly to the required contour with little or no lateral confinement; operations involving mandrels are included. The term hand forge refers to the operation performed, while hand forging applies to the part produced.
- **hand straightening**
  - A straightening operation performed on a surface plate to bring a forging within straightness tolerance. A bottom die from a set of finish dies is often used instead of a surface plate. Hand tools used include mallets, sledges, blocks, jacks, and oil gear presses in addition to regular inspection tools.

- **Hartmann lines**
  - See Lüders lines .
- **header**
  - See forging machine .
- **heading**
  - The upsetting of wire, rod, or bar stock in dies to form parts that usually contain portions that are greater in cross-sectional area than the original wire, rod, or bar.
- **heel block**
  - A block or plate usually mounted on or attached to a lower die that serves to prevent or minimize the deflection of punches or cams.
- **hemming**
  - A bend of 180° made in two steps. First, a sharp-angle bend is made; next, the bend is closed using a flat punch and a die.
- **HERF**
  - A common abbreviation for high-energy-rate forging or high-energy-rate forming .
- **high-energy-rate forging**
  - The production of forgings at extremely high ram velocities resulting from the sudden release of a compressed gas against a free piston. Forging is usually completed in one blow. Also known as HERF processing, high-velocity forging, and high-speed forging.
- **high-energy-rate forming**
  - A group of forming processes that applies a high rate of strain to the material being formed through the application of high rates of energy transfer. See also explosive forming , high-energy-rate forging , and electromagnetic forming .
- **hold-down plate (pressure pad)**
  - A pressurized plate designed to hold the workpiece down during a press operation. In practice, this plate often serves as a stripper and is also called a stripper plate.
- **hole flanging**
  - The forming of an integral collar around the periphery of a previously formed hole in a sheet metal part.
- **Hooke's law**
  - A material in which the stress is linearly proportional to strain is said to obey Hooke's law. See also modulus of elasticity .
- **hot forming**
  - See hot working .
- **hot isostatic pressing (HIP)**
  - A process for simultaneously heating and forming a power metallurgy compact in which metal powder, contained in a sealed flexible mold, is subjected to equal pressure from all directions at a temperature high enough for sintering to take place.
- **hot trimming**
  - The removal of flash or excess metal from a hot part (such as a forging) in a trimming press.
- **hot upset forging**
  - A bulk forming process for enlarging and reshaping some of the cross-sectional area of a bar, tube, or other product form of uniform (usually round) section. It is accomplished by holding the heated forging stock between grooved dies and applying pressure to the end of the stock, in the direction of its axis, by the use of a heading tool, which spreads (upsets) the end by metal displacement. Also called hot heading or hot upsetting. See also heading and upsetting .
- **hot working**
  - The plastic deformation of metal at such a temperature and strain rate that recrystallization takes place simultaneously with the deformation, thus avoiding any strain hardening . Also referred to as hot forging and hot forming. Contrast with cold working .
- **hub**
  - A boss that is in the center of a forging and forms a part of the body of the forging.
- **hubbing**
  - The production of die cavities by pressing a male master plug, known as a hub , into a block of metal.
- **hydraulic hammer**
  - A gravity-drop forging hammer that uses hydraulic pressure to lift the hammer between strokes.
- **hydraulic-mechanical press brake**

    - A mechanical press brake that uses hydraulic cylinders attached to mechanical linkages to power the ram through its working stroke.
- **hydraulic press**
    - A press in which fluid pressure is used to actuate and control the ram.
- **hydraulic press brake**
    - A press brake in which the ram is actuated directly by hydraulic cylinders.
- **hydraulic shear**
    - A shear in which the crosshead is actuated by hydraulic cylinders.
- **hydrostatic extrusion**
    - A method of extruding a billet through a die by pressurized fluid instead of the ram used in conventional extrusion .
- **I**
- **impact extrusion**
    - The process (or resultant product) in which a punch strikes a slug (usually unheated) in a confining die. The metal flow may be either between punch and die or through another opening. The impact extrusion of unheated slugs is often called cold extrusion.
- **impact line**
    - A blemish on a drawn sheet metal part caused by a slight change in metal thickness. The mark is called an impact line when it results from the impact of the punch on the blank; it is called a recoil line when it results from transfer of the blank from the die to the punch during forming, or from a reaction to the blank being pulled sharply through the draw ring .
- **impression**
    - A cavity machined into a forging die to produce a desired configuration in the workpiece during forging.
- **impression-die forging**
    - See closed-die forging .
- **indirect (backward) extrusion**
    - See extrusion .
- **ingot**
    - A casting intended for subsequent rolling, forging, or extrusion.
- **ironing**
    - An operation used to increase the length of a tube or cup through reduction of wall thickness and outside diameter, the inner diameter remaining unchanged.
- **isostatic pressing**
    - A process for forming a powder metallurgy compact by applying pressure equally from all directions to metal powder contained in a sealed flexible mold. See also hot isostatic pressing .
- **isothermal forging**
    - A hot-forging process in which a constant and uniform temperature is maintained in the workpiece during forging by heating the dies to the same temperature as the workpiece.
- **K**
- **knockout**
    - A mechanism for releasing workpieces from a die.
- **knockout mark**
    - A small protrusion, such as a button or ring of flash, resulting from depression of the knockout pin from the forging pressure or the entrance of metal between the knockout pin and the die.
- **knockout pin**
    - A power-operated plunger installed in a die to aid removal of the finished forging.
- **L**
- **laser beam cutting**
    - A cutting process that severs material with the heat obtained by directing a laser beam against a metal surface. The process can be used with or without an externally supplied shielding gas.
- **lateral extrusion**
    - An operation in which the product is extruded sideways through an orifice in the container wall.
- **leveler lines**
    - Lines on sheet or strip running transverse to the direction of roller leveling . These lines may be seen upon stoning or light sanding after leveling (but before drawing) and can usually be removed by moderate stretching.
- **leveling**

    - The flattening of rolled sheet, strip, or plate by reducing or eliminating distortions. See stretcher leveling and roller leveling .
- **liftout**
    - The mechanism also known as knockout .
- **limiting drawing ratio (LDR)**
    - See deformation limit .
- **liners**
    - Thin strips of metal inserted between the dies and the units into which the dies are fastened.
- **lock**
    - In forging, a condition in which the flash line is not entirely in one plane. Where two or more plane changes occur, it is called compound lock. Where a lock is placed in the die to compensate for die shift caused by a steep lock, it is called a counterlock.
- **locked dies**
    - Dies with mating faces that lie in more than one plane.
- **lower punch**
    - The lower part of a die, which forms the bottom of the die cavity and which may or may not move in relation to the die body; usually movable in a forging die.
- **lubricant**
    - A material applied to dies, molds, plungers, or workpieces that promotes the flow or metal, reduces friction and wear, and aids in the release of the finished part.
- **lubricant residue**
    - the carbonaceous residue resulting from lubricant that is burned onto the surface of a hot forged part.
- **Lüders lines**
    - Elongated surface markings or depressions, often visible with the unaided eye, that form along the length of a round or sheet metal tension specimen at an angel of approximately 55° to the loading axis. Caused by localized plastic deformation, they result from discontinuous (inhomogeneous) yielding. Also known as Lüders bands, Hartmann lines, Piobert lines, or stretcher strains.
- **M**
- **mandrel**
    - (1) A blunt-ended tool or rod used to retain the cavity in a hollow metal product during working. (2) A metal bar around which other metal can be cast, bent, formed, or shaped. (3) A shaft or bar for holding work to be machined.
- **mandrel forging**
    - The process of rolling or forging a hollow blank over a mandrel to produce a weldless, seamless ring or tube.
- **manipulator**
    - A mechanical device for handling an ingot or billet during forging.
- **Mannesmann process**
    - A process for piercing tube billets in making seamless tubing. The billet is rotated between two heavy rolls mounted at an angle and is forced over a fixed mandrel.
- **Marforming process**
    - A rubber-pad forming process developed to form wrinkle-free shrink flanges and deep-drawn shells. It differs from the Guerin process in that the sheet metal blank is clamped between the rubber pad and the blankholder before forming begins.
- **master block**
    - A forging die block used primarily to hold insert dies. See also die insert .
- **match**
    - A condition in which a point in one die half is aligned properly with the corresponding point in the opposite die half within specified tolerance.
- **matched edges (match lines)**
    - Two edges of the die face that are machined exactly at 90° to each other, and from which all dimensions are taken in laying out the die impression and aligning the dies in the forging equipment.
- **matching draft**
    - The adjustment of draft angles (usually involving an increase) on parts with asymmetrical ribs and sidewalls to make the surfaces of a forging meet at the parting line.
- **mechanical press**

- A forging press with an inertia flywheel, a crank and clutch, or other mechanical device to operate the ram.
- **mechanical press brake**
  - A press brake using a mechanical drive consisting of a motor, flywheel, crankshaft, clutch, and eccentric to generate vertical motion.
- **mechanical upsetter**
  - A three-element forging press, with two gripper dies and a forming tool, for flanging or forming relatively deep recesses.
- **mechanical working**
  - The subjecting of material to pressure exerted by rolls, hammers, or presses in order to change the shape or physical properties of the material.
- **metalworking**
  - See forming .
- **mill**
  - (1) A factory in which metals are hot worked, cold worked, or melted and cast into standard shapes suitable for secondary fabrication into commercial products. (2) A production line, usually of four or more stands , for hot or cold rolling metal into standard shapes such as bar, rod, plate, sheet, or strip. (3) A single machine for hot rolling, cold rolling, or extruding metal; examples include blooming mill , cluster mill , four-high mill , and Sendzimir mill . (4) A shop term for a milling cutter. (5) A machine or group of machines for grinding or crushing ores and other minerals.
- **mill edge**
  - The normal edge produced in rolling. Can be contrasted with a blanked or sheared edge which has a burr .
- **mill finish**
  - A nonstandard (and typically nonuniform) surface finish on mill products that are delivered without being subjected to a special surface treatment (other than a corrosion-preventive treatment) after the final working or heat-treating step.
- **mill product**
  - Any commercial product of a mill .
- **mill scale**
  - The heavy oxide layer that forms during the hot fabrication or heat treatment of metals.
- **mismatch**
  - The misalignment or error in register of a pair of forging dies; also applied to the condition of the resulting forging. The acceptable amount of this displacement is governed by blueprint or specification tolerances. Within tolerances, mismatch is a condition; in excess of tolerance, it is a serious defect. Defective forgings can be salvaged by hot-reforging operations.
- **modulus of elasticity, *E***
  - The measure of rigidity or stiffness of a metal; the ratio of stress, below the proportional limit, to the corresponding strain. In terms of the stress-strain diagram , the modulus of elasticity is the slope of the stress-strain curve in the range of linear proportionality of stress to strain. Also known as Young's modulus . For materials that do not conform to Hooke's law throughout the elastic range, the slope of either the tangent to the stress-strain curve at the origin or at low stress, the secant drawn from the origin to any specified point on the stress-strain curve, or the chord connecting any two specific points on the stress-strain curve is usually taken to be the modulus of elasticity. In these cases, the modulus is referred to as the tangent modulus , secant modulus , or chord modulus , respectively.
- **multiple**
  - A piece of stock for forging that is cut from bar or billet lengths to provide the exact amount of material needed for a single workpiece.
- **multiple-slide press**
  - A press with individual slides, built into the main slide or connected to individual eccentrics on the main shaft, that can be adjusted to vary the length of stroke and the timing. See also slide .
- ***m*-value**
  - See strain-rate sensitivity .
- **N**
- **natural draft**
  - Taper on the sides of a forging, due to its shape or position in the die, that makes added draft unnecessary.

- **necking**
  - (1) The reduction of the cross-sectional area of metal in a localized area by uniaxial tension or by stretching. (2) The reduction of the diameter of a portion of the length of a cylindrical shell or tube.
- **no-draft (draftless) forging**
  - A forging with extremely close tolerances and little or no draft that requires minimal machining to produce the final part. Mechanical properties can be enhanced by closer control of grain flow and by retention of surface material in the final component.
- **nonfill (underfill)**
  - A forging condition that occurs when the die impression is not completely filled with metal.
- ***n*-value**
  - See strain-hardening exponent .
- **O**
- **offset**
  - The distance along the strain coordinate between the initial portion of a stress-strain curve and a parallel line that intersects the stress-strain curve at a value of stress (commonly 0.2%) that is used as a measure of the yield strength . Used for materials that have no obvious yield point .
- **offset yield strength**
  - The stress at which the strain exceeds by a specified amount (the offset) an extension of the initial proportional portion of the stress-strain curve; expressed in force per unit area.
- **oil canning**
  - Same as canning .
- **Olsen ductility test**
  - A cupping test in which a piece of sheet metal, restrained except at the center, is deformed by a standard steel ball until fracture occurs. The height of the cup at the time of fracture is a measure of the ductility.
- **open dies**
  - Dies with flat surfaces that are used for performing stock or producing hand forgings.
- **open-die forging**
  - The hot mechanical forming of metals between flat or shaped dies in which metal flow is not completely restricted. Also known as hand or smith forging. See also hand forge (smith forge) .
- **orbital forging**
  - See rotary forging .
- **P**
- **pad**
  - The general term used for that part of a die which delivers holding pressure to the metal being worked.
- **pancake forging**
  - A rough forged shape, usually flat, that can be obtained quickly with minimal tooling. Considerable machining is usually required to attain the finish size.
- **parting line**
  - The line among the surface of a forging where the dies meet, usually at the largest cross section of the part. Flash is formed at the parting line.
- **parting plane**
  - The plane that includes the principal die face and is perpendicular to the direction of ram travel. When parting surfaces of the dies are flat, the parting plane coincides with the parting line. Also referred to as the forging plane.
- **pass**
  - (1) A single transfer of metal through a stand of rolls. (2) The open space between two grooved rolls through which metal is processed.
- **perforating**
  - The punching of many holes, usually identical and arranged in a regular pattern, in a sheet, workpiece blank, or previously formed part. The holes are usually round, but may be any shape. The operation is also called multiple punching. See also piercing .
- **permanent set**
  - The deformation or strain remaining in a previously stressed body after release of the load.
- **pickup**
  - Small particles of oxidized metal adhering to the surface of a mill product .
- **piercing**

- The general term for cutting (shearing or punching) openings, such as holes and slots, in sheet material, plate, or parts. This operation is similar to blanking ; the difference is that the slug or piece produced by piercing is scrap, while the blank produced by blanking is the useful part.
- **pinch trimming**
  - The trimming of the edge of a tubular part or shell by pushing or pinching the flange or lip over the cutting edge of a stationary punch or over the cutting edge of a draw punch.
- **Piobert lines**
  - See Lüders lines .
- **plastic deformation**
  - The permanent (inelastic) distortion of metals under applied stresses that strain the material beyond its elastic limit . The ability of metals to flow in a plastic manner without fracture is the fundamental basis for all metal-forming processes.
- **plastic flow**
  - The phenomenon that takes place when metals or other substances are stretched or compressed permanently without rupture.
- **plastic-strain ratio (*r*-value)**
  - The ratio of the true width strain to the true thickness strain in a sheet tensile test, $r = \epsilon_w/\epsilon_t$. A formability parameter that relates to drawing, it is also known as the anisotropy factor. A high *r*-value indicates a material with good drawing properties.
- **plasticity**
  - The ability of a metal to undergo permanent deformation without rupture.
- **platen**
  - The sliding member, slide, or ram of a press.
- **plug**
  - (1) A rod or mandrel over which a pierced tube is forced. (2) A rod or mandrel that fills a tube as it is drawn through a die. (3) A punch or mandrel over which a cup is drawn. (4) A protruding portion of a die impression for forming a corresponding recess in the forging. (5) A false bottom in a die.
- **Poisson's ratio, ν**
  - The absolute value of the ratio of transverse (lateral) strain to the corresponding axial strain resulting from uniformly distributed axial stress below the proportional limit of the material in a tensile test.
- **powder forging**
  - The plastic deformation of a powder metallurgy compact or preform into a fully dense finished shape by using compressive force; usually done hot and within closed dies.
- **power-driven hammer**
  - A forging hammer with a steam or air cylinder for raising the ram and augmenting its downward blow.
- **precision forging**
  - A forging produced to closer tolerances than normally considered standard by the industry.
- **preform**
  - (1) The forging operation in which stock is preformed or shaped to a predetermined size and contour prior to subsequent die forging operations. When a preform operation is required, it will precede a forging operation and will be performed in conjunction with the forging operation and in the same heat. (2) The initially pressed powder metallurgy compact to be subjected to repressing .
- **press**
  - A machine tool with a stationary bed and a slide or ram that has reciprocating motion at right angles to the bed surface; the slide is guided in the frame of the machine.
- **press brake**
  - An open-frame single-action press used to bend, blank, corrugate, curl, notch, perforate, pierce, or punch sheet metal or plate.
- **press capacity**
  - The rated force a press is designed to exert at a predetermined distance above the bottom of the stroke of the slide.
- **press forging**
  - The forging of metal between dies by mechanical or hydraulic pressure; usually accomplished with a single work stroke of the press for each die station.
- **press forming**

- Any sheet metal forming operation performed with tooling by means of a mechanical or hydraulic press.
- **press load**
  - The amount of force exerted in a given forging or forming operation.
- **press slide**
  - See slide .
- **pressure plate**
  - A plate located beneath the bolster that acts against the resistance of a group of cylinders mounted to the pressure plate to provide uniform pressure throughout the press stroke when the press is symmetrically loaded.
- **profile (contour) rolling**
  - In ring rolling , a process used to produce seamless rolled rings with a predesigned shape on the outside or the inside diameter, requiring less volume of material and less machining to produce finished parts.
- **progression**
  - The constant dimension between adjacent stations in a progressive die.
- **progressive die**
  - A die with two or move stations arranged in line for performing two or more operations on a part; one operation is usually performed at each station.
- **progressive forming**
  - Sequential forming at consecutive stations with a single die or separate dies.
- **proof**
  - Any reproduction of a die impression in any material; often a lead or plaster cast. See also die proof .
- **proof load**
  - A predetermined load, generally some multiple of the service load, to which a specimen or structure is submitted before acceptance for use.
- **proof stress**
  - (1) The stress that will cause a specified small permanent set in a material. (2) A specified stress to be applied to a member or structure to indicate its ability to withstand service loads.
- **proportional limit**
  - The greatest stress a material is capable of developing without a deviation from straight-line proportionality between stress and strain. See also elastic limit and Hooke's law .
- **punch**
  - (1) The male part of a die--as distinguished from the female part, which is called the die. The punch is usually the upper member of the complete die assembly and is mounted on the slide or in a die set for alignment (except in the inverted die). (2) In double-action draw dies, the punch is the inner portion of the upper die, which is mounted on the plunger (inner slide) and does the drawing. (3) The act of piercing or punching a hole. Also referred to as punching .
- **punching**
  - The die shearing of a closed contour in which the sheared out sheet metal part is scrap.
- **R**
- **radial draw forming**
  - The forming of sheet metals by the simultaneous application of tangential stretch and radial compression forces. The operation is done gradually by tangential contact with the die member. This type of forming is characterized by very close dimensional control.
- **radial forging**
  - A process using two or move moving anvils or dies for producing shafts with constant or varying diameters along their length or tubes with internal or external variations in diameter. Often incorrectly referred to as rotary forging .
- **radial roll (main roll, king roll)**
  - The primary driven roll of the rolling mill for rolling rings in the radial pass. The roll is supported at both ends.
- **radial rolling force**
  - The action produced by the horizontal pressing force of the rolling mandrel acting against the ring and the main roll.
- **radius**
  - To remove the sharp edge or corner of forging stock by means of a radius or form tool.
- **ram**

- The moving or falling part of a drop hammer or press to which one of the dies is attached; sometimes applied to the upper flat die of a steam hammer. Also referred to as the slide .
- **recoil line**
  - See impact line .
- **redrawing**
  - The second and successive deep-drawing operations in which cuplike shells are deepened and reduced in cross-sectional dimensions.
- **reduction**
  - In cupping and deep drawing, a measure of the percentage of decrease from blank diameter to cup diameter, or of the diameter reduction in redrawing. (2) In forging, extrusion, rolling, and drawing, either the ratio of the original to the final cross-sectional area or the percentage of decreased in cross-sectional area.
- **reduction in area**
  - The difference between the original cross-sectional area and the smallest area at the point of rupture in a tensile test; usually stated as a percentage of the original area.
- **repressing**
  - The application of pressure to a sintered compact; usually done to improve a physical or mechanical property or for dimensional accuracy.
- **rerolling quality**
  - Rolled billets from which the surface defects have not been removed or completely removed.
- **reset**
  - The realigning or adjusting of dies or tools during a production run; not to be confused with the operation setup that occurs before a production run.
- **residual stress**
  - Stresses that remain within a body as the result of nonuniform plastic deformation or heating and cooling.
- **restriking**
  - (1) The striking of a trimmed but slightly misaligned or otherwise faulty forging with one or more blows to improve alignment, improve surface condition, maintain close tolerances, increase hardness, or effect other improvements. (2) A sizing operation in which coining or stretching is used to correct or alter profiles and to counteract distortion. (3) A salvage operation following a primary forging operation in which the parts involved are rehit in the same forging die in which the pieces were last forged.
- **reverse drawing**
  - Redrawing of a sheet metal part in a direction opposite to that of the original drawing.
- **reverse flange**
  - A sheet metal flange made by shrinking, as opposed to one formed by stretching.
- **rib**
  - (1) A long V-shaped or radiused indentation used to strengthen large sheet metal panels. (1) A long, usually thin protuberance used to provide flexural strength to a forging (as in a rib-web forging).
- **ring rolling**
  - The process of shaping weldless rings from pierced disks or shaping thick-wall ring-shaped blanks between rolls that control wall thickness, ring diameter, height, and contour.
- **rod**
  - A solid round section 9.5 mm ($\frac{3}{8}$ in.) or greater in diameter, whose length is great in relation to its diameter.
- **roll bending**
  - The curving of sheets, bars, and sections by means of rolls.
- **roll flattening**
  - The flattening of sheets that have been rolled in packs by passing them separately through a two-high cold mill with virtually no deformation. Not to be confused with roller leveling .
- **roll forging**
  - A process of shaping stock between two driven rolls that rotate in opposite directions and have one or more matching sets of grooves in the rolls; used to produce finished parts of preforms for subsequent forging operations.
- **roll forming**
  - Metal forming through the use of power-driven rolls whose contour determines the shape of the product; sometimes used to denote power spinning .

- **roll threading**
  - The production of threads by rolling the piece between two grooved die plates, one of which is in motion, or between rotating grooved circular rolls.
- **roller leveler breaks**
  - Obvious transverse breaks on sheet metal usually about 3 to 6 mm ($\frac{1}{8}$ to $\frac{1}{4}$ in.) apart that the caused by the sheet fluting during roller leveling . These will not be removed by stretching.
- **roller leveling**
  - Leveling by passing flat sheet metal stock through a machine having a series of small-diameter staggered rolls that are adjusted to produce repeated reverse bending.
- **rolling**
  - The reduction of the cross-sectional area of metal stock, or the general shaping of metal products, through the use of rotating rolls.
- **rolling mandrel**
  - In ring rolling, a vertical roll of sufficient diameter to accept various sizes of ring blanks and to exert rolling force on an axis parallel to the main roll.
- **rolling mills**
  - Machines used to decrease the cross-sectional area of metal stock and to produce certain desired shapes as the metal passes between rotating rolls mounted in a framework comprising a basic unit called a stand . Cylindrical rolls produce flat shapes; grooved rolls produce rounds, squares, and structural shapes. See also four-high mill , Sendzimir mill , and two-high mill .
- **roll straightening**
  - The straightening of metal stock of various shapes by passing it through a series of staggered rolls (the rolls usually being in horizontal and vertical planes) or by reeling in two-roll straightening machines.
- **rotary forging**
  - A process in which the workpiece is pressed between a flat anvil and a swiveling (rocking) die with a conical working face; the platens move toward each other during forging. Also called orbital forging. Compare with radial forging .
- **rotary shear**
  - A sheet metal cutting machine with two rotating-disk cutters mounted on parallel shafts driven in unison.
- **rotary swager**
  - A swaging machine consisting of a power-driven ring that revolves at high speed, causing rollers to engage cam surfaces and force the dies to deliver hammerlike blows on the work at high frequency. Both straight and tapered sections can be produced.
- **rotary swaging**
  - A bulk forming process for reducing the cross-sectional area or otherwise changing the shape of bars, tubes, or wires by repeated radial blows with one or more pairs of opposed dies.
- **rough blank**
  - A blank for a forming or drawing operation, usually of irregular outline, with necessary stock allowance for process metal, which is trimmed after forming or drawing to the desired size.
- **roughing stand**
  - The first stand (or several stands) of rolls through which a reheated billet passes in front of the finishing stands. See also rolling mills and stand .
- **rubber forming**
  - A sheet metal forming process in which rubber is used as a functional die part.
- **rubber-pad forming**
  - A sheet metal forming operation for shallow parts in which a confined, pliable rubber pad attached to the press slide (ram) is forced by hydraulic pressure to become a mating die for a punch or group of punches placed on the press bed or baseplate. Developed in the aircraft industry for the limited production of a large number of diversified parts, the process is limited to the forming of relatively shallow parts, normally not exceeding 40 mm(1.5 in.) deep. Also known as the Guerin process. Variations of the Guerin process include the Marforming process , the fluid-cell process , and fluid forming .
- **S**
- **scoring**
  - (1) The marring or scratching of any formed part by metal pickup on the punch or die. (2) The reduction in thickness of a material along a line to weaken it intentionally along that line.
- **screw press**

- A high-speed press in which the ram is activated by a large screw assembly powered by a drive mechanism.
- **secant modulus**
  - The slope of the secant drawn from the origin to any specified point on the stress-strain curve. See also modulus of elasticity .
- **segment die**
  - Same as split die .
- **semifinisher**
  - An impression in a series of forging dies that only approximates the finish dimensions of the forging. Semifinishers are often used to extend die life or the finishing impression, to ensure proper control of grain flow during forging, and to assist in obtaining desired tolerances.
- **Sendzimir mill**
  - A type of cluster mill with small-diameter work rolls and larger-diameter backup rolls, backed up by bearings on a shaft mounted eccentrically so that it can be rotated to increase the pressure between the bearing and the backup rolls. Used to roll precision and very thin sheet and strip.
- **shank**
  - The portion of a die or tool by which it is held in position in a forging unit or press.
- **shear**
  - (1) A machine or tool or cutting metal and other material by the closing motion of two sharp, closely adjoining edges; for example, squaring shear and circular shear. (2) An inclination between two cutting edges, such as between two straight knife blades or between the punch cutting edge and the die cutting edge, so that a reduced area will be cut each time. This lessens the necessary force, but increases the required length of the working stroke. This method is referred to as angular shear. (3) The act of cutting by shearing dies or blades, as in a squaring shear. (4) The type of force that causes or tends to cause two contiguous parts of the same body to slide relative to each other in a direction parallel to their plane of contact.
- **shear strength**
  - The maximum shear stress a material can sustain. Shear strength is calculated from the maximum load during a shear or torsion test and is based on the original dimensions of the cross section of the specimen.
- **shear stress**
  - (1) A stress that exists when parallel planes in metal crystals slide across each other. (2) The stress component tangential to the plane on which the forces act.
- **shearing**
  - The parting of material that results when one blade forces the material past an opposing blade.
- **sheet**
  - Any material or piece of uniform thickness and of considerable length and width as compared to its thickness. With regard to metal, such pieces under 6.5 mm ($\frac{1}{4}$ in.) thick are called sheets, and those 6.5 mm ($\frac{1}{4}$ in.) thick and over are called plates. Occasionally, the limiting thickness for steel to be designated as sheet steel is No. 10 Manufacturer's Standard Gage for sheet steel, which is 3.42 mm (0.1345 in.) thick.
- **sheet forming**
  - The plastic deformation of a piece of sheet metal by tensile loads into a three-dimensional shape, often without significant changes in sheet thickness or surface characteristics. Compare with bulk forming .
- **shim**
  - A thin piece of material used between two surfaces to obtain a proper fit, adjustment, or alignment.
- **shrinkage**
  - The contraction of metal during cooling after hot forging. Die impressions are made oversize according to precise shrinkage scales to allow the forgings to shrink to design dimensions and tolerances.
- **shut height**
  - For a press, the distance from the top of the bed to the bottom of the slide with the stroke down and adjustment up. In general, it is the maximum die height that can be accommodated for normal operation, taking the bolster plate into consideration.
- **side thrust**
  - The lateral force exerted between the dies by reaction of a forged piece on the die impressions.

- **single-stand mill**
    - A rolling mill designed such that the product contacts only two rolls at a given moment. Contrast with tandem mill .
- **sinking**
    - The operation of machining the impression of a desired forging into die blocks.
- **sintering**
    - The densification and bonding of adjacent particles in a powder mass or compact by heating to a temperature below the melting point of the main constituent.
- **sizing**
    - (1) Secondary forming or squeezing operations needed to square up, set down, flatten, or otherwise correct surfaces to produce specified dimensions and tolerances. See restriking . (2) Some burnishing, broaching, drawing, and shaving operations are also called sizing. (3) A finishing operation for correcting ovality in tubing. (4) Final pressing of a sintered powder metallurgy part.
- **slab**
    - A flat-shaped semifinished rolled metal ingot with a width not less than 250 mm (10 in.) and a cross-sectional area not less than 105 cm^2 (16 $in.^2$).
- **slabbing**
    - The hot working of an ingot to a flat rectangular shape.
- **slide**
    - The main reciprocating member of a press, guided in the press frame, to which the punch or upper die is fastened; sometimes called the ram . The inner slide of a double-action press is called the plunger or punch-holder slide; the outer slide is called the blankholder slide. The third slide of a triple-action press is called the lower slide, and the slide of a hydraulic press is often called the platen.
- **slide adjustment**
    - The distance that a press slide position can be altered to change the shut height of the die space. The adjustment can be made by hand or by power mechanism.
- **slitting**
    - Cutting or shearing along single lines to cut strips from a sheet or to cut along lines of a given length or contour in a sheet or workpiece.
- **slug**
    - (1) The metal removed when punching a hole in a forging; also termed punchout. (2) The forging stock for one workpiece cut to length. See also blank .
- **smith forging**
    - See hand forge (smith forge) .
- **sow block**
    - A block of heat-treated steel placed between the anvil of the hammer and the forging die to prevent undue wear to the anvil. Sow blocks are occasionally used to hold insert dies. Also called anvil cap.
- **spinning**
    - The forming of a seamless hollow metal part by forcing a rotating blank to conform to a shaped mandrel that rotates concentrically with the blank. In the typical application, a flat-rolled metal blank is forced against the mandrel by a blunt, rounded tool; however, other stock (notably, welded or seamless tubing) can be formed. A roller is sometimes used as the working end of the tool.
- **split die**
    - A die made of parts that can be separated for ready removal of the workpiece. Also known as segment die.
- **springback**
    - (1) The elastic recovery of metal after stressing. (2) The extent to which metal tends to return to its original shape or contour after undergoing a forming operation. This is compensated for by overbending or by a secondary operation of restriking .
- **stamping**
    - The general term used to denote all sheet metal pressworking.
- **stand**
    - A piece of rolling mill equipment containing one set of work rolls. In the usual sense, any pass of a cold- or hot-rolling mill. See also rolling mills .
- **steam hammer**

- A type of drop hammer in which the ram is raised for each stroke by a double-action steam cylinder and the energy delivered to the workpiece is supplied by the velocity and weight of the ram and attached upper die driven downward by steam pressure. The energy delivered during each stroke can be varied.

- **stock**
  - A general term used to refer to a supply of metal in any form or shape and also to an individual piece of metal that is formed, forged, or machined to make parts.
- **stop**
  - A device for positioning stock or parts in a die.
- **straightening**
  - A finishing operation for correcting misalignment in a forging or between various sections of a forging.
- **strain**
  - The unit of change in the size or shape of a body due to force, in reference to its original size or shape.
- **strain aging**
  - The changes in ductility, hardness, yield point, and tensile strength that occur when a metal or alloy that has been cold worked is stored for some time. In steel, strain aging is characterized by a loss of ductility and a corresponding increase in hardness, yield point, and tensile strength.
- **strain hardening**
  - An increase in hardness and strength caused by plastic deformation at temperatures below the recrystallization range. Also known as work hardening.
- **strain-hardening coefficient**
  - See strain-hardening exponent .
- **strain-hardening exponent**
  - The value *n* in the relationship $\sigma = K\epsilon^n$, where σ is the true stress; ϵ is the true strain; and *K*, which is called the strength coefficient, is equal to the true stress at a true strain of 1.0. The strain-hardening exponent, also called *n*-value, is equal to the slope of the true stress/true strain curve up to maximum load, when plotted on log-log coordinates. The *n*-value relates to the ability of a sheet material to be stretched in metalworking operations. The higher the *n*-value, the better the formability (stretchability).
- **strain-rate sensitivity (*m*-value)**
  - The increase in stress (σ) needed to cause a certain increase in plastic strain rate ($\dot{\epsilon}$) at a given level of plastic strain (ϵ) and a given temperature (*T*).

$$\text{Strain-rate sensitivity} = m = \left(\frac{\Delta \log \sigma}{\Delta \log \dot{\epsilon}}\right)_{\epsilon T}$$

- **stress**
  - The intensity of the internally distributed forces or components of forces that resist a change in the volume or shape of a material that is or has been subjected to external forces. Stress is expressed in force per unit area. Stress can be normal (tension or compression) or shear.
- **stress raisers**
  - Design features (such as sharp corners) or mechanical defects (such as notches) that act to intensify the stress at these locations.
- **stress-strain curve**
  - See stress-strain diagram .
- **stress-strain diagram**
  - A graph in which corresponding values of stress and strain from a tension, compression, or torsion test are plotted against each other. Values of stress are usually plotted vertically (ordinates or *y*-axis) and values of strain horizontally (abscissas or *x*-axis). Also known as deformation curve and stress-strain curve.
- **stretcher leveling**
  - The leveling of a piece of sheet metal (that is, removing warp and distortion) by gripping it at both ends and subjecting it to a stress higher than its yield strength.
- **stretcher straightening**
  - A process for straightening rod, tubing, and shapes by the application of tension at the ends of the stock. The products are elongated a definite amount to remove warpage.
- **stretcher strains**

    - Elongated markings that appear on the surface of some sheet materials when deformed just past the yield point. These markings lie approximately parallel to the direction of maximum shear stress and are the result of localized yielding. See also Lüders lines .
- **stretch former**
    - (1) A machine used to perform stretch forming operations. (2) A device adaptable to a conventional press for accomplishing stretch forming.
- **stretch forming**
    - The shaping of a sheet or part, usually of uniform cross section, by first applying suitable tension or stretch and then wrapping it around a die of the desired shape.
- **stretching**
    - The extension of the surface of a sheet in all directions. In stretching, the flange of the flat blank is securely clamped. Deformation is restricted to the area initially within the die. The stretching limit is the onset of metal failure.
- **striking surface**
    - Those areas on the faces of a set of dies that are designed to meet when the upper die and lower die are brought together. The striking surface helps protect impressions from impact shock and aids in maintaining longer die life.
- **strip**
    - A flat-rolled metal product of some maximum thickness and width arbitrarily dependent on the type of metal; narrower than sheet .
- **stripper**
    - A plate designed to remove, or strip, sheet metal stock from the punching members during the withdrawal cycle. Strippers are also used to guide small precision punches in close-tolerance dies, to guide scrap away from dies, and to assist in the cutting action. Strippers are made in two types: fixed and movable.
- **stripper punch**
    - A punch that serves as the top or bottom of the die cavity and later moves farther into the die to eject the part or compact. See also ejector rod and knockout .
- **stroke (up or down)**
    - The vertical movement of a ram during half of the cycle, from the full open to the full closed position or vice versa.
- **sub-sow block (die holder)**
    - A block used as an adapter in order to permit the use of forging dies that otherwise would not have sufficient height to be used in the particular unit or to permit the use of dies in a unit with different shank sizes.
- **superplasticity**
    - The ability of certain metals to develop extremely high tensile elongations at elevated temperatures and under controlled rates of deformation.
- **support plate**
    - A plate that supports a draw ring or draw plate. it also serves as a spacer.
- **swage**
    - (1) The operation of reducing or changing the cross-section area of stock by the fast impact of revolving dies. (2) The tapering of bar, rod, wire, or tubing by forging, hammering, or squeezing; reducing a section by progressively tapering lengthwise until the entire section attains the smaller dimension of the taper.
- **Swift cup test**
    - A simulative test in which circular blanks of various diameter are clamped in a die ring and deep drawn into a cup by a flat-bottomed cylindrical punch. The ratio of the largest blank diameter that can be drawn successfully to the cup diameter is known as the limiting drawing ratio (LDR) or deformation limit .
- **T**
- **tandem die**
    - Same as follow die .
- **tandem mill**
    - A rolling mill consisting of two or more stands arranged so that the metal being processed travels in a straight line from stand to stand. In continuous rolling, the various stands are synchronized so that the strip can be rolled in all stands simultaneously. Contrast with single-stand mill .
- **tangent bending**

    - The forming of one or more identical bends having parallel axes by wiping sheet metal around one or more radius dies in a single operation. The sheet, which may have side flanges, is clamped against the radius die and then made to conform to the radius die by pressure from a rocker-plate die that moves along the periphery of the radius die. See also wiper forming (wiping) .
- **tangent modulus**
    - The slope of the stress-strain curve at any specified stress or strain. See also modulus of elasticity .
- **template (templet)**
    - A gage or pattern made in a die department, usually from sheet steel; used to check dimensions on forgings and as an aid in sinking die impressions in order to correct dimensions.
- **tensile strength**
    - In tensile testing, the ratio of maximum load to original cross-sectional area. Also known as ultimate strength. Compare with yield strength .
- **tensile stress**
    - A stress that causes two parts of an elastic body, on either side of a typical stress plane, to pull apart. Contrast with compressive stress .
- **tension**
    - The force or load that produces elongation.
- **thermal-mechanical treatment**
    - See thermomechanical working .
- **thermomechanical working**
    - A general term covering a variety of processes combining controlled thermal and deformation treatments to obtain synergistic effects, such as improvement in strength without loss of toughness. Same as thermal-mechanical treatment.
- **three-point bending**
    - The bending of a piece of metal or a structural member in which the object is placed across two supports and force is applied between and in opposition to them. See V-bend die .
- **throw**
    - The distance from the centerline of the crankshaft or main shaft to the centerline of the crankpin or eccentric in crack or eccentric presses. Equal to one-half of the stroke. See also crank press and eccentric press .
- **toggle press**
    - **A** mechanical press in which the slide is actuated by one or more toggle links or mechanisms.
- **tong hold**
    - The portion of a forging billet, usually on one end, that is gripped by the operator's tongs. It is removed from the part at the end of the forging operation. Common to drop hammer and press-type forging.
- **tooling marks**
    - Indications imparted to the surface of the forged part from dies containing surface imperfections or dies on which some repair work has been done. These marks are usually slight rises or depressions in the metal.
- **torsion**
    - A twisting deformation of a solid or tubular body about an axis in which lines that were initially parallel to the axis become helices.
- **torsional stress**
    - The shear stress on a transverse cross section resulting from a twisting action.
- **total elongation**
    - The total amount of permanent extension of a test piece broken in a tensile test usually expressed as a percentage over a fixed gage length. See also elongation, percent .
- **trimmer**
    - The dies used to remove the flash or excess stock from a forging.
- **trimmer blade**
    - The portion of the trimmers through which a forging is pushed to shear off the flash.
- **trimmer die**
    - The punch press die used for trimming flash from a forging.
- **trimmer punch**
    - The upper portion of the trimmer that contacts the forging and pushes it through the trimmer blades; the lower end of the trimmer punch is generally shaped to fit the surface of the forging against which it pushes.

- **trimmers**
    - The combination of trimmer punch, trimmer blades, and perhaps, trimmer shoe used to remove flash from a forging.
- **trimming**
    - The mechanical shearing of flash or excess material from a forging with a trimmer in a trim press; can be done hot or cold.
- **trimming press**
    - A power press suitable for trimming flash from forgings.
- **triple-action press**
    - A mechanical or hydraulic press having three slides with three motions properly synchronized for triple-action drawing, redrawing, and forming. Usually, two slides--the blankholder slide and the plunger--are located above and a lower slide is located within the bed of the press. See also hydraulic press , mechanical press , and slide .
- **tryout**
    - Preparatory run to check or test equipment, lubricant, stock, tools, or methods prior to a production run. Production tryout is run with tools previously approved; new die tryout is run with new tools not previously approved.
- **tube stock**
    - A semifinished tube suitable for subsequent reduction and finishing.
- **two-high mill**
    - A type of rolling mill in which only two rolls, the working rolls, are contained in a single housing. Compare with four-high mill and cluster mill .
- **U**
- **U-bend die**
    - A die, commonly used in press-brake forming, that is machined horizontally with a square or rectangular cross-sectional opening that provides two edges over which metal is drawn into a channel shape.
- **ultimate strength**
    - The maximum stress (tensile, compressive, or shear) a material can sustain without fracture; determined by dividing maximum load by the original cross-sectional area of the specimen. Also known as nominal strength or maximum strength.
- **underfill**
    - A portion of a forging that has insufficient metal to give it the true shape of the impression.
- **upset**
    - The localized increase in cross-sectional area of a workpiece or weldment resulting from the application of pressure during mechanical fabrication or welding.
- **upset forging**
    - A forging obtained by upset of a suitable length of bar, billet or bloom.
- **upsetter**
    - A horizontal mechanical press used to make parts from bar stock or tubing by upset forging , piercing, bending, or otherwise forming in dies. Also known as a header.
- **upsetting**
    - The working of metal so that the cross-sectional area of a portion or all of the stock is increased. See also heading .
- **V**
- **V-bend die**
    - A die commonly used in press-brake forming, usually machined with a triangular cross-sectional opening to provide two edges as fulcrums for accomplishing three-point bending .
- **vent**
    - A small hole in a punch or die for admitting air to avoid suction holding or for relieving pockets of trapped air that would prevent die closure or action.
- **vent mark**
    - A small protrusion resulting from the entrance of metal into die vent holes.
- **W**
- **warm working**
    - Deformation at elevated temperatures below the recrystallization temperature. The flow stress and rate of strain hardening are reduced with increasing temperature; therefore, lower forces are required than in cold working. See also cold working and hot working .
- **web**

- A relatively flat, thin portion of a forging that effects an interconnection between ribs and bosses; a panel or wall that is generally parallel to the forging plane. See also rib .
- **wiper forming (wiping)**
  - Method of curving sheet metal sections or tubing over a form block or die in which this form block is rotated relative to a wiper block or slide block.
- **wire**
  - A thin, flexible, continuous length of metal, usually of circular cross section and usually produced by drawing through a die.
- **wire drawing**
  - Reducing the cross section of wire by pulling it through a die.
- **wire rod**
  - Hot-rolled coiled stock that is to be cold drawn into wire.
- **work hardening**
  - See strain hardening .
- **workability**
  - See formability .
- **wrap forming**
  - See stretch forming .
- **wrinkling**
  - A wavy condition obtained in deep drawing of sheet metal, in the area of the metal between the edge of the flange and the draw radius. Wrinkling may also occur in other forming operations when unbalanced compressive forces are set up.
- **Y**
- **yield**
  - Evidence of plastic deformation in structural materials. Also known as plastic flow or creep.
- **yield point**
  - The first stress in a material, usually less than the maximum attainable stress, at which an increase in strain occurs without an increase in stress. Only certain metals--those which exhibit a localized, heterogeneous type of transition from elastic to plastic deformation--produce a yield point. If there is a decrease in stress after yielding, a distinction can be made between upper and lower yield points. The load at which a sudden drop in the flow curve occurs is called the upper yield point. The constant load shown on the flow curve is the lower yield point.
- **yield strength**
  - The stress at which a material exhibits a specified deviation from proportionality of stress and strain. An offset of 0.2% is used for many metals. Compare with tensile strength .
- **yield stress**
  - The stress level of highly ductile materials, such as structural steels, at which large strains take place without further increase in stress.
- **Young's modulus**
  - A term used synonymously with modulus of elasticity . The ratio of tensile or compressive stresses to the resulting strain.
