The truncated cone was developed as a test that minimizes the effects of surface flaws and the variability they produce in workability (Ref 31). This test has been primarily used in cold forging.

Tests for Flow Localization

Complex forgings frequently develop regions of highly localized deformation. Shear bands may span the entire cross section of a forging and, in extreme cases, produce shear cracking. Flow localization can arise from constrained deformation due to die chill or high friction. However, flow localization can also occur in the absence of these effects if the metal undergoes flow softening or negative strain hardening.

The simplest workability test for detecting the influence of heat transfer (die chilling) on flow localization is the nonisothermal upset test, in which the dies are much colder than the workpiece. Figure 25 illustrates zones of flow localization made visible by sectioning and metallographic preparation.

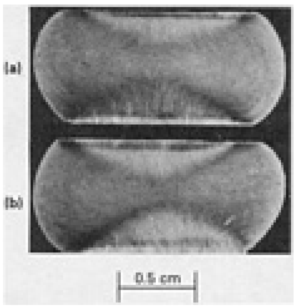

Fig. 25 Axial cross sections of specimens of Ti-6Al-2Sn-4Zr-2Mo-0.1Si with an equiaxed α starting microstructure. Specimens were nonisothermally upset at 954 °C (1749 °F) to 50% reduction in a mechanical press ($\dot{\epsilon} \approx$30 s^{-1}) between dies at 191 °C (376 °F). Dwell times on the dies prior to deformation were (a) 0 s and (b) 5 s. Source: Ref 32.

The sidepressing test conducted in a nonisothermal manner can also be used to detect flow localization. Several test specimens are sidepressed between flat dies at several workpiece temperatures, die temperatures, and working speeds. The formation of shear bands is determined by metallography (Fig. 26). Flow localization by shear band formation is more likely in the sidepressing test than in the upset test. This is due to the absence of a well-defined axisymmetric chill zone. In the sidepressing of round bars, the contact area starts out at zero and builds up slowly with deformation. In addition, because the deformation is basically plane strain, surfaces of zero extension are present, along which block shearing can initiate and propagate. These are natural surfaces along which shear strain can concentrate into shear bands.

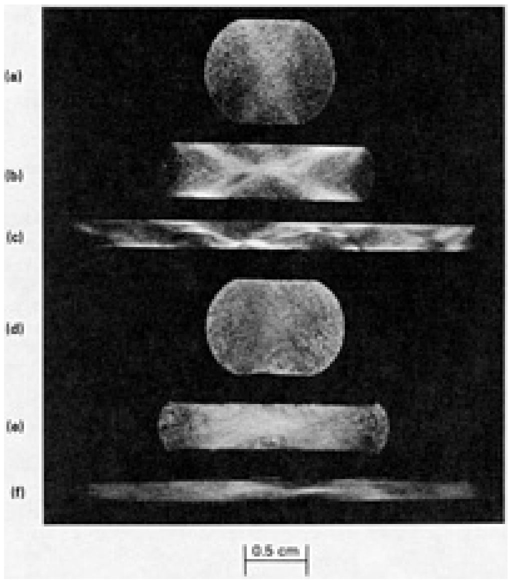

Fig. 26 Transverse metallographic sections of specimens of Ti-6Al-2Sn-4Zr-2Mo-0.1Si with an equiaxed α structure. Specimens were nonisothermally sidepressed with zero dwell time in a mechanical press ($\dot{\epsilon} \approx 30$ s^{-1}) between dies heated to 191 °C (376 °F). Specimen preheat temperatures (T_s) and percent reductions (*R*), relative to the initial specimen diameter, were as follows: (a) T_s: 913 °C (1675 °F); *R*: 14%. (b) T_s: 913 °C (1675 °F); *R*: 54%. (c) T_s: 913 °C (1675 °F); *R*: 77%. (d) T_s: 982 °C (1800 °F); *R*: 21 %. (e) T_s: 982 °C (1800 °F); *R*: 57%. (f) T_s: 982 °C (1800 °F); *R*: 79%. Source: Ref 32.

Testing to evaluate material susceptibility to localized deformation can also involve the use of a cylindrical upset specimen with a reduced gage section (Ref 33), as shown in Fig. 27. The ability of the material to distribute deformation (Fig. 28) is measured by an empirical parameter--percent distributed gage volume (DGV). The larger the DGV percentage, the greater the penetration of the deformation into the heavy ends of the specimen and the greater the ability of the material to distribute deformation. Figure 29 shows the metallographic appearance of the condition with distributed flow (Fig. 29a) and concentrated deformation (Fig. 29b). Figure 30 illustrates that the DGV percentage is a sensitive parameter for detecting flow localization.

Forging Defects

Cracking in Cold Forging. The types of cracks that develop in cold forging by upsetting-type processes are discussed in Ref 31. The various geometric forms of cold forging are shown in Fig. 31. The classification of cracks is given in Fig. 32. Table 3 provides a detailed description of each type of crack.

Table 3 Characteristics of cracks and crack growth mechanism

Cracking type	**No. of working method in the chart (see Fig. 31)**	Characteristics of cracking and estimation of crack growth mechanism
α	00, 01, 11, 02, 21, 22, 08, 87, 07, 77, 09, 03, 33, 04, 44,	**External cracking that appears at midheight of side surface of the specimen in the upsetting; two types of cracks, longitudinal and oblique, occur according to the degree of end constraint**

	43	**of specimen; they are all shear cracks**
β	08, 88, 87, 89, 04, 44, 43	**Longitudinal cracking that occurs at the bottom of the concave part of the specimen (in upsetting by a circular truncated cone punch); it is a shear crack based on the section of the specimen and is caused by the expansion of material under the cone punch due to circumferential flow; prevention requires selection of a suitable punch shape** γ	03, 33, 05, 55, 07, 77, 87, 43, 06, 66, 65	**Shear cracking that appears at the corner of extruded material in free extrusion (coining); cracking occurs at the boundary between dead-metal and plastic zones; surface cracking is caused by cracks that occur at the corners; prevention requires selection of a suitable diameter for the die** δ	33	**Cracking that occurs at midheight of material in flange in two direction free extrusion without side constraint; the material is extruded forward and backward; therefore, cracking is caused by the depression of material in flange; prevention requires selection of a suitable diameter die** ε	08, 87, 88, 89	**Cracking that occurs at midheight on inside surface of the concave part and is advanced in a circumferential direction in upsetting by the circular truncated cone punch; crack starts at the point where the material around the concave portion bends toward the inside; prevention requires selection of a suitable punch shape** α+ β	08, 87, 88, 89	**Cracking in which α and β cracks coexist**
ζ	55	**Cracking that occurs at the center of material with the sides constrained and forward and backward extrusion; the cavity occurs at the center of material, as material is extruded forward and backward** 
η	08, 87, 88, 89	**Cracking that appears to advance from upper and side surface of concave portion to the top of specimen (in upsetting by a circular truncated cone punch); in cross section, the cracks are distributed radially; in the case of a large tapered punch, cracks are caused by the expansion of upper part of specimen by the punch; prevention requires selection of a suitable punch shape**
κ	05, 55	**Cracking that occurs at the center of specimen when excessive reduction is imposed on the specimen in extrusion and drawing**

μ	66	**Peripheral cracking that occurs at midheight on the side surface of the specimen in forward and backward piercing and 45° shearing crack with respect to longitudinal axis**
λ	06, 65, 66	**Cracking that occurs at the bottom of the concave portion in piercing**
θ	**07, 99**	**Microscopic cracks that occur at the boundary between top and bottom dead metal and at the point of inflection of the metal flow in case of excessive upsetting of a bolt head in bolt forging; in practical use, the splitting off of the head is caused by these microscopic cracks**

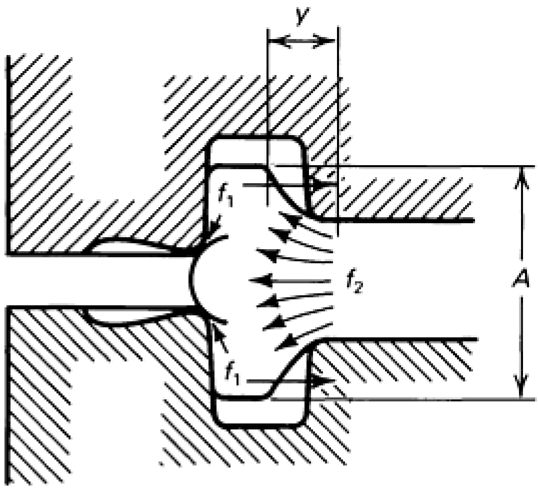
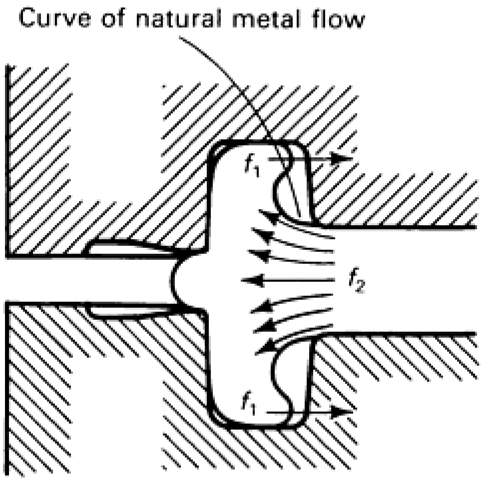
Defects in Closed-Die Forging. The defects discussed above can also occur in closed-die forging. However, other defects in addition to fracture and localized flow occur in closed-die forging. These defects often result from such factors as improper selection of the starting or preform shape of the workpiece, poor die design, improper selection of lubricant, temperature, or working speed.

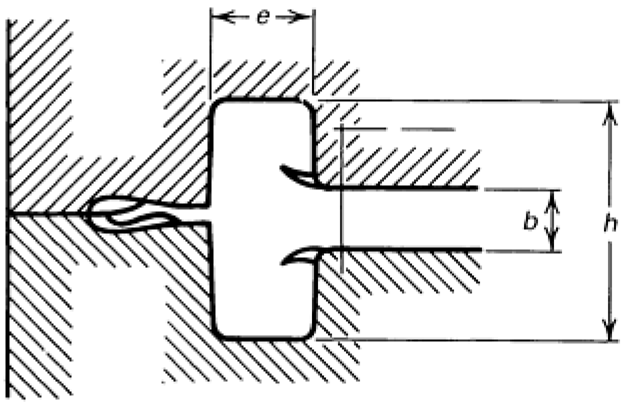
The principal defects in closed-die forging are laps, flow-through defects, extrusion defects, and cold shuts. Laps are defects that form when metal folds back over itself during forging. For example, in the finish forging of a webbed forging in which the preform web is too thin, the web may buckle and fold back onto itself. In addition, in the forging of a web, the metal may flow nonuniformly and cause a lap (Fig. 33). Frequently, a lap results from an excessively sharp radius in the forging die. Figure 34 shows a forging lap at a sharp radius.



Formation of flash



Reverse flow forming a fold



Formed forging defect

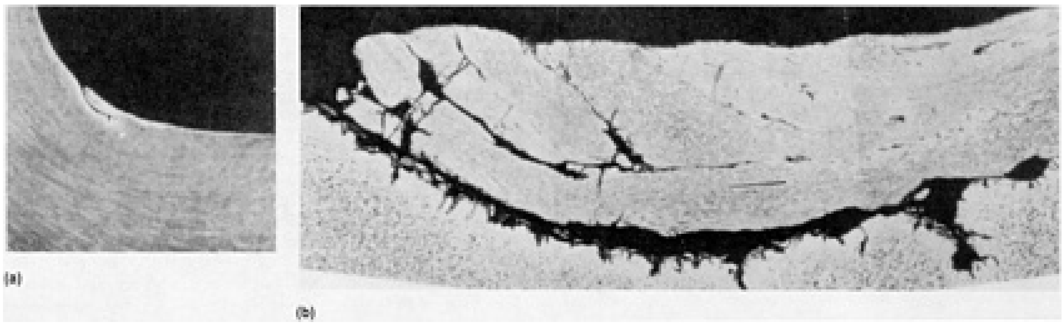

Fig. 34 Lap defect in Ti-6Al-4V bulkhead forging. (a) $3\frac{1}{3}\times$. (b) $50\times$. Courtesy of F. Lake and D. Moracz, TRW, Inc.

Flow-through defects are flaws that form when metal is forced to flow past a recess after the recess has filled or when material in the recess has ceased to deform because of chilling (Fig. 35). Similar to laps in appearance, flow-through defects can be shallow, but they are indicative of an undesirable grain flow pattern or shear band that extends much deeper into the forging. Flow-through defects can also occur when trapped lubricant forces metal to flow past an impression.

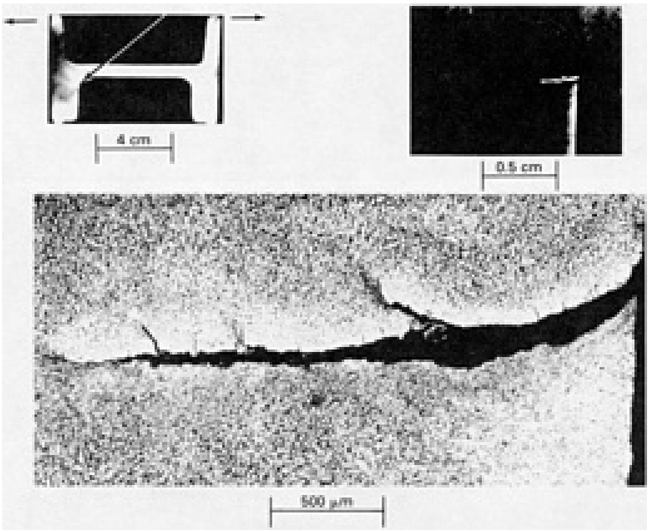

Fig. 35 Flow-through defect in Ti-6Al-4V rib-web structural part. Source: Ref 35.

Extrusion-type defects are formed when centrally located ribs formed by extrusion-type flow draw too much metal from the main body or web of the forging. A defect similar to a pipe cavity is thus formed (Fig. 36). Methods of minimizing the occurrence of these defects include increasing the thickness of the web or designing the forging with a small rib opposite the larger rib, as shown in Fig. 36.

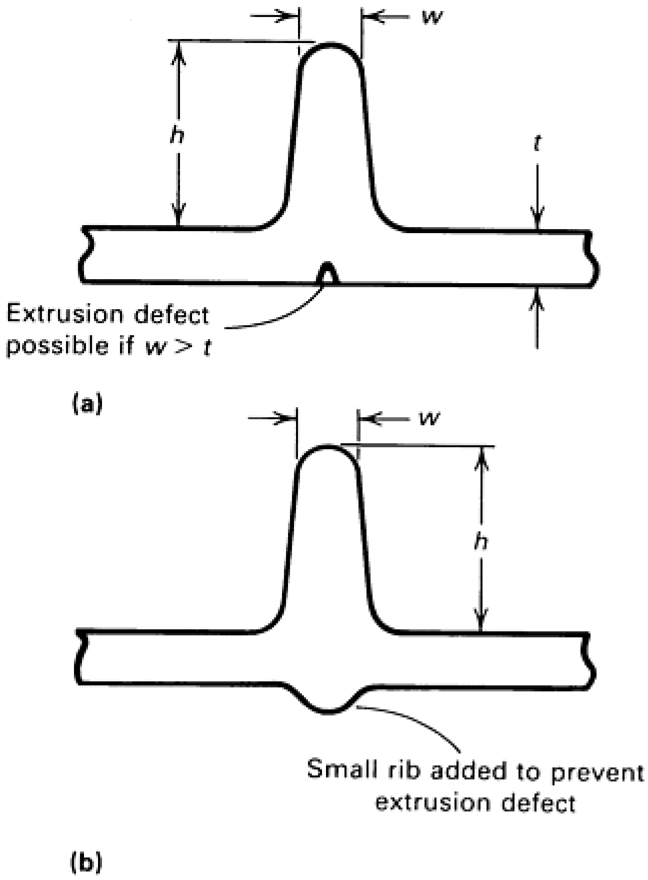

Fig. 36 Extrusion-type defect in centrally located rib (a) and die-design modification (b) used to avoid defect. Source: Ref 34.

Most of the defects summarized above occur in hot forging, which is most common for impression-die forging. Therefore, defect formation may also involve entrapment of oxides and lubricant. When this occurs, the metal is incapable of rewelding under the high forging pressures; the term cold shut is frequently applied in conjunction with laps, flow-through defects, and so on, to describe the flaws generated.

These defects are all related to the velocity field distribution of the deforming metal. They can be avoided by proper die design, preform design, and choice of lubrication system. Strictly speaking, these defects are not fundamental to the workability of the material. However, knowledge of these common forging defects is necessary for a practical understanding of workability. These are the defects that commonly limit deformation in the forging process.

Workability Theory and Application in Bulk Forming Processes

Howard A. Kuhn, University of Pittsburgh

Introduction

WORKABILITY, as described in the two previous articles in this Section, is not merely a property of a material but a characteristic of the material/process system. The role of the material is measured by a simple test or tests and should be expressed in a quantitative form that is universally applicable. This measure is taken to be a basic property of the material composition and structure, and it reflects the macroscopic outcome of the micromechanisms of plastic flow perturbed by such inhomogeneities as voids, inclusions, and grain boundaries (see, for example, Fig. 3 to 5 in the article "Introduction to Workability" in this Section). Such phenomena are dependent not only on the material structure but also on the process parameters (strain rate and temperature), which define the role of the process in determining workability.

The micromechanisms of ductile fracture in bulk forming processes are strongly influenced by the stress and strain environment imposed by the process. It was shown in Fig. 14 in the article "Introduction to Workability" in this Section that an overall measure of strain to fracture could be related to an overall value of hydrostatic stress in the material during processing. In the spectrum of processes (extrusion, rolling, forging, and wire drawing), the average hydrostatic stress becomes increasingly tensile, and the strain to fracture progressively decreases. Within each of these processes, however, the stress and strain states can be considered on a localized basis in the specific regions in which fractures initiate. These localized conditions are controlled by the geometry of the workpiece, die design, and friction at the die/workpiece interface. These three factors, in addition to the strain rate and temperature parameters mentioned above, embody the role of the process in determining workability.

This article will focus on the effects of mechanical plasticity on workability, that is, process control of localized stress and strain conditions to enhance workability. First, the nature of local stress and strain states in bulk forming processes will be described, leading to a classification scheme that facilitates the application of workability concepts. This defines testing procedures and specific process measurements for an experimental approach to workability evaluation. Theoretical models and fracture criteria will then be described and compared with experimental results. Finally, the application of workability concepts to forging, rolling, and extrusion processes will be discussed.

Workability Theory and Application in Bulk Forming Processes

Howard A. Kuhn, University of Pittsburgh

Stress and Strain States

Forging, extrusion, and rolling processes are generally considered to involve the application of compressive force to material to impart a change in shape and dimensions. Upon close examination, however, it is clear that deformation resulting from the applied load causes secondary stress and strain states that vary from point to point throughout the deforming workpiece. These stress and strain states may include tension, so fracture can occur at certain locations in a material even though the primary (applied) load is compressive.

To explore this possibility further, it is useful to review plasticity theory briefly. In the article "Introduction to Workability" in this Section, the von Mises yield criterion was given; this yield criterion is the foundation of plasticity theory for isotropic materials. It gives the relationships between normal and shear stress components at yielding. From this, relationships between stress and strain components are derived:

$$\begin{aligned}
\epsilon_1 &= \lambda \left[\sigma_1 - \frac{1}{2}\sigma_2 - \frac{1}{2}\sigma_3\right] \\
\epsilon_2 &= \lambda \left[\sigma_2 - \frac{1}{2}\sigma_3 - \frac{1}{2}\sigma_1\right] \\
\epsilon_3 &= \lambda \left[\sigma_3 - \frac{1}{2}\sigma_1 - \frac{1}{2}\sigma_2\right]
\end{aligned} \qquad \textbf{(Eq 1)}$$

where ε denotes strain, σ denotes stress, and the subscripts 1, 2, and 3 designate the three directions in an orthogonal coordinate system. Here, λ is a proportionality factor dependent on the deformation history and flow stress curve of the material. The resulting strain in a given direction is affected by the stress in all three coordinate directions. In addition, these relationships satisfy the volume constancy condition, $\varepsilon_1 + \varepsilon_2 + \varepsilon_3 = 0$.

To illustrate these relationships, it is useful to consider a two-dimensional case of plane stress, $\sigma_3 = 0$:

$$\epsilon_1 = \lambda \left[\sigma_1 - \frac{1}{2}\sigma_2\right]$$
$$\epsilon_2 = \lambda \left[\sigma_2 - \frac{1}{2}\sigma_1\right] \quad \text{(Eq 2)}$$

Referring to Fig. 1 and Eq 2, a reduction in thickness (compressive strain in the 2-direction) can be accomplished either by a compressive stress, P_2 (or $-\sigma_2$), or by a tensile stress, σ_1. Although the nature of the deformation is the same in both cases, accomplishing that deformation in the latter case could risk fracture because it involves a tensile stress.

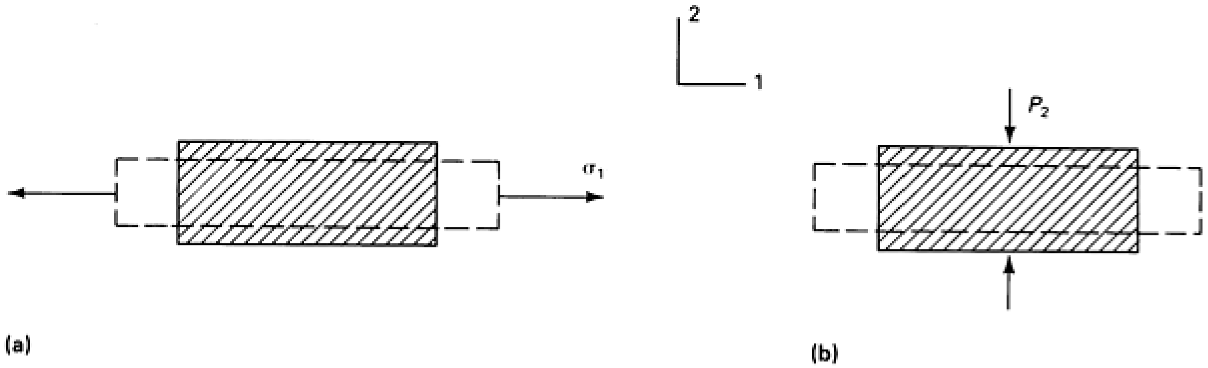

Fig. 1 Similarity of deformation under horizontal tension (a) and vertical compression (b).

For more general cases, Eq 2 can be rearranged to determine the following stresses:

$$\sigma_1 = \frac{4}{3\lambda}\left[\epsilon_1 + \frac{1}{2}\epsilon_2\right] = \frac{4}{3\lambda}\epsilon_1\left[1 + \frac{1}{2}\frac{\epsilon_2}{\epsilon_1}\right]$$
$$\sigma_2 = \frac{4}{3\lambda}\left[\epsilon_2 + \frac{1}{2}\epsilon_1\right] = \frac{4}{3\lambda}\epsilon_1\left[\frac{1}{2} + \frac{\epsilon_2}{\epsilon_1}\right] \quad \text{(Eq 3)}$$
$$\sigma_3 = 0$$

Therefore, the stresses depend on the localized strains ε_1 and ε_2 that result from metal flow. Equation 3 is a more convenient representation of plasticity relationships for workability study.

For example, the cylindrical surface of a compression test undergoes various combinations of axial and circumferential strains, depending on the aspect ratio and the friction at the die contact surfaces (Fig. 2). When no friction exists, the ratio of circumferential strain to axial strain is $\varepsilon_1/\varepsilon_2 = -\frac{1}{2}$. According to the first part of Eq 3, $\sigma_1 = 0$ for this case. The deformation in this case is referred to as homogeneous compression, because the only stress acting is σ_2 and it is uniform throughout the specimen. Therefore, the homogeneous compression test is suitable for measuring flow stress.

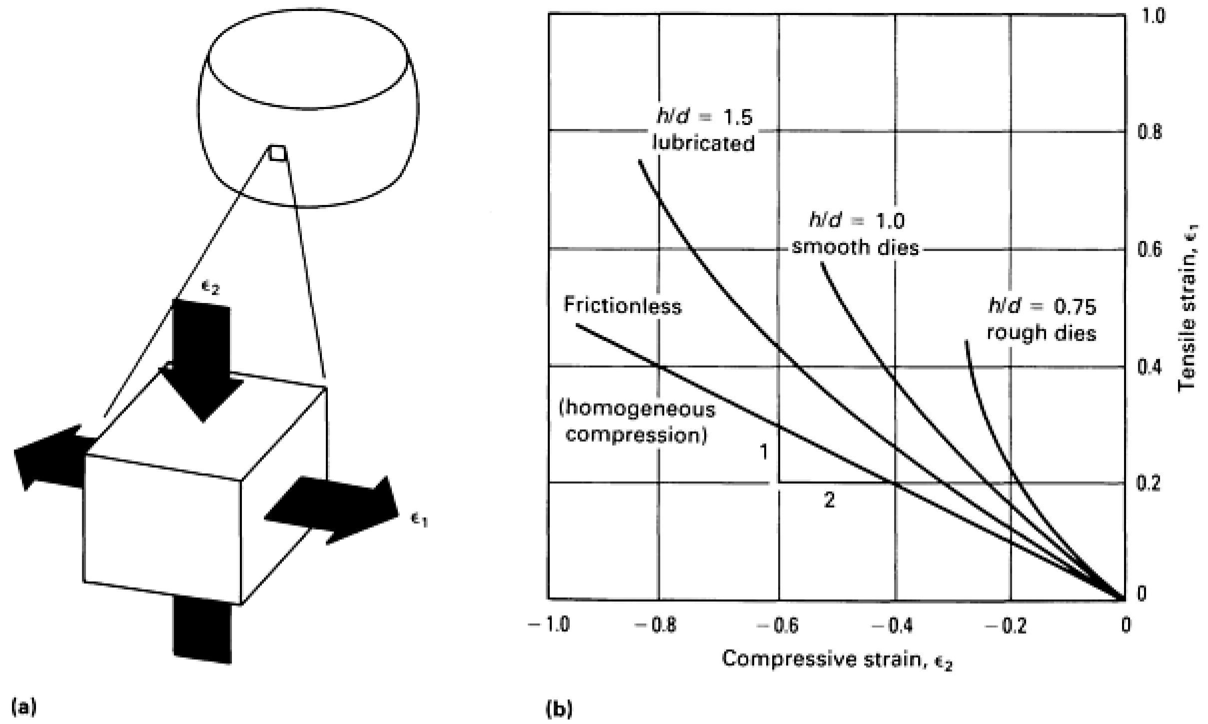

Fig. 2 Localized strains on the bulging cylindrical surface of an upset test (a) and their variation with aspect ratio and friction conditions (b). Source: Ref 1.

When friction exists at the die contact surfaces, material at these surfaces is constrained from moving outward, while material at the midplane is not constrained. As a result, bulging occurs, as shown in Fig. 2(a). Under these conditions, the circumferential strain ε_1 (>0) increases, and the localized axial compressive strain ε_2 (<0) decreases. From Eq 3 as $\varepsilon_1/\varepsilon_2$ becomes more negative ($< -\frac{1}{2}$), σ_1 becomes more positive. Therefore, increasing bulging due to friction during the compression of a cylinder increases the secondary tensile stress σ_1 and enhances the likelihood of fracture.

Similarly, at the edges of bars during rolling (Fig. 3), the elongation strain ϵ_1 is determined by the overall reduction in area. The localized compressive vertical strain ε_2, however, depends on the shape of the edge. Greater convexity and sharpness of the edge decrease the compressive vertical strain for a given reduction, which, from the first part of Eq 3, increases the secondary tensile stress σ_1 at the edge. Therefore, edge cracking during rolling is also due to secondary stress states.

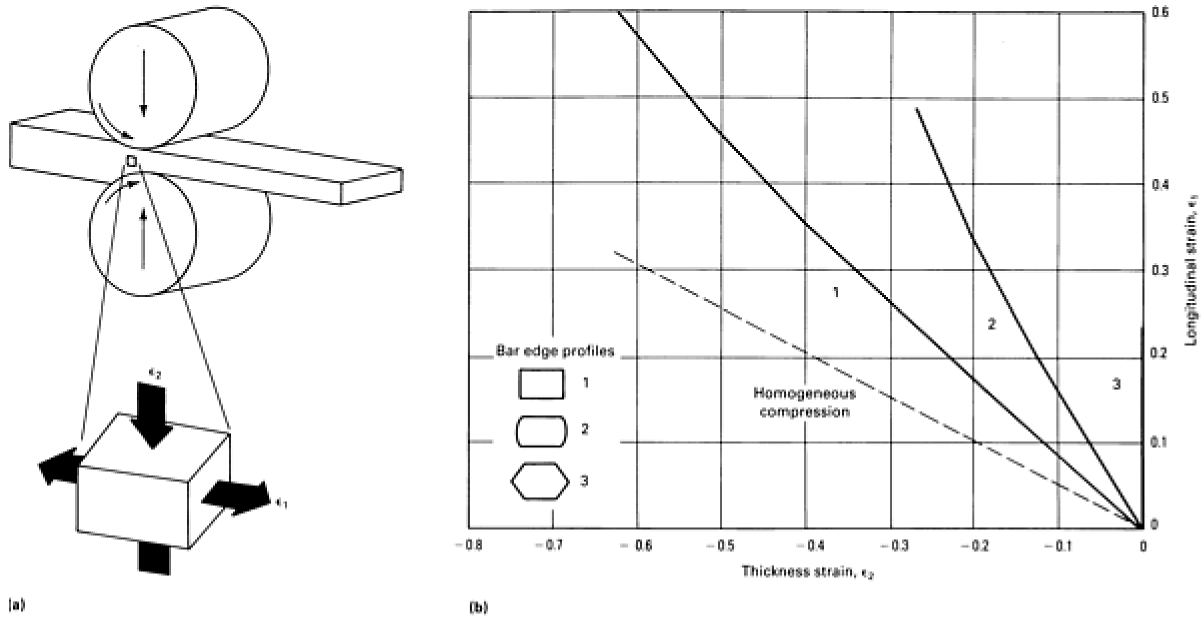

Fig. 3 Localized strains at the edges of bars during rolling (a) and their variation with edge profile (b). Source: Ref 2.

More complex cases of the same type of secondary tensile stress states occur in forging (Fig. 4). During the forging of a hub shape, for example, the top surface of the hub is subjected to biaxial tension because of friction during flow around the die radius (Fig. 4a). This is identical to the conditions present at the nose of a billet that is being extruded or rolled. Similarly, during forging, the top surface of a rib undergoes tensile strain in the direction of curvature, and essentially no strain occurs along the length direction of the rib (Fig. 4b). In both cases, localized secondary tensile stresses are generated that may cause fracture. These stresses can be calculated from measured strain values using Eq 3.

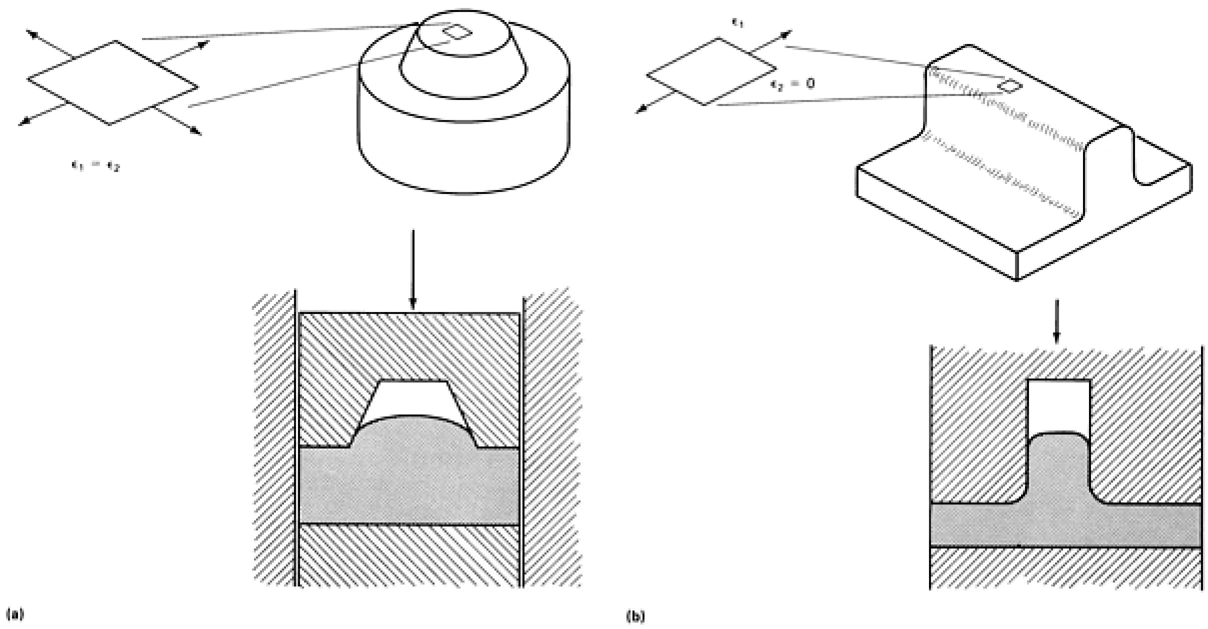

Fig. 4 Strains at the free surfaces of forgings. (a) Axisymmetric hub. (b) Rib-web forging.

Figures 2, 3, and 4 show examples of plane stress, with the stress normal to the free surface being zero. Other regions of workpieces in bulk deformation processes, however, are subjected to three-dimensional stress states. For example, material at the die contact surfaces in forging, rolling, and extrusion (Fig. 5) is subjected to strains ϵ_1 and ϵ_2 in the plane of the surface, as in Fig. 2, 3, and 4. In Fig. 5, however, this surface is also acted upon by pressure P_3 normal to the plane. Similarly, at internal locations of the workpieces in such processes as forging or wire drawing (Fig. 6), a material element of the central longitudinal plane is subjected to strains ϵ_1 and ϵ_2 and stress normal to the plane.

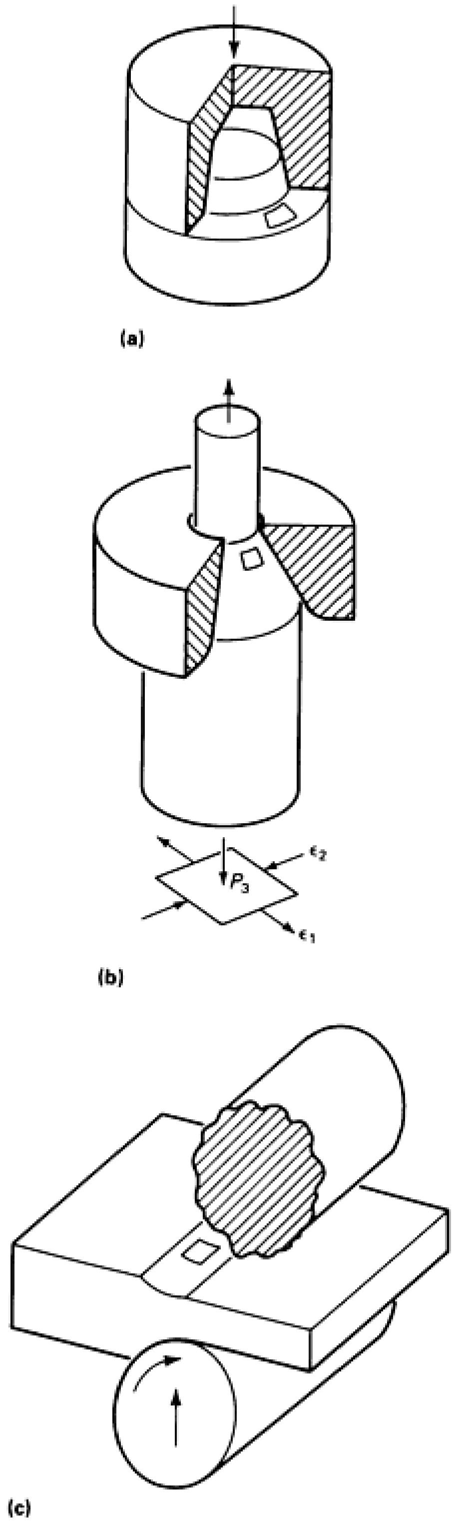

Fig. 5 An element of material at the die contact surfaces during forging (a), drawing or extrusion (b), and rolling (c).

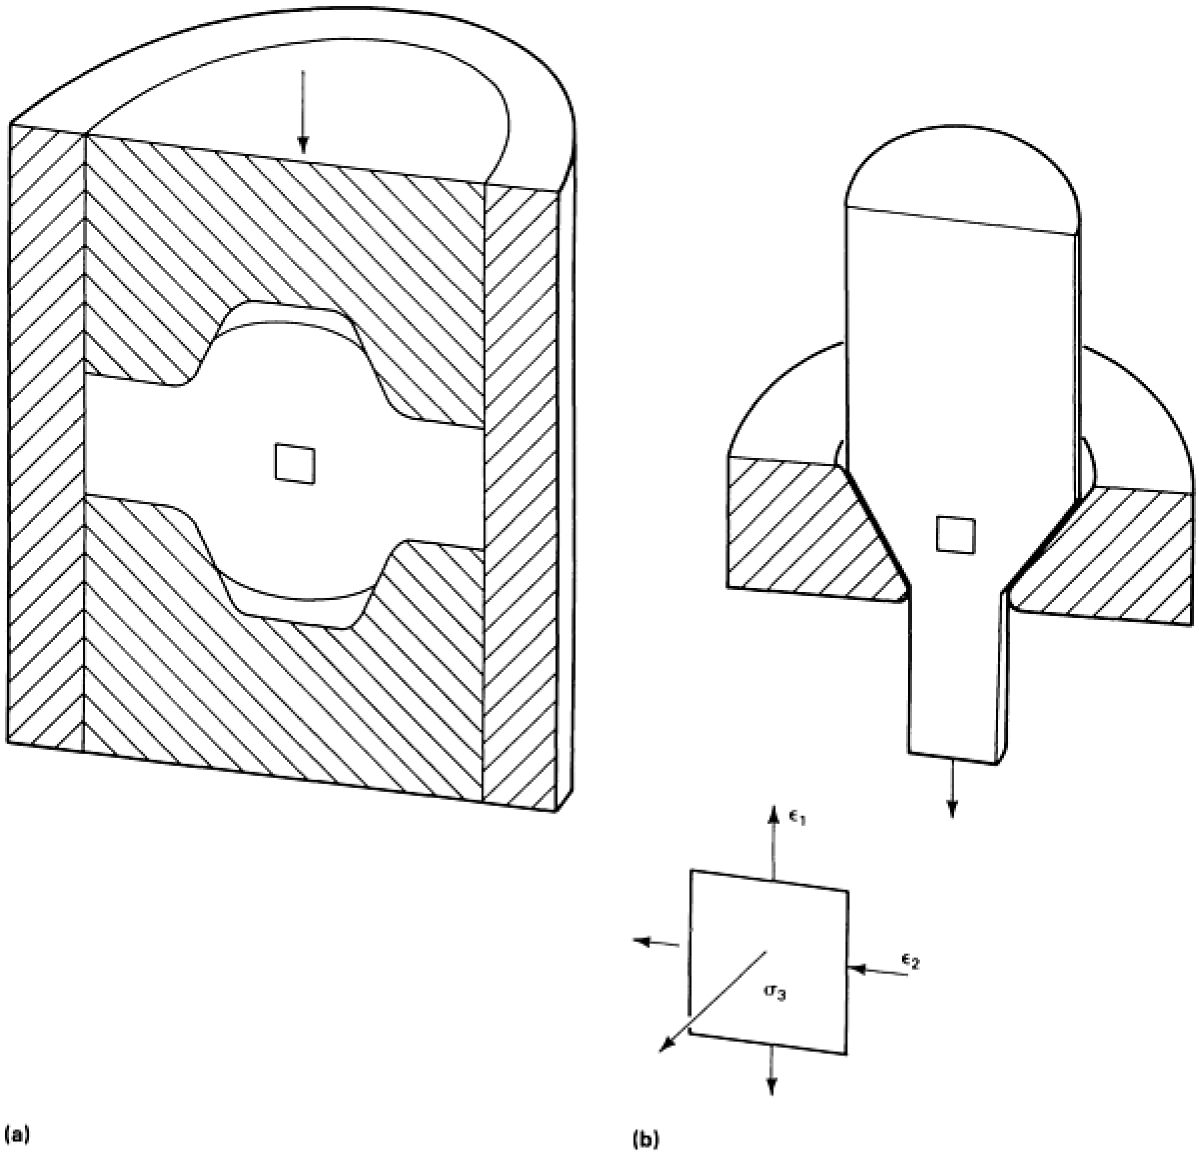

Fig. 6 An element of material at the center of a forging undergoing double extrusion (a) and at the center of wire being drawn (b). The element undergoes strains ε_1 and ε_2, as in Fig. 2, 3, and 4, with stress σ_3 normal to the 1-2 plane.

In Fig. 5 and 6, the material element can be thought of as the plane-stress elements in Fig. 2, 3, and 4 with σ_3 acting normal to the plane. If ε_1 and ε_2 are taken to be the strains in this plane, then Eq 3 becomes:

$$\sigma_1 = \frac{4}{3\lambda}\left[\epsilon_1 + \frac{1}{2}\epsilon_2\right] + \sigma_3$$

$$\sigma_2 = \frac{4}{3\lambda}\left[\epsilon_2 + \frac{1}{2}\epsilon_1\right] + \sigma_3$$

$$\sigma_3 = \sigma_3$$

In other words, for the same deformation (that is, the same values of ε_1 and ε_2 as in Fig. 2, 3, 4), the stresses σ_1 and σ_2 in Eq 3 are biased by σ_3. The stress normal to the surface, then, increases the hydrostatic stress component of the stress state by σ_3. This reflects the basic concept that hydrostatic stress does not affect yielding or plastic deformation. As shown in Fig. 14 in the article "Introduction to Workability" in this Section, however, the hydrostatic stress has a significant effect on fracture. In Fig. 5, the compressive stress (die pressure) P_3 would increase the strains at fracture, but in Fig. 6 the internal stress σ_3 may be tensile and decrease the strains at fracture.

The above discussion of stress and strain states in various regions of workpieces suggests a convenient method of classifying cracking defects, including those shown in Fig. 32 in the article "Workability Tests" in this Volume. Figures 2, 3, and 4 in this article illustrate the locations at which free surface cracks occur in forging and rolling, as well as the nose ends of billets in extrusion or rolling. They are represented by α cracks in Fig. 32 in the article "Workability Tests." Figure 5 in this article shows examples of circumstances in which contact surface cracking occurs--for example, the fir tree defect in extrusion or the longitudinal surface cracks in rolled plates. Other examples in forging include γ, η, and λ cracks as shown in Fig. 32 in the article "Workability Tests."

Empirical Criterion of Fracture

The stress and strain environments described in the previous section in this article suggest that a workability test should be capable of subjecting the material to a variety of surface strain combinations. A capability for testing under superimposed normal stress would also be desirable.

When considering workability tests, it is important to recognize that fractures initiate in localized regions where interaction between the stress and strain states and the material structure reaches a critical level. Orientation, shape, and volume fraction of inclusions and other inhomogeneities have a dominant effect on the fracture process. Therefore, it is critically important that workability test specimens contain material having the same microstructural features as the material in the localized, potential fracture regions of the actual process.

Specifically, when evaluating a workpiece for surface fractures, specimen surfaces must contain the as-received surface of the workpiece under consideration because it may contain laps, seams, a decarburized layer, and so on, which affect fracture initiation. By the same argument, evaluation of material for internal fractures, such as central burst, must involve test specimens taken from the middle of the workpiece, where, for example, segregation of second phases may have occurred. Also, because of possible anisotropy effects, orientation of the critical stresses with respect to any inclusion alignment must be the same in the test specimens as it is in the actual process and material of interest.

The compression test has become a standard for workability evaluation. As shown in Fig. 2, a range of strain combinations can be developed at the cylindrical free surface simply by altering friction and geometry conditions. The influence of friction and consequent bulging on circumferential tensile stress development is clearly shown in Fig. 7. Compression with friction produces circumferential tension that leads to fracture, while frictionless compression avoids barreling, tension, and cracking as described in Fig. 2 and Eq 3.

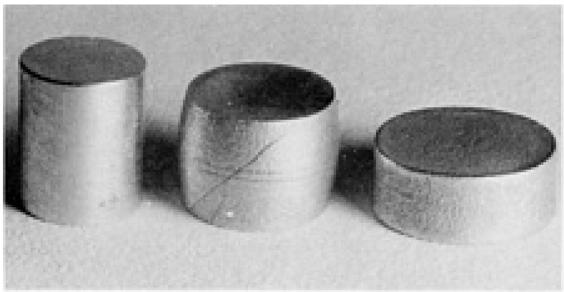

Fig. 7 Compression tests on 2024-T35 aluminum alloy. Left to right: undeformed specimen, compression with friction (cracked), compression without friction (no cracks).

Alterations of the compression test geometry have been devised to extend the range of surface strains available toward the vertical, tensile strain axis, ε_1 (Ref 3). Test specimens are artificially pre-bulged by machining a taper or a flange on the cylinders (Fig. 8). Compression then causes lateral spread of the interior material, which expands the rim circumferentially while applying little axial compression to the rim. Therefore, the tapered and flanged upset test specimens provide strain states consisting of small compressive strain components. Each combination of height, *h,* and thickness, *t,* gives a different ratio of tensile to compressive strain. The strain states developed at the surfaces of straight, tapered, and flanged compression test specimens are summarized in Fig. 9.

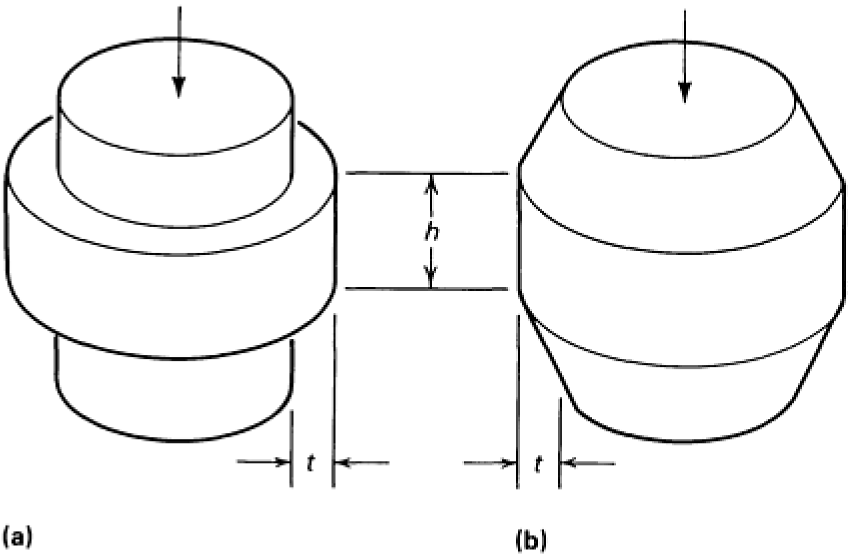

Fig. 8 Flanged (a) and tapered (b) prebulged compression test specimens. Lateral spread of interior material under compression expands the rim circumferentially while little axial compression is applied. See Fig. 9.

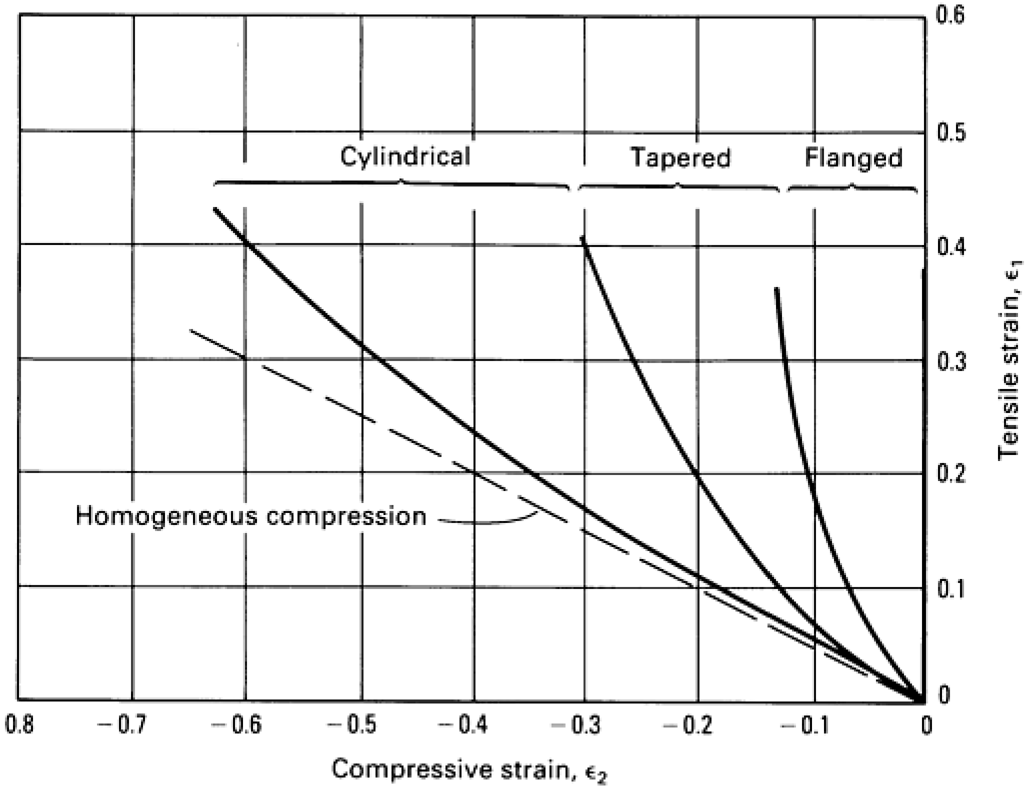

Fig. 9 Range of free surface strain combinations for compression tests having cylindrical (Fig. 2), tapered and flanged (Fig. 8) edge profiles. The ranges shown are approximate and they may overlap a small amount.

The variety of strain combinations available in compression tests offers the possibility for material testing over most of the strain combinations that occur in actual metalworking processes. A number of samples of the same material and condition are tested, each one under different friction and geometry parameters. Tests are carried out until fracture is observed, and the local axial and circumferential strains are measured at fracture. Figures 10, 11, and 12 give some examples of results for AISI 1045 carbon steel, 2024-T351 aluminum alloy at room temperature, and 2024-T4 alloy at a hot-working temperature. In some cases, the fracture strains fit a straight line of slope -$\frac{1}{2}$; in others, the data fit a dual-slope line with slope -$\frac{1}{2}$ over most of the range and slope -1 near the tensile strain axis. Similar data have been obtained for a wide variety of materials. In each case, the straight line behavior (single or dual slope) appears to be characteristic of all materials, but the height of the line varies with the material, its microstructure, test temperature, and strain rate.

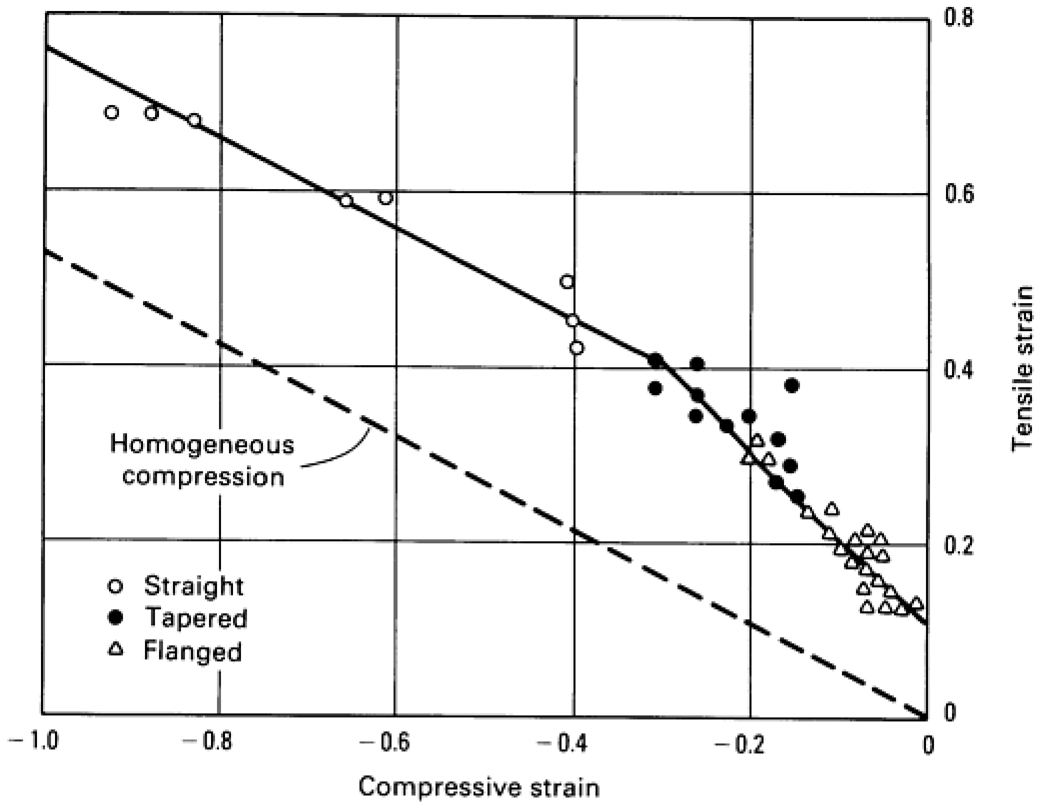

Fig. 10 Fracture locus for AISI 1045 cold-drawn steel.

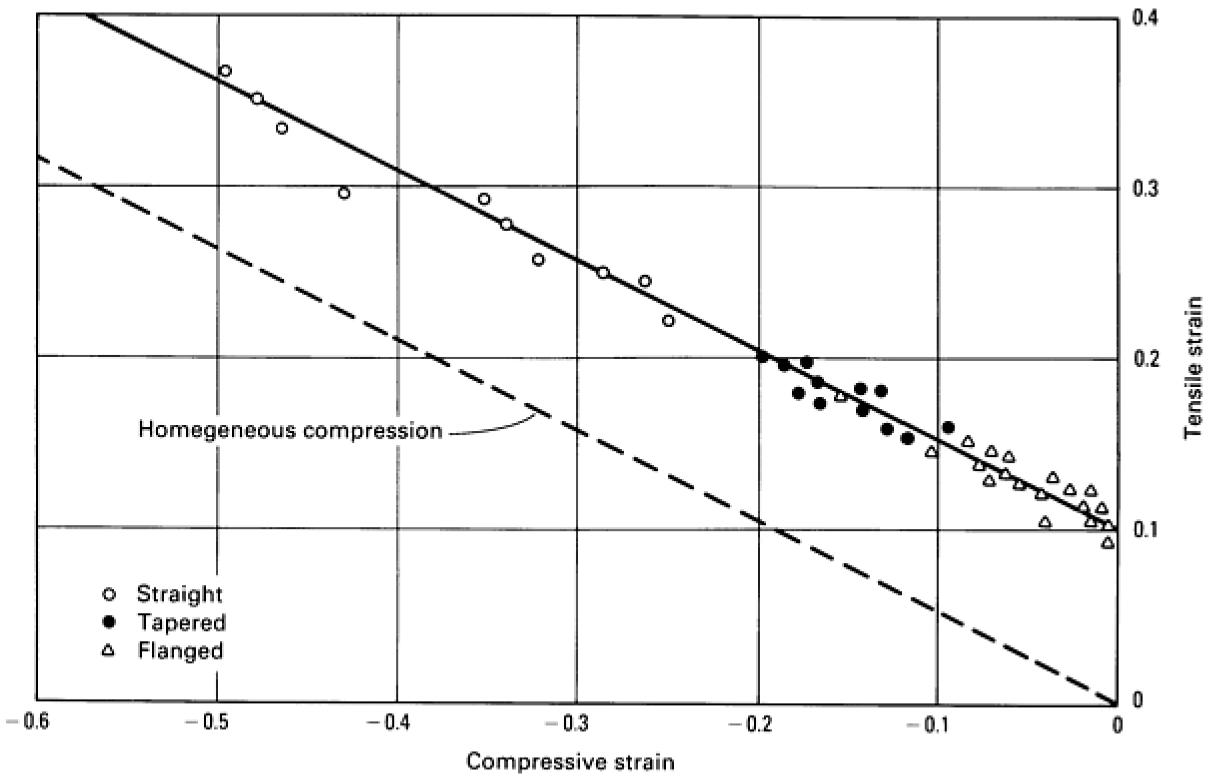

Fig. 11 Fracture locus for aluminum alloy 2024-T351 at room temperature.

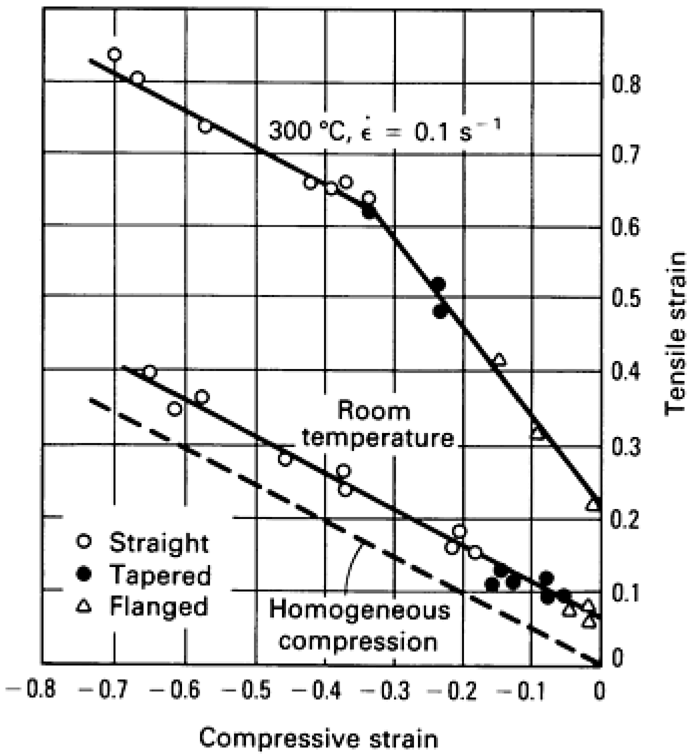

Fig. 12 Fracture locus for aluminum alloy 2024-T4 at room temperature and at 300 °C (570 °F). $\dot{\epsilon}$ **= 0.1 s**$^{-1}$**.**

The nature of the fracture loci shown in Fig. 10, 11, and 12 suggests an empirical fracture criterion representing the material aspect of workability. The strain paths at potential fracture sites in material undergoing deformation processing (determined by measurement or mathematical analysis) can then be compared to the fracture strain loci. Such strains can be altered by process parameter adjustment, and they represent the process input to workability. If the process strains exceed the fracture limit lines of the material of interest, fracture is likely. Other approaches to establishing fracture criteria, as well as applications of the criteria, are given in the following two sections of this article.

Theoretical Fracture Models and Criteria

Fracture criteria for metalworking processes have been developed from a number of viewpoints. The most obvious approach involves modeling of the void coalescence phenomenon normally associated with ductile fracture (see Fig. 3 in the article "Introduction to Workability" in this Section). Another approach involves a model of localized thinning of sheet metal that has been adapted to bulk forming processes. In addition to models of fracture, criteria have been developed from macroscopic concepts of fracture. The Cockcroft criterion is based on the observation that both tensile stress and plastic deformation are necessary ingredients, which lead to a tensile deformation energy condition for fracture.

The upper bound method has been used to predict fracture in extrusion and drawing. Other approaches are based on the calculation of tensile stress by slip-line fields.

Void Growth Model. Microscopic observations of void growth and coalescence along planes of maximum shear leading to fracture have led to the development of a model of hole growth (Ref 4). Plasticity mechanics is applied to the analysis of deformation of holes within a shear band. When the elongated holes come into contact, fracture is considered to have occurred (Fig. 13). When the McClintock model is evaluated for a range of applied stress combinations, a fracture strain line can be constructed.

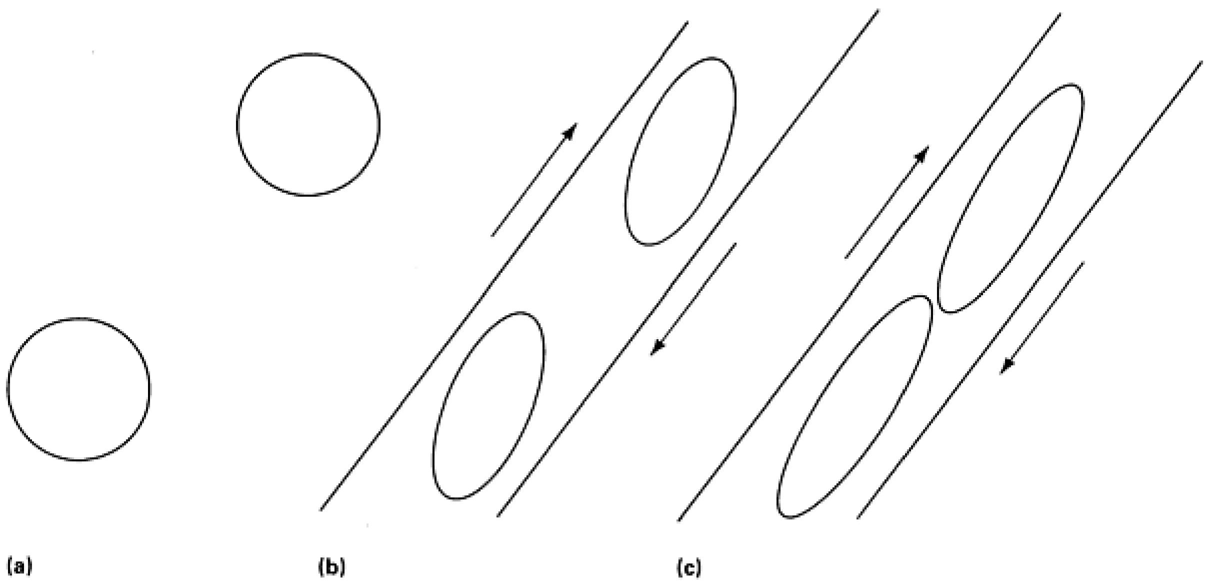

Fig. 13 McClintock model of void coalescence by shear from initial circular voids (a), through growth (b), and void contact (c).

Figure 14 shows the calculated results from the McClintock model in comparison with the experimental fracture line. The predicted fracture strain line has a slope of $-\frac{1}{2}$ over most of its length, matching that of the experimental fracture line. Near the tensile strain axis, the slope of the predicted line is -1, matching that of actual material results shown in Fig. 10 and 12.

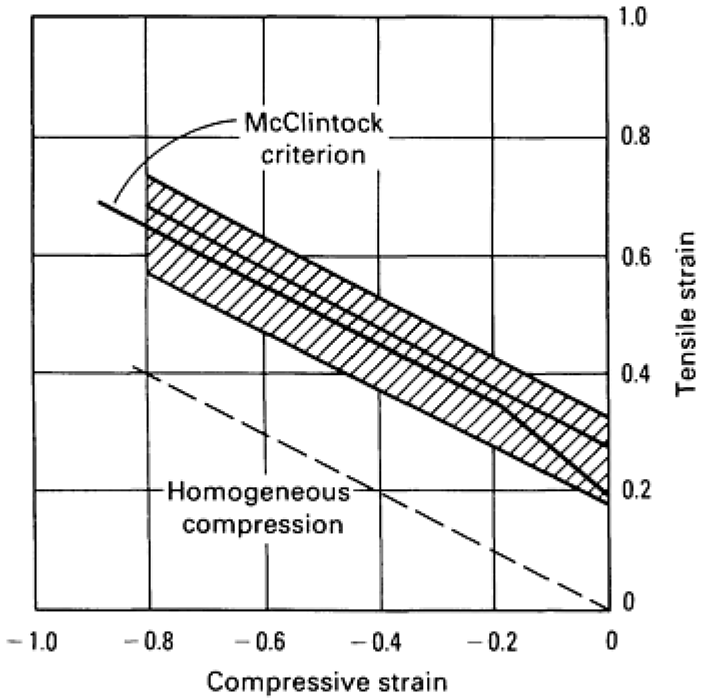

Fig. 14 Fracture strain locus predicted by the McClintock model of void growth. The shaded area represents typical experimental fracture loci, such as Fig. 10, 11, and 12.

Localized Thinning Model. In sheet forming, the observation that a neck forms before fracture, even under biaxial stress conditions in which localized instability cannot occur, has prompted consideration of the effects of inhomogeneities in the material. For example, a model of localized thinning due to a small inhomogeneity has been devised (Ref 5). Beginning with the model depicted in Fig. 15, plasticity mechanics is applied to determine the rate of thinning of the constricted region t_B in relation to that of the thicker surrounding material t_A. When the rate of thinning reaches a critical value, the limiting strains are considered to have been reached, and a forming limit diagram can be constructed. The analysis includes the effects of crystallographic anisotropy, work-hardening rate, and inhomogeneity size.

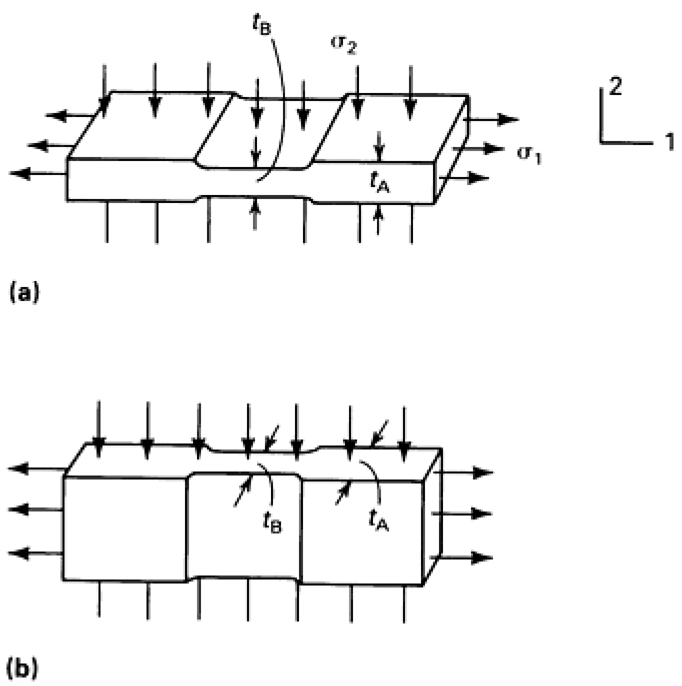

Fig. 15 Models for the analysis of localized thinning and fracture at a free surface. (a) R-model, (b) Z-model. Source: Ref 6.

This model was applied to free surface fracture in bulk forming processes because of evidence that localized instability and thinning also precede this type of ductile fracture (Ref 6). Two model geometries were considered, one having a groove in the axial direction (Z-model) and the other having a groove in the radial direction (R-model) as shown in Fig. 15. Applying plasticity mechanics to each model, fracture is considered to have occurred when the thin region, t_B, reduces to zero thickness. When these fracture strains are plotted for different applied stress ratios, a fracture strain line can be constructed. As shown in Fig. 16, the predicted fracture line matches the essential features of the experimental fracture lines. The slope is -½ over most of the strain range and approximately -1 near the tensile strain axis. Again, this model is in general agreement with the dual-slope fracture loci shown in Fig. 10 and 12.

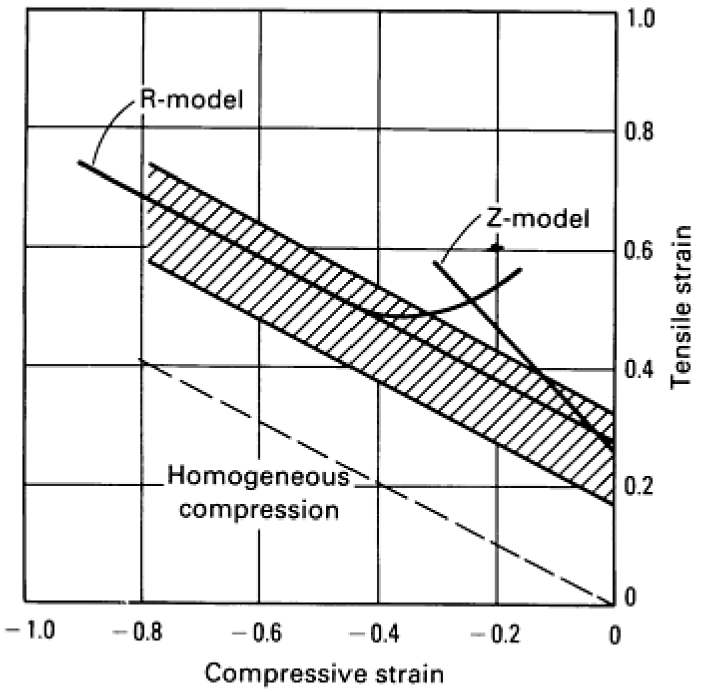

Fig. 16 Fracture strain locus predicted by the model of localized thinning. The shaded area represents typical experimental fracture loci.

Cockcroft Model. The Cockcroft criterion of fracture is not based on a micromechanical model of fracture, but simply recognizes the macroscopic roles of tensile stress and plastic deformation (Ref 7). It is suggested that fracture occurs when the tensile strain energy reaches a critical value:

$$\int_0^{\bar{\epsilon}_f} \sigma^* d\bar{\epsilon} = C$$

where σ^* is the maximum tensile stress; $\bar{\epsilon}$ is the equivalent strain; and C is a constant determined experimentally for a given material, temperature, and strain rate. The criterion has been successfully applied to cold-working processes. It has also been reformulated to provide a predicted fracture line for comparison with the experimental fracture strain line. Figure 17 shows that the fracture strain line predicted by the Cockcroft criterion is also in reasonable agreement with experimental results. This criterion does not show the dual-slope behavior of the previous models and some actual materials. The question of why some materials exhibit the dual-slope fracture locus and others only a single slope remains the subject of speculation, discussion, and further study.

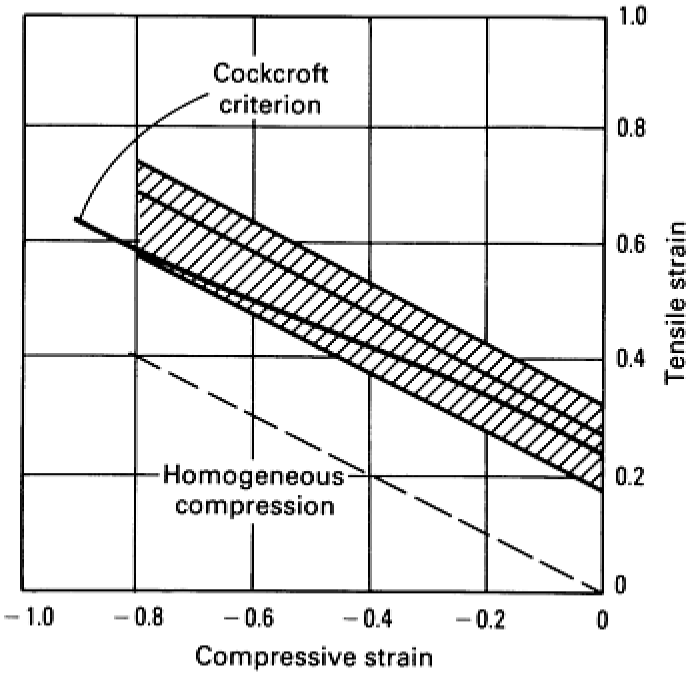

Fig. 17 Fracture strain locus predicted by the Cockcroft criterion.

The upper bound method of plasticity analysis requires the input of a flow field in mathematical function form. The external work required to produce this flow field is determined through extensive calculation. This value for external work is an upper bound on the actual work required. Through optimization procedures, the flow field can be found that minimizes the calculated external work done, and this flow field is closest to the actual metal flow in the process under analysis. The upper bound method has been applied to a number of metalworking processes (Ref 8).

In consideration of metal flow fields, perturbations can be incorporated that simulate defect formation. In some situations, the external work required to create the flow field with defects is less than the work required to create the flow field without defects (sound flow). According to the upper bound concept, defects would occur in these situations.

The upper bound method has been applied to the prediction of conditions for central burst formation in extrusion and wire drawing. As shown in Fig. 18, for die angles less than α_1, sound flow requires less drawing force than flow with central burst formation. Above α_2, extrusion with a dead-metal zone near the die requires lower drawing force. In the range of die angles between α_1 and α_2, central burst is energetically more favorable (Ref 9).

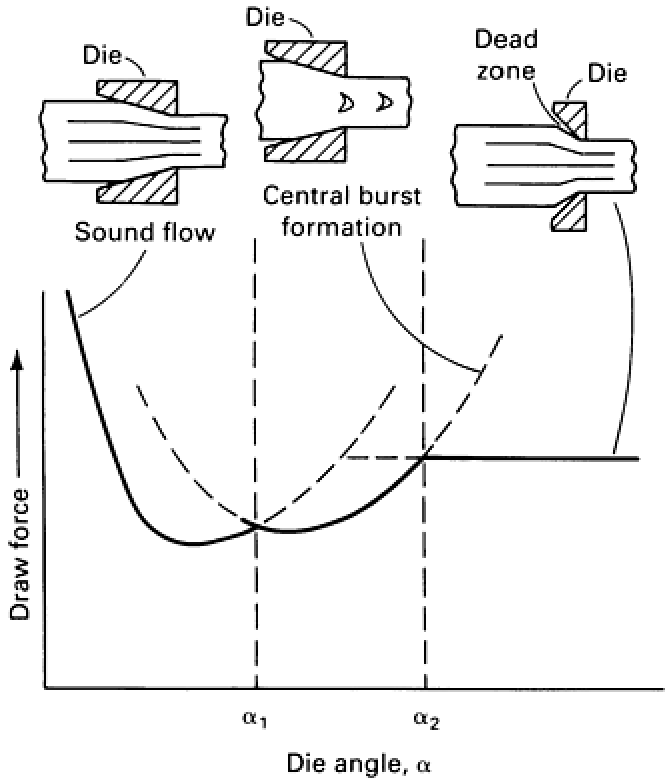

Fig. 18 Variation in mode of flow with die angle in wire drawing. The mode requiring the smallest force at any die angle is the active mode. This is a schematic for one value of reduction. Source: Ref 9.

Repeated calculations using the upper bound method provide the combinations of die angle and reduction that cause central burst (Fig. 19). Friction at the die contact surface affects the results. If operating conditions are in the central burst region, defects can be avoided by decreasing the die angle and/or increasing the reduction so that the operating conditions are in the safe zone. This example is a clear illustration of the role of process parameters (in this case, geometric conditions) in workability. An application of this method is given in the section "Applications" in this article.

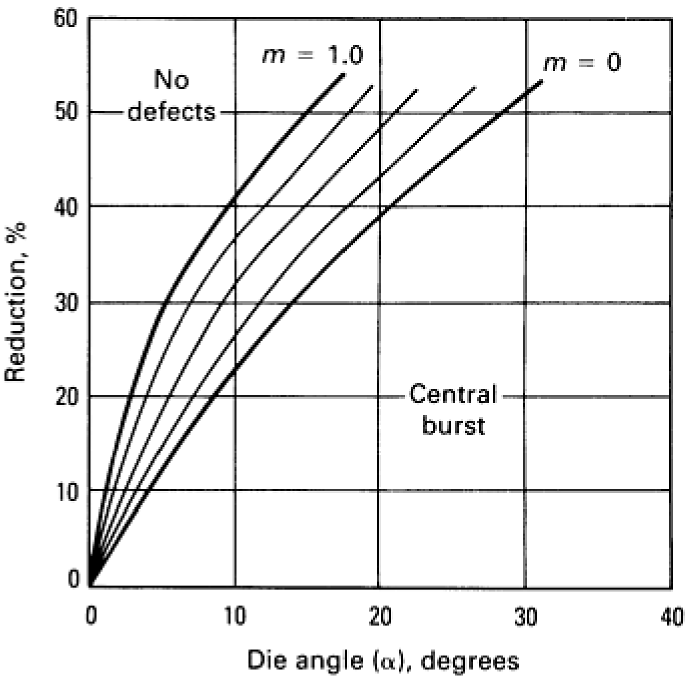

Fig. 19 Upper bound prediction of central burst in wire drawing. Increasing friction, expressed by the friction factor *m*, increases the defect region of the map. Source: Ref 10.

It should be pointed out that the upper bound method for defect prediction gives only a necessary condition. The strain-hardening and strain rate hardening characteristics of the material have been included in the analysis (Ref 10), but the microstructural characteristics have been omitted. Therefore, when operating in the central burst range illustrated in Fig. 19, fracture can occur; whether or not it will depends on the material structure (voids, inclusions, segregation, and so on). When operating in the safe area shown in Fig. 19, central burst will not occur, regardless of the material structure.

Tensile Stress Criterion. The role of tensile stress in fracture is implicit yet overwhelmingly clear throughout the discussion of fracture and fracture criteria. The calculation of tensile stresses in localized regions, however, requires the use of advanced plasticity analysis methods, such as slip-line fields or finite-element analysis. One result of slip-line field analysis that has wide application in workability studies is discussed below.

Double indentation by flat punches is a classical problem in slip-line field analysis (Fig. 20). The boundaries of the deformation zone change as the aspect ratio *h*/*b* (workpiece thickness-to-punch width) increases. For $h/b > 1$, the slip-line field meets the centerline at a point, and for $h/b < 1$ the field is spread over an area nearly as large as the punch width.

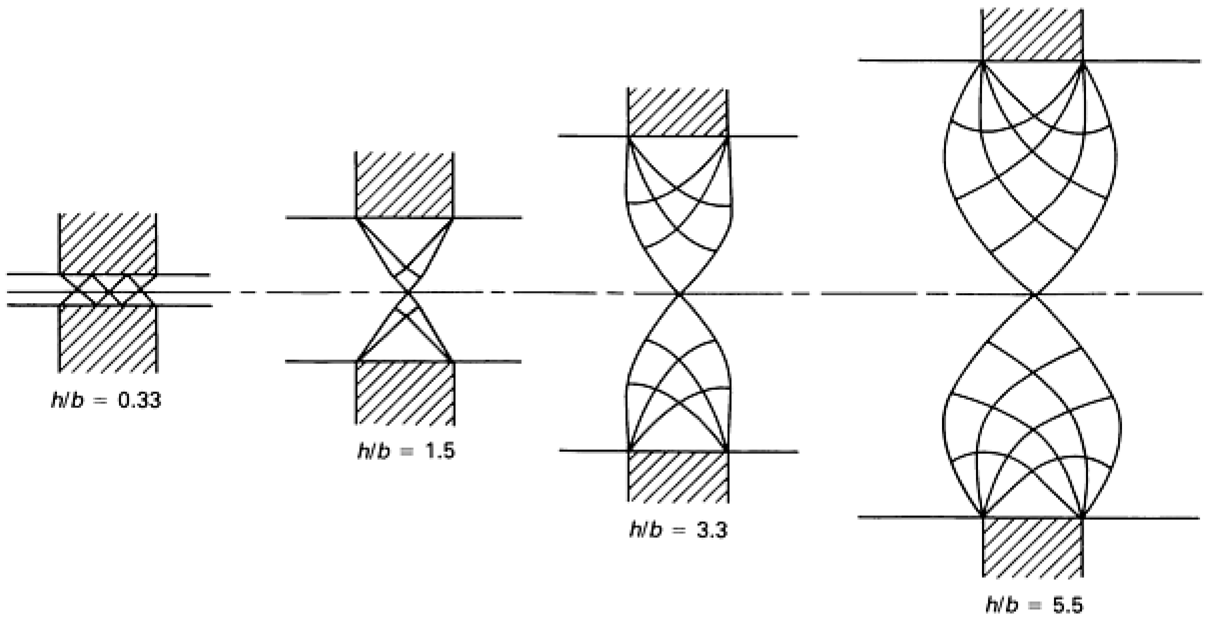

Fig. 20 Slip-line fields for double indentation at different *h*/*b* ratios. Source: Ref 11.

This tooling arrangement and deformation geometry approximates several other metalworking processes, as shown in Fig. 21. For similar *h*/*b* ratios in these processes, then, the stresses throughout the deformation zone of the process can be approximated by those calculated from slip-line field analysis for double indentation.

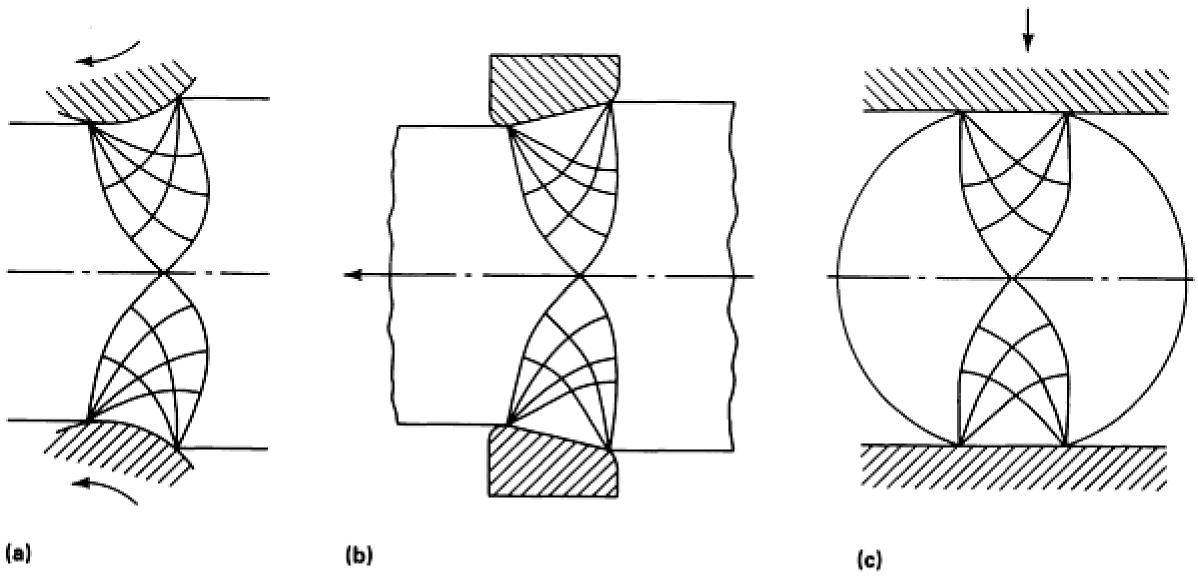

Fig. 21 Slip-line fields for rolling (a), drawing (b), and side pressing (c). These fields are similar to those for double indentation shown in Fig. 20.

Most of the work on double indentation has focused on the calculation of punch pressure and the extrapolation of these results to other processes--for example, those in Fig. 21. In a very detailed study of double indentation, remarkable agreement was found between experimental results and slip-line field results (Ref 12).

For workability studies, however, it is necessary to locate and to calculate the critical tensile stresses. It can be shown that the hydrostatic stress is always greatest algebraically at the centerline of the material and that this stress is tensile for $h/b > 1.8$. The calculated results for punch pressure and centerline hydrostatic stress are given in Fig. 22. Therefore, it is necessary to specify die and workpiece geometric parameters such that $h/b < 1.8$ in order to avoid tensile stress and potential fracture at the centerline of the processes shown in Fig. 21.

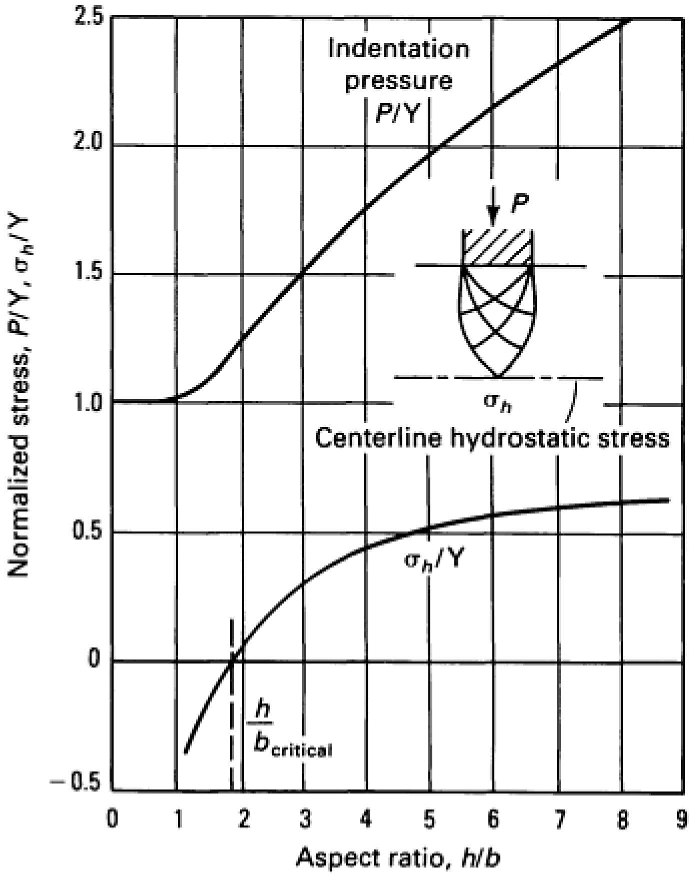

Fig. 22 Variation of the normalized indentation pressure (*P*/Y where Y is the yield strength) and the normalized centerline hydrostatic stress (σ_h/Y) with *h*/*b* ratio as calculated from slip-line field analysis.

For example, in extrusion, *h*/*b* is approximated by:

$$h/b = \frac{\alpha[1 + (1 - R)^{1/2}]^2}{R}$$

where α is the die half-angle and *R* is area reduction. Taking *h*/*b* = 1.8, the relationship between α and *R* that produces tensile hydrostatic stress at the centerline can be calculated. The result is given in Fig. 23, which is shown to be similar to the relationship predicted by upper bound analysis (Fig. 19). The correlation is remarkable in view of the dissimilarity in die shape between extrusion and double indentation. Furthermore, the similarity emphasizes that the flow mode for defect formation in the upper bound method is physically equivalent to the development of tensile hydrostatic stress.

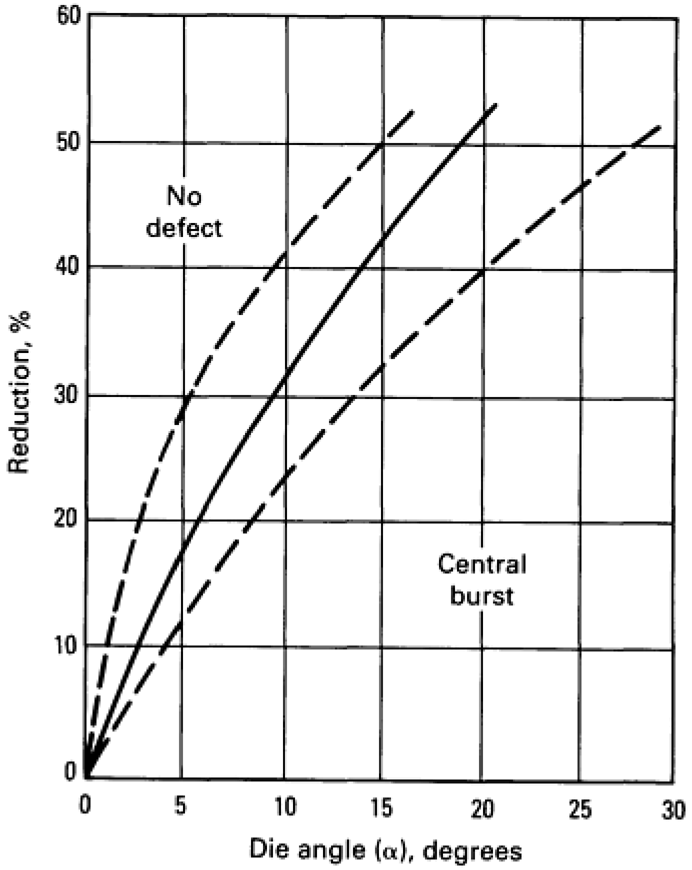

Fig. 23 Prediction of central burst in wire drawing by the tensile stress criterion and slip-line field analysis of double indentation. The range of predictions by upper bound analysis (Fig. 19) is shown by dashed lines.

As in the case of the upper bound method, the existence of a tensile hydrostatic stress does not ensure fracture, but it is a necessary ingredient. The material structure must be considered in conjunction with the tensile stress. In other words, the upper bound and tensile stress criteria are useful for defining approximate deformation limits and successful process parameters, but more detailed criteria or models are required to provide more exact values. An experimental-analytical approach, then, would be most useful in which an experimental value reflecting the inherent material ductility is determined first (this value is used to define a point on the fracture strain locus), followed by development of the rest of the fracture limit line, as in Fig. 10, 11, 12, 14, 16, and 17.

Workability Theory and Application in Bulk Forming Processes

Howard A. Kuhn, University of Pittsburgh

Applications

The fracture criteria discussed previously in this article can be used as tools for troubleshooting fracture problems in existing processes or for designing/modifying processes for new products. In either case, graphical representation of the criteria permits independent consideration of the process and material parameters in quantitative or qualitative form.

An example is the bolt-heading process shown in Fig. 24(a). If it is required to form a bolt head diameter *D* from the rod of diameter *d,* the required circumferential strain is ln (*D*/*d*), indicated by the horizontal dashed line in Fig. 24(b). The strain paths that reach this level, however, depend on process parameters, as shown previously in Fig. 2(b), and the fracture strain loci vary with material, as shown in Fig. 10, 11, and 12. Referring to Fig. 24(b), if strain path ***a*** describes the strain state at the expanding free surface for one set of processing conditions and the material used has a forming limit line labeled A, then, in order to reach the required circumferential strain, the strain path must cross the fracture line, and fracture is likely to occur. As shown, one option for avoiding defects is to use material B, which has a higher fracture limit. Another option is to alter the process so that strain path ***b*** is followed by the material. The latter option represents a process change, which in this case involves improved lubrication, as shown in Fig. 2. This procedure has been quantified and implemented in a computerized tool for upsetting process design (Ref 13).

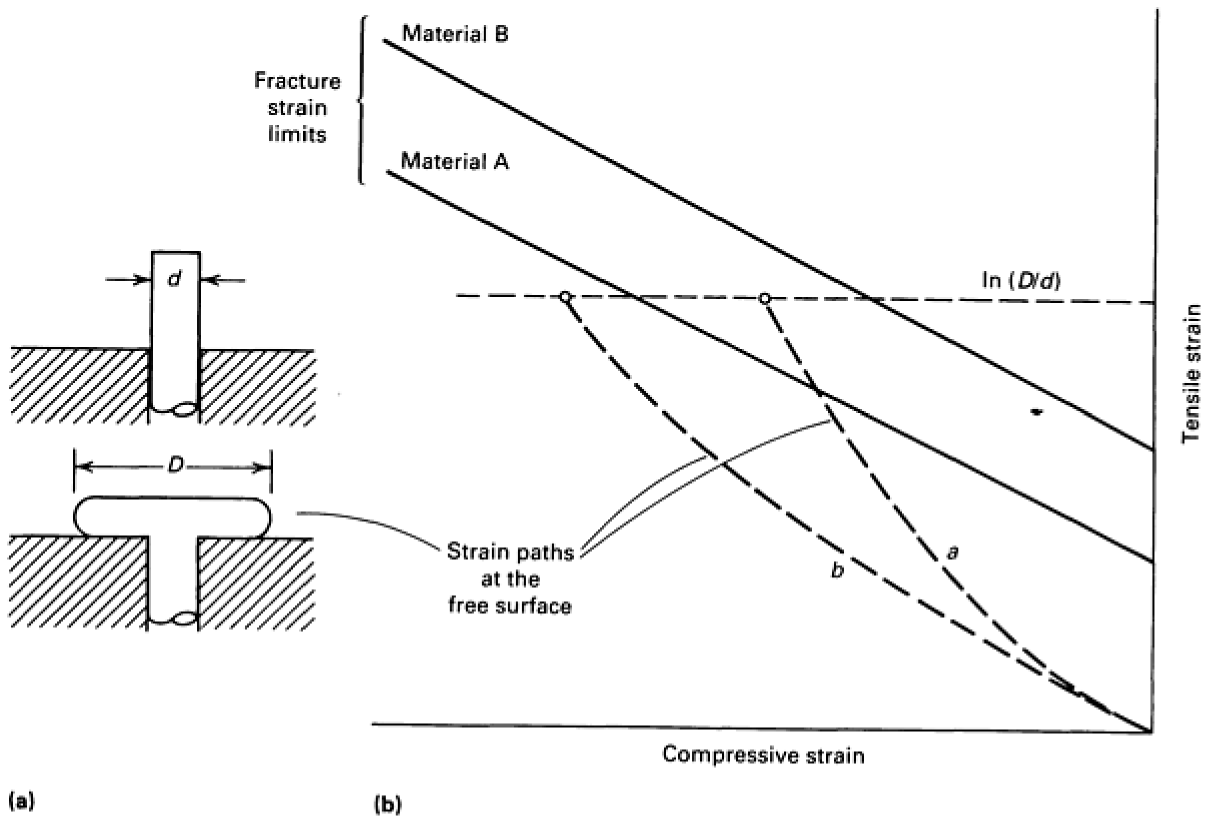

Fig. 24 Upsetting (a) of bar diameter *d* to head diameter *D.* (b) Material fracture strain limits are superimposed on strain paths reaching the final required strain. Strain path *b* (low friction) prevents fracture for both

materials. Material B avoids fracture for either strain path.

In more complex cases, other means are available for altering the strain path, such as modification of die design, workpiece (preform) design, and redistribution of lubricant. Examples of application to powder forging preform design and other metalworking processes are given in Ref 14 and 15.

The workability concept presented above provides a useful supplement to the experience and intuition of the die designer because it presents a graphical and quantitative description of the relationship between material and process parameters. Below are some examples of the application of the workability analysis procedures described previously.

Bar Rolling. As shown in Fig. 3, the strains at the edges of bars during rolling are similar to those at the bulging free surface of a cylinder during compression. It should be possible, then, to predict fracture in bar rolling from compression tests on the alloy of interest. This is pertinent in current attempts to roll ingots of high alloy content into bar form. The complete workability study of bar rolling includes physical modeling of bar rolling to obtain the strain states at the edges of the bar, compression tests to obtain the material fracture limits, and comparison of the two sets of results to establish roll pass reduction limits.

Such a study is illustrated by the analysis of cracking during the rolling of 2024-T351 aluminum alloy bars. The intent was to roll square bars into round wire without resolutioning. Rolling was done on a two-high reversible bar mill with 230 mm (9 in.) diam rolls at 30 rpm (approximate strain rate: 4 s^{-1}). The roll groove geometry is shown in Fig. 25. Defects occurred primarily in the square-to-diamond passes (1-2 and 3-4), but the two diamond-to-square passes (2-3 and 4-5), the square-to-oval pass (5-6), and the oval-to-round pass (6-7) were also examined for completeness.

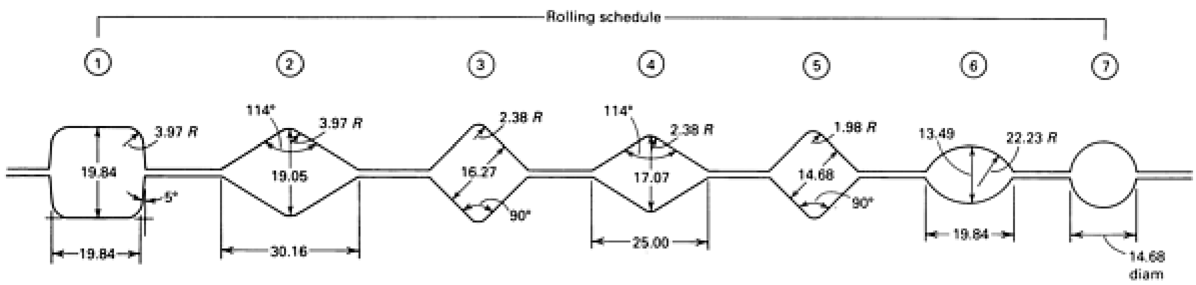

Fig. 25 Roll groove geometry for rolling square bars into round wire. Dimensions given in millimeters.

Lead was used as the simulation material for the physical modeling of bar rolling. Pure (99.99%) lead was cast and extruded into 25 mm (1 in.) round bars and then squared in the box pass (step 1, Fig. 25). Grids were placed on the lateral edges of the bars by an impression tool, and the grid spacing was measured before and after each pass for calculation of the longitudinal, ε_1, and vertical, ε_2, strains. Different reductions in area were achieved by feeding various bar sizes and by changing roll separation distances. A transverse slice was cut from the bars after each pass for measurement of the cross-sectional area and calculation of the reduction.

Results of the strain measurements are summarized in Fig. 26, in which tensile strain is plotted simultaneously with the compressive strain and reduction. As expected, the square-to-diamond passes involve the least compressive vertical strain, and the square-to-oval pass has the greatest compressive strain. The tensile strain versus reduction plot is the same for all cases, reflecting volume constancy.

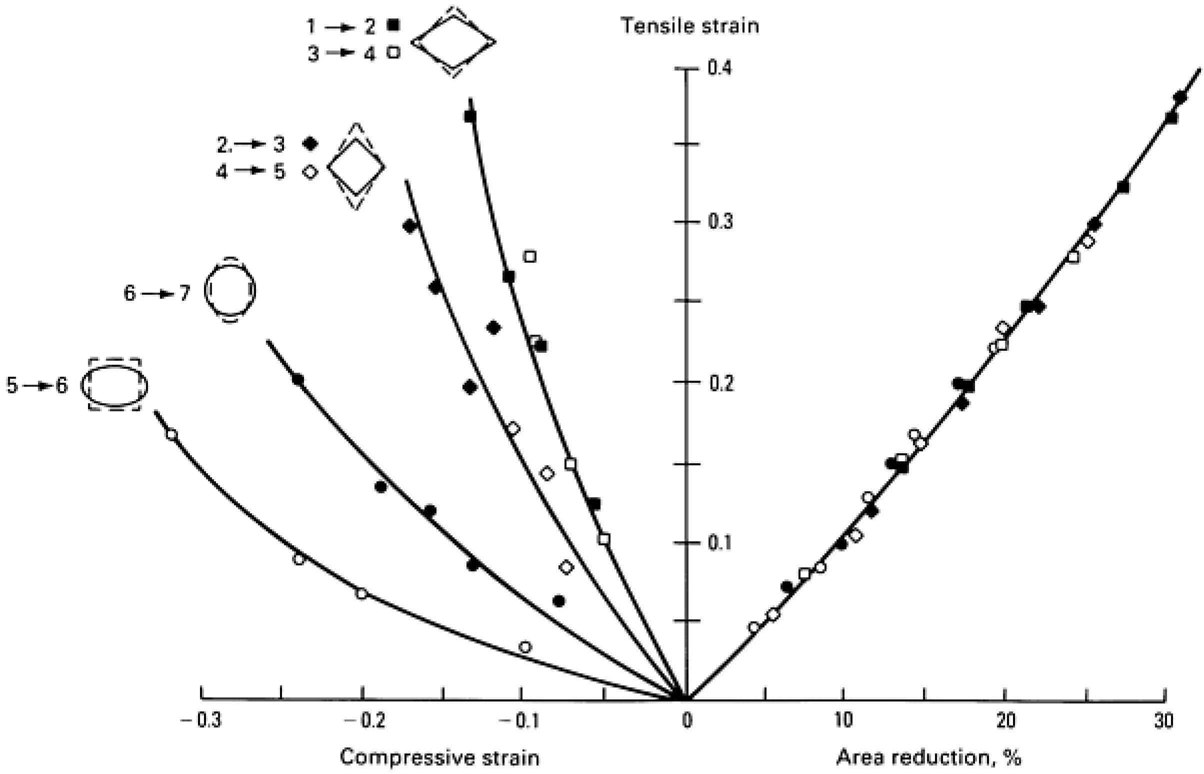

Fig. 26 Measured localized strains during the rolling of lead bars. Left side shows longitudinal tensile strain versus vertical compressive strain. Right side shows longitudinal strain versus cross-sectional area reduction at room temperature.

Compression tests were performed on the 2024 aluminum alloy at room temperature and at 250 °C (480 °F) at a strain rate of 4 s^{-1} to determine fracture limit lines. Straight, tapered, and flanged specimen profiles were used. Results are given in Fig. 27. Superposition of Fig. 26 onto Fig. 27 gives the rolling deformation limits.

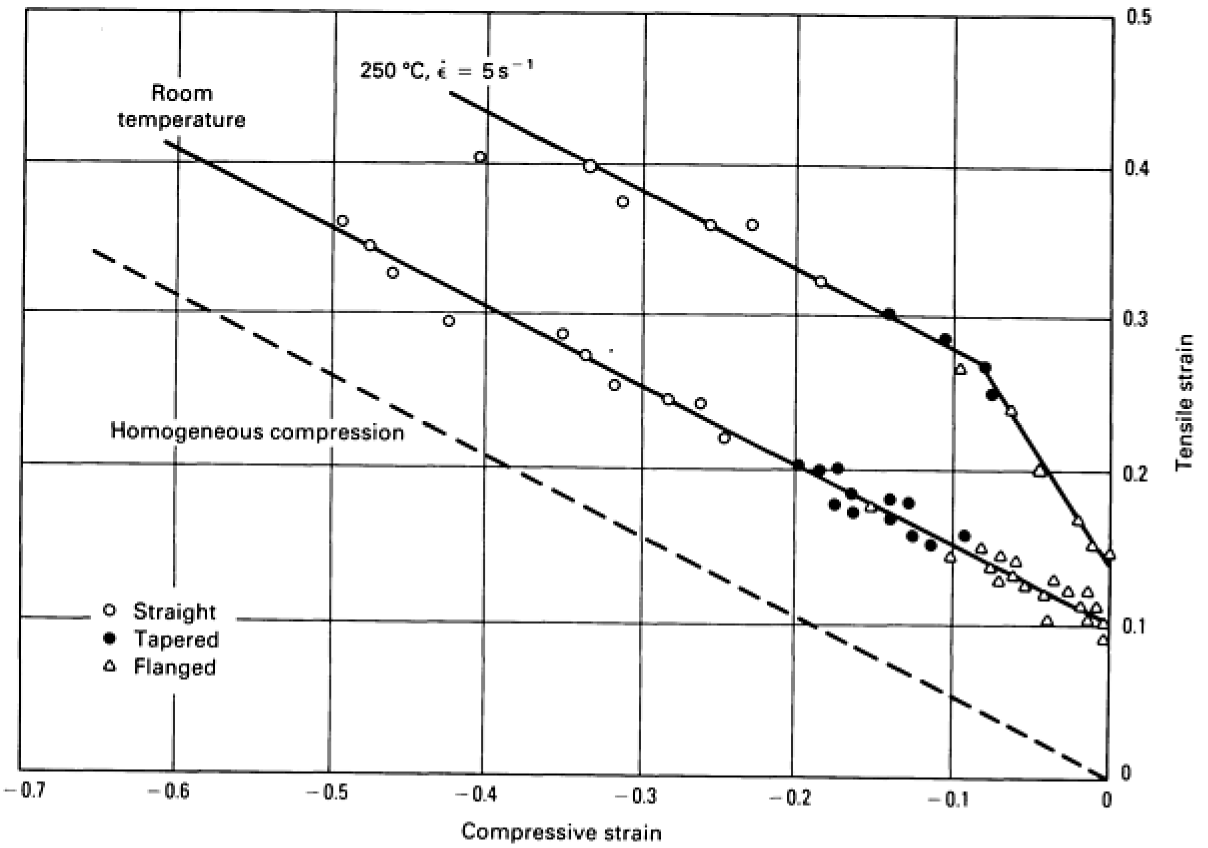

Fig. 27 Fracture strain lines for 2024 aluminum alloy in the T351 temper, measured by compression tests at room temperature and at 250 °C (480 °F).

To test the workability predictions, aluminum alloy bars were rolled at room temperature and at 250 °C (480 °F). Grid and area reduction measurements were made for the square-to-diamond passes. Figure 28 shows the measured strains at room temperature, which agree with those measured in lead bars for the same pass (Fig. 26). Open circles indicate fracture, and closed circles indicate no fracture. The fracture line for the aluminum alloy at room temperature is superimposed as the dashed line. It is clear that edge cracking in bar rolling conformed with the material fracture line, and the limiting reduction is approximately 13% for this combination of material and pass geometry. Similarly, at 250 °C (480 °F), there was conformance between fracture in bar rolling (Fig. 29) and the fracture line of the alloy (Fig. 28). In this case, the limiting reduction is approximately 25%.

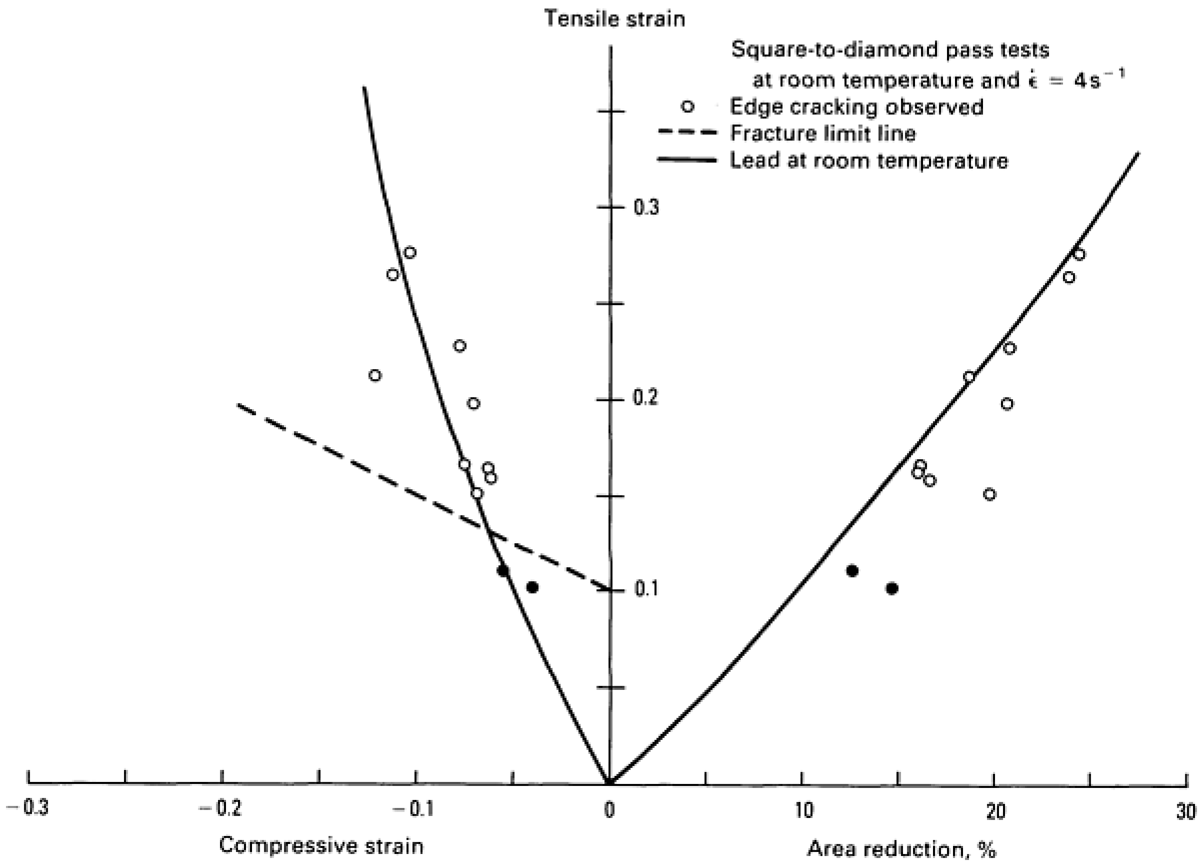

Fig. 28 Superposition of fracture line (dashed) on measured strains during rolling of 2024-T351 aluminum alloy bars at room temperature. Solid line represents the strain path measured during rolling of the lead model material shown in Fig. 26.

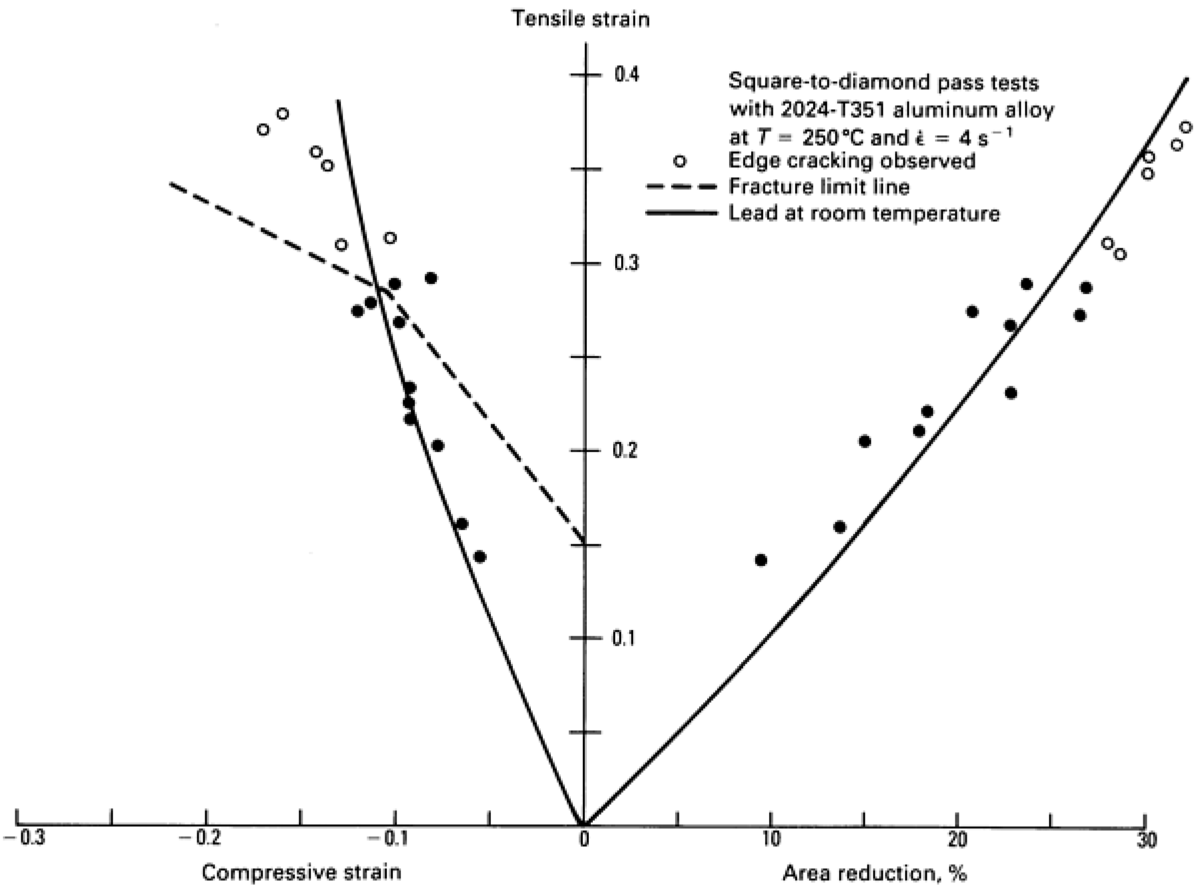

Fig. 29 Superposition of fracture line (dashed) on measured strains during the rolling of 2024-T351 aluminum alloy bars at 250 °C (480 °F). Solid line represents the strain path measured during rolling of the lead model material shown in Fig. 26.

Extrapolating the above results for cold rolling, the limiting reduction for diamond-to-square passes would be approximately 15%; for the oval-to-round pass, approximately 20%; and for the square-to-oval pass, approximately 25%. Similarly, in the hot rolling of this aluminum alloy, the reduction limit for diamond-to-square passes would be approximately 27%; for oval-to-round passes, approximately 30%; and for square-to-oval passes, approximately 40%. The latter two are beyond the reduction normally used because of fin formation, so cracking rarely occurs in such passes.

Example 1: Preform Design for a Ball Bearing Race.

A low-load high-torque ball bearing outer race was cold forged from a low-alloy steel powder preform (Fig. 30). The preforms were compacted from 4600 grade powder with carbon added to give 0.20% C in the sintered material. The sintered preforms were 80% of theoretical density.

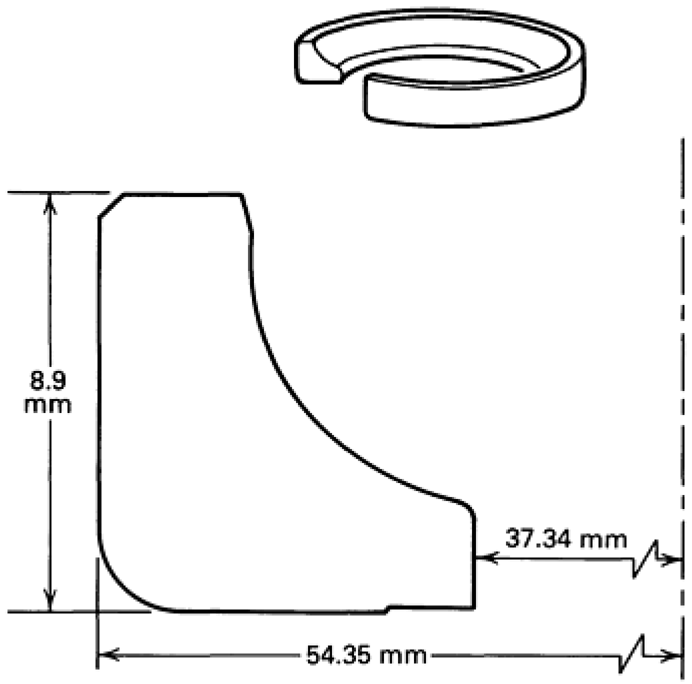

Fig. 30 Ball bearing outer race that was cold forged from sintered powder preform of 4620 low-alloy steel.

Initial efforts led to cracking through the preform along a diagonal beginning at the point of contact between the punch and preform (Fig. 31). The large shear stress developed by the contact was beyond the fracture limit of the porous preform, and two solutions were considered that would avoid such stresses (Fig. 32). The first solution was the use of a flat preform that involves back extrusion flow into the outer rim, and the second was the use of a tall, thin-wall preform that involves radial inward flow into the inner flange. The first option was rejected because it would generate circumferential tension that would most likely cause fracture. The second option is desirable because compression is applied at the top face; this option was pursued through physical modeling.

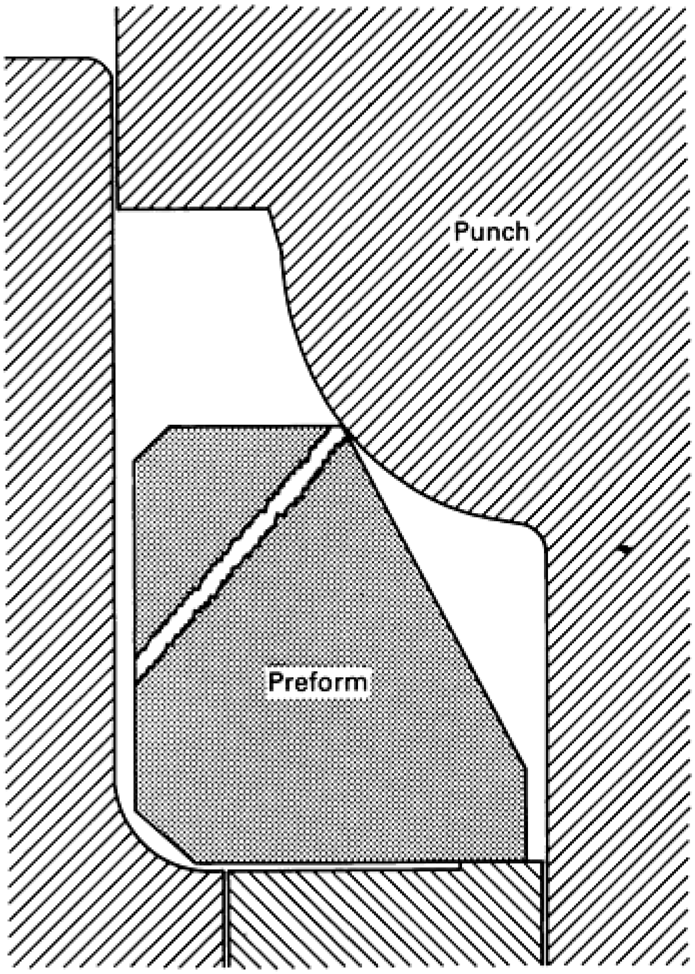

Fig. 31 Cracks initiated at the point of contact between the punch and preform in the original preform design. The preform had a taper of 30° on the inside diameter.

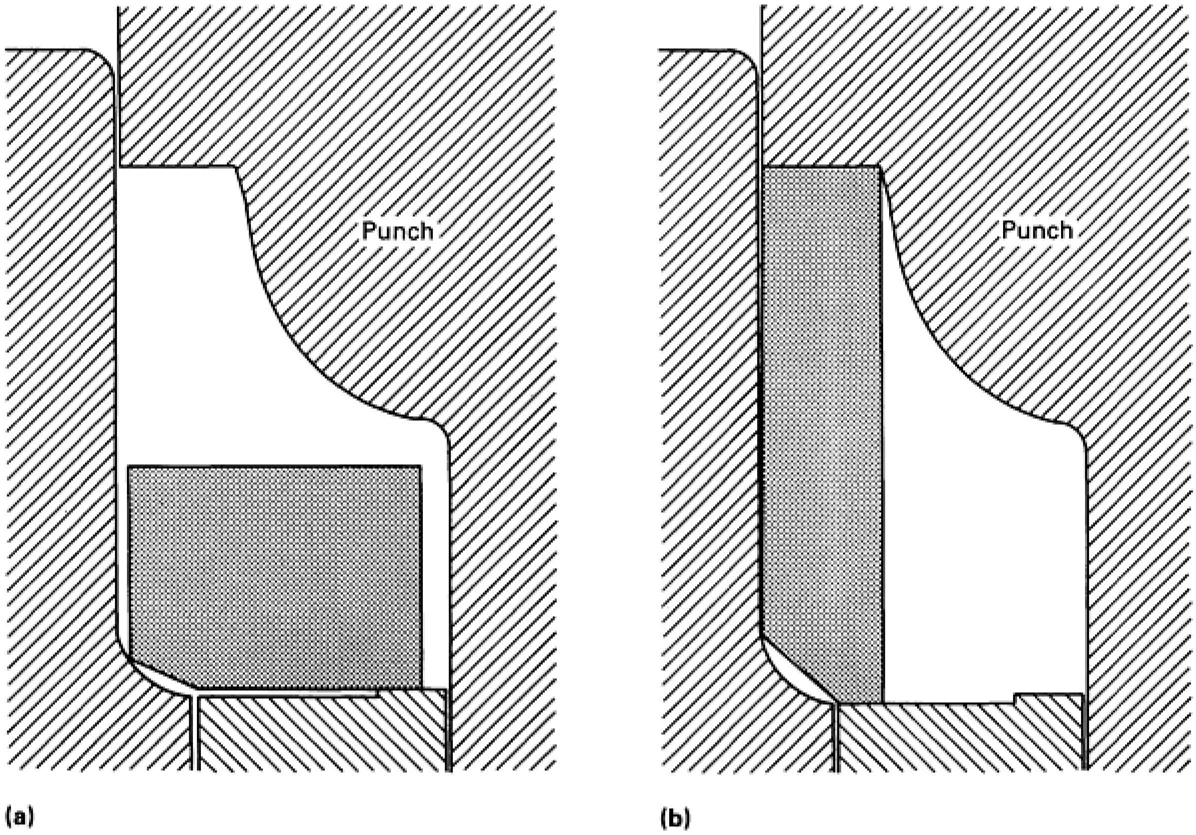

Fig. 32 Preform alternatives for forging the ball bearing outer race shown in Fig. 30. (a) Back extrusion. (b) Compression and radial inward flow.

The primary concern with the second option (Fig. 32b) was the large amount of radially inward deformation required to form the inner flange. As a result, this option was examined by physical modeling. Model preforms were produced from sintered 601AB aluminum alloy powder and gridded on the inside surface (Fig. 33a). Grid displacements were measured after each of several increments of deformation, and the calculated strains were plotted along with the fracture line of the material (Fig. 33b). It is clear that both the axial and circumferential strains are compressive throughout the process and do not exceed the fracture line. Some wrinkling of the inside surface occurred, but this was smoothed out when the surface contacted the mandrel under pressure.

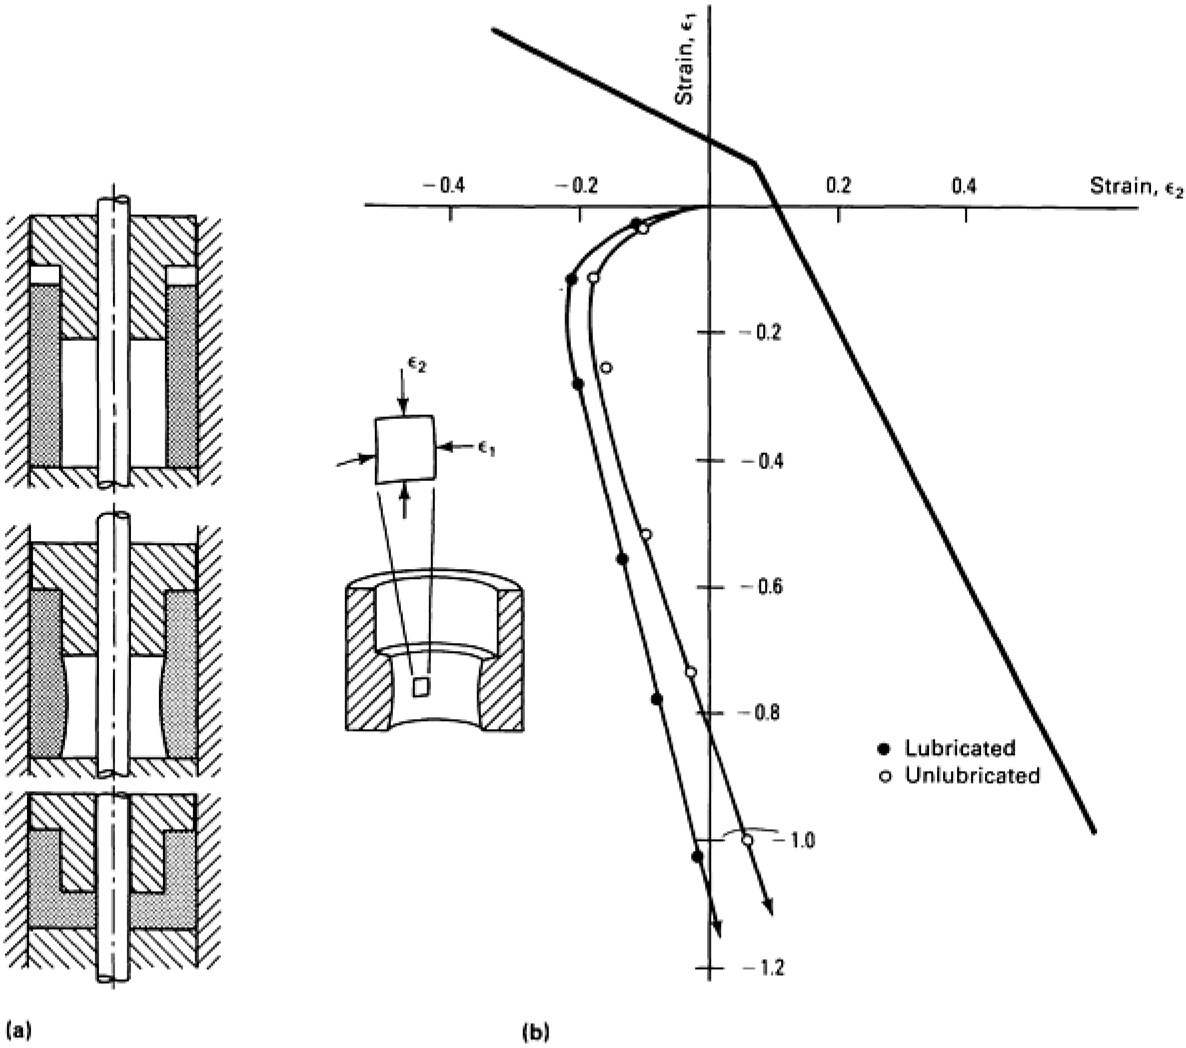

Fig. 33 Physical model (a) for the second option (Fig. 32b) and the measured strains (b) during forging of the preform. The heavy line is the material fracture line. It is clear that the strain path never crosses the fracture line and that defects are prevented.

Actual production of straight-wall preforms, as in Fig. 33(a), was not feasible, because the height-to-thickness ratio is too large for compaction. A compromise was developed in which the preform angle was 17° instead of 30°, as used in the original preform, or 0°, as used in the physical model (Fig. 33b). This ensured initial punch contact at the top face of the preform and generated compressive strains on the inside surface, as in Fig. 33(b). Cold-forging trials on these preforms produced no cracks, developed the desired full density in the ball path region, and showed the added benefit of a smooth ball path surface that did not require grinding.

Example 2: Back Extrusion of Copper Alloy.

A low-ductility dispersion-strengthened copper alloy was back extruded into a cup shape, as shown in Fig. 34. The deformation was carried out at room temperature on a mechanical press. Crack formation on the rim caused high rejection rates. The original slugs for this process were smaller in diameter (16 mm, or 0.625 in.) than the die inside diameter (19 mm, or 0.75 in.), as shown in Fig. 35(a). Deformation of such preforms involves circumferential expansion strain (equal to ln (D/d), where D is the die bore diameter and d is the slug diameter), along with very little compressive strain at the rim (Fig. 35b). For this case, the circumferential strain is ln (0.75/0.625) = 0.18. Workability analysis would then require only measurement of the material fracture line and comparison with the required circumferential strain 0.18.

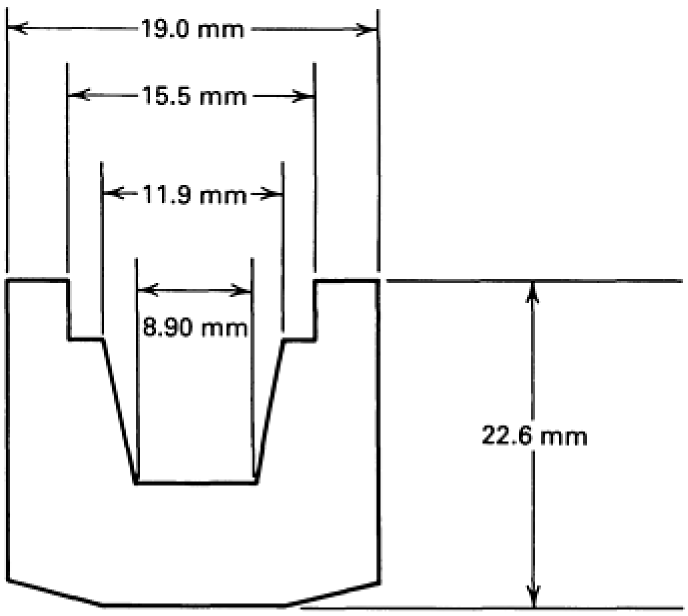

Fig. 34 Part that was back extruded from copper alloy.

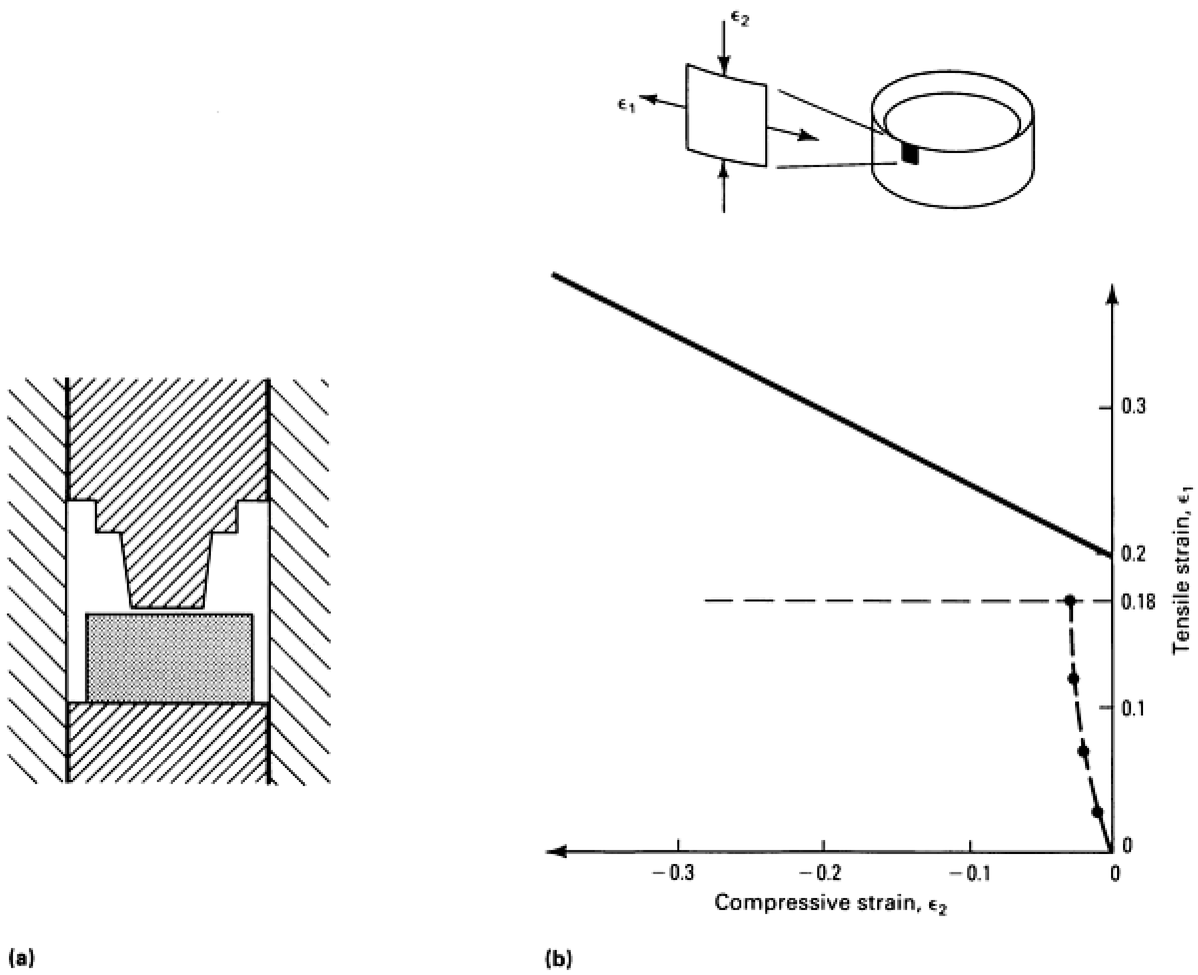

Fig. 35 Back extrusion of the cup shape shown in Fig. 34. (a) The preform slug was 16 mm (0.625 in.) in diameter; the die was 19 mm (0.75 in.) in diameter. (b) Strains at the cup rim where fracture occurred consist of circumferential tension to a value of 0.18, and very little compressive strain. The heavy line is the material

fracture strain line.

Fracture strains were measured in flange compression tests, as shown in Fig. 36, giving a minimum circumferential strain of 0.2, which is sufficiently above the required strain for avoidance of fracture. A hydraulic press was used (giving a strain rate of approximately 0.5 s^{-1}), on the assumption that there is no strain rate effect at room temperature. Because the workability analysis showed that fracture should not be a problem, the effect of strain rate was explored further.

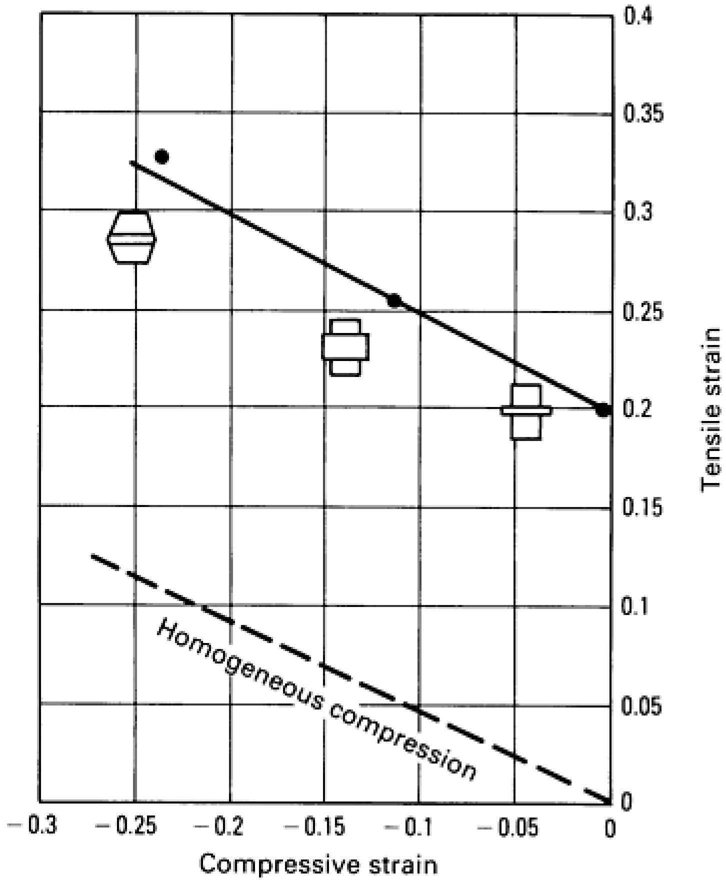

Fig. 36 Fracture strain line for copper alloy, determined by flanged and tapered compression tests. Specimen geometries used for each test are also shown.

Tests were performed on the same alloy using controlled strain rate servohydraulic test equipment at strain rates of 5, 10, and 15 s^{-1}; the third strain rate given is close to that in the production mechanical press. Figure 37 shows the surprising result that the fracture limit line decreases with increasing strain rate. In particular, the minimum circumferential strain falls below the required value of 0.18 for successful forming of the rim; this explains the occurrence of fracture on the production press. The problem was corrected by using slugs of larger diameter to decrease the circumferential tension and by preforming a taper on the top face (Fig. 38), which produced some axial compression in the material at the rim. The strain path then avoided crossing the fracture line (Fig. 39), and the rejection rate during production on the mechanical press was nil.

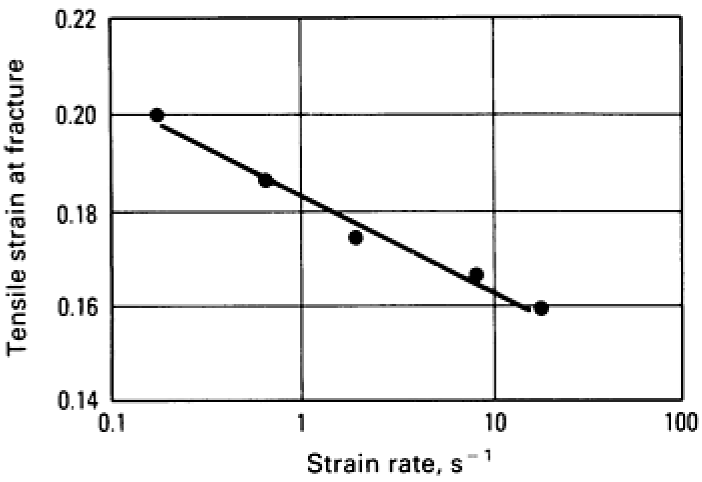

Fig. 37 Decrease in circumferential tensile strain at fracture with increasing strain rate for the copper alloy tested in Fig. 36. Results are for thin-flanged compression specimens, which have the lowest fracture strain.

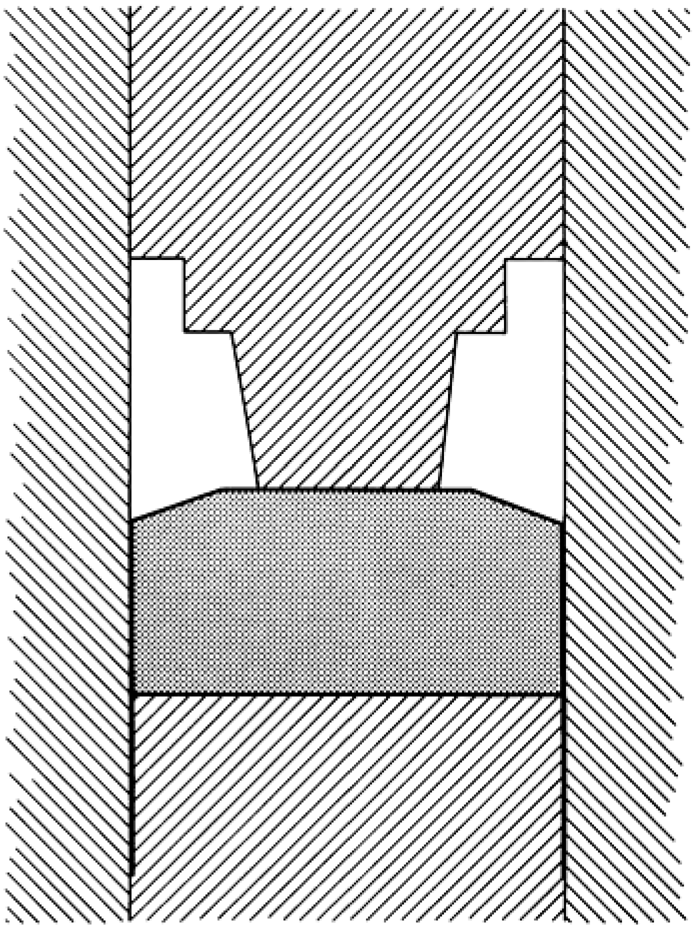

Fig. 38 Modified preform slug for the back extrusion of the cup shape shown in Fig. 34. The slug diameter is 18.8 mm (0.74 in.) and has a 5° taper on the top surface.

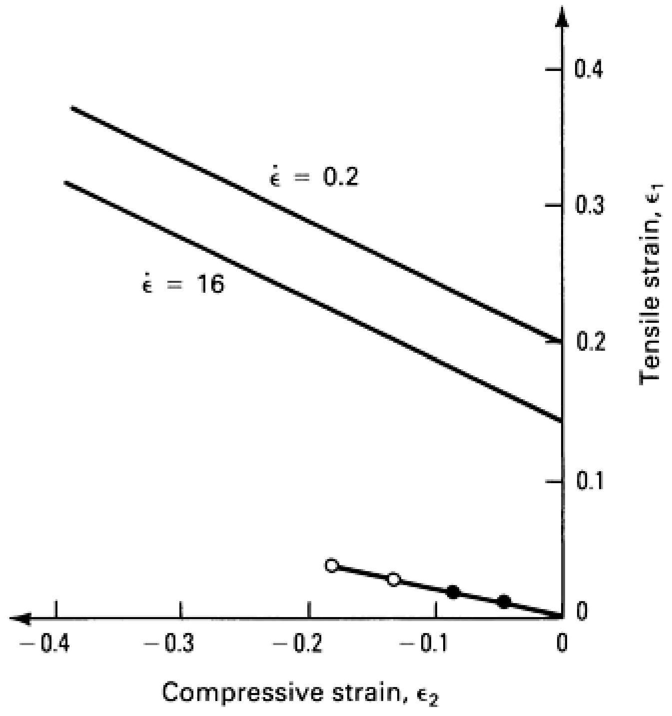

Fig. 39 Comparison of measured strains at the cup rim during back extrusion of the modified preform slug shown in Fig. 38. The strains do not exceed the material fracture strain line for low or high strain rate forming.

Contact Surface Fracture and Internal Fracture. All of the previous applications and examples involved free surface fractures and could be treated directly by the fracture line. Consideration of contact surface fractures (Fig. 5) and internal fracture (Fig. 6), however, requires modification of this approach or use of a new approach. In the following, an example is given of the application of the upper bound and tensile stress criteria to central burst in extrusion. The empirical workability concept described previously is then modified for application to contact surface fracture as well as central burst.

Example 3: Central Burst During Extrusion.

Central burst can occur in extrusion when light reductions and large die angles are used (Fig. 19) and it is encountered in the production of shafts for transmissions and suspension systems. A test of the central burst criterion was carried out by processing shafts from hot-rolled 1024 steel bars 22 mm ($\frac{7}{8}$ in.) in diameter (Ref 16). The processing sequence consisted of initial drawing followed by three extrusion steps in a boltmaker:

Process	**Reduction, %**	Die half-angle, degrees
Drawing	8	**9**
Extrusion	22	**22.5**
Extrusion	23	**22.5**

Extrusion	**16**	**22.5 or 5**

All passes are in the central burst area of Fig. 40, except for the last pass with a 5° die angle.

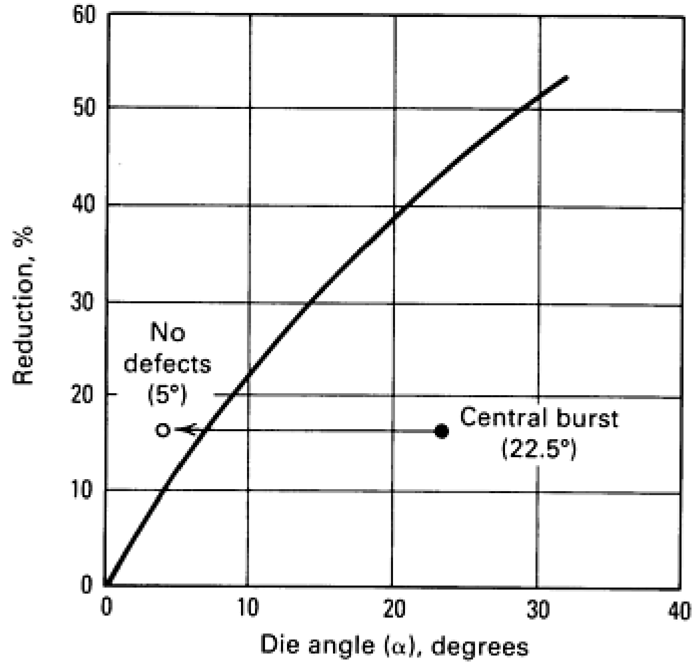

Fig. 40 Location of process conditions on a theoretical central burst map. For an angle of 22.5°, central burst occurred in 4.5% of the extruded shafts. For a die angle of 5° no central burst occurred.

A total of 1000 shafts were processed with the 22.5° die, and 500 shafts with the 5° die. All shafts were tested ultrasonically for internal defects. Central bursting was detected in 4.5% of the shafts extruded with the 22.5° die, and no defects were detected in the shafts extruded with the 5° die. These results show that the upper bound central burst criterion is a necessary condition. It was further shown in Ref 16 that central burst was avoided in other heats with slightly different compositions because their strain-hardening coefficients were larger than the original heat. This confirmed the predicted results in Ref 10.

Modified Empirical Criterion. It was shown previously in this article that measured free surface strains at fracture fit a linear or bilinear line that constitutes a fracture locus for the material tested (Fig. 10, 11, 12). This is a convenient representation of the complexities of ductile fracture, which are controlled by stress and deformation. The experimental fracture locus is also reproduced by several theoretical fracture criteria (Fig. 14, 16, and 17).

For contact surface and internal fractures, however, the surface on which the strains can be monitored is subjected to stress normal to that surface. It was shown in Eq 3 that stress states leading to a given set of surface strains differ only by a hydrostatic stress component, and this component is equal to the applied stress normal to the surface on which the strains are monitored. Experience shows that this hydrostatic stress affects fracture, and it should also affect the fracture strain locus. It should be possible, then, to use the theoretical fracture criteria to predict the effects of hydrostatic stress on the fracture strain locus.

The simplest criterion described previously in this article is that due to Cockcroft; therefore, it was modified to predict the effects of stress normal to the plane (Fig. 5 and 6) on the fracture strains $_1$, and $_2$. The result (Fig. 41) shows that superimposed pressure (P > 0) increases the height of the fracture strain line and also increases its slope slightly. Superimposed tension (P < 0) decreases the height of the fracture line, decreases its average slope, and gives it a slight downward curvature. It is clear that the increase in strains to fracture due to additional pressure is unlimited as pressure increases, but the strains to fracture due to additional tension are limited by zero as tension increases. This result is discussed below with regard to internal fracture and die contact surface fracture.

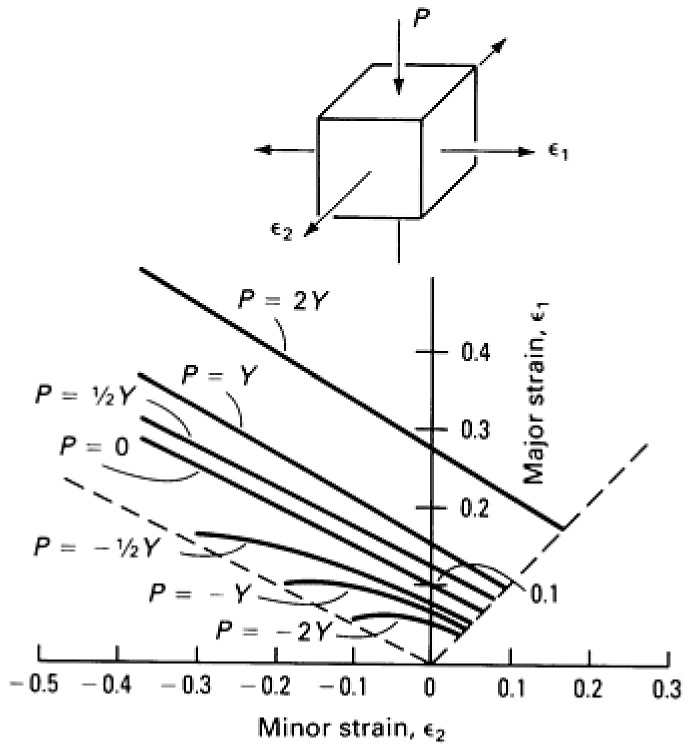

Fig. 41 Movement of the fracture strain line due to superimposed hydrostatic stress. Applied stress is represented in terms of multiples of the yield strength, *Y.* Negative values of *P* indicate hydrostatic tension. Calculations are based on a modification of the Cockcroft criterion.

Central Burst in Forgings. Internal fractures along the centerline of extruded or drawn bars were discussed above (Fig. 18, 19, 23, and 40). Similar fractures are observed served in forged shapes, such as that shown in Fig. 42 for heat-treated 6061 aluminum alloy. Here, as the outer region is compressed between dies, material flows radially inward and then vertically into the opposed hubs. This develops a hydrostatic tensile stress state at the center (Fig. 6a), and fracture is a strong possibility.

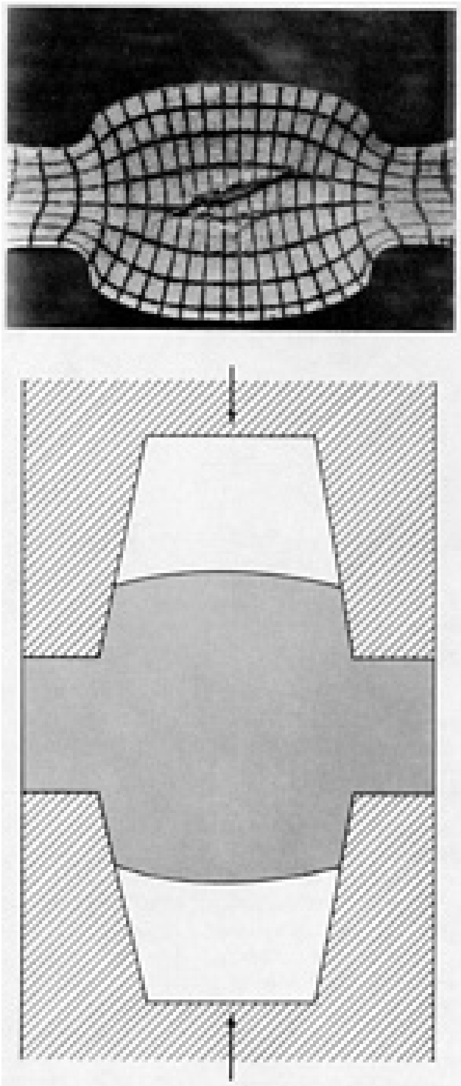

Fig. 42 Internal fracture during the double-extrusion forging of aluminum alloy 6061. Grid deformations on the middle longitudinal plane are shown. Stress and strain states are defined by Fig. 6(a).

Through visioplasticity analysis on split, gridded specimens (Fig. 42), the strain and stresses at the center of the workpiece were calculated for several increments of deformation. The hydrostatic stress state at the center of the specimen is not always tensile; initially, it is compressive, and then it reverses, becoming tensile as the flange thickness is reduced and flow into the hub occurs. Meanwhile, the strains at the center are increasing monotonically as deformation progresses. This is illustrated in Fig. 43 by the steps 0-1-2-3. As deformation proceeds, the strains at the center increase; but the hydrostatic pressure is also increasing, so the fracture line moves upward. Then, as the flange thickness approaches one-half of the hub base diameter (die orifice diameter), the hydrostatic stress becomes tensile, so the fracture line decreases in height. The strains at the center continue to rise, however, and cross the fracture line, leading to the central burst. The calculated hydrostatic tension at fracture was $0.3Y$. This approach could be used for predicting central burst in drawing and extrusion to provide a material-dependent criterion, as opposed to the more simplistic upper bound and tensile stress criteria described previously.

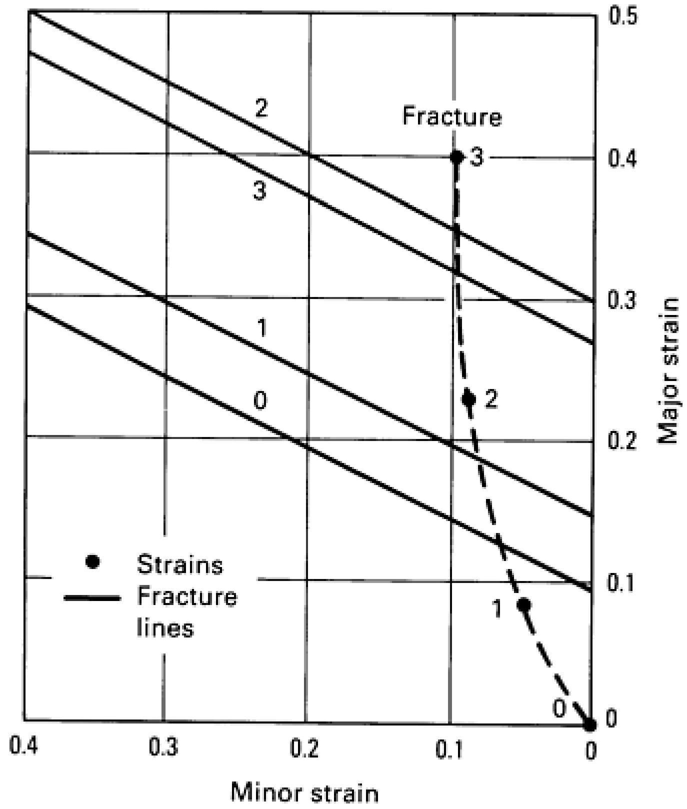

Fig. 43 Progression of surface strains and fracture line at the central internal location of the double-extrusion forging shown in Fig. 42. The fracture line rises from 0 to 1 to 2 as internal pressure increases and then falls to point 3 as the internal stress becomes tensile.

Die Contact Surface Fracture. Frequently, cracks occur during forging on surfaces that are in contact with the dies (Fig. 5). One common location of such defects is the vicinity of a die or punch corner. From the observation of a variety of such defects, it appears that a common characteristic is an abrupt change in frictional shear traction distribution in the region of the crack. High friction to retard metal flow in advance of the crack location is one method for preventing such defects.

A technique for studying die contact surface cracks was developed by means of a disk compression test and dies having a rough surface in the central region and a smooth surface in the outer region. Figure 44 shows the top view of a 6061 aluminum alloy disk compressed between such dies.In the transition region between the rough central die surface and the smooth outer region, radial cracks initiate and propagate outward. Such cracks occurred at approximately 30% reduction when the smooth outer region was lubricated with Teflon.The cracks occurred at approximately 45% reduction when grease lubrication was used in the outer smooth region. No cracks occurred even for very large reductions when the smooth outer region was not lubricated.

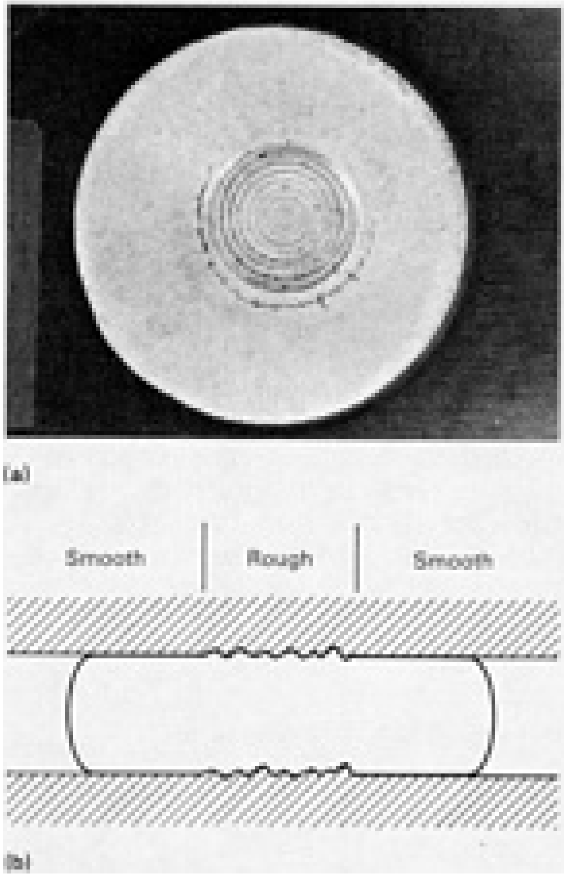

Fig. 44 Top view of aluminum alloy 6061 disk (a) compressed between dies (b). Cracks form at the transition region between rough and smooth areas of the die.

Grid marks placed on the die contact surface of the disks were used to measure the distribution of surface strains in the radial direction. Figure 45 gives an example of such measurements. In the rough central region, the strains are zero, while in the smooth outer region the strains are equal and constant. In the transition, however, the circumferential strain, θ, jumps abruptly from zero to its constant value in the outer region, and the radial strain, $_r$, overshoots to a very high value before returning to its constant value in the smooth outer region.

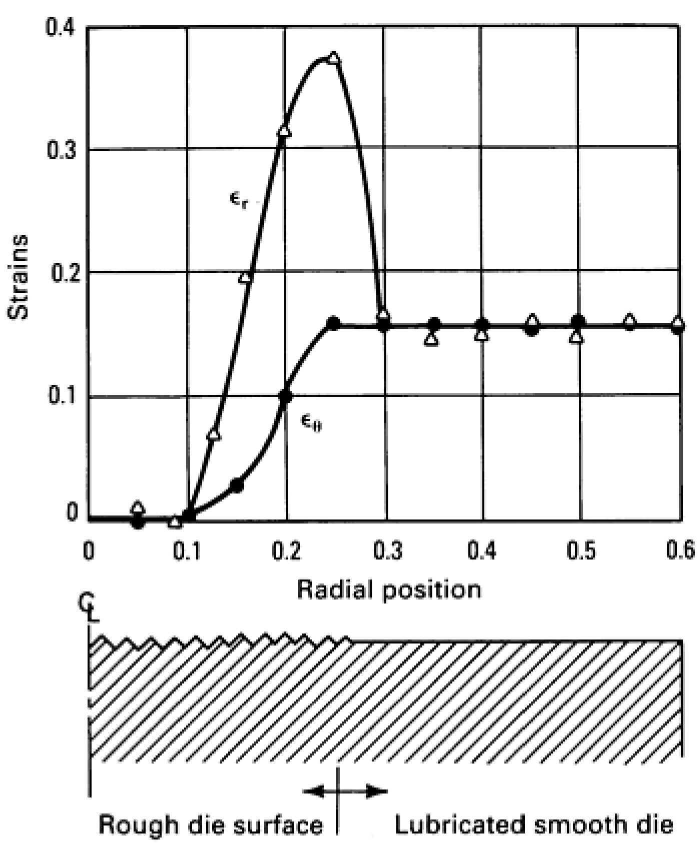

Fig. 45 Radial variation of contact surface strains after 30% compression of the disk shown in Fig. 44.

The strains shown in Fig. 45 were the same regardless of the friction condition in the smooth outer region. Therefore, fractures in the transition region occur because of the combination of large tensile surface strains and low hydrostatic stress state.This explains the occurrence of cracks at low reduction when Teflon is used, and no occurrence of fracture when no lubricant is used. The Teflon, having a near-zero friction coefficient, results in very low radial back pressure on the transition region, while grease and no lubricant provide progressively larger back pressures.

By means of visioplasticity analysis, the stresses were determined at the contact surface in the vicinity of the transition region. The resulting normal die pressure plus the surface radial and circumferential strains define the stress and strain states in the transition region and can be illustrated on a forming limit diagram. Figure 46 shows the change in surface strains and the increase in the fracture line due to increasing normal pressure during compression of a disk with grease lubricant in the outer region (indicated by the increments of reduction to 45%). The fracture line increases at a slower rate than the strains increase with increasing pressure, and at 45% reduction the strain path exceeds the fracture line and cracks are observed. For Teflon lubricant, the crossover occurs at about 30% reduction, while in the case of no lubricant the fracture line moves progressively away from the strain path.

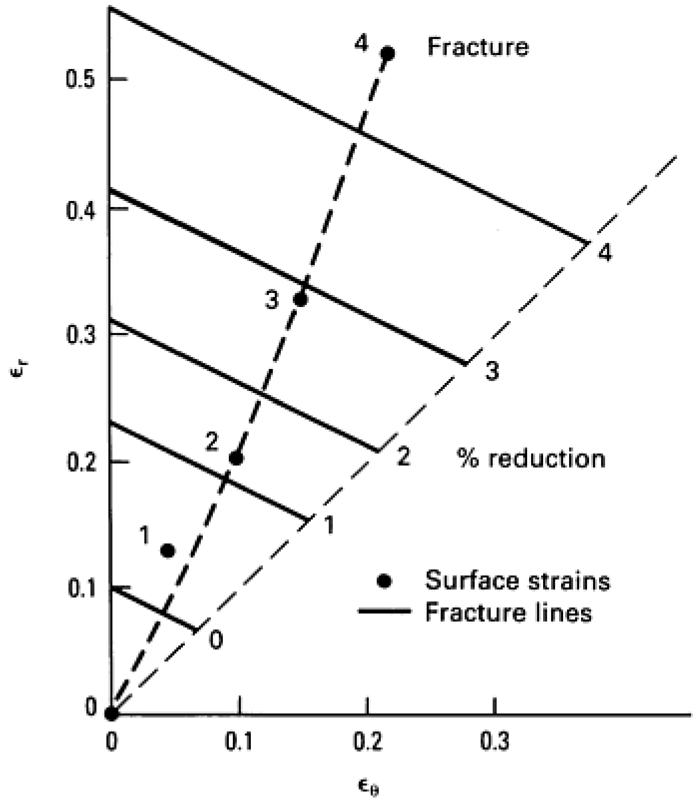

Fig. 46 Progression of surface strains and fracture line at the transition region between rough and smooth zones of the compressed disk shown in Fig. 45. Points 1, 2, 3, and 4 represent 10, 20, 30, and 45% reduction, respectively.

Example 4: Fir Tree Defect.

The criterion for contact surface fracture can be applied qualitatively for interpretation of the fir tree defect in extrusion. Such defects occur on the surfaces of extruded bars as well as in localized areas of forgings containing ribs.

In a section of a rib-web forging from a preform of sintered aluminum alloy powder, small cracks formed with a regular spacing on the rib surfaces (Fig. 47). Such defects occurred only when the thickness of the rib was greater than approximately one-half the web length (that is, extrusion reduction less than one-half). Each crack formed by shear at the corner as material flowed from the web into the vertical rib.

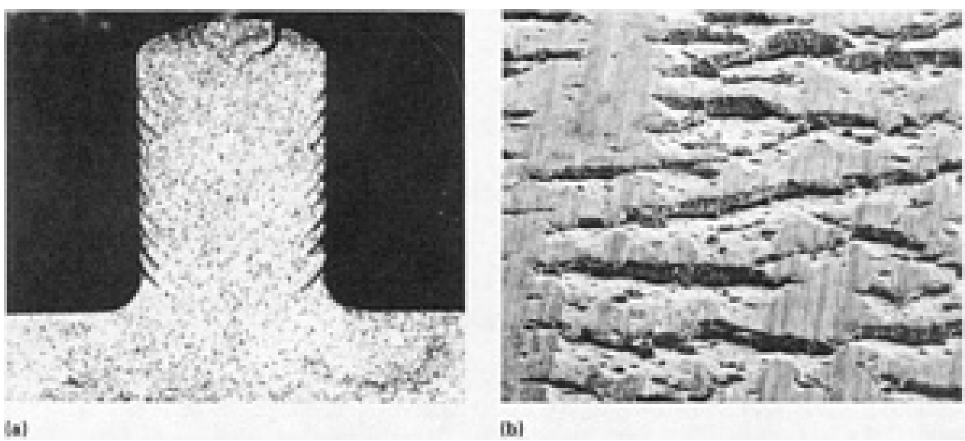

Fig. 47 Die contact surface cracking during forging extrusion of aluminum alloy powder compact. (a) Cross section. (b) Normal to vertical rib surface. Note also the cracks at the top free surface. Stress and strain states

are defined in Fig. 4(b).

The stress and strain state on a surface material element is shown in Fig. 48. As material in the web is compressed, the surface element experiences tensile strain in the direction of flow, and the strain increases as the element approaches the die corner. At the same time, there is a compressive stress from the die onto the surface element. This pressure diminishes, however, as the element nears the die corner and almost disappears as the element moves around the corner.

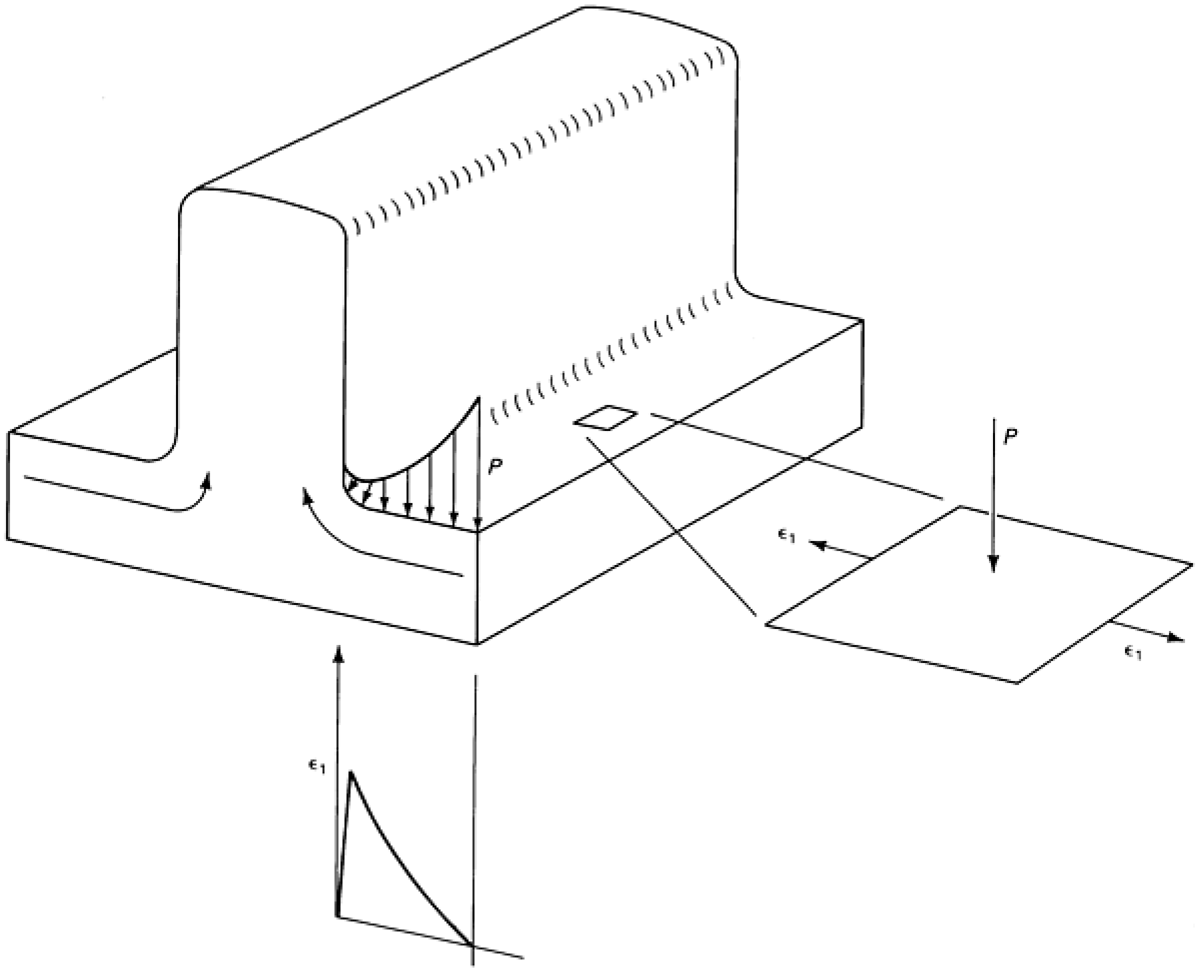

Fig. 48 Increase in strain $_1$ and decrease in die contact pressure *P* on a surface element as it moves from the web into the rib section of the extrusion forging shown in Fig. 47. Stress and strain states are defined in Fig. 5(a).

This can be illustrated schematically on the fracture strain diagram shown in Fig. 49. Because the deformation is in a state of plane strain, the strain path is represented as a vector of increasing length along the vertical axis. Meanwhile, the fracture line decreases in height because the pressure acting normal to the element is progressively decreasing. When the strains cross the fracture line, fracture occurs.

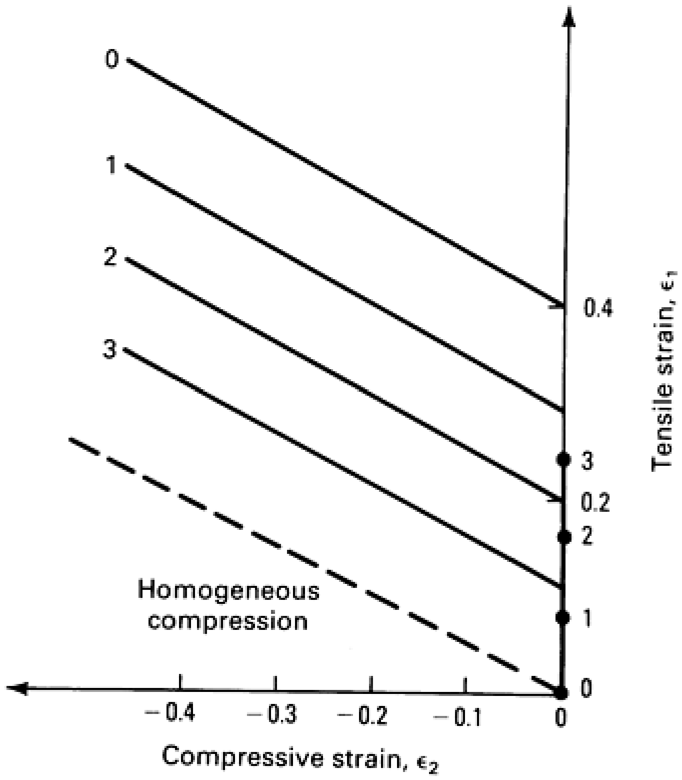

Fig. 49 Progression of strain $_1$ and decline of fracture line due to decrease in pressure *P* for an element moving from the web to rib section during the forging extrusion shown in Fig. 48. At stage 3, the strain exceeds the fracture line.

This phenomenon does not take place when extruding ribs of small thickness, because the extrusion reduction, and therefore the pressure, is larger, which maintains the fracture line at a high level. For thick ribs, two solutions were considered. One approach is to increase friction along the rib walls by roughening the die surface or avoiding lubrication of the die rib. This produces greater back pressure at the die corner, elevating the fracture line and preventing cracking. Such an approach is difficult to implement and can be used only with segmented dies because the formed rib cannot be removed from the die. The second approach is to use a draft angle on the rib, which has the same effect as increased friction. An angle of 10° prevented fracture in the current case, but other alloys may require a smaller or larger angle. A quantitative analysis combining the pressure effect on the fracture line and plasticity analysis would provide a method of predicting he draft angle in order to prevent fracture.

Introduction to Process Design for Bulk Forming

H.L. Gegel and J.C. Malas, Air Force Wright Aeronautical Laboratories/Materials Laboratory; S.M. Doraivelu and V.A. Shende, Universal Energy Systems, Knowledge Integration Center

Introduction

In designing material-working processes for components made of complex engineering materials, the most important task is the selection of the controlling process parameters that will ensure part quality as well as specific mechanical and physical characteristics. The controlling process parameters are the sequence and number of material flow operations, the heat-treating conditions, and the associated quality assurance tests. When designing forging processes, special features such as nonlinear irreversible finite-deformation flow must be considered. Simultaneously, the complex interdependence of forging process parameters, as shown in Fig. 1, and their effect on the quality of the finished part, the reliability, and the ability to inspect must be considered.

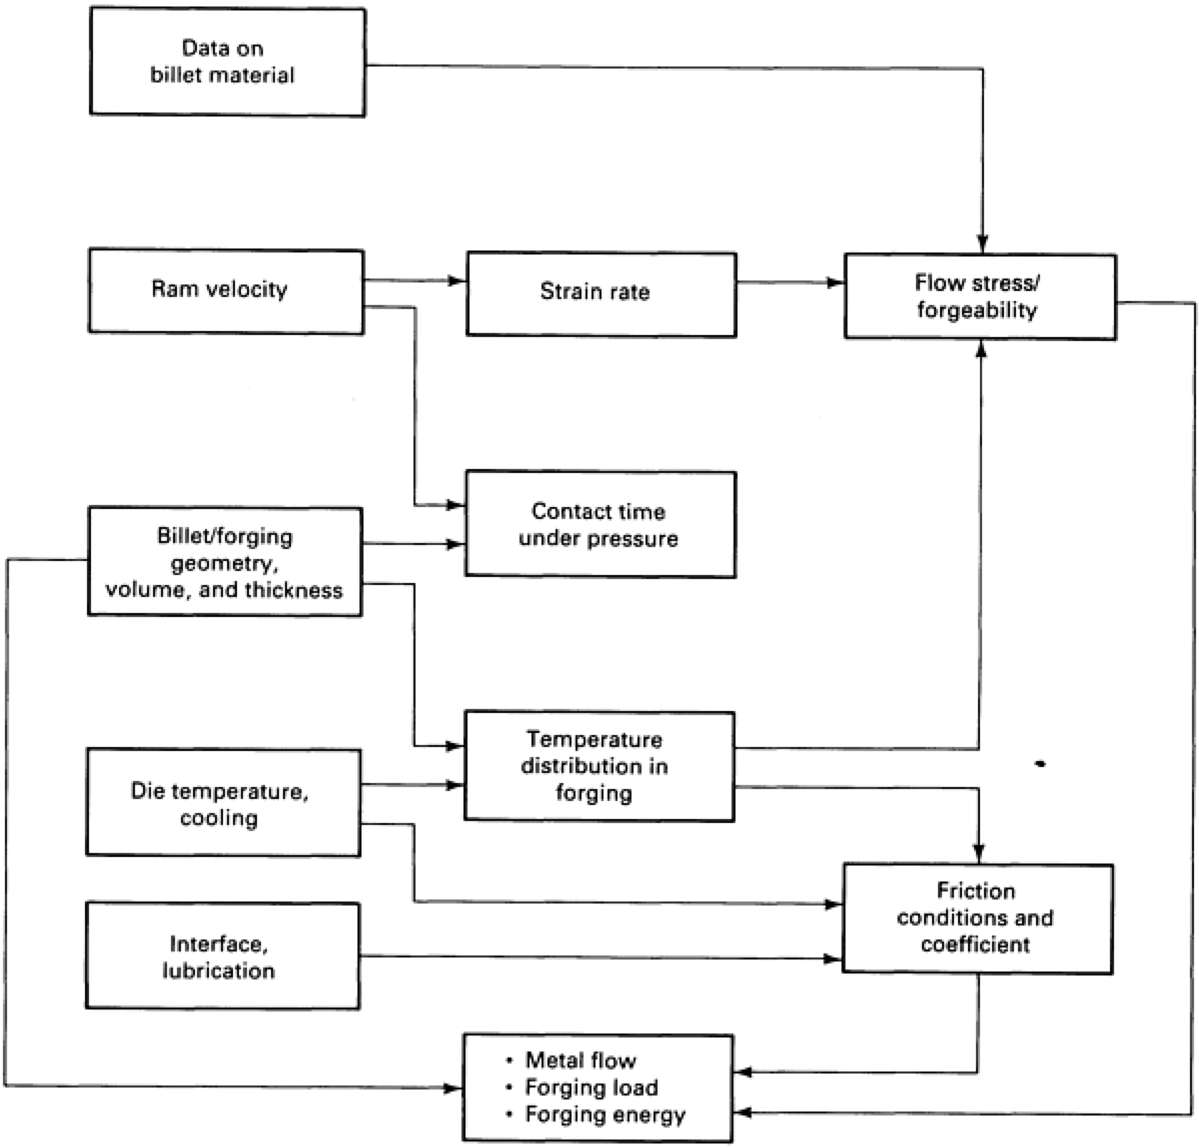

Fig. 1 Interdependence of forging process parameters.

Another important goal in forging is to determine the optimum means for producing defect-free parts on a repeatable basis. The optimization criteria depend on the manufacturing goals and the product specifications; establishing the appropriate criteria requires in-depth views--both global and local--of manufacturing processes and material behavior. From an optimization viewpoint, manufacturing processes require the determination of material flow mechanics to achieve proper process design and to develop a rational strategy for process control.

Modeling

Modeling of the forging process involves both mechanics and thermodynamics. The process, as a rule, is inhomogeneous and transient over a large volume of workpiece material, and the material flow process can be characterized as highly irreversible and stochastic in nature. The mechanics of the forging process are well established, and different analytical tools are available for analyzing most of the important steps of a total forging process. Three articles in this Volume illustrate how the various analytical tools and material behavior models can be used in cooperation to design complex forging processes. The first article, "Forging Process Design," summarizes:

- The controllable factors in the forging process
- The various tasks performed in the manufacture of forgings and the software available to support task automation
- The required data base of information required to support the software
- The methodology of forging process design

The next article, "Modeling Techniques Used in Forging Process Design," reviews:

- The concepts involved in material modeling and the approaches used to understand the fundamentals of flow, fracture, and workability
- The methods available for the analytical modeling of the forging process and the application of these methods for various forging operations
- Physical modeling through simulation using model materials (for example, Plasticine, wax, and polymers) or through laboratory tests

Finally, the third article, "Acquisition of Data for Forging Process Design," discusses the use of compression testing for:

- Generating flow curves
- Determining workability parameters
- Developing and interpreting processing maps

- Obtaining interfacial frictional data

In addition to the articles mentioned above in this Section, supplementary information on computer-aided forging process design can be found in the articles "Open-Die Forging," "Closed-Die Forging," and "Introduction to Workability" in this Volume.

Forging Process Design

Introduction

THE TRADITIONAL BUILD-AND-TEST METHODS of developing a complete manufacturing process were heavily experience based, because the analytical approach to process design was inadequately developed. The part geometries are generally quite complex, and the simpler analytical methods (as opposed to the computer-aided numerical methods) could not handle the task of providing accurate solutions to engineering problems. The advent of numerical methods such as general-purpose finite-element method (FEM) codes to handle large deformation plasticity has made accurate analysis possible, but these techniques still have several limitations. FEM codes such as ALPID (Ref 1, 2) (developed under programs funded by the U.S. Air Force) are analysis tools, not design tools, and are quite expensive to use in terms of required computer time and facilities. Because the potentially viable processing routes are numerous, many FEM process simulations would be necessary to identify optimal processing methods unless some means of restricting the solution space are implemented.

The problem of large design solution spaces is not restricted to the design of the deformation process, but also applies to the selection of correct combinations of processing temperatures and strain rates and to the identification of optimal heat treatment techniques.

In the design and manufacture of forging dies, two methodologies can be used. In the first method, the design of the die is obtained by making use of a computer-aided engineering (CAE) systems approach. This approach integrates dynamic materials behavior modeling, geometric modeling, and analytical process modeling (Ref 3). Advanced process modeling is the heart of this approach, and the understanding of dynamic materials behavior in a quantitative way for all materials--composites, metals, alloys, polymers, and ceramics--makes the integration possible and generic.

In the second method, well-established empirical rules are used to arrive at an acceptable design alternative. Currently, both of these procedures follow a trial-and-error approach to achieve the required goal. Either one used by itself is a time-consuming and costly process. The CAE procedure lacks empirical aids during the selection of an initial design, and the experience-based method lacks analytical aids for verification of the final design. The optimum die design procedure would be to use both of these methods.

An initial design can be selected on the basis of empirical rules; such a design can be further refined by computation involving analysis and simulation as followed in the CAE approach. This procedure is complex because it involves two fundamental types of activities, information handling and problem solving. This can be made easier if an intelligent system that makes use of the techniques is available from software engineering (SE), data base management systems (DBMS), operating systems (OS), analytical modeling (AM), or artificial intelligence (AI).

To summarize, automation of engineering methodology in forging design and manufacture should address the following basic issues:

- Engineering disciplines of significant diversity are involved and need to be integrated in a uniform fashion
- The potential design solution space is large and needs to be intelligently reduced so that the design-analysis iterations remain practical

The global approach to automation is conceptually straightforward, and is suitable for incremental implementation as newer software tools become available. The automation of the initial-guess design is done through the use of knowledge-based expert systems (KBES); when possible, a rough analysis (for example, using slab analysis for plasticity) is provided as a pre-screen to detail analysis (usually FEM), and the detail analysis is used primarily as a verification tool. It is useful at this point to note that the solution space is reducible through two means:

- The use of KBES rough analysis-detail analysis iterations can provide a local reduction of admissible solutions, that is, in a specific domain such as plasticity, heat transfer, or material engineering
- The use of a knowledge-based integration shell provides a more global reduction of the solution space by implementing a methodology that controls design procedures across interdisciplinary domains; this approach embeds procedural knowledge in the integration shell, and also provides a uniform user interface

This article provides a list of controllable factors, various tasks performed in the manufacture of forgings, software tools available to support task automation, and data bases of information required to support software tools. Forging process design tasks are then outlined to illustrate how the various tools and data are used in the method.

Controllable Factors In Forging Process Development

As a first step towards identifying the procedures, it is useful to define the features of the product or process that are controllable, and by whom. Table 1 shows applicable product specification, process design, and die design related factors. This basic inspection can then be used to guide the development of the task hierarchy, or method.

Table 1 Applicable product specification, process design, and die design related factors

Controllable factor	**Controlled by**
Product specification related factors	
Final component geometry	Customer/end-user
Sonic outline	Customer/end-user

Alloy composition	Primary melter
Alloy cleanliness	Primary melter
Mechanical properties	Heat treater/forging metallurgist
Final microstructure	Heat treater/forging metallurgist
Final finishing (for example, chem-milled)	End-user/forger
Forging identification	Forger
Process design related factors	
Heat treatment	End-user/forging metallurgist
Forging sequence design	Forging designer/metallurgist
Preform design	Forging designer
Stock allowances	Manufacturing/forging designer
Billet size requirements	Forging designer
Forging temperature	Forging metallurgist
Forging die temperature	Forging metallurgist
Lubrication practice	Forger
Forging strain rate	Forging metallurgist
Load/ram velocity requirements	Forging designer/FEM analyst
Press selection	Manufacturing engineer
Die design related factors	
Forging dimensional accuracy	Die designer/FEM analyst
Defect-free forgings (no laps, and so forth)	Die designer/FEM analyst

Tasks Performed in Forging Manufacture

If the overall procedure in the production of forgings in a typical company were examined, the following major tasks would be found to be necessary components of the manufacturing operation:

- Receive and interpret request for quotation (RFQ)
- Input part geometry into computer-aided design (CAD) system
- Identify constraints imposed by specifications in RFQ
- Identify billet stock sources
- Check incoming billet stock for quality
- Prepare billet for heating/forging
- Determine forging sequence (blocking, preforming, and so forth)
- Design dies
- Select forging temperatures and strain-rates
- Choose forging technique (hot-die, isothermal, and so forth)
- Select forging equipment
- Manufacture dies
- Ascertain furnace cycles and environments (atmosphere control, and so forth)
- Determine lubricants required
- Select intermediate operations such as trimming of preforms
- Inspect finish forging
- Use identification method (serial numbers, and so forth) to track workpieces, drawings, dies, and so on
- Determine heat treating and finishing operations
- Test finish forging to see it meets customer specifications
- Verify packing and shipping requirements

Most forge houses have standard in-house process specification sheets, and "travelers," or specification sheets that actually go with the individual forging (or batch of forgings) to ensure that proper practice is followed.

Software Tools Available to Support Task Automation

Five main classes of tools are necessary for the implementation of an integrated system for forging process design:

- *Geometry Representation Tools.* A significant portion of the design and analysis task is manipulation and definition of geometry
- *Knowledge-based expert systems (KBES)* provide experience-based initial guesses to design problems. These initial guesses can then be iterated upon by rough and detailed analysis tools
- *Rough analysis tools* are fast and cost effective: They prescreen initial guesses provided by the KBES so that inappropriate designs are not passed to more expensive detail analysis tools
- *High-accuracy detail analysis tools* serve mainly to validate selected designs
- *An intelligent DBMS* stores all data used by the aforementioned tools. Access to this data, whether it be by the user or by one of the aforementioned tools, should be guided and controlled; the forging knowledge-based DBMS must control the sequence of creation and use of the data by users and tools according to the dictates of the methodology

These tools are further examined below, with a brief discussion of their functionality, input requirements, and outputs. The input requirements and outputs do not represent a description of the "file formats," but rather of the conceptual use of the tools. Further, input data that would be data based is not noted here, but is described later in the section "Required Data Base to Support Software Tools." (Data base information is data that is insensitive to a specific forging operation; for example, materials flow stress, thermophysical properties, and so forth.)

Geometry Representation Tools

CAD Systems. It is necessary to provide geometry information to the simulation and expert systems programs in an appropriate fashion. Much of the U.S. manufacturing industry has already started to use computer-aided drafting systems, and it would be ideal to use this computerized geometry representation for forging process design.

Computer-aided design commercialization is fairly mature, and options range from low-cost PC-based systems to full-function mainframe software. The choice is mostly a matter of performance versus cost.

- *Input requirement:* Interactive geometry creation, or geometry data files (IGES, that is Initial Graphics Exchange Specification, or proprietary) (Ref 4)
- *Output:* Engineering drawings, cross sections for analysis, section geometric properties, solid model geometric properties, numerical control (NC) machining "tapes"

Callable Graphics Libraries. The above-mentioned CAD software is generally highly proprietary and, as such, is not readily useable in applications software. Furthermore, CAD systems offer a capability exceeding the requirements of graphics application codes. It is therefore necessary to use callable graphics libraries that can be integrated into graphics application routines. Several such graphics libraries are commercially available.

- *Input:* These are not used directly by the end-user, rather, they are programming tools for the software applications developer
- *Output:* Graphics output to and input from the user

Knowledge-Based Expert Systems

Automated forging design (AFD) is a knowledge-based system implementing rules for establishing stock allowances to a finished part for the various manufacturability criteria, such as forgeability, machining, die mismatch, and so forth. In addition, it establishes a suitable parting line. This software is being developed under a U.S. Air Force Manufacturing Science program (Ref 5).

The program can currently handle two-dimensional geometries; thus, for general three-dimensional components, the designer has to determine which set of two-dimensional sections should be provided to the AFD expert system.

- *Input requirements:* Material specification, two-dimensional geometry of the required part
- *Output:* Two-dimensional geometry of the required part with a forging envelope applied as well as a

parting line for final forging operation

Blocker Initial Design (BID). This program (Ref 6) adds allowances to the finish forging according to experience guidelines that generate a preform geometry for the finish forging. The BID program is also being developed under the U.S. Air Force Manufacturing Science program.

BID could be used iteratively to work back all the way to a starting billet requirement. The program can currently handle two-dimensional geometries; thus, for general three-dimensional components, the designer has to determine which set of two-dimensional sections should be provided to the AFD expert system.

It is worth noting that the use of a two-dimensional section is quite appropriate, because this is in fact the way experts currently handle design. It would be advantageous to attempt to identify the two-dimensional sections that should be given to the KBES.

- *Input requirements:* Geometry at the end of a forging step, and material specification
- *Output:* Preform geometry for the forging step

Material Modeling Environment (MME). Given the nominal strain to be developed in a deformation step, MME (Ref 7) provides a material processing map that identifies ranges of the stable temperature and strain rate required to forge the part. Further, based on microstructural observation data, a desired range for generating the required microstructure can be superimposed on the stability map. This allows determination of press velocities and forging temperatures.

- *Input requirements:* Flow stress data as a function of strain, strain rate, and temperature; microstructural observations
- *Output:* Multiple graphic views of the data set, stability and structure evolution maps, and constitutive representation of the material response suitable for ALPID (Analysis of Large Plastic Incremental Deformation) simulations

Rough Analysis Tools

FINISHR. This FORTRAN program (Ref 5) is intended to give approximate load distributions on the forging dies using the slab method. Again, this program operates on two-dimensional sections; however, this is consistent with the functionality of the KBES.

- *Input requirements:* Geometry at the end of forging step, and material specification
- *Output:* Estimated load distribution on the dies

Detail Analysis Tools

ALPID System. This system of programs includes two-dimensional rigid-visco-plastic FEM analysis programs, including a coupled heat-transfer capability. The system also includes a remeshing-interpolation program to permit continued simulation after the initial mesh becomes too distorted. There is a postprocessor included in the system. More details about ALPID are given in the section "Required Data Base to Support Software Tools" in this article. The ALPID program has been actively used in various research programs as well as in industry, and is considered reliable and mature.

- *Input requirements:* Geometry of dies and workpiece, FEM mesh, boundary conditions, material constitutive "equation," thermal/physical properties of materials
- *Output:* Geometric description, in textual or graphic representation, of the progress of deformation in terms of mesh distortion, detailed distributions of strain, strain rate, velocity, stress, and temperature

TOPAZ. This is a FEM heat transfer analysis program developed at Lawrence Livermore Laboratories. TOPAZ (Ref 8) provides complete capabilities, including convection, conduction, and radiation. An associated program, FACET (a subprogram of TOPAZ), can provide view factor calculation for the radiation.

- *Input requirements:* Geometric description of part, FEM mesh, thermophysical properties of forging, boundary conditions, heat transfer coefficients, and view factors for radiation
- *Output:* Transient temperature field in the forging, as a stand-alone result or as input to NIKE for analyzing the thermally induced stresses

NIKE. This FEM stress analysis program (Ref 9) (also developed at Lawrence Livermore Laboratories) can provide several material models, that is, elastic, elastic-plastic, and so forth. For one of the intended applications in the integrated forging methodology, the elastic-plastic capability is of interest, to simulate heat treatment induced stresses in the forged part. It is also possible to use NIKE for detailed stress analysis of the dies, although other commercial packages are popularly used.

It is important to note that NIKE and TOPAZ are coupled to provide thermal-stress analysis. At present, remeshing is not provided; however, if significant deflections do occur, the heat treatment is not viable anyway, so the simulations are quite appropriately terminated at this point.

- *Input requirements:* Geometric description of the part, FEM mesh, boundary conditions, and thermomechanical properties
- *Output:* Stress and deflection field in the forging/die

NIKE and TOPAZ are provided with their own mesh generator and postprocessor, and if integration and uniform user interface are required, some code development will be necessary.

Knowledge-Based Intelligent DBMS

KI SHELL. This is a knowledge-based integration shell (Ref 10) for providing a frame-based methodology. The shell is built on top of a relational data base. This shell has been under development for 10 years at The Ohio State University, and is now being used commercially.

Relational Data Base. The KI SHELL is mapped onto a relational data base.

Required Data Base to Support Software Tools

Workpiece and Die Thermophysical Properties. The data for performing heat treatment simulations on the finish forging include specific heat, density, thermal conductivity and elastic modulus of the forging material, all as a function of temperature. The thermal properties of the die material are necessary to conduct the deformation simulation for nonisothermal forging. The elastic modulus of the die is necessary for the stress analysis of the dies to verify the capability to withstand the loading.

Workpiece Constitutive Response. The flow stress of the workpiece, or billet material, as a function of strain, strain rate, and temperature is required for dynamic material modeling (using MME), as well as for deformation simulation (using FINISHR and ALPID). The constitutive response is also important if plastic deflections are to be predicted in heat treatment simulations (NIKE and TOPAZ).

Process Window for Microstructure Control in the Forging. The dynamic material modeling approach implemented by the material modeling environment (MME) package provides direct guidance for selecting stable processing conditions when taking defects into consideration. It is still necessary to further restrict the viable processing range in terms of microstructure control. Thus data on processing-microstructure correlations is necessary to ensure that forging is done at a temperature and strain rate that not only gives stable flow but also develops the desired microstructure.

Die-Workpiece Interface Data. The thermomechanical deformation simulation (ALPID) requires data on the effective friction factor and the heat transfer coefficient at the interface. In general, these data vary with the lubricant used during forging and the force applied on the interface.

Tooling Data Base. A typical tool setup involves back-up die-blocks behind the forging die; further, these back-up dies are frequently used in conjunction with multiple sets of contour dies. It is useful to data base this inventory, in order to help determine whether new back-up tools will be necessary. In general, the contour dies are useful for only a specific part, and the need to data base them is uncertain.

Press/Hammer Data. In order to determine the appropriate forging equipment for a particular forging operation, information on the press/hammer capacity is needed. Equipment data of relevance for presses is the velocity load capability and the velocity stroke capability. For hammers, the energy availability and stroke frequency are important. This data can be compared with the requirements computed by the deformation analysis tools, to support equipment selection.

Forging Process Design Method

Having outlined the conceptual method of automating forging design and manufacturing, it is appropriate to examine the detailed, domain-specific aspects of the methodology. In the previous sections, the tasks that must be performed and the available tools to support these tasks were examined. The proper sequencing of these tasks, propagation of information between tasks, and the correct data basing of the results to prevent redundancy while maintaining a uniform user interface are the objectives of knowledge-based integration. Providing the detailed description of sequence, information propagation, and so forth, in a specific application (in this case, forging manufacture) is referred to as method design.

Forging Process Design Task Outline. An overview of the tasks that must be performed in developing a forging manufacturing plan is presented in Fig. 1. This representation shows inputs, redesign when analysis invalidates a design, and data base information required by a process designer or planner. This section provides a conceptual description of the tasks presented in the representation in Fig. 1.

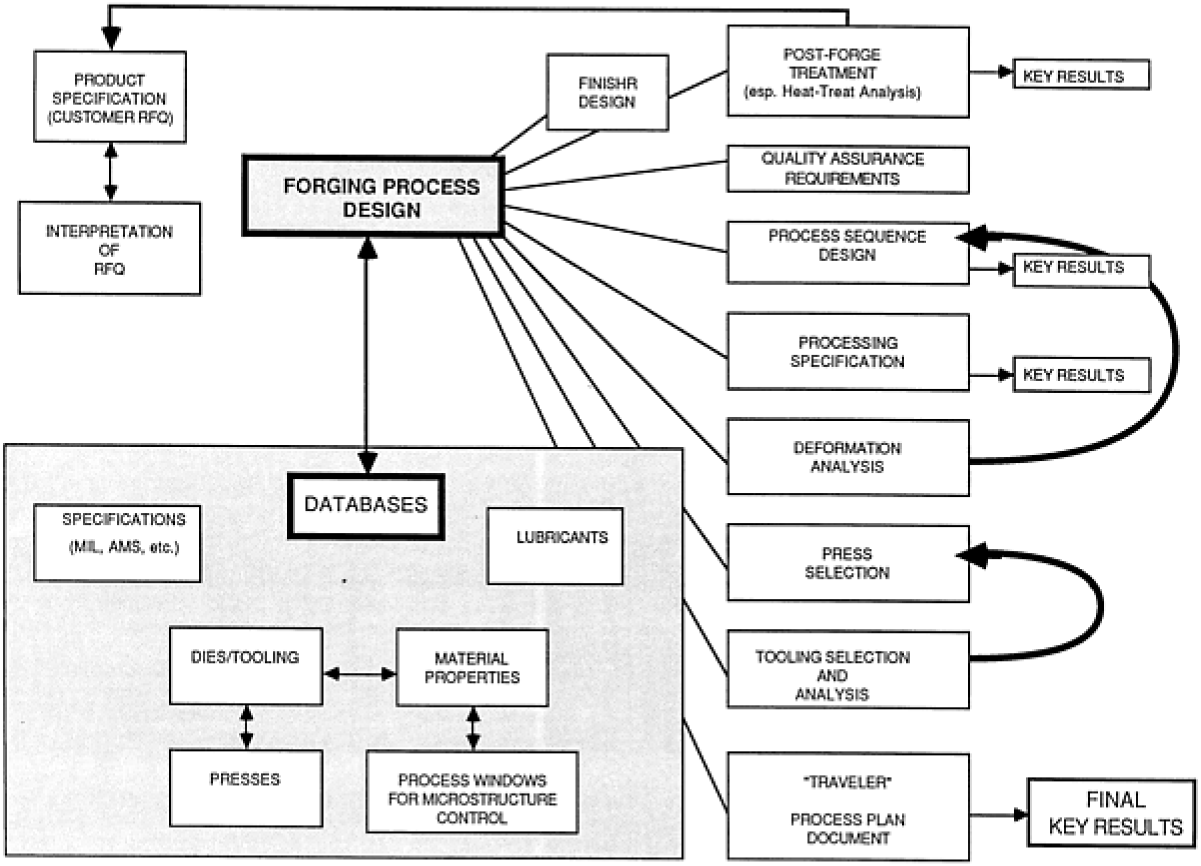

Fig. 1 Forging process design task overview.

Task 1: Integration of Geometry Representation. As is the case with most process design, forging design is conducted backwards, starting with the finished component requirement. The finished part representation is usually in the form of a computer-aided drafting geometry data base, plus the structure/property specifications, which are typically not data based at this point. The approach, therefore, will be to leave the integration of structure and property data to future work.

Computer-aided drafting technology is already in the marketplace as a competitive business, and such tight coupling with the data base would require access to proprietary data base structures. It has been proposed that integration be accomplished through standardized geometry files by means of standards such as the IGES.

Task 2: Initial-Guess Finished Forging Geometry. The identification of an initial-guess finished forging must take into account criteria such as the forging material, recommended process, available equipment, and so forth. In addition, if the property and structure specifications require the finished forging to be heat treated, the selected design should be capable of developing the required properties with available heat treatment practices without resulting in either cracking or distortion.

At present, a KBES prototype is available to provide an initial guess for a finished forging AFD along with the rough analysis tool (FINISHR) to estimate producibility of the finished forging. (Both the codes were developed under U.S. Air

Force funded programs.) There is, however, no such KBES rough-analysis support to evaluate the heat treatability of the finish forging, so it will be necessary to go directly to detail analysis. NIKE and TOPAZ can be used for evaluation of heat treatability. NIKE, a stress analysis code coupled with TOPAZ, a heat transfer code, can be used to provide thermal transients and associated stresses and deflections, if any, to determine heat treatability.

It is already apparent at this point that a large amount of data is necessary to support each aspect of design and analysis. This need to access significant amounts of diverse data in a context-sensitive fashion is a circumstance ideally suited to the capabilities of knowledge-based integration, which makes all data readily accessible to the user.

Task 3: Forging Sequence Design. After the finished forging has been adequately defined, it is necessary to design a sequence of forging steps, tracing backwards to an acceptable starting billet geometry (usually a cylinder or a cuboid).

In this task, the solution space can again be reduced through another KBES prototype, BID. This expert system starts with the finish forged geometry (or the intermediate step geometry) and applies criteria sensitive to the material, equipment, and geometry to provide an input geometry to that forging step.

Task 4: Processing Parameter Selection. The dynamic material modeling approach implemented in the MME product provides a fundamental methodology for selecting temperature and strain-rate at which stable deformation can be expected.

In addition to stable flow, data base information on processing-microstructure correlations will be used to identify the process window within which both stable metal flow and appropriate evolution of microstructure are achieved.

Task 5: Detail Analysis of the Forging Sequence. The initial-guess design and rough analysis constitute the automatic die and process design. In order to avoid costly die tryouts, the proposed sequence for manufacturing the forging can be verified using the ALPID system for FEM analysis. This system of programs, developed under U.S. Air Force sponsorship, is capable of analyzing any two-dimensional metal forming operation, including temperature-transient effects.

The ALPID system is integrated into the knowledge-based system by means of an intelligent preprocessor, to which relevant design information can be propagated. The preprocessor then generates the necessary inputs, including an appropriate constitutive "equation" representation, to the ALPID program.

It should be noted that unlike the design tasks, which work backwards from the final requirement, the analysis task progresses in the forward direction. This reversal of methodology is done primarily because, in general, initial conditions are not known for intermediate steps in a nonisothermal forging sequence without reheats.

Task 6: Die Design and Stress Analysis. The detail analysis of the deformation sequence, using ALPID, also provides the detailed loading distribution on the die surface. At present, there is no KBES for recommending an appropriate die block size, and designer judgment must be relied on. However, the KI SHELL can provide support in terms of propagating the forging design geometry to any appropriate stress analysis program.

Task 7: Generate Key Results. The culmination of process design and analysis is the generation of an appropriate manufacturing plan. In the forging industry, especially for critical applications, the manufacturing specification (plan) actually accompanies the forging. These "travelers" should be generated by an integrated system. In addition, because the design and analysis tasks may extend over several terminal sessions, intermediate status should be made available as "key results" (see Fig. 2 and 3). An actual traveler is an extended and complex document, but a schematic representation is provided in Fig. 4.

---

Introduction

AN UNDERSTANDING of the flow behavior of the workpiece material under processing conditions is necessary in order to exploit the full potential of process modeling techniques. Mechanistic and dynamic material modeling approaches are being used to understand the fundamentals of flow, fracture, and workability. The former approach is based on activation energy analysis and is limited to processes that can be described by steady-state equations applied to pure, crystalline, and simple alloys. The latter approach is based on continuum and thermodynamic fundamentals and is used to understand the intrinsic workability of simple as well as complex alloys. Dynamic material modeling is required for obtaining realistic predictions of the total performance of any nonlinear deformation process and for reducing the cost of the design process. The basic concepts and procedures involved in each of these approaches will be discussed in this article.

Constitutive Equations for Material Modeling

Constitutive equations describe the nonlinear relationship that exists among such process variables as effective stress, effective strain rate, and temperature at different deformation levels. They are required for the development of dynamic material models and for the realistic modeling of various unit processes. They are unique for each material under each processing condition. Therefore, these equations are developed by using data, obtained under simplified experimental conditions, that can be extended to complex situations by means of well-known hypotheses or, for the case of plastic deformation, such criteria as the von Mises yield criterion. These equations affect the convergence and accuracy of finite-element modeling and must satisfy certain requirements, including the following:

- The constitutive equations must be continuous
- The surface generated by the constitutive equations must have the same characteristics as the surface generated by the function that describes the dissipation of power applied to a specimen under testing conditions
- The equations are to be generated to cover the range of processing conditions experienced during the production process
- The equations should be represented in a form compatible with a finite-element analysis program

Basic Concepts (Yield Criteria)

Fully Dense Materials. In general, the constitutive equations for material modeling are expressed as:

$$\bar{\sigma} = f(\dot{\bar{\epsilon}}, T, \sigma^*) \qquad \textbf{(Eq 1)}$$

where $\dot{\bar{\epsilon}}$ is effective strain rate, T is instantaneous temperature, and σ^* is a history-dependent variable defining the current state of the material. Each of these variables is discussed in more detail in this section.

According to the Tresca and the von Mises yield criteria, the flow stress $\bar{\sigma}$ of homogeneous and isotropic materials without porosity can be expressed by:

$$\bar{\sigma} = \sigma_{\mathrm{I}} - \sigma_{\mathrm{III}} \qquad \textbf{(Eq 2)}$$

$$\bar{\sigma} = \sqrt{\frac{1}{2}[(\sigma_{\mathrm{I}} - \sigma_{\mathrm{II}})^2 + (\sigma_{\mathrm{II}} + \sigma_{\mathrm{III}})^2 + (\sigma_{\mathrm{III}} - \sigma_{\mathrm{I}})^2]} \qquad \textbf{(Eq 3)}$$

where $\bar{\sigma}$ is the effective stress and σ_{I}, σ_{II}, and σ_{III} are the principal stresses.

In the case of a uniaxial stress state ($\sigma_{\mathrm{II}} = \sigma_{\mathrm{III}} = 0$), both criteria lead to the same result, namely:

$$\bar{\sigma} = \sigma_{\mathrm{I}} \qquad \textbf{(Eq 4)}$$

Therefore, in uniaxial loading, the stress $\bar{\sigma}$ applied externally on the cross-sectional area of the specimen is equal to the flow stress and is given by:

$$\bar{\sigma} = \sigma_{\mathrm{I}} = \frac{F}{A} \qquad \textbf{(Eq 5)}$$

where F is the instantaneous force and A is the instantaneous cross-sectional area. Hereafter, $\sigma = \bar{\sigma}$ = flow stress.

The true strain for compression $\bar{\epsilon}$ is defined as:

$$\bar{\epsilon} = \int_{h_0}^{h_f} \frac{dh}{h} = \ln \frac{h_f}{h_0} = -\ln \frac{h_0}{h_f} \qquad \textbf{(Eq 6)}$$

where h, h_0, and h_f are the instantaneous, initial, and final heights of the specimen, respectively. Hereafter, $\epsilon = \bar{\epsilon}$ = true strain.

The effective strain rate $\dot{\bar{\epsilon}}$ is defined as:

$$\dot{\bar{\epsilon}} = \frac{d\bar{\epsilon}}{dt} = \frac{dh/h}{dt} = \frac{1}{h}\frac{dh}{dt} = \frac{v}{h} \qquad \textbf{(Eq 7)}$$

where v is the instantaneous velocity of the cross head. Hereafter, $\dot{\epsilon} = \dot{\bar{\epsilon}}$ = effective strain rate.

If the strain rate does not remain constant during the test, the mean strain rate is considered for representing the flow stress values. This mean strain rate is defined as the average strain rate experienced during the deformation.

The instantaneous temperature T of the specimen during deformation is referred to as the adiabatic temperature. It is defined as $T = T_0 + \Delta T$, where T_0 is the forming temperature or the initial test temperature of the specimen and ΔT is the increase in temperature during forming.

The current state of the material, such as plastic hardness, is defined by the history-dependent variable σ^* (Ref 1). Experimental results are used to arrive at the exact functions.

Porous Materials. The design of billet consolidation processes requires a special yield function for development of the plasticity analysis. The plastic flow behavior of porous powder metallurgy (P/M) materials is more complicated than that of ingot materials because the hydrostatic component of stress influences the onset of plastic flow. The effect of hydrostatic stress is taken into account by considering a yield function of the form:

$$AJ'_2 + BJ_1^2 = Y_R^2 = \delta Y_0^2 \qquad \textbf{(Eq 8)}$$

where J_2 is the second invariant of the deviatoric stress; J_1 is the first invariant (that is, the hydrostatic component of stress); Y_0 and Y_R are the yield stresses of fully dense and partially dense materials, respectively; and A, B, and δ are functions of relative density.

Many researchers have determined these constants through heuristic arguments and the use of experimental results. For example, R.J. Green presented an analytical method that considered a uniform cubic array of spherical voids in a solid under states of stress corresponding to pure shear and hydrostatic compression (Ref 2). The results for these two stress states allowed determination of the two variables A and B. He assumed that the stress distribution is uniform in two directions through the minimum section of the array and that the effect of the voids on the stress in the third direction is negligible on the planes riding between the voids. M. Oyane, S. Shima, and Y. Kono determined A and B using more stringent assumptions (Ref 3). They found poor agreement between their theoretical and experimental results and therefore reported experimentally determined values in a paper published later. Shima and Oyane abandoned this analytical approach entirely; instead, they refined empirical relations obtained for their experimental values (Ref 4). H.A. Kuhn and G.L. Downey also presented experimentally obtained values for these two variables (Ref 5). S.M. Doraivelu *et al.* determined these variables while taking into account the distortion energy due to the total stress tensor (Ref 6). The final equation obtained in Ref 6 is:

$$(2 + R^2) J'_2 + \frac{(1 - R^2)}{3} J_1^2 = (2R^2 - 1)\, Y_0^2 \qquad \textbf{(Eq 9)}$$

Flow Curves

The relationship between flow stress (or true stress or effective stress) and true strain is frequently called the flow curve because it determines the stress required to cause the material to flow plastically at any given strain. Many attempts have been made to fit mathematical equations to these curves at different temperatures and strain rates. Table 1 lists the various equations as well as the materials, temperatures, and strain rate ranges for which they are valid.

Table 1 Summary of flow stress-true strain equations

Equation	Materials studied	Temperature studied		Strain rate range studied, s^{-1}
		°C	°F	
$\sigma = K\epsilon^n$ **(Eq 10)**	Aluminum, Al-Mg-Si alloy, copper, low-carbon steel, nickel, zirconium, Inconel alloy, uranium	30-700	85-1290	**10^1-10^3**

Source: Ref 3, 4, 5, 6, 7, 8, 9

(a) T_m, melting temperature of the alloy.

It is clear from the different equations proposed that none is entirely satisfactory for all materials and testing conditions. One researcher has attempted to fit his data on aluminum to Eq 10, 11, 12, and 13 (Table 1) and has concluded that Eq 10 provides the best fit (Ref 7). Other researchers have found that the flow curves for copper deviate from Eq 10 and consist of two parabolic curves, as given in Eq 11 (Ref 8). At higher strains, the exponential form of Eq 14, 15, and 16 seems to be appropriate because these lead to a steady-state stress at higher strains.

In most cases, the behavior of these alloy systems during forced dissipative flow has characteristics that are strongly dependent on initial conditions, such as the α+ β and β(Widmanstätten) microstructures shown in Fig. 1. Both of these microstructures are used as forging preform conditions, and each microstructure requires different thermomechanical processing during billet conditioning.

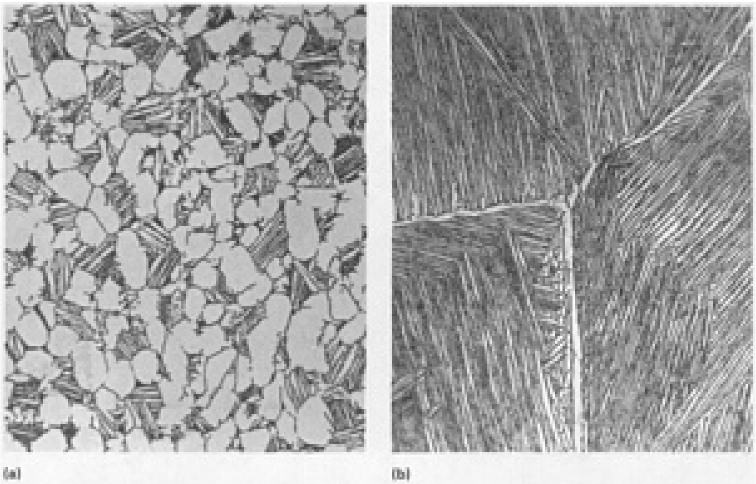

Fig. 1 Two types of initial microstructures in Ti-6Al-2Sn-4Zr-2Mo alloy. (a) α+ β preform microstructure. (b) β(Widmanstätten) preform. Both 500×

Isothermal constant strain rate testing of these materials at elevated temperatures reveals that, with time, the flow curves evolve into what is sometimes called a steady state. This evolution with time toward steady-state behavior is shown in Fig. 2 for a Ti-6Al-2Sn-4Zr-2Mo alloy having both types of initial microstructure. When the two flow curves approach each other asymptotically at approximately 0.60 effective strain, the transients associated with structural change have died away, and the Widmanstätten initial condition has evolved toward an equiaxed structure. Diffusional processes, if given sufficient time, will cause the structure to become equiaxed.

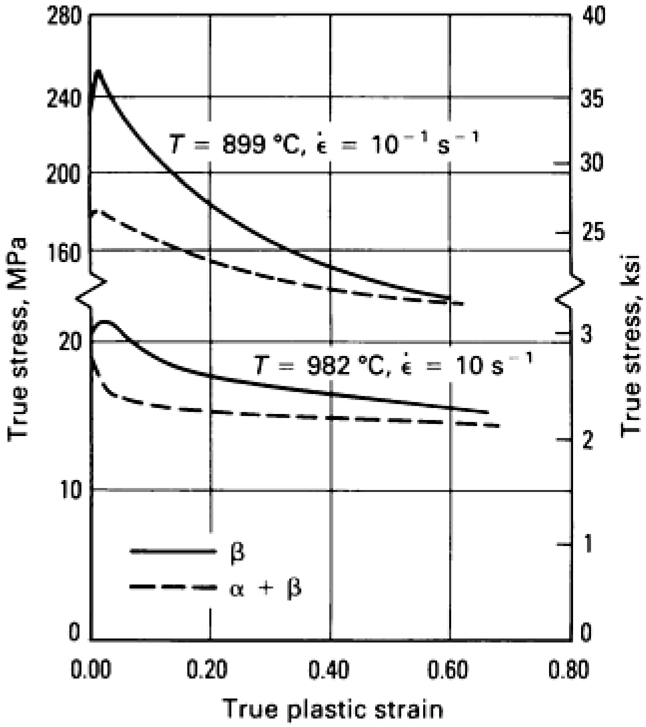

Fig. 2 Evolution with time of α + β and β Ti-6Al-2Sn-4Zr-2Mo alloy preforms to the same steady-state behavior

Deterministic modeling cannot be used to predict accurately the long-term behavior of complex engineering alloys, because it is necessary to choose *a priori* which atomic mechanisms may be operating and to decide how they can be used to control microstructural evolution and mechanical stability during forced dissipative flow. The problem that must be confronted in developing material behavior models for use in computer-aided engineering is of a statistical nature in a very complex setting. The mechanism, for example, by which the effort variable $\sigma(t)$ reaches the value $\sigma(t_2)$, where $t_2 > t$, is generally irrelevant to its behavior after time t_2 because the forced dissipative flow process is irreversible. The behavior of the workpiece material at t_2 is dependent on the evolution of certain intrinsic control parameters that govern how power is dissipated by random, fluctuating, generalized forces. These forces, for example, may be such system variables as chemical potential, temperature, and stress field gradients.

In practice, experimentation by measuring the flow stress of the workpiece material (the output) as a function of the kinematic variables (the input) of the system, in combination with mathematical modeling based on physical laws, is used to derive constitutive equations and information about workability. This methodology is called the black-box approach, and it can be used to derive a material model for the intrinsic workability of any material.

Flow Stress-Strain Rate Relationships

The most common relationships used to correlate flow stress-strain rate data at various temperatures and strain levels are summarized in Table 2, along with the materials and temperature and strain rate ranges for which they are valid. It can be seen that, for most materials, the power law or logarithmic expression seems to fit well. In the case of steel, Eq 18 (Table 2) seems to fit well. Equations 17 and 18 (Table 2) are analogous to the relationships obtained from creep data at low and high stresses, respectively (Ref 10).

Table 2 Summary of flow stress-true strain rate equations

Equation	**Materials studied**	**Temperature range studied**		Strain rate range studied, s^{-1}

(a) T_m, melting point of alloy.

In Eq 17 and 18, *K* is a temperature-dependent strength parameter, and *m* is the strain rate sensitivity factor. The *m* value is one of the most important control parameters, and the physical meaning behind it and its effect on intrinsic workability must be understood. For complex alloys, at a given deformation, *m* varies as a function of strain rate and temperature.

Flow Stress-Temperature Relations

Equation 19 has been used to represent the flow stress as a function of temperature (Ref 11, 12, 13):

$$\bar{\sigma} = \bar{\sigma}T_{Az} e^{-sT} \quad \textbf{(Eq 19)}$$

where $\bar{\sigma}T_{Az}$ and *s* are constants and T_{Az} is absolute zero temperature (-273.13 °C, or -459.5 °F).

A similar relationship has been defined between Brinell hardness (HB) and temperature, as follows (Ref 14):

$$HB = HBT_{Az}\ e^{-sT} \quad \textbf{(Eq 20)}$$

Many researchers have found that Eq 20 is valid for many metals and alloys in temperature ranges in which structural transformation, precipitation, dynamic strain aging, and so on, are not present (Ref 14). Whenever softening takes place by dynamic recovery and recrystallization, the value of *s* changes (Ref 15).

In the temperature range in which structural transformation takes place, the flow stress increases; this is represented as a small hump in the flow stress-temperature diagrams. This effect has also been found by many researchers for a number of metals and alloys (Ref 15, 16, 17, 18). The increase in flow stress has been observed at approximately 850 °C (1560 °F) for alloy steels (Ref 15, 16).

In high strain rate testing at a definite temperature range, thermal instability occurs, and deformation takes place in the form of bands (due to adiabatic heating). This is known as adiabatic shearing, and it can lead to fracture if it is severe (Ref 19). In this region, an increase in flow stress also occurs because of the hindrance of dislocation motion by the shear bands. This type of adiabatic shearing occurs in testing under very high strain rate conditions (Ref 19). In the case of alloy steels, similar increases have been observed at the low temperature range of 150 to 200 °C (300 to 390 °F) (Ref 16). Therefore, Eq 19 has been found to be invalid in regions in which the increase in flow stress occurs.

Combined Effect of Temperature and Strain Rate

To correlate flow stress and strain rate at different forming temperatures, it has been proposed that (Ref 20):

$$\bar{\sigma} = f(\dot{\bar{\epsilon}}\, e^{[Q/(RT)]}) = f(z) \qquad \textbf{(Eq 21)}$$

where Q is the activation energy and R is the gas constant.

A slightly different approach to this problem has also been taken (Ref 21). It has been proposed that strain rate and temperature be combined into velocity-modified temperature. The flow stress at a particular strain is then a function of velocity-modified temperature T_{Av}, which is defined as:

$$T_{Av} = T\left(1 - k \ln \frac{\dot{\epsilon}}{\dot{\epsilon}}\right) \qquad \textbf{(Eq 22)}$$

where k is the Boltzmann constant. Equation 22 has been verified for the case of steel and aluminum over a large temperature range, but only for a small range of strain rates (Ref 20). Based on Eq 22, values of activation energy, Q, independent of temperature have been obtained for a number of pure metals and simple alloys deformed at temperatures greater than 0.5 T_m (Ref 22).

However, this approach has been found to be invalid at lower temperatures and for more complex alloys, in which precipitation processes can occur within the temperature range of interest. In addition, in high strain rate tests where adiabatic conditions are approached, there is some ambiguity as to whether the initial temperature or a corrected temperature should be used.

The combined effect of temperature and strain rate has been described through the use of the following exponential relationship (Ref 23):

$$\dot{\epsilon} = \alpha_3\, e^{(\beta_3 \sigma)}\, e^{[-Q/(RT)]} \qquad \textbf{(Eq 23)}$$

Because Eq 23 does not correspond to any theoretical model, the parameters α_3 and β_3 do not have simple physical interpretations. This difficulty has been overcome through the use of Eq 24 (Ref 24, 25). Equation 24 is based on the thermally activated motion of dislocations over local and long-range barriers:

$$\dot{\epsilon} = \alpha_5\, e^{[(-\Delta H)/(kT)]}\, e^{[V(\sigma - \sigma_\beta)/(kT)]} \qquad \textbf{(Eq 24)}$$

where $\sigma\beta$ is the internally developed back stress and V is the activation volume.

It has been proposed that, under steady-state conditions, Eq 24 can be written as (Ref 25):

$$\dot{\epsilon} = \alpha_5\, e^{[(-\Delta H)/(kT)]}\, e^{[(V'\sigma)/(kT)]} \qquad \textbf{(Eq 25)}$$

where $V' = V(\lambda - 1/\lambda)$ is the apparent activation volume and $\lambda = \sigma\beta/\sigma$. However, other researchers have related experimental steady-state stress, strain rate, and temperature by using the following hyperbolic equation (Ref 26):

$$\dot{\epsilon} = \alpha_6\, [\sin h\, (\beta_6 \sigma)]^{1/m}\, e^{[Q/(RT)]} \qquad \textbf{(Eq 26)}$$

In Eq 23, 24, 25, and 26, α_3 to σ_6 are constants that depend on strain and temperature, and β_3 to β_6 are also constants.

With Eq 26, the average activation energy has been calculated on a computer for copper at somewhat lower strain rates. One researcher has used Eq 26 to fit his experimental data for various steels, aluminum, and copper and has also calculated activation energies (Ref 27).

For process modeling applications, continuous low-order polynomial equations are adequate because they generally help obtain rapid convergence and yield good accuracy in finite-element modeling. For example, this method has been used to describe the constitutive behavior of Ti-6Al-2Sn-4Zr-2Mo for both the transformed β and the $\alpha + \beta$ microstructures (Ref 28). The polynomial representations describe flow softening and steady-state behavior with a high degree of accuracy.

Deformation Mechanisms and Deformation Maps

Deformation Mechanisms. The activation analysis discussed in Ref 29 has been used to obtain quantitative data on the deformation mechanisms that take place in metals and alloys. According to Ref 29, the activation enthalpy ΔH is given by:

$$\Delta H \cong Q = -k \left[\frac{\delta \ln \dot{\epsilon}}{\delta(1/T)}\right]_{\sigma} = kT^2 \left(\frac{\delta\sigma}{\delta T}\right)_{\dot{\epsilon}} \left(\frac{\delta \ln \dot{\epsilon}}{\delta\sigma}\right)_{T} \quad \textbf{(Eq 27)}$$

and the activation volume V is given by:

$$V = kT \left(\frac{\delta \ln \dot{\epsilon}}{\delta\sigma}\right)_{T} \quad \textbf{(Eq 28)}$$

Substituting Eq 28 in Eq 27 gives:

$$\Delta H \cong Q = -VT \left(\frac{\delta\sigma}{\delta T}\right) \quad \textbf{(Eq 29)}$$

Because Eq 27, 28, and 29 are used for creep and interrupted tests, they are modified for continuous compression tests as follows:

$$\Delta H = 2.3\ k \left[\frac{\delta \log \dot{\epsilon}}{\delta \log \sin h\ (\alpha\sigma)}\right]_{T} \left[\frac{\delta \log \sin h\ (\alpha\sigma)}{\delta\ (1/T)}\right]_{\dot{\epsilon}} \quad \textbf{(Eq 30)}$$

$$\Delta H = 2.3\ k \left[\frac{\delta \log \dot{\epsilon}}{\delta \log \sigma}\right] \left[\frac{\delta \log \sigma}{\delta\ (1/T)}\right]_{\dot{\epsilon}} \quad \textbf{(Eq 31)}$$

The experimental activation energy values have been calculated for various metals and alloys using several independent flow stress-true strain curves rather than the more often used single-interruption test, which accounts for sudden changes in strain rate and temperature. One researcher, while calculating the activation energy of Fe-30Cr alloy steel, has shown that correct values of ($\delta\sigma/\delta\dot{\epsilon}$) or ($\delta\sigma/\delta T$) can also be obtained from flow stress measurements made on continuous tests at varying temperatures and strain rates (Ref 30). Therefore, there is justification for the use of flow stress-true strain curves obtained from continuous tests for the calculation of experimental activation energies. These experimental values are compared with the available creep and self-diffusion data to predict the deformation mechanism based on available dislocation models. The activation energy values for various materials under self-diffusion, creep, and hot-working conditions are available in the literature.

When the structure changes because of the occurrence of other mechanisms along with the thermally activated diffusion or recovery or recrystallization mechanism, the activation energy given by Eq 27 is modified as follows:

$$\frac{\Delta H}{k} = -\left[\frac{\delta \ln \dot{\epsilon}}{\delta (1/T)}\right]_{\sigma} + \left[\frac{\delta \ln \alpha_5}{\delta (1/T)}\right]_{\sigma} + \frac{\sigma}{k}\left[V + \frac{1}{T}\frac{\delta}{\delta(1/T)}\right]_{\sigma} \quad \textbf{(Eq 32)}$$

In such cases (for example, copper), it would be difficult to predict the mechanism from the existing dislocation models alone. Other mechanisms have lower activation energies, so their possible frequency of occurrence is higher than the frequency demanded by the thermally activated process (Ref 31). It can therefore be concluded that compression, like creep, is also a thermally activated process, despite the difference of order in strain rate values (Ref 31).

Rate-controlling dislocation mechanisms (see below) are often identified from the magnitude of the measured activation parameters and their variation with temperature. Details on the effects of stress and temperature on the activation parameters are available in the literature. Some of the important mechanisms include:

- Overcoming *P-N* stress
- Intersection of dislocation
- Nonconservative motion of jogs
- Cross slip of screw dislocation
- Climb of edge dislocations
- Recovery and recrystallization

The deformation mechanisms that control the plastic behavior of various materials at different temperatures and strain rates have been identified by calculating the values of activation energy Q and activation volume V and comparing them with those of the above mechanisms.

Deformation Maps. During the past two decades, various investigators have extensively researched and reviewed the effects of strain, strain rate, temperature, and microstructure on the flow behavior of metals during deformation processing (Ref 1, 10, 32, 33). More recently, attempts have been made by H.J. Frost and M.F. Ashby (Ref 34) and R. Raj (Ref 35) to describe the deformation and fracture processes that occur during deformation processing. Both approaches are deterministic in the sense that shear strain rate equations (valid for steady state) are written, assuming that the equations are dependent on a number of basic atomic processes, such as dislocation motion, diffusion, grain-boundary sliding, twinning, and phase transformation. These approaches, as well as an extension of the work of Raj, are briefly described below.

Ashby-Frost Deformation Maps. Deformation maps of normalized stress versus absolute temperature for any polycrystalline material can theoretically be constructed, showing the area of dominance of each flow mechanism. Each flow mechanism must have an equation relating to shear strain rate $\dot{\gamma}$, shear stress τ, absolute temperature T (°K), and structure. The term structure includes all parameters describing the atomic structure, such as bonding, crystal class, defect structure, grain size, dislocation density and arrangement, solute concentration, and volume fraction of second-phase particles. Maps of this type are limited to pure polycrystalline materials, simple alloys, and steady-state conditions. A typical example is shown in Fig. 3.

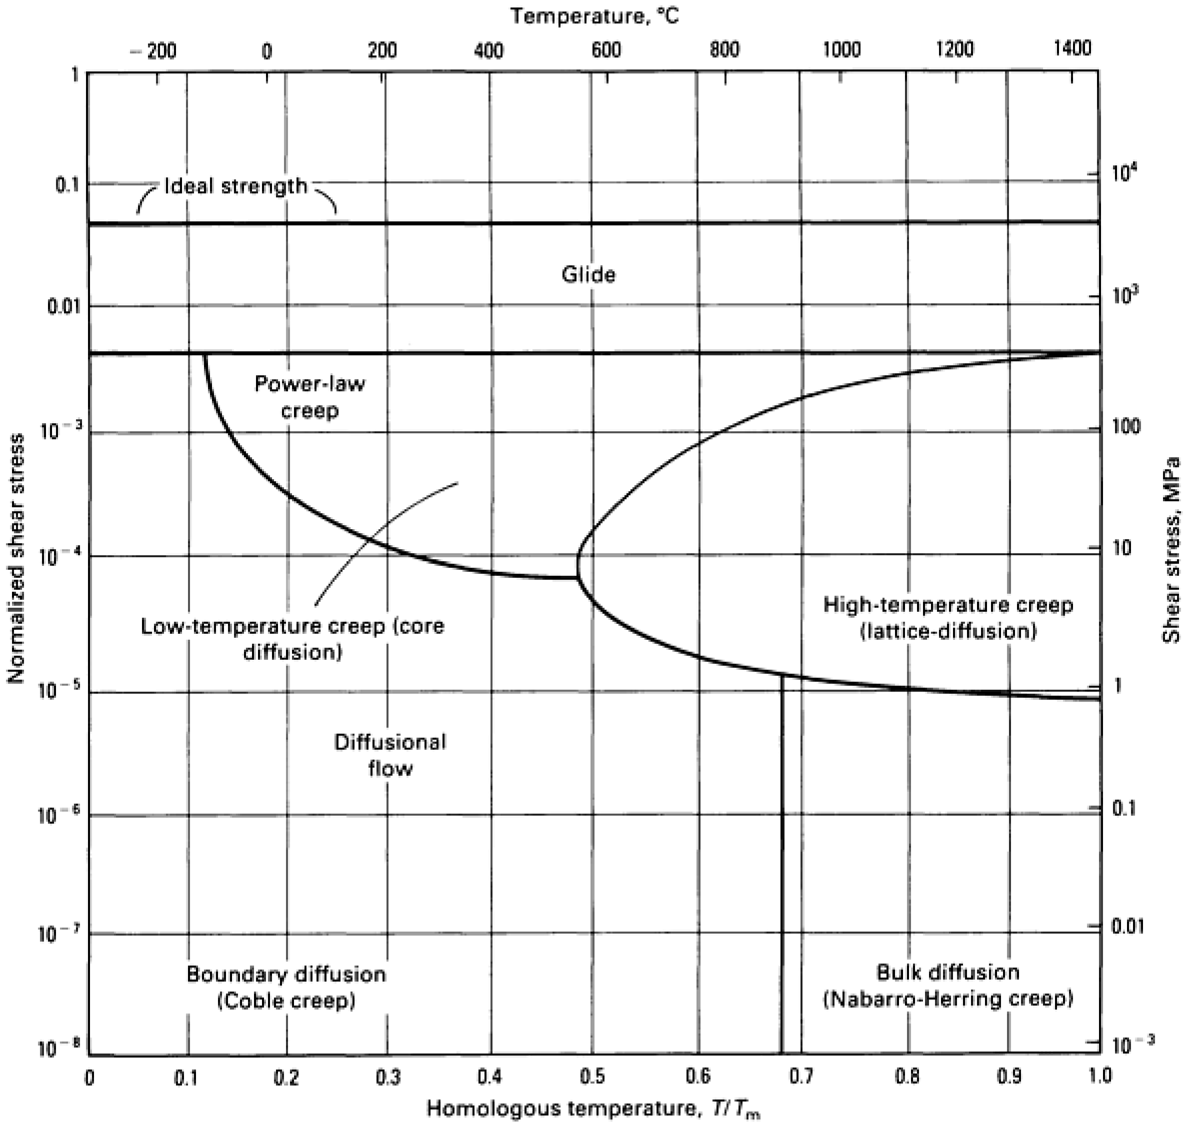

Fig. 3 Example of an Ashby-Frost deformation map

Damage Nucleation Maps. R. Raj extended the deformation map concept to a processing map that represents the nucleation of damage as a function of temperature *T* and effective strain rate $\dot{\bar{\epsilon}}$(Ref 35). A Raj processing map, such as that shown in Fig. 4, is a composite processing map based on various damage mechanisms. The processing map is very useful in that it defines regions in which it is safe to process the workpiece material and avoid defect nucleation. The boundaries are the loci of bifurcation points, where the differential equation takes on a new solution or where the flow process changes from a stable to an unstable process.

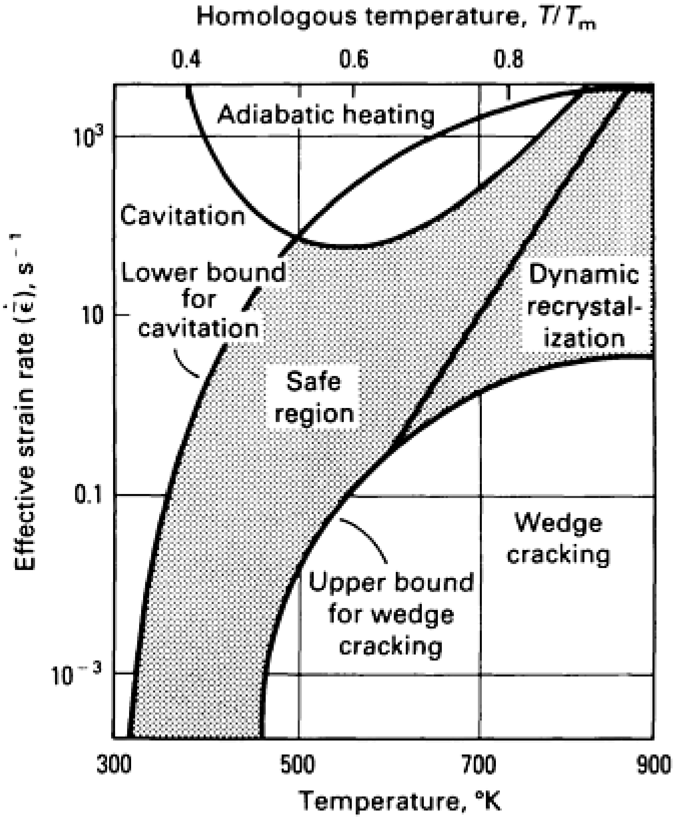

Fig. 4 Example of a Raj damage nucleation deformation map

Like the Ashby-Frost deformation maps, the Raj processing map is highly idealized. Neither approach to describing the workability of materials is suitable for complex engineering alloys, because these models consider only the deterministic aspect of predicting the behavior of a workpiece material under processing conditions. Experience in designing bulk forming processes clearly indicates that predicting the future behavior of a material involves not only deterministic aspects but also statistical and indeterministic features.

Rao-Raj Deformation Maps. K.P. Rao superimposed room-temperature ductility data for specimens deformed under various elevated-temperature and strain rate combinations onto a Raj damage nucleation map (Ref 36). Rao observed that low ductility values are located in the region where the Raj map predicts wedge cracking, which is a form of plastic instability. Peak values of ductility were found in the middle of the safe region. This behavior is shown in Fig. 5.

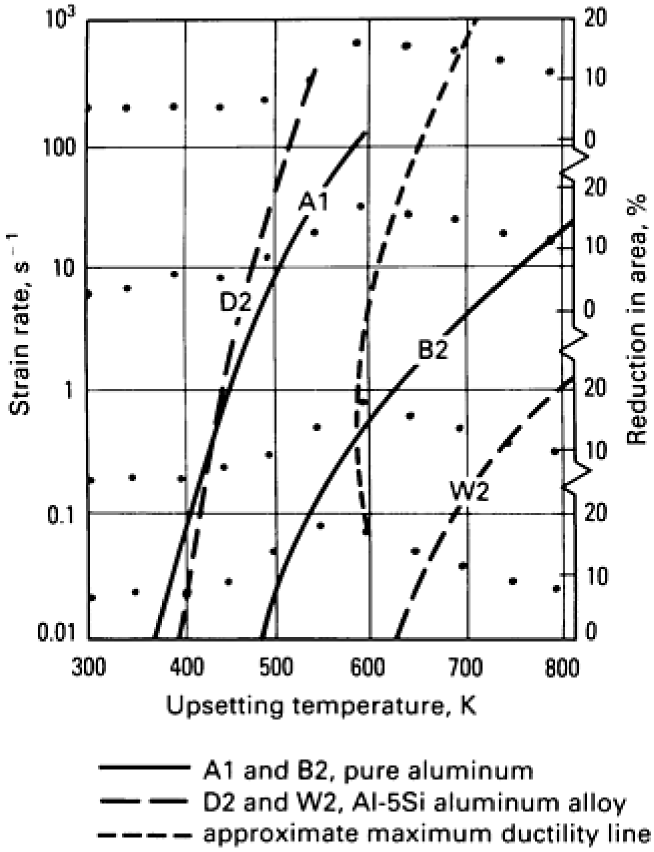

Fig. 5 Raj damage nucleation map with superimposed room-temperature ductility data for specimens previously deformed under various temperature-strain ratio conditions

Dynamic Material Modeling

Control of microstructure during any material-processing operation requires answers to two fundamental questions:

- What conditions does the process require the workpiece material to withstand?
- How does the workpiece material respond to the demands imposed by the process?

The first question can be answered by modeling the process with finite-element methods. The second question, which deals with how the workpiece material responds to the demands of the process, can be answered only if the flow behavior of the workpiece material has been adequately characterized under processing conditions. This necessitates an understanding of how the workpiece will dissipate the instantaneous power applied to it by the process.

For example, during the forging process, the press provides instantaneous power to the workpiece in the amount described by:

$$\bar{\sigma}\dot{\bar{\epsilon}} = \sigma_1\dot{\epsilon}_1 + \sigma_2\dot{\epsilon}_2 + \sigma_3\dot{\epsilon}_3 \quad \textbf{(Eq 33)}$$

where $\bar{\sigma}$ is the effective stress, $\dot{\bar{\epsilon}}$ is the effective strain rate, and the terms on the right-hand side are the products of principal stresses and principal strain rates.

The workpiece will dissipate the instantaneous power applied by a metallurgical process commensurate with the level of power supplied. For example, when energy is supplied at a very high strain rate, the material dissipates it by fracture processes. On the other hand, when energy is supplied at a lower and more controlled rate, the material dissipates it by superplastic flow if the material has the correct microstructure and is deformed under superplastic conditions. The efficiency of energy dissipation of these metallurgical processes in both cases may be the same, but the variation of efficiency with respect to strain rate may not be favorable for achieving a steady-state condition.

The applied power also sets up an entropy production rate by a material system. This rate is controlled by the second law of thermodynamics and is directly related to grain size. The rate of entropy production by the material system reaches a maximum level when the material system has the potential to develop very fine grain structure. The rate of entropy production begins decreasing when grain growth takes place. To study this phenomenon, a parameter known as entropy rate ratio *s* has been defined by the dynamic material modeling approach (Ref 37, 38). Therefore, to control microstructures and to avoid defect formation, a new type of material behavior model termed a dynamic material model is required in order to understand how the workpiece dissipates power while producing entropy to satisfy the demands of the process. This model is capable of producing information consistent with the unifying aspects of the finite-element model in such a way that it can become a nonholonomic constraint in the finite-element model for obtaining optimal solutions during the design of various unit processes.

Basic Concepts

According to the dynamic material models described in Ref 37 and 38, power *P* (rate of work done) is dissipated coherently by partitioning it into *J,* whose energy primitive is potential energy, and *G,* which is heat. Kinetic energy *K* is the primitive for *G.* The partitioning is given by:

$$P = \bar{\sigma}\dot{\bar{\epsilon}} = \int_0^{\bar{\sigma}} \dot{\bar{\epsilon}}\, d\bar{\sigma} = \int_0^{\dot{\bar{\epsilon}}} \bar{\sigma}\, d\dot{\bar{\epsilon}} \quad \textbf{(Eq 34)}$$

Power dissipated by plastic work is denoted by the area *G* under the curve, which is illustrated schematically in Fig. 6. This is designated as the dissipator content. Area *J*, above the curve, is designated as the dissipator co-content. The fundamental assumption in Ref 37 and 38 is that *J* is related to structural changes and that *G* is related to continuum effects. Plastic instability and fracture processes are associated with *G*, and microstructure evolution is associated with *J*. Both *J* and *G* are complementary functions, and they are related by a Legendre transformation (Ref 39).

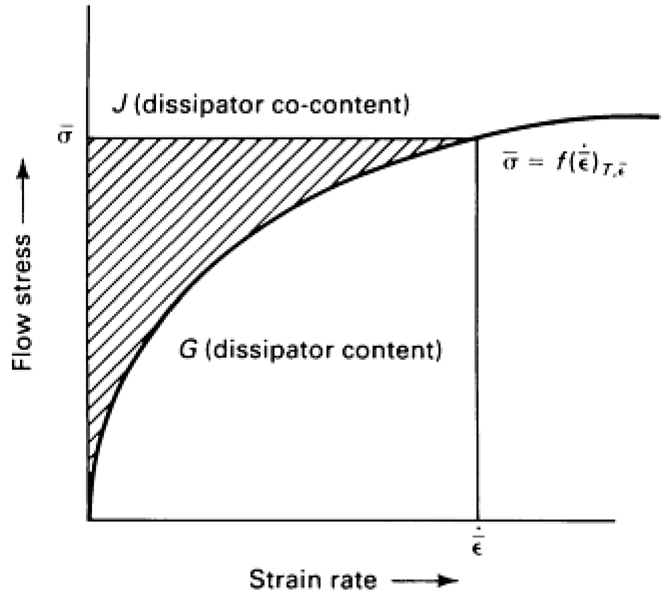

Fig. 6 Schematic showing the constitutive relation of the material system as an energy dissipator during forming. See text for details.

It follows from Eq 34 that the partitioning of power between *J* and *G* is given by:

$$\frac{dJ}{dG} = \frac{\dot{\bar{\epsilon}}\, d\bar{\sigma}}{\bar{\sigma}\, d\dot{\bar{\epsilon}}} = \frac{d \log \bar{\sigma}}{d \log \dot{\bar{\epsilon}}} \qquad \text{(Eq 35)}$$

This ratio is generally known as the strain rate sensitivity parameter, *m*, of the workpiece material. Using this parameter, the dynamic constitutive equation given below can be developed:

$$\sigma = k\dot{\bar{\epsilon}}^m \qquad \text{(Eq 36)}$$

Equation 36 is termed a dynamic constitutive equation because it is a result of integrating along the dynamic (actual) path that an element of material takes according to the principle of least action, when it is instantaneously deformed at a particular strain rate. The strain rate sensitivity is assumed to be constant along this trajectory up to that strain rate and at the temperature and effective strain under consideration. The strain rate sensitivity parameter, calculated from continuous flow stress values measured at different constant strain rate tests, has generally been observed to be independent of temperature and strain rate for pure metals, but in engineering alloys it has been shown to vary with temperature and strain rate:

$$J = \frac{m}{m+1}\bar{\sigma}\dot{\bar{\epsilon}} \qquad \text{(Eq 37)}$$

$$G = \frac{1}{m+1}\bar{\sigma}\dot{\bar{\epsilon}} \qquad \text{(Eq 38)}$$

Equations 37 and 38 have been obtained by integrating $dJ = \dot{\bar{\epsilon}} d\bar{\sigma}$ and $dG = \bar{\sigma} d\dot{\bar{\epsilon}}$ (from Eq 35). The upper limit of $m = 1$ fixes the maximum value of J to be $0.5P$. By normalizing instantaneous J with this maximum value, an efficiency factor η can be defined as $\eta = J/J_{max} = 2m/(m + 1)$. This dimensionless parameter η becomes important for controlling the dissipated power J and for formulating a Liapunov function, because the system reaches a maximum value of η at the lowest energy state during stable conditions. The Liapunov function is a system quantity associated with Liapunov stability criteria and is regarded as a general and accepted method in engineering design (Ref 40). This function is an arbitrary term that relates changes in the total energy of a given system. The Liapunov criteria for stability require the system to lower its total energy continuously.

Therefore, the Liapunov function V_1 is formulated as shown below:

$$V_1 = \eta(\log \dot{\bar{\epsilon}}) \quad \textbf{(Eq 39)}$$

Because η itself forms the condition for stability, $\delta\eta/\delta$ ($\log \dot{\bar{\epsilon}}$) should be less than 0 in the stable region. This condition definitely ensures that the system is approaching the steady-state condition in which it experiences a minimum energy state and maximum η without fracture.

The next step is to identify a dimensionless control parameter in order to study the influence of temperature on material behavior and workability. For this purpose, the total power dissipated is represented in terms of the rate of entropy applied $\dot{S}_{app}$ and temperature T as shown below, and a methodology has been established to determine the relationship between the rate of entropy produced by the system $\dot{S}_{sys}$, and the rate of entropy applied to the system $\dot{S}_{app}$, using the following steps:

$$P = \bar{\sigma}\dot{\bar{\epsilon}} = \dot{S}_{app} T \quad \textbf{(Eq 40)}$$

and by definition:

$$\left.\frac{\delta P}{\delta T}\right|_{\dot{S}} = \dot{S}_{sys} \quad \textbf{(Eq 41)}$$

Furthermore:

$$\frac{\delta P}{\delta T} = \frac{P}{-T^2}\frac{\delta(\ln P)}{\delta(1/T)} = \frac{P}{T}\left[-\frac{1}{T}\frac{\delta(\ln P)}{\delta(1/T)}\right] \quad \textbf{(Eq 42)}$$

where:

$$\left.\frac{1}{T}\frac{\delta(\ln P)}{\delta(1/T)}\right|_{\dot{\epsilon}} = -\frac{1}{T}\frac{\delta(\ln\bar{\sigma})}{\delta(1/T)} \quad \textbf{(Eq 43)}$$

define a new coefficient s such that:

$$s = \left[-\frac{1}{T}\frac{\delta \ln\bar{\sigma}}{\delta(1/T)}\right] \quad \textbf{(Eq 44)}$$

The minus sign in Eq 42, 43, and 44 can be neglected and the value can be treated as a positive because flow stress decreases with respect to T.

It follows that the rate of entropy production by the system is given by:

$$\dot{S}_{sys} = \frac{P}{T} s \qquad \textbf{(Eq 45)}$$

where P/T can be thought of as the applied rate of entropy input $\dot{S}_{app}$.

According to the second law of thermodynamics, s should be greater than unity for stable material flow. This implies that the workpiece should store entropy at least as fast as the entropy production rate of working heat for stable flow. Therefore, $\delta s/\delta (\log \dot{\bar{\epsilon}})$ should also be less than 0 for stable flow if s is treated as a Liapunov function, that is:

$$V_2 = s (\log \dot{\bar{\varepsilon}}) \qquad \textbf{(Eq 46)}$$

These two conditions--$\delta \eta/\delta (\log \dot{\bar{\epsilon}}) < 0$ and $\delta s/\delta (\log \dot{\bar{\epsilon}}) < 0$--are important and are used for the development of processing maps.

The processing map provides the necessary conditions for working a material under stable processing conditions. It represents a conservative estimate of the conditions in terms of T and $\dot{\bar{\epsilon}}$. However, it is necessary to examine the effective stress rate path, which is determined by process modeling, to determine whether instability can be caused by such processes as grain-boundary cavitation or wedge cracking when the processing conditions are marginal. A value of $\sigma_m/\bar{\sigma}$ of $\frac{1}{3}$ corresponds to a pure tensile state of stress.

Under this condition, any deformation process leading to cavity nucleation would eventually produce ductile fracture. When $\sigma_m/\bar{\sigma}$ is equal to $-\frac{2}{3}$, large amounts of plastic flow are possible. This state of stress corresponds to conditions that can be associated with ideal streamlined flow during extrusion. Figure 7 shows the distribution of $\sigma_m/\bar{\sigma}$ during the uniaxial compression of a cylindrical rod, and Fig. 8 shows plane-strain compression. Both of these are under conditions of high friction.

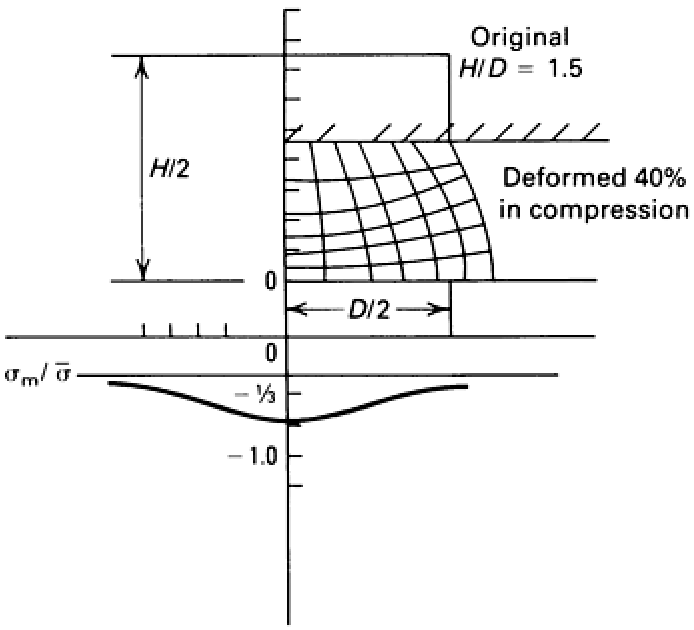

Fig. 7 Mesh distortion and distribution of $\sigma_m/\bar{\sigma}$ during uniaxial compression (from finite-element method analysis)

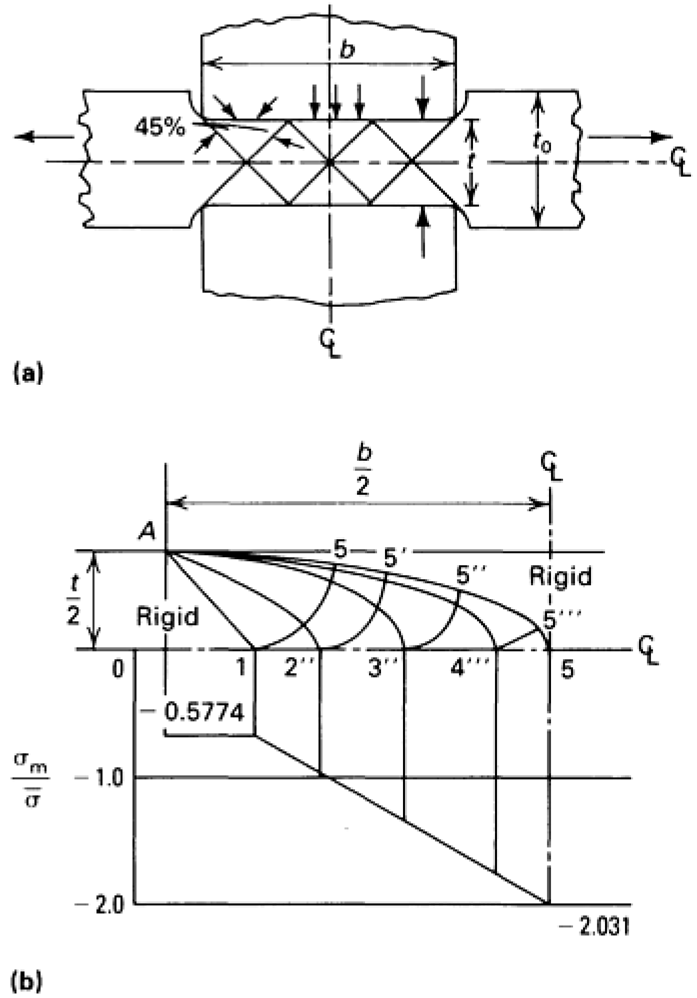

Fig. 8 Slip line field (a) and distribution of $\sigma_m/\bar{\sigma}$ (b) during plane-strain compression

Intrinsic Workability

Materials being formed (forged) undergo large, nonlinear, irreversible deformation that is made possible by linking together several atomic processes. This string of processes, in addition to providing the degree of freedom needed for producing large deformation, is also responsible for the evolution of structure. Each of these processes can be thought of as a channel for dispersing energy supplied by the forging process, and each can give rise to entropy production. Forging, as a rule, is a shape-changing process in which the deformation is generally inhomogeneous and transient over a large volume of the deforming continuum. Steady-state phenomena often represent a limiting condition that can be achieved only under unique combinations of temperature T and effective strain rate $\dot{\bar{\varepsilon}}$. Therefore, it is highly desirable to be able to define stable regions in terms of the kinematic variables T, $\bar{\varepsilon}$, and $\dot{\bar{\varepsilon}}$.

A solution to this problem would require identification of the limiting conditions. These limiting conditions would be loci of bifurcation points where two atomic mechanisms are operating simultaneously to produce a maximum in the energy dispersal rate at a unique combination of temperature T and effective strain rate $\dot{\bar{\varepsilon}}$. Under these unique conditions, the deformation process would be steady state. One branch of the deformation process would be stable, and the other would be unstable. Processes such as grain-boundary cavitation, wedge cracking, and cleavage are considered to cause the deforming continuum to become unstable, because the free surfaces formed increase the free energy of the system rather than decrease it. Therefore, workability is an intrinsic characteristic of the material; the ability of the material to dissipate power at any state of stress by favorable metallurgical mechanisms generates entropy at a faster rate than it is applied and maintains the total energy of the system at the lowest level possible.

Determination of Processing Maps

Using flow stress values calculated at different temperatures and effective strain rates, the parameters η and s are determined as functions of temperature and effective strain rate. From these values, $\delta\eta/\delta$ (log $\dot{\bar{\epsilon}}$) and $\delta s/\delta$ (log $\dot{\bar{\epsilon}}$) values are calculated, and all the values less than or equal to 0 are grouped to determine the stable region. The stable region and the contours of η are presented as a processing map of effective strain rate versus temperature, as shown in Fig. 9.

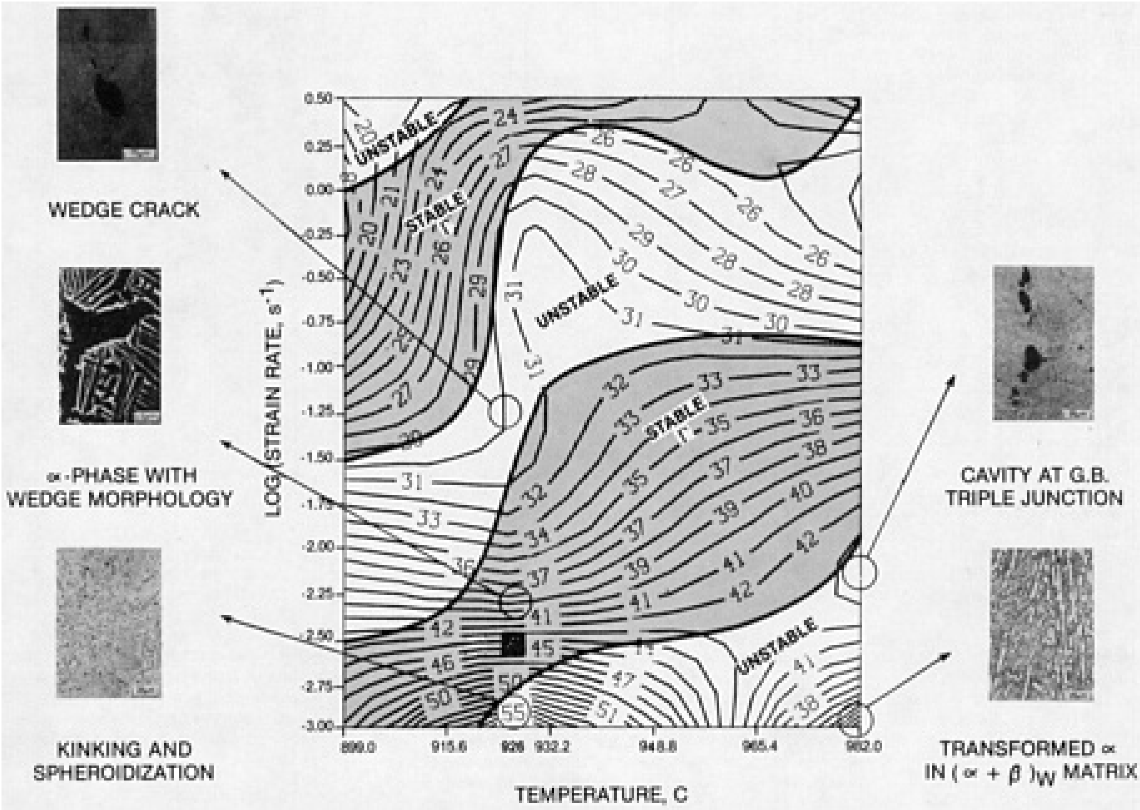

Fig. 9 Processing map for βTi-6Al-2Sn-4Zr-2Mo alloy with stable (Γ) regions and unstable regions identified

Selection of Processing Conditions

According to the processing map developed for βTi-6Al-2Sn-4Zr-2Mo (Fig. 9) using the above procedure, two Γ(stable) regions can be obtained in the map. There is one Γregion in the high strain rate regime in which the efficiency is of the order of 26% (upper left portion of Fig. 9). If hammers are to be used for forging, this processing region can be selected. However, if a press is to be used, then it is highly recommended to select processing conditions in the Γregion in the low strain rate regime and high-efficiency regime (lower-central portion of Fig. 9). Parts produced by either hammer forging or press forging have acceptable quality. This confirms the prediction that two stable regions in the Ti-6Al-2Sn-4Zr-2Mo processing map are valid.

The next obvious question is how to determine the optimum processing conditions from the processing map in order to obtain maximum intrinsic workability of the workpiece material. It is possible to answer this question to a certain extent by using the efficiency values, although it is not possible to characterize the metallurgical mechanisms based on efficiency alone. In the Γregion, where higher efficiency is observed, it is always possible to obtain higher workability because the rate of dissipation by the favorable stable mechanism is higher. This conclusion requires thorough experimental and metallurgical studies that are beyond the scope of this article. However, a few microstructures are included in the Ti-6Al-2Sn-4Zr-2Mo processing map in which peaks in the efficiency surface are observed. Peaks outside the stable regions clearly show defects in the microstructure, while peaks inside the stable Γregions show an acceptable and stable microstructure.

Another interesting point concerns the microstructure observed at 926 °C (1700 °F) and a strain rate of 5.6×10^{-3} s^{-1}. Although observed in the stable region, this microstructure (center micrograph on the left side of Fig. 9) is not acceptable, because the α-phase formation at the grain-boundary triple junction is a potential initiation site for low-cycle fatigue cracking. Therefore, additional microstructural studies are required for selecting optimum processing conditions for the given application. Based on a similar argument, a temperature in the range of 899 to 920 °C (1650 to 1690 °F) and a strain-rate of the order of 1 to 10 s^{-1} are recommended if the use of hammer-forging equipment is preferred.

It is also of interest to include observations made by some forging companies. These companies have tried to forge billets at temperatures beyond 926 °C (1700 °F) using a low strain rate of 10^{-3} s^{-1}. These forgings have poor properties when compared to forgings produced below 926 °C (1700 °F) at the same strain rate. Again, this observation confirms the prediction of unfavorable material flow under the unstable conditions of low strain rates at temperatures greater than 926 °C (1700 °F). Wedge cracks were observed in these regions.

Therefore, the successful application of Liapunov stability theory for determining optimum processing conditions for Ti-6Al-2Sn-4Zr-2Mo demonstrates that this is a viable engineering approach for defining safe regions in processing space. This information can then be incorporated into the finite-element code used for the simulation of metal-forming operations.

Analytical Process Modeling of Forging Operations

Several methods are available for the analytical modeling of the forging process. Generally, they fall into the following categories:

- The slab method, which restricts the change of stress to only one direction
- The uniform deformation energy method, which neglects redundant work involved in internal shearing due to nonuniform deformation
- The slip-line field solution, which is limited to rigid-plastic materials under plane-strain conditions
- The bounding methods, which can provide fairly good estimates of upper and lower limits of the deformation force but cannot provide details of local stress and strain distributions
- The finite-element method, which provides the information required for die design and process control

All of the above approaches, except the finite-element method, are capable of providing approximate solutions to processing problems, but are subject to some limitations. Therefore, the following discussion will consider the most commonly used approximate methods separately from the finite-element method.

Approximate and Closed Form Solutions

In general, the boundary conditions in metal-forming operations are too complicated to be accounted for by analytical solutions to the plasticity problem. The need to obtain at least approximate solutions has been satisfied by simplifying assumptions, but each of the analytical approaches has its limitations. The most commonly used approximate methods will be briefly discussed without attempting a rigorous description of the equations that are solved, because this information is available in several other sources (Ref 41, 42, 43, 44, 45, 46, 47). These methods are described in detail with examples in the above references and are presented in increasing order of complexity.

The Sachs (Slab) Method. In this approach, the deformation is assumed to be homogeneous, and the force equilibrium equations are set up and solved using an appropriate yield criterion. The major deficiencies of this approach are:

- Redundant work is not accounted for
- Stress and strain gradients are accounted for in only one direction and are assumed to be uniform in the perpendicular direction

The slab method is a quick way of obtaining approximate load and strain estimates in axisymmetric and plane-strain problems and is therefore widely used.

The slip-line field approach was developed for plane-strain problems. It assumes that the material is rigid and ideally plastic (that is, the material does not strain harden). The theory is based on the fact that any state of stress in plane strain can be represented as the sum of a hydrostatic stress and a pure shear stress. Given the force and velocity boundary conditions, this slip-line field is constructed. The main advantage of this method over the slab method is that it can provide local stress calculations even when the deformation is not homogeneous. The major limitations of the slip-line field approach are:

- It is usable only for plane-strain problems
- It assumes rigid and ideally plastic materials
- The method is tedious, and solutions are difficult to verify

The upper bound method is based on the limit theorem stating that the power dissipated by the boundary forces at their prescribed velocities is always less than or equal to the power dissipated by the same forces under any other kinematically acceptable velocity field. A kinematically acceptable velocity field must satisfy the velocity boundary conditions and material incompressibility. This method allows kinematically admissible velocity fields to be set up as a function of an unknown parameter. Power dissipation is then minimized with respect to the unknown parameter to yield a reasonable estimate of load.

The main disadvantage of this method is that the choice of velocity field is rather arbitrary, and the poorer the selection, the more the estimated load will exceed the true load. Another limitation is that no local stress field is compared.

The lower bound method is not of great practical significance, because forming loads are underestimated. However, it does provide an indication of how conservative the upper bound solution is if the lower bound solution is known.

The lower bound approach is based on the limit theorem stating that the power dissipation of the actual surface forces at their prescribed velocities is always greater than the power dissipation of the surface tractions corresponding to any other statically admissible stress field. A statically admissible stress field must satisfy force equilibrium and not violate the yield criterion.

Finite-Element Methods

Because of the rapid advancement of high-speed digital computer technology, numerical methods of analysis have been developed. These include the finite-element method (FEM) and the finite-difference method (FDM). Due to the complexity of material flow during metal forming, the finite-element method is the most suitable for analyzing such problems. Finite-element methods, as applied to metal-forming analysis, can be classified into either elastic-plastic or rigid-viscoplastic methods, depending on the assumptions made with regard to the material flow behavior.

The elastic-plastic method assumes that the material deformation includes a small, recoverable elastic part and a much larger, nonrecoverable plastic part. It can give details regarding deformation loads, stresses and strains, and residual stresses. This method has been applied to a large variety of problems, including upsetting (Ref 48), indentation (Ref 49), extrusion (Ref 50), and expansion of a hole in a plate (Ref 51). However, because of the large change in the material flow behavior between elastic and plastic deformation and the need to check the status of each element, the deformation steps must be small, and this makes the method uneconomical.

The rigid-viscoplastic method assumes that the deformation stresses are primarily dependent on deformation (strain) rates. Several programs based on the variational approach have been written by various researchers and have been applied to the same range of problems as the elastic-plastic finite-element method (Ref 52). Although predictions regarding residual stresses cannot be made with the rigid-viscoplastic finite-element method, the larger steps that can be used in modeling metal-forming procedures make the method very economical, especially for modeling hot deformation.

Analysis of Large Plastic Incremental Deformation (ALPID)

The computer program ALPID, a rigid-viscoplastic FEM program that uses the approach of Kobayashi *et al.,* was developed at Battelle Columbus Laboratories under the Air Force Processing Science Program (Ref 53). Important contributions (Ref 53) to the FEM formulation included the incorporation of convenient features, such as capabilities for handling arbitrary die geometries and remeshing. Details of this FEM formulation and some of its applications to practical problems can be found in Ref 53. The features of ALPID are discussed below.

Finite-Element Problem Formulation in ALPID. The Cartesian coordinate is used to derive the minimum principle. Generalization of this formulation to other coordinate systems can be made without difficulty. With regard to Eq 47, 48, 49, 50, 51, 52, 53, 54, and 55, a body of volume, *V*, is considered with the traction, *F*, prescribed on a part of the surface, S_F, and the velocity, *V*, prescribed on the remainder of the surface, S_U. The body is composed of a rigid-plastic material that obeys the von Mises yield criterion and its associated flow rule. Body forces are assumed to be absent. The actual stress, σ_{ij}, and velocity field, *v*, satisfy the following relations.

Equilibrium conditions, neglecting body forces, are:

$$\sigma_{ij,j} = 0 \qquad \textbf{(Eq 47)}$$

where σ_{ij} is the stress tensor and $_{,j}$ denotes partial differentiation with respect to *j*.

The compatibility condition is given by:

$$\dot{\epsilon}_{ij} = (V_{i,j} + V_{j,i}) \qquad \textbf{(Eq 48)}$$

where $\dot{\epsilon}_{ij}$ and V_i are the strain rate and velocity, respectively.

The constitutive relations are given in Eq 49, 50, and 51:

$$\sigma'_{ij} = \frac{2}{3}\left[\frac{\bar{\sigma}}{\dot{\bar{\epsilon}}}\dot{\epsilon}_{ij}\right] \qquad \textbf{(Eq 49)}$$

where σ'_{ij} is the deviatoric component of the stress tensor:

$$\bar{\sigma} = \sqrt{\frac{3}{2}[\sigma'_{ij}\ \sigma'_{ij}]} \qquad \textbf{(Eq 50)}$$

and

$$\dot{\bar{\epsilon}} = \sqrt{\frac{2}{3}[\dot{\epsilon}_{ij}\ \dot{\epsilon}_{ij}]} \qquad \textbf{(Eq 51)}$$

Equations 49, 50, and 51 are valid for fully dense ingot metallurgy alloys. For powder metallurgy alloys, Eq 49, 50, and 51 must be modified to include hydrostatic stress, as shown in a later section in this article. The flow stress is generally a function of total strain, strain rate, temperature, relative density, and microstructure.

The boundary conditions are given by:

$$\sigma_{ij}\, n_i = F_j \text{ on } S_F \qquad \textbf{(Eq 52)}$$

and

$$v_i = V_i \text{ on } S_U \qquad \textbf{(Eq 53)}$$

and |*fs*| is the frictional stress with the proper sign, where n_i is the unit vector normal to the surface.

Equations 51, 52, and 53 can be put into the variational principle as:

$$\delta\Phi = \sigma\left[\int E(\dot{\epsilon}^*)\, dV + \int \frac{1}{2} K(\dot{\epsilon}^*)^2\, dV - \int (f_s dv_s)\, ds - \{F_j V_j^*\, ds\}\right] = 0 \qquad \text{(Eq 54)}$$

where the work function $E(\dot{\epsilon})$ can be expressed as:

$$E(\dot{\epsilon}) = \int_0^{\dot{\epsilon}} \bar{\sigma}\, d\dot{\bar{\epsilon}} \qquad \text{(Eq 55)}$$

In Eq 54, K is a large positive constant that penalizes the dilational strain, and * denotes the restriction of the velocity fields to the trial space. The standard procedure of discretionization of this function can be found in Ref 54.

Computational Scheme of ALPID. The processing phase of ALPID has two major stages. The first is the guess generation stage, which generates an initial solution (guess) assuming a linear material relationship. The second is the solution stage for the actual nonlinear constitutive behavior of the material. These stages will be briefly discussed; Fig. 10 shows a simplified flow chart that outlines the operation of ALPID.

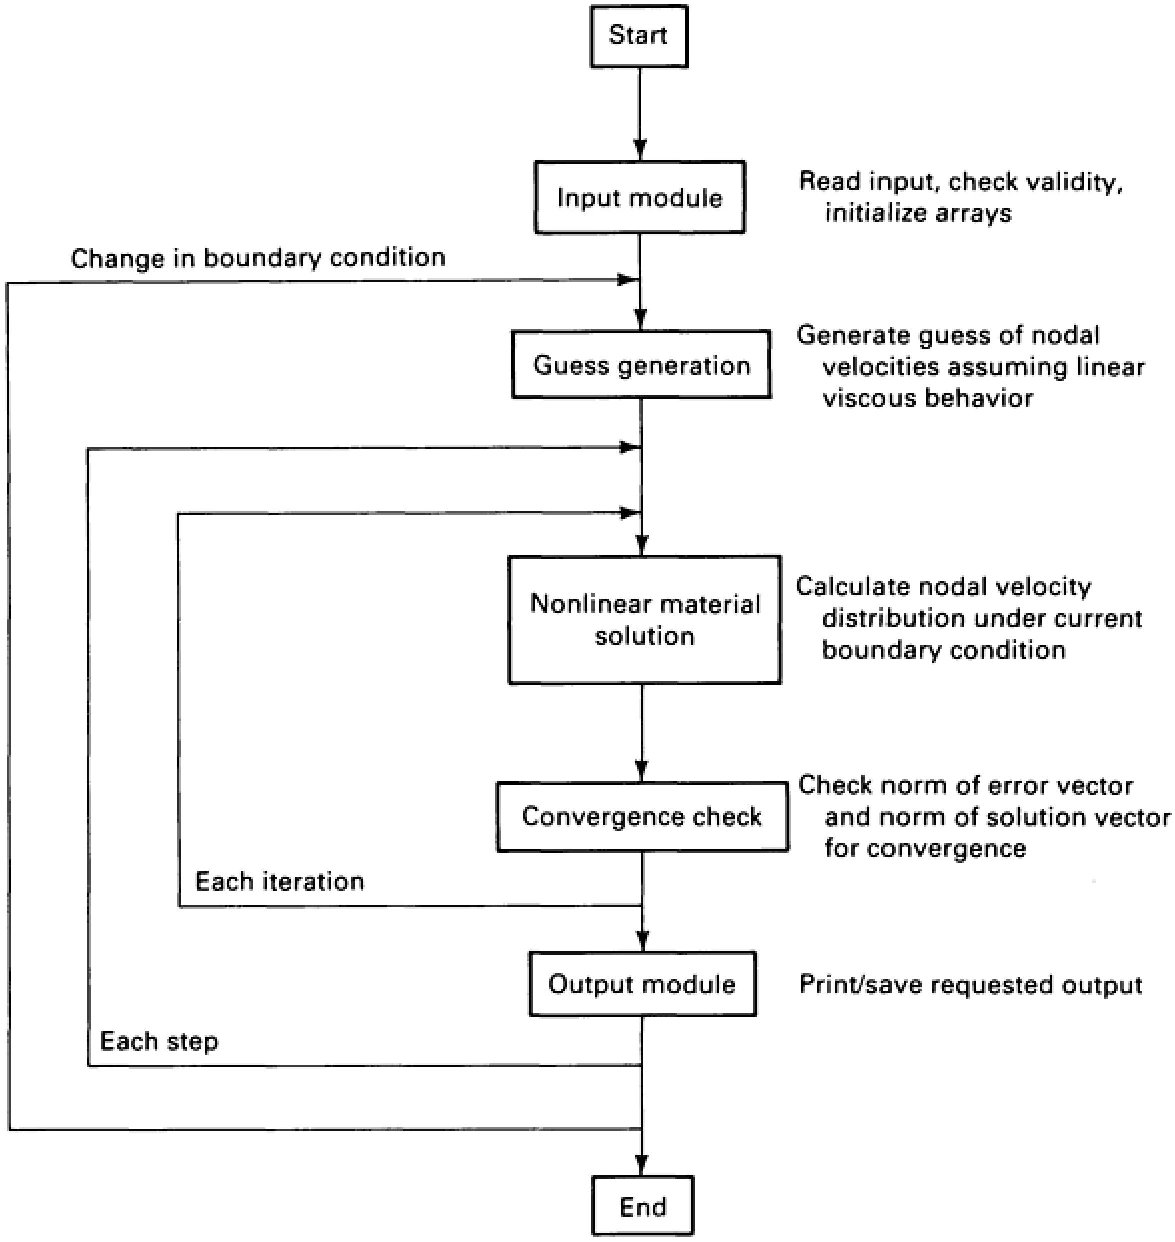

Fig. 10 Simplified flow chart showing steps in the operation of ALPID

Guess generation provides a good guess of the velocities at the nodal points in the finite-element mesh. Because ALPID uses the Newton-Raphson method to solve the nonlinear system of equations, it is important to have a good initial guess. This initial guess is necessary when previous solutions are not available or not applicable. A guess of the velocity distribution is also required each time the boundary conditions change. Boundary conditions change whenever a node comes into contact with a die or whenever a node in contact with a die becomes a free node. The steps in guess generation are:

- Generation of the element stiffness matrix assuming linear behavior of the materials
- Application of displacement boundary conditions
- Addition of element stiffness matrices to the global stiffness matrix
- Application of force boundary condition
- Solution of resulting linear equations

Solution Stage for Nonlinear Materials. The guesses of velocities generated in the previous stage of execution are used to estimate the material properties and to identify rigid and viscoplastic elements. This information is used to generate the element stiffness matrix. The steps involved in the solution for nonlinear materials are:

- Obtain yield stress of the elements to identify the rigid element
- Generate element stiffness matrix using

    1. linear behavior for rigid elements and
    2. actual constitutive behavior for viscoplastic elements

- Apply shear friction boundary condition, if applicable
- Add to the global stiffness matrix
- Apply Coulomb friction boundary condition, if applicable
- Determine iteration strategy and step length
- Solve a system of linear equations
- Check for convergence

This process is repeated until convergence is obtained. Execution stops if the solution does not converge in a specified number of attempts. When convergence is obtained, the nodal coordinates are updated, and all of the post calculations are completed. If there is no change in the boundary conditions, the solution from each step is used as the initial guess for the next step.

The stiffness matrix generation involves the following steps:

- Obtain the shape function and shape function derivatives at the Gauss integration points of an element
- Change from natural to global coordinates to obtain the [B] matrix
- Obtain the strain rate hardening parameter
- Calculate $[B]^T$ [D] [B] matrix at each integration point and multiply by weighting factor
- Repeat for each integration point to obtain the stiffness matrix of each element
- Impose volume constancy constraint on stiffness matrix

Versions of ALPID. Many versions of ALPID are available. ALPID 1.0 was validated for solving two-dimensional (2-D) plane-strain and axisymmetric problems related to metal forming under isothermal processing conditions. In ALPID 2.0, the rigid-viscoplastic formulation is coupled with a heat-transfer module to solve these problems under hot-working conditions (Ref 55). A new yield function was developed to enable the analysis of compressible materials (Ref 6). Based on these criteria and on plasticity theory developed for porous materials, ALPID 1.4 was developed to solve 2-D plane-strain and axisymmetric problems related to P/M metal-forming operations under isothermal processing conditions (Ref 56).

ALPID-3D was also developed and validated to solve problems involving complex material flow in three directions (Ref 57). These finite-element programs are being used for simulating such metal-forming operations as forging, extrusion, and rolling and for predicting lap or folding formation in rib-web forging, center burst formation in extrusion, and the occurrence of plastic instability (such as adiabatic shearing) in rolling. Some industries are using these tools for press selection, for optimizing process and die design, and for ensuring die filling in 2-D axisymmetric and plane-strain problems.

Attempts at developing process control algorithms have been successful (Ref 58). Optimal design procedures have been introduced as nonholonomic constraints for the development of control algorithms to ensure that, during spike forging, the control elements keep the deforming material within the allowable temperature and strain rate range as specified by the dynamic material modeling approach. Therefore, the technical feasibility of using analytical techniques to solve process design and control problems in metal forging has been established.

ALPID Results: Field Variables and Flow Lines. The available results of finite-element analysis include the following field variables:

- Stress distribution
- Strain distribution
- Strain rate distribution
- Velocity distribution
- Displacement as represented by FEM mesh distortion

These results are normally too tedious to evaluate as printed numbers; graphical representation by way of contour plots, velocity vector plots, and mesh distortion plots are usually used. The resolution (accuracy) with which the field variables are computed are a direct function of the FEM mesh density. In addition to the above field variables, the load requirement as a function of stroke is also computed, and a graphical dis la of results is available.

The mesh distortion results from ALPID can be used to obtain some estimate of the expected orientation of flow lines (Fig. 11), but are not always adequate for two reasons. First, the grid distortion plots represent the FEM mesh distortion, not the actual flow lines. The original FEM mesh may have arbitrary topology, and this can result in distortion plots that have no relationship to flow lines. This technique is adequate only when the initial FEM mesh is uniform and suitably oriented. Second, even when the original FEM mesh has suitable orientation and topology to represent flow lines, if remeshing is performed in the course of simulation, all flow line orientation developed prior to remeshing is lost.

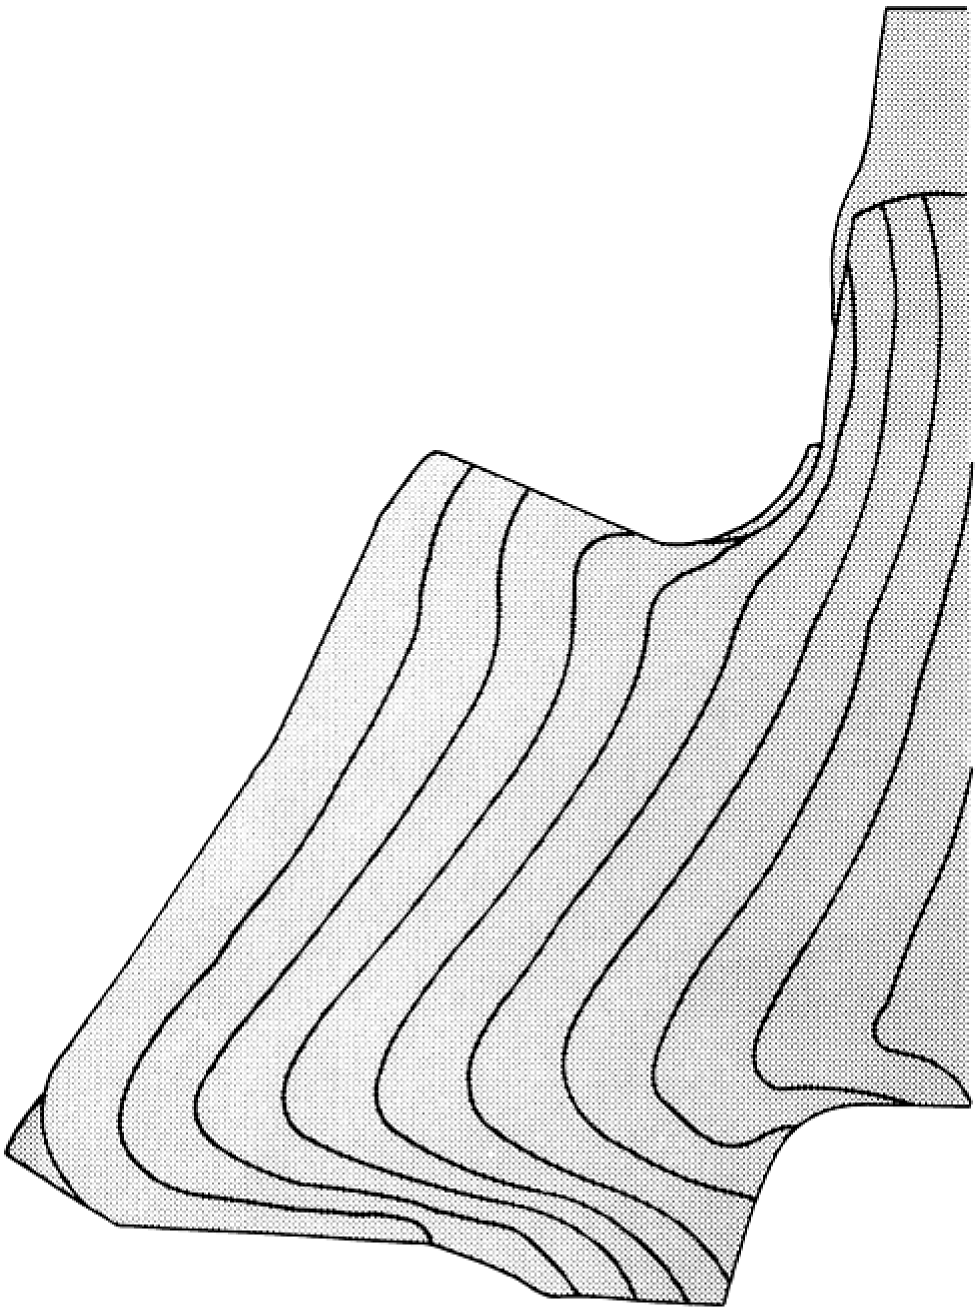

Fig. 11 Typical flow lines in a forging

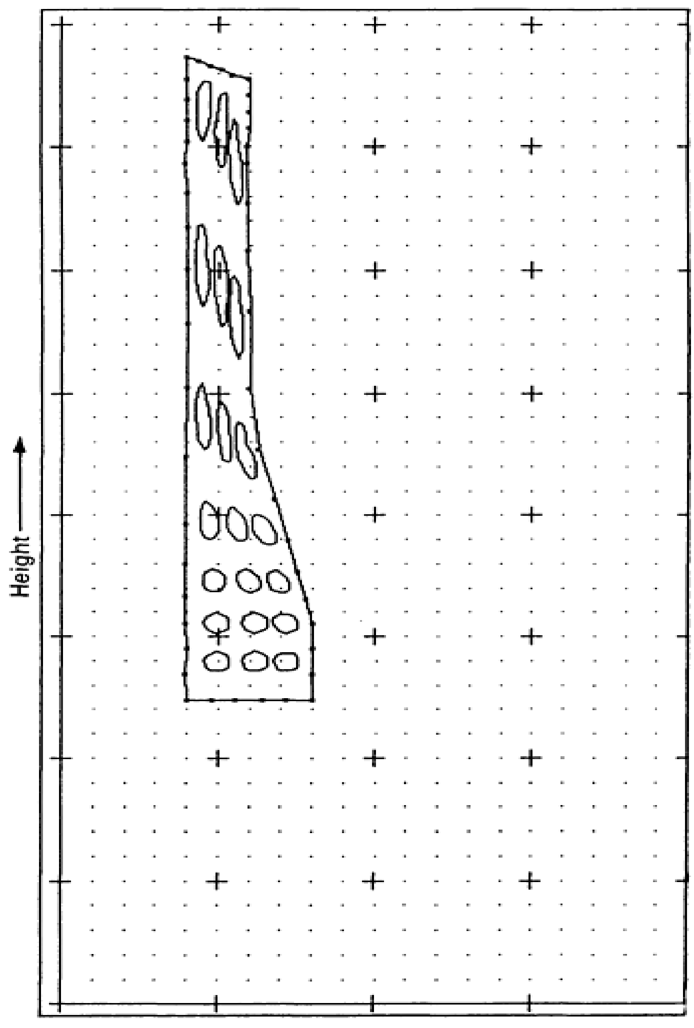
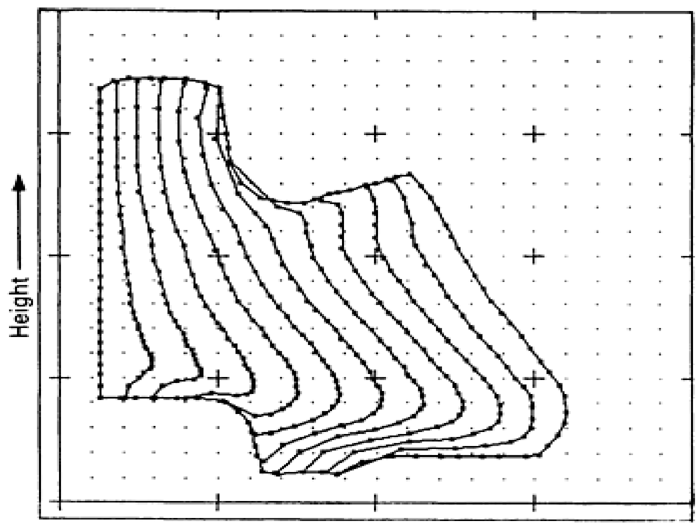
An ALPID postprocessing feature has recently been added for representing flow lines typically observed in worked metals (Ref 59). It is especially significant that the ability to develop the simulated flow lines can bridge remeshing operations. The addition of this feature offers two options to account for the cases typically encountered, as follows.

No Preexisting Flow Lines in Billet. When the ALPID simulation is for a primary working operation, no prior flow lines exist. The technique offered here is to place circles on the simulation cross section and then provide the ability to follow the distortion of these circles into flow lines. An example of this technique is given in Fig. 12(a).



(a)



(b)

Fig. 12 ALPID simulations of metal flow after forming. (a) Flow lines in extrusion of a cast billet; distance between consecutive dots is 3.18 mm (0.125 in.). (b) Flow lines in a disk forging; distance between consecutive dots is 19.7 mm (0.775 in.).

Preexisting Flow Lines in Billet. When the ALPID simulation is for an operation using an already worked billet or a forged preform, prior flow lines exist. In this case, the technique offered is to provide flow lines as input to the simulation and then to follow these flow lines through the course of the simulation. An example of this technique is given in Fig. 12(b).

Example Applications of ALPID

Spike Forging. In spike forging, a cylindrical billet is forged in an impression die containing a central cavity (Ref 60). The deformation characteristics of spike forging are such that the portion of the material near the outside diameter flows radially, while the portion near the center of the top of the surface is extruded, forming a spike.

In this application, the primary objective was to determine the conditions that would allow complete die filling in spike forging. For this purpose, the constitutive equations for the $\alpha+\beta$ Ti-6Al-2Sn-4Zr-2Mo microstructure at 954 °C (1750 °F), which exhibits strain rate hardening, were selected for the analysis. The die shape and the specimen with the selected mesh pattern are illustrated in Fig. 13.

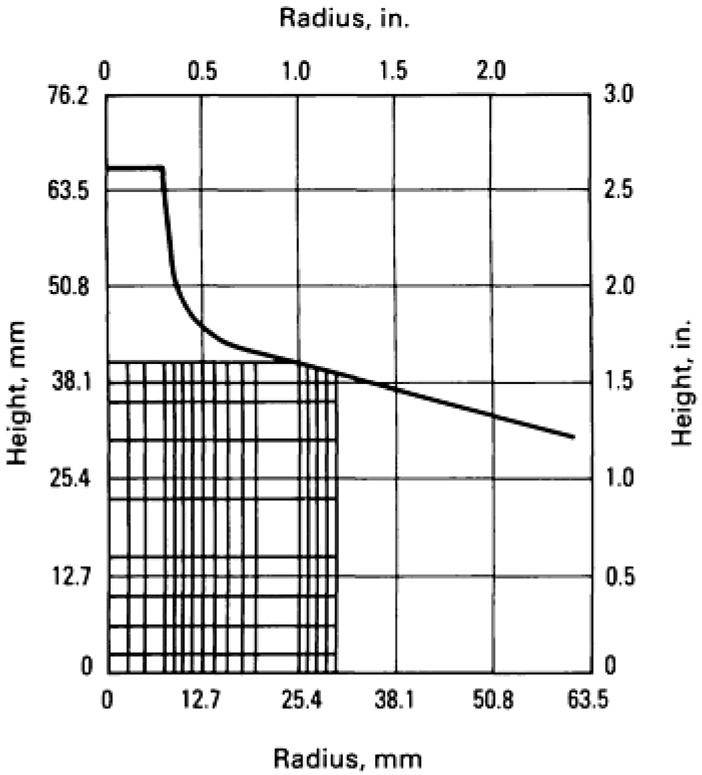

Fig. 13 Die shape and specimen showing mesh pattern selected for ALPID simulation of spike forging. See also Fig. 14.

Simulations were performed for frictional conditions of friction parameter *m*' = 0 to 0.8 in steps of 0.2. However, the results are presented for only two frictional conditions, namely, *m*' = 0.2 and 0.6. Figures 14(a) and 14(b) show the flow pattern obtained for various steps in the operation at these two frictional conditions. Complete die filling was obtained without remeshing when a frictional condition of *m*' = 0.6 was used. The total average deformation undergone by the billet during die filling was 67%. The lateral flow and the radial flow were found to be sensitive to frictional conditions--the higher the friction, the higher the spike height for the amount of ram displacement.

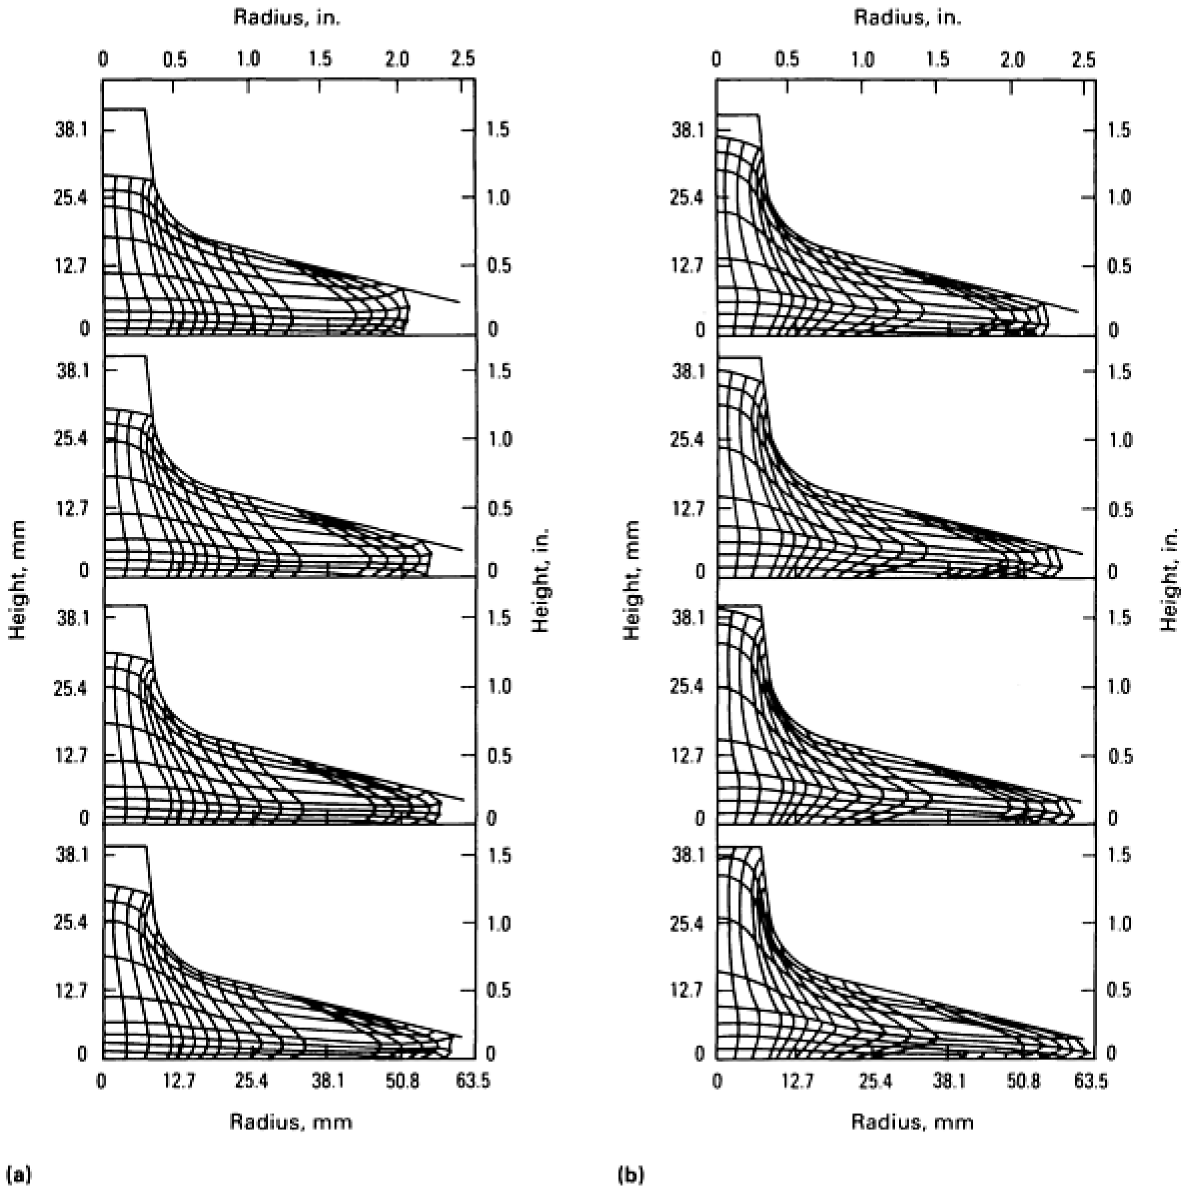

Fig. 14 Simulations of flow patterns during spike forging at reductions of (top to bottom) 64, 65, 66, and 67% and two different friction conditions. (a) Friction parameter, *m*' = 0.2. (b) *m*' = 0.6

The simulation of a rib-web forging of titanium alloy is shown in Fig. 15 and was made to investigate the possibility of defect generation due to improper die design (Ref 61). These isothermal predictions substantiated the intuition and experience of titanium forging designers. The defect that would have formed in the actual forging was a lap. Other simulations for the nonisothermal forging of the same titanium alloy showed that temperature gradients worsened the problem, indicating that this die design was very poor.

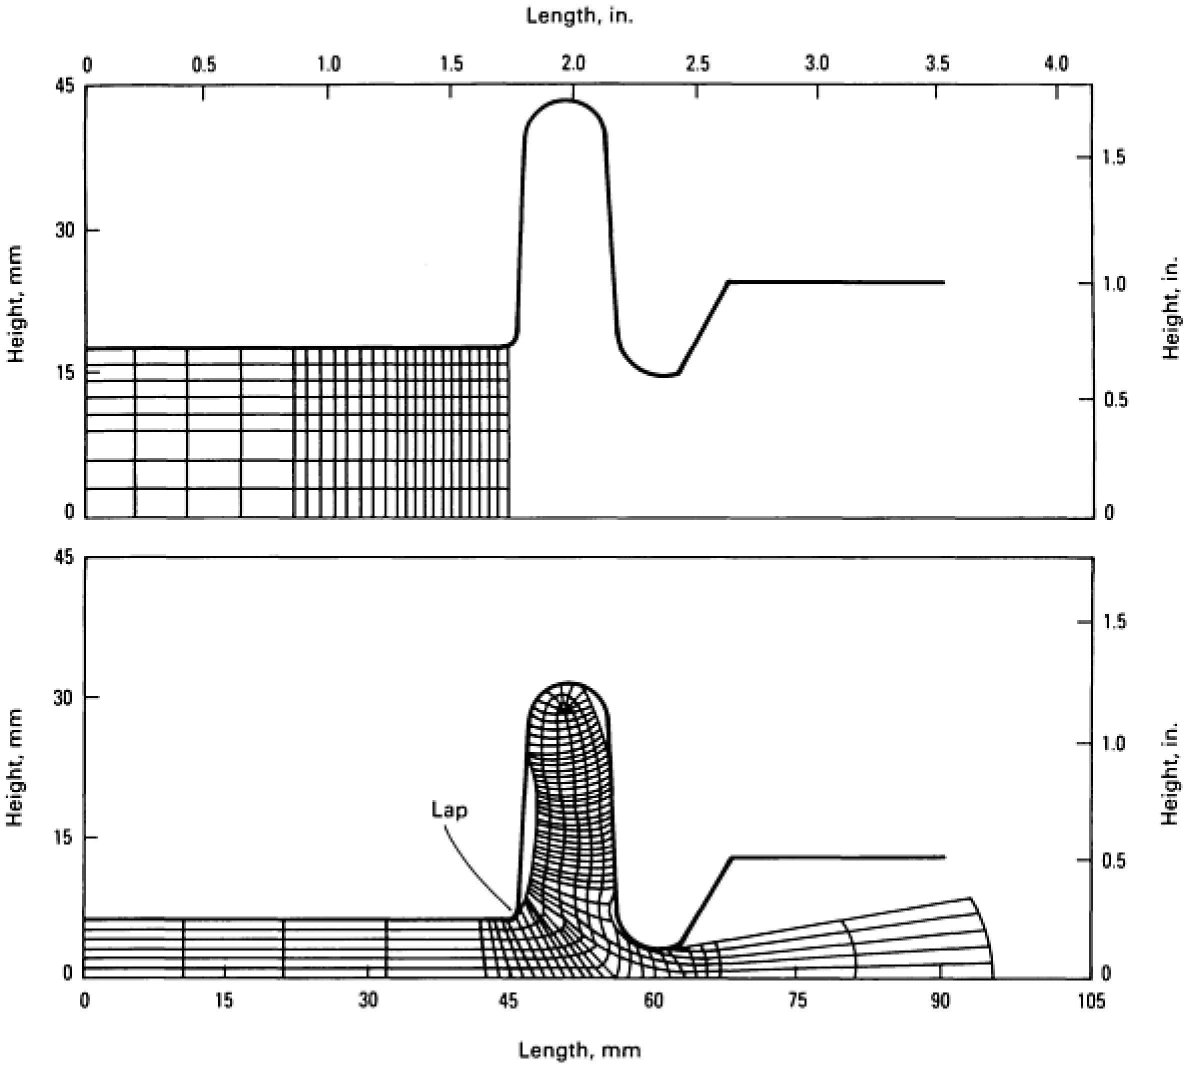

Fig. 15 ALPID simulation of metal flow during the forging of a rib-web titanium part. In this case, ALPID correctly predicted formation of a forging defect (lap).

For a truck-gear forging, the nature of the grid distortion in the final die position is shown in Fig. 16 (Ref 61, 62). The significance of this simulation is that various flash geometries can be simulated for optimizing material flow and obtaining complete filling. This is an axisymmetric forging of a steel alloy; it should be noted that the flash at the part centerline (left-hand side in Fig. 16) has buckled, as observed in the actual forging, because of the material from opposite sides meeting along the central axis.

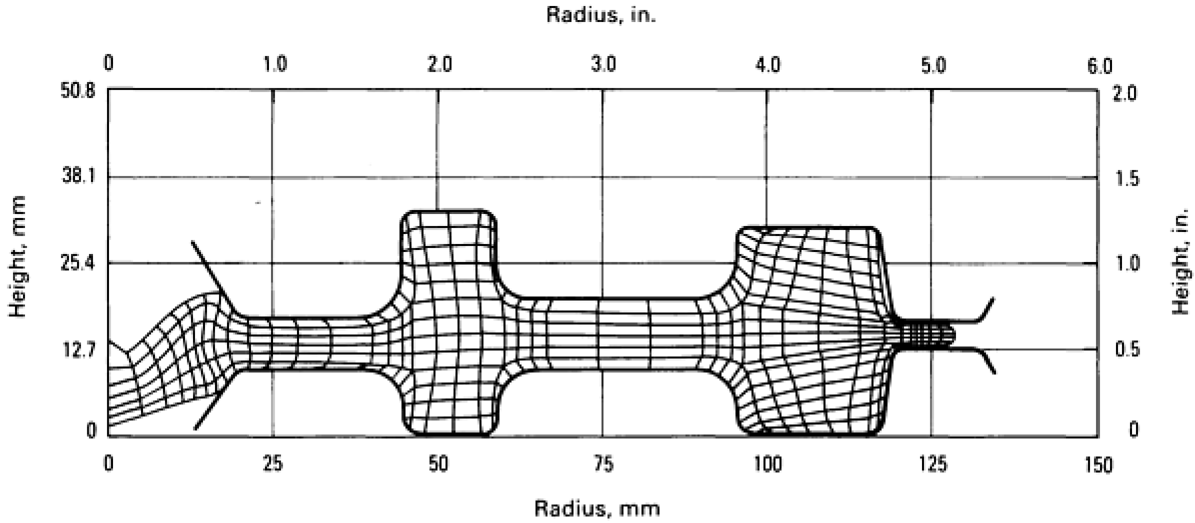

Fig. 16 ALPID simulation of final die position in the forging of a truck gear showing bending of flash that occurs at the center of the part (left)

Three-Dimensional Wedge Deformation by Forging. Metal flow during a three-dimensional (3-D) deformation process is illustrated in Fig. 17 (Ref 61, 62). The 3-D shape changes that occur during forging were accurately predicted by the ALPID model. Careful examination of the deformation steps reveals that the specimen bulges at the anticipated locations and rotates at the thin side of the tapered wedge. This simulation represents one of the first attempts at modeling 3-D metal flow during open-die design.

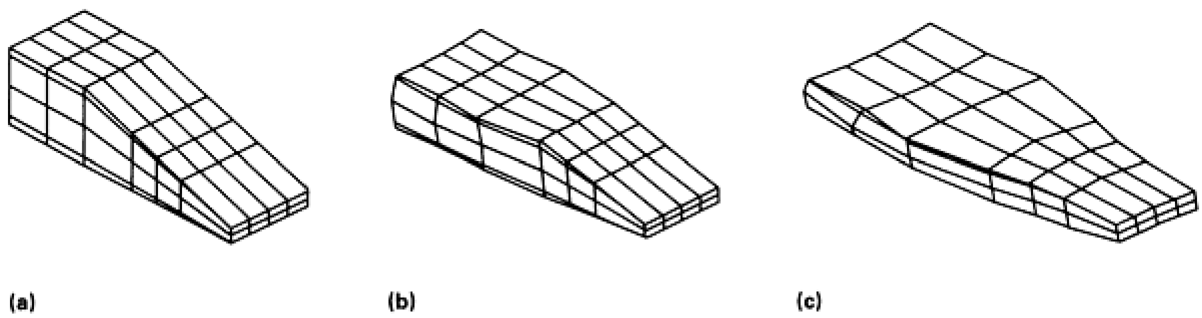

Fig. 17 Wedge formation simulated by 3-D finite-element modeling. Friction parameter *m*' = 0.4. (a) 0% reduction. (b) 30% reduction. (c) 60% reduction.

Powder Consolidation by Double-end Pressing. Double-end pressing (Fig. 18a) is generally used for the consolidation of P/M forging preforms. To obtain quality preforms, density distributions along the length and across the cross section must be controlled during consolidation. For this reason, ALPID 1.4 was utilized to predict density distribution in this application (Fig. 18b).

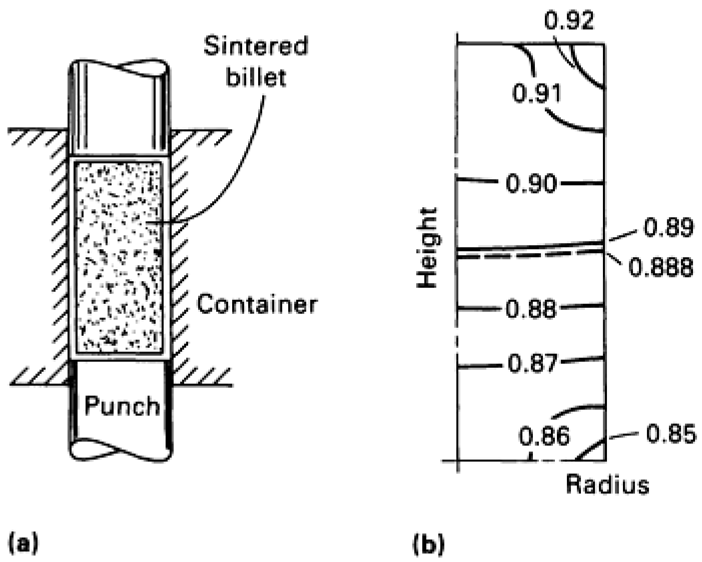

Fig. 18 Schematic showing double-end pressing process for the forging of P/M materials (a) and ALPID-predicted relative density distribution in the forged billet (b). Initial relative density was 0.8; agreement with actual density measurement (dashed line) was excellent.

Only one-fourth of the cylinder is shown in Fig. 18(b) because of the geometrical symmetry of the process. The excellent agreement between predicted and observed results is worth noting. Figure 18(b) illustrates the density distribution predicted by ALPID (solid contour lines), along with an experimental validation of the predictions (dashed contour lines).

Optimization of Ti-6Al-2Sn-4Zr-2Mo Disk-Forming Process. The approach of optimizing deformation processes by using material-stability-preserving maps is demonstrated in the design of a Ti-6Al-2Sn-4Zr-2Mo disk-forging process (Ref 58). The closed-die isothermal forging of this disk was previously analyzed using ALPID, with emphasis on the prediction of metal flow near the flash (Ref 63). Because of symmetry, it is sufficient to analyze only one quarter of the cross section of the forging. The predicted nodal-point velocity plots for 48, 68, and 72.1% reductions in height are shown in Fig. 19. The plots clearly show the transition in metal flow from primarily upsetting deformation to die cavity filling to the final stage of forming flash.

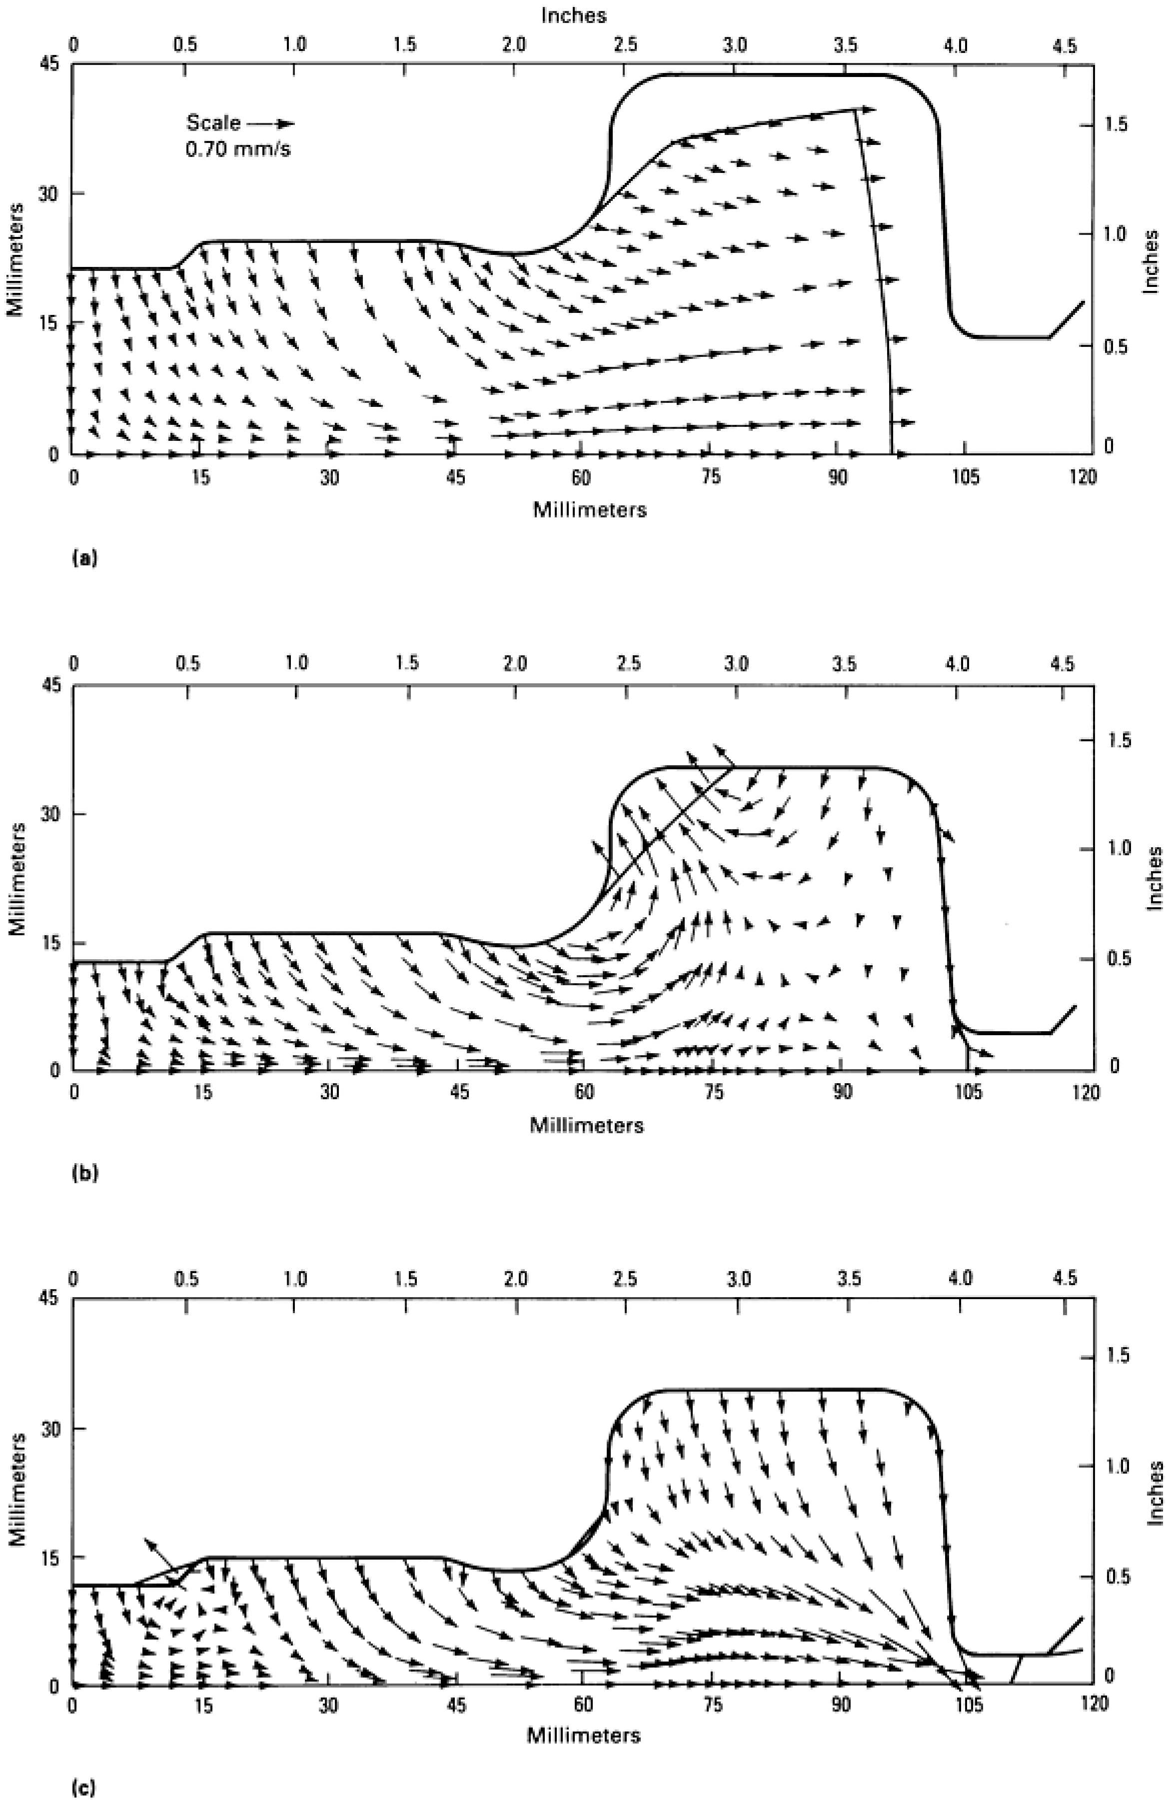

Fig. 19 Nodal-point velocity plots of disk-forging simulation with constant die velocity at 48% (a), 68% (b),

and 72.1 % (c) reductions in height. See also Fig. 20, 21, and 22.

In the current study, the process design goal was to fill the die cavity completely and to avoid the possibility of creating defects that are governed by the state of stress in the forging process. The state of stress is described here as the stress rate path, which is defined as the ratio of the mean hydrostatic stress to the effective stress $\overline{\sigma}$. This is a fundamental quantity in plasticity theory because a material changes shape according to the applied effective stress rate path. When this ratio is positive, a tensile state of stress exists; when it is negative, a compressive state of stress exists. The magnitude of the ratio describes the approximate state of stress. For example, when $\sigma_m / \overline{\sigma} = +\frac{1}{3}$, the stress state is uniaxial tension; when $\sigma_m / \overline{\sigma} = -\frac{2}{3}$, the deformation state of ideal axisymmetric extrusion exists.

The distributions of the stress rate path ratio for the disk simulation at 48, 68, and 72.1% reductions in height are shown in Fig. 20. At 48% reduction (Fig. 20a), the bore region of the disk has an approximate value of -1.0, and the rim region has positive values that reach a maximum of +0.37.

The transition from compression to tension (neutral surface) is controlled by the die radii. As the workpiece touches the outside die wall and continues to fill the die cavity, the tensile state of stress reduces to a small region that is filling the inside die corner. This situation presents a potential problem, namely, that of producing defects such as cavities or cracks in the finished forging. Therefore, enhanced metal flow and good intrinsic workability of the workpiece are needed in this location at the final stages of die filling in order to relax the stresses and thus avoid the possibility of defect formation.

Based on the stability map for Ti-6Al-2Sn-4Zr-2Mo with an initial β (Widmanstätten) microstructure, a strain rate of 3×10^{-3} s^{-1} and a temperature of 926 °C (1700 °F) were determined as the optimum conditions for this material and application. In optimizing the ALPID simulation of the isothermal disk-forging process, the die velocity was changed to maintain an effective strain rate of 3×10^{-3} s^{-1} with a 0.1% tolerance limit in Element No. 47, which is positioned near the inside die corner (Fig. 21) where final die filling is critical.

The optimal die velocity as a function of stroke is shown in Fig. 22, and a total deformation time of 413.4 s was required for this type of process control. The die velocity gradually increases from 0.04 mm/s to a speed of 0.20 mm/s at a stroke of 17 mm; the die velocity remains constant at about 0.20 mm/s until the workpiece touches the die wall at a stroke of 26.5 mm. At this point, the die velocity decreases drastically to a speed of 0.01 mm/s at the final stroke. The time-varying die velocity results of this simulation would provide the enhanced workability and metal flow required for the workpiece to flow around the die corner radii, to fill the inside die corner, and to fill the die cavity completely. Similarly, for complicated die geometries, it is possible to vary die velocity as a function of time and to optimize the material flow to achieve a given range of strain rate.

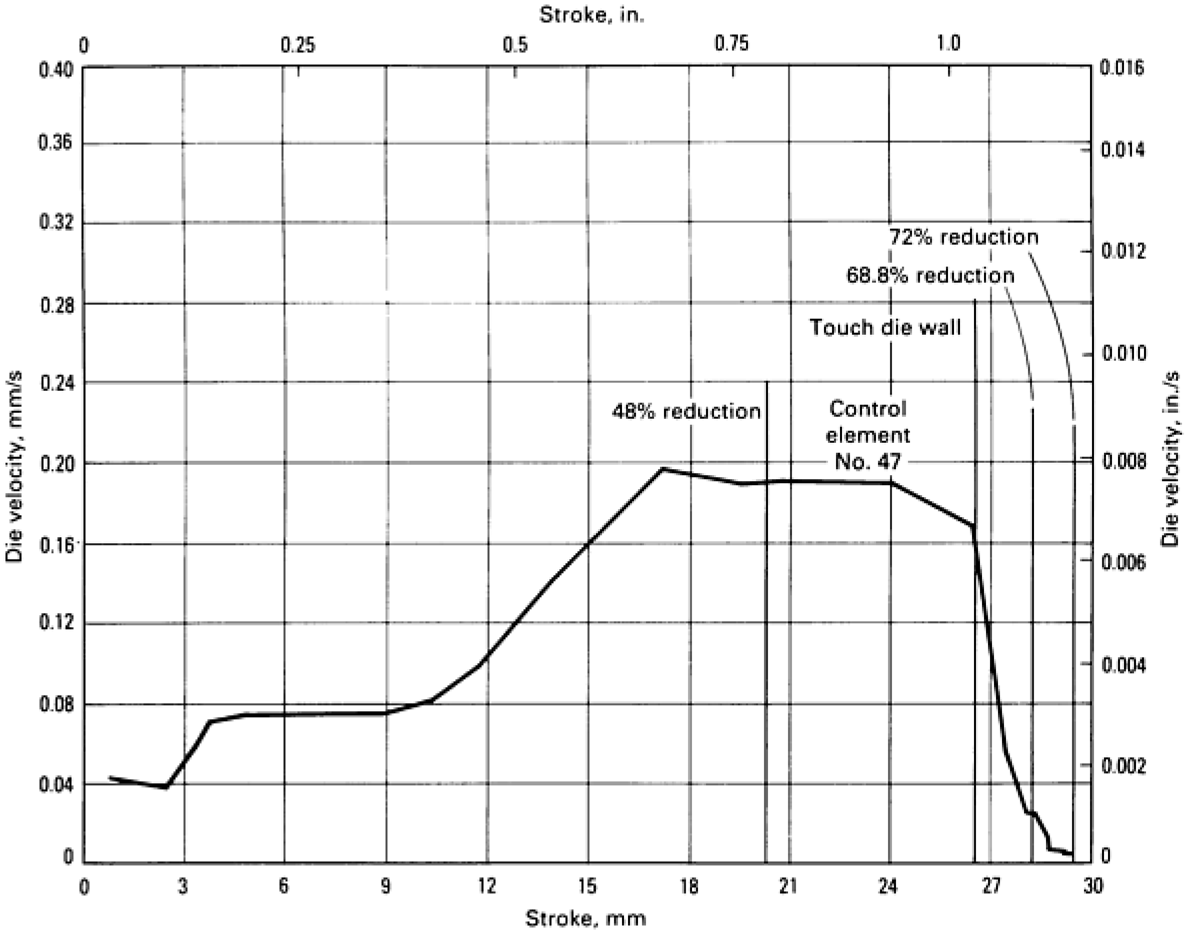

Fig. 22 Die velocity versus stroke curve for disk-forging simulation. See also Fig. 19, 20, and 21.

It is currently feasible to preprogram large hydraulic forging presses for constant or variable die velocity over a given load range (Ref 64, 65). Feedback control systems can also be installed for regulating the ram speed with respect to forging pressure or product temperature. Continuous control of the ram speed requires a combination of direct pumping and accumulator drive systems in order to maintain the time-dependent power requirements of the forging process. The accumulator drive system provides a higher penetration speed, but toward the end of the stroke, as the force required for forging increases, the ram speed and load available at the ram decrease. The direct-drive system delivers the maximum available load during the entire ram stroke and thus provides the very high pressures required for final die filling. Therefore, the two drive systems are complementary, with the result being higher deformation rates and pressures. More information on drive systems for both hydraulic and mechanical forging presses is available in the article "Hammers and Presses for Forging" in this Volume.

Physical Modeling

Whenever an analytical method for designing a physical system is devised, it is essential that its validity be tested by physical modeling. Such testing not only provides the feedback that aids in the development/refinement of the analytical model but also demonstrates the accuracy of the analytical predictions. Therefore, physical modeling provides greater confidence in the application of these analytical techniques toward the solution of actual problems.

Approaches

Two approaches are generally used in designing physical models. The first consists of simulating, as closely as possible, a production unit process on a laboratory scale and monitoring or controlling the important process parameters. The product resulting from such a test can then be analyzed to determine how closely its characteristics match those predicted by the analytical model. The second approach to physical modeling is to devise a laboratory test that is faster, easier, and less expensive than a subscale production process and yet provides an equally thorough test of the accuracy and robustness of the analytical model. Model materials and visioplasticity techniques are utilized in this approach for analyzing flow behavior.

Model Materials

Model materials such as Plasticine, wax, and polymers are used for physical simulation because:

- The load required for deformation is relatively small
- Observation of the deformation pattern is easy
- Test specimens are easy and inexpensive to make
- Inexpensive die materials such as wood and plastic can be used

- Experimental procedures are simple

Plasticine and wax are perhaps the most commonly used model materials; they are discussed in more detail below.

Plasticine is widely used in qualitative comparisons of different conditions in the hot forming of steels, especially in studies of flow patterns in extrusion, rolling, and forging and in studies of shape profile in rolling and upsetting (Ref 66, 67). There are two methods for investigating the flow pattern with Plasticine. One method is to paint a grid on the surface of the specimen with a stamp. In this method, the investigation is reduced to a two-dimensional problem, the painted grid is visible throughout the experiment, and the grid is photographed through an acrylic plate. The second method is to build up the specimen with layers of different-colored Plasticines. In this method, flow patterns cannot be observed continuously. The strain rate sensitivity factor, *m*, of Plasticine is approximately 0.06; therefore, Plasticine cannot be used as the model material for the physical simulation of the isothermal forging of superplastic alloys.

Wax has also been used, and the flow properties of many wax-base model materials have been measured experimentally (Ref 68, 69). The *m* values of wax are higher than those of Plasticine. Recently, wax has been used in studies of the hot isothermal forging of superplastic alloys. However, because *m* values depend significantly on temperature, the experimental conditions must be controlled exactly. In addition, many investigators are not yet experienced in handling the wax. Data are limited on the properties of wax compared to those of Plasticine.

Strain-Rate Sensitive Model Materials. The *m* values of the Plasticine-base model materials were changed by the addition of kaolin, petroleum jelly, lanolin, and resin to Plasticine (Ref 70). A resin that was solid at room temperature was produced. Petroleum jelly was generally used when the flow stress of Plasticine had to be decreased, and kaolin was used when the flow stress had to be increased. In this case, the proportion of petroleum jelly or kaolin was up to 5%. In the mixtures of resin/lanolin and petroleum jelly or lanolin, the proportion of resin/lanolin was up to 10%.

Table 3 shows the *m* values at a compression strain of 20% and the composition of materials indicated by weight ratio. The flow stress in plane compression at two constant cross-head velocities was measured by using an electronically controlled tensile-testing machine. Cross-head velocities of 10 and 100 mm/min (0.4 and 4 in./min) were used. The *m* values were calculated from two flow stresses at the two velocities at a strain of 0.2. The dimensions of the compression specimen were 20 × 15 × 30 mm (0.8 × 0.6 × 1.2 in.). The specimens were kept for 2 days in a thermostatic oven controlled at 20 °C (70 °F).

Table 3 *m* values of mixtures of Plasticine and various additives

Source: Ref 71

(a) Ratio of resin to lanolin 10 to 4.

(b) Ratio of resin to lanolin 10 to 5.

The *m* value of Plasticine was 0.05. The *m* value of the mixture of Plasticine and kaolin was 0.03, and the flow stress increased. The *m* value of the mixtures of Plasticine and petroleum jelly or lanolin increased slightly, and the flow stress decreased. The *m* values increased significantly with the addition of resin to Plasticine. The highest *m* values were obtained in mixtures containing both resin and lanolin. Consequently, mixtures of Plasticine, resin, and lanolin should be valid model materials for the isothermal forging of superplastic alloys.

Aluminum as a Model Material. Aluminum alloys 1100-O and 6061-O are also used for physical modeling. Grids can be easily made on the surface of the sample by etching or engraving. Excellent results have been obtained when these materials have been used for the simulation of aluminum precision forging processes.

Computation of Strain for Two-Dimensional Flow

To analyze the metal flow in deformation processing, it is necessary to determine the distribution of the effective strain values in the deformed body. The formulas defining these strains are derived in terms of the position of an element before and after deformation with reference to some coordinate system. Therefore, the strains are computed by measuring the deformation of some geometrical pattern using a grid mesh or an array of circles. Choice of the pattern depends on such factors as the type and accuracy of the information sought, the material, and the extent of specimen deformation.

In most commercial metal-forming processes, the resultant deformation may not be homogeneous. Deformation in the present case, however, can be assumed to be homogeneous because the deformed material can be divided into a number of small regions of homogeneous deformation. The most common method used to compute strains, called visioplasticity, involves establishing a velocity vector field to obtain strains by the grid method (Ref 72). The method is tedious and time consuming, and its accuracy depends on the computation of the velocity field. The technique is exact only in an engineering sense. It cannot be used for the case of unsymmetrical deformation, such as the wedge test, where a reference coordinate system cannot be established. Other methods involving the measurement of the dimensions of the deformed and undeformed grids are more appropriate for this case, because they are direct and easier to use.

A method has recently been developed for computing strains in deformation processing from the dimensions of the deformed and undeformed grid mesh (Ref 73). In this method, the deformation of a linear element in a small quadrilateral block is expressed in terms of normal and shear strains. Because actual strains in deformation processing are large, no limitations are applied to their magnitude, and the equations for strain are developed in terms of coordinate displacement.

Consider an element *OABC* (Fig. 23), which, after plane-strain deformation, assumes the shape of *O'A'B'C'*.Let l_1, m_1 and l_2, m_2 be the direction cosines of two line segments *OB* and *OA*, respectively. The lengths *OB* and *OA* can be computed from the digitized data of the deformed and undeformed grids. The strain parameter in the *x* direction e_{xx}, can then be obtained from a quadratic equation of the form:

$$A' e_{xx}^2 + B' e_{xx} + D' = 0 \quad \textbf{(Eq 56)}$$

where A', B', and D' are related to the lengths of the deformed and undeformed line segments and the direction cosines of the undeformed segments. All necessary relationships are given below:

$$e_{xx} = \frac{\partial u}{\partial x} + \frac{1}{2}\left\{\left(\frac{\partial u}{\partial x}\right)^2 + \left(\frac{\partial v}{\partial x}\right)^2 + \left(\frac{\partial w}{\partial x}\right)^2\right\} \quad \textbf{(Eq 57)}$$

$$A' = A_1C_2 - A_2C_1 \quad \textbf{(Eq 58)}$$

$$B' = B_1C_2 - B_2C_1 \quad \textbf{(Eq 59)}$$

$$D' = D_1C_2 - D_2C_1 \quad \textbf{(Eq 60)}$$

where:

$$A_1 = 4l_1^2;\ A_2 = 4l_2^2 \quad \textbf{(Eq 61)}$$

$$B_1 = 2\left[1 - \left(\frac{O'B'}{OB}\right)^2 + l_1^2 - m_1^2\right]; \quad B_2 = 2\left[1 - \left(\frac{O'A'}{OA}\right)^2 + l_2^2 - m_2^2\right] \quad \textbf{(Eq 62)}$$

$$C_1 = 2l_1m_2;\ C_2 = 4l_2m_2 \quad \textbf{(Eq 63)}$$

$$D_1 = 1 - \left(\frac{O'B'}{OB}\right)^2; \quad D_2 = 1 - \left(\frac{O'A'}{OA}\right)^2 \quad \textbf{(Eq 64)}$$

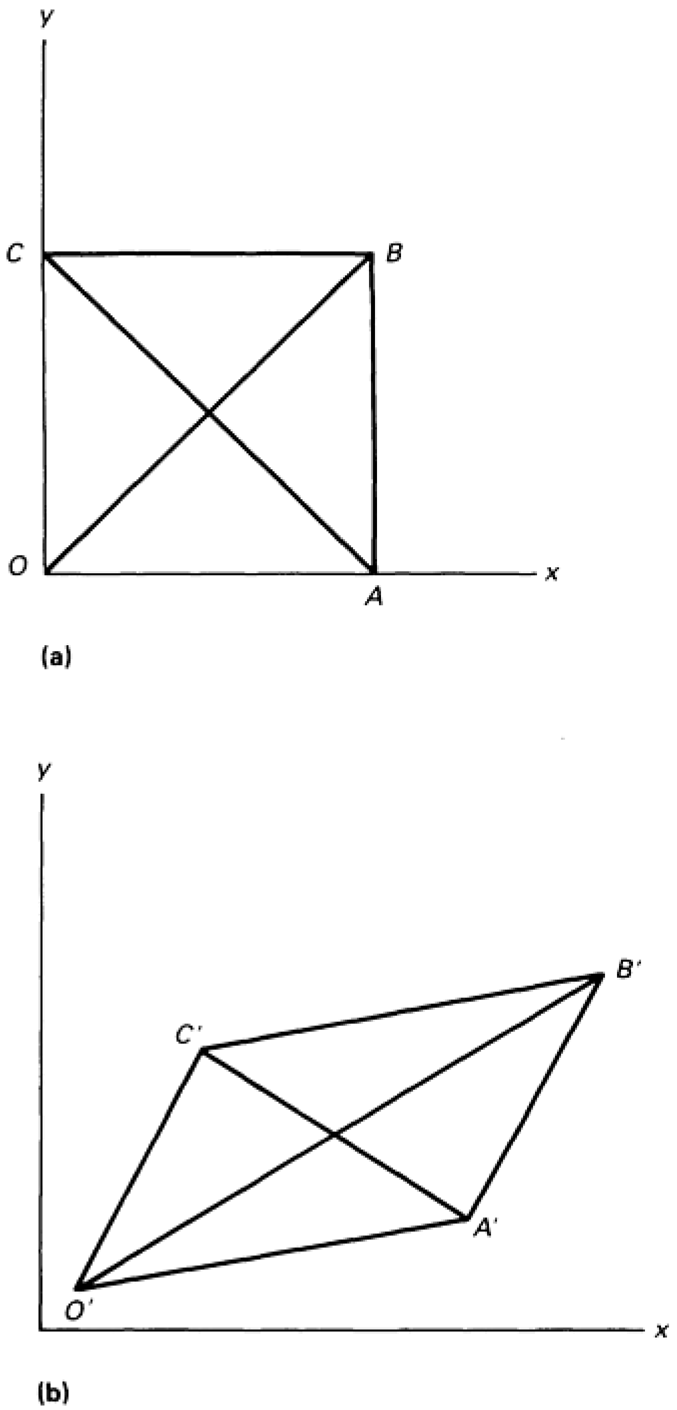

Fig. 23 Undeformed orthogonal grid (a) and deformed grid following homogeneous strain (b)

Shear strain e_{xy}, can be obtained by using Eq 65 or 66:

$$A_1 e_{xx}^2 + B_1 e_{xx} + C_1(1 + 2e_{xx})e_{sy}\ D_1 = 0 \quad \textbf{(Eq 65)}$$

$$A_2 e_{xx}^2 + B_2 e_{xx} + C_2(1 + 2e_{xx})e_{sy}\ D_2 = 0 \quad \textbf{(Eq 66)}$$

The true effective and principal strains are given as:

$$\bar{\epsilon} = \frac{2}{3}\sqrt{3\epsilon_x^2 + \frac{3}{4}e_{xy}^2} \quad \textbf{(Eq 67)}$$

$$e_{1,2} = \frac{e_x + e_y}{2} \pm \sqrt{\left(\frac{e_x - e_y}{2}\right)^2 + \frac{1}{4}(e_{xy})^2} \quad \textbf{(Eq 68)}$$

$$\epsilon_{1,2} = \ln(1 + e_{1,2}) \quad \textbf{(Eq 69)}$$

Equation 56 will result in two values of e_{xx}, one of which will be inadmissible and can therefore be discarded. The values of normal strains in the *x* and *y* directions are determined as follows:

$$e_x = \sqrt{1 + 2e_{xx}} - 1 \quad \textbf{(Eq 70)}$$

$$e_y = -\frac{e_x}{1 + e_x} \quad \textbf{(Eq 71)}$$

It should be pointed out that Eq 70 and 71 are based on the Lagrangian definition of strain and make no assumptions concerning the extent of deformation. The true effective strain is given by:

$$\bar{\epsilon} = \ln(1 + e) \quad \textbf{(Eq 72)}$$

where *e* is the effective engineering strain.

Therefore, the analysis of grids to compute strain variations on the meridian plane of the specimen involves three steps:

- Digitization of the undeformed and deformed grids
- Calculation of the effective strain using Eq 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, and 72.
- Displays of the effective strain as contour plots

Development of Grid Mesh

Deformation in a body is characterized by the distribution of strain. The grid deformation method of strain measurement involves applying a grid mesh on the surface or on an interior plane of a specimen. The grid can be defined as an array of lines or dots that indicate points on the specimen, and it is usually rectangular, with dots or lines being repeated in two perpendicular directions. The distance between the discrete nodes on the grid before and after the deformation is measured, and the resulting data are analyzed. The grid method is an optical technique. Sighting of the grid is accomplished with or without photography. The accuracy of the grid depends on the precision with which sighting can be carried out.

Accuracy in the measurement of the grid does not lie in the precision of the measuring instrument but in the ability of the investigator to view the points clearly. If a dot or point (obtained by the intersection of two grid lines) is much larger than the resolution of the instrument, the resulting measurement will be inaccurate. The size of the point, therefore, plays an important role in the measuring process. In addition, a point under consideration should be clearly visible with the least amount of distortion before and after deformation has occurred.

A number of methods have been used in attempts to apply a suitable grid pattern to wedge-shaped specimens. These include photochemical etching and engraving techniques. The engraving techniques are accomplished by means of a computer numerical controlled engraver and are found to be accurate and appropriate. A typical specimen with engraved grid lines is shown in Fig. 24.

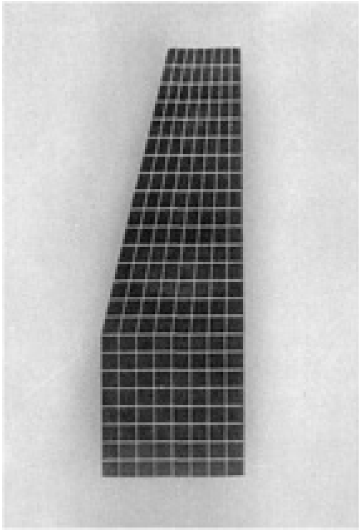

Fig. 24 Undeformed wedge specimen with grids engraved on meridian plane.

Tool Setup (Segmented Die Design) for Plane-Strain Wedge Testing

To analyze the two-dimensional flow of metal and to verify the ALPID code for complex deformation, wedge-shaped specimens with grids engraved on the meridian plane were compressed such that a range of strains varying from 0 to 0.75 was obtained. A one-piece channel-shaped die with a punch was designed and fabricated for a 90 Mg (200 kip) testing machine. A specimen of aluminum alloy 2024-O was compressed using this die. The compressed specimen could not be ejected undamaged from the die. The concept of segmented dies was therefore developed for convenient ejection of the specimen without damage. These dies (Fig. 25) consisted of several segments assembled to provide the same die cavity as that of a one-piece die, and they could be dismantled, after forging was complete, to eject the workpiece. The major advantage of segmented dies is that, through the use of different inserts, a new family of parts can be forged. The major disadvantage of these dies is that metal tends to extrude through the various joints of the die during metal deformation. The segments must therefore be held together with a pressure greater than the flow stress of the metal during deformation but must still be easy to dismantle after the forging process is complete.

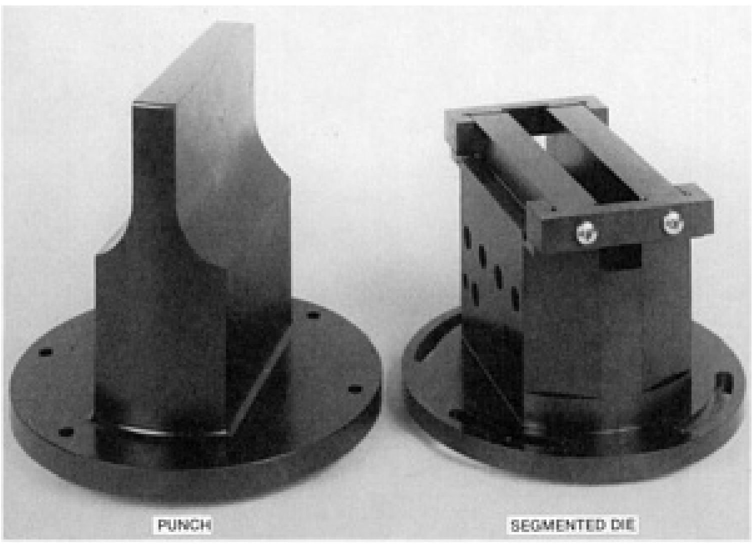

Fig. 25 Components of segmented dies for two-dimensional wedge testing

Example of Experimental Procedure

To verify ALPID for a variety of materials and deformation spectra, wedge specimens were machined from aluminum alloys 1000-F and 6061-T6. The specimens were annealed at 450 °C (840 °F) for 1 h. One 1100-O aluminum specimen was compressed to a deformation of 54.5%, and three 6061-O aluminum alloy specimens were compressed to height reductions of 14, 32, and 40% for this study.

Before the actual compression of the wedge specimen, the punch, die, and specimen surfaces were coated with a high-pressure molybdenum disulfide-base spray lubricant to minimize friction along the sliding interfaces. The specimen was then mounted in the die, and the die segments were fastened together with bolts and restrainers. The duration of the test was determined by the extent of deformation--typically 250 s for a 50% reduction in height (12.7 mm, or 0.5 in., ram displacement).

The deformed specimens were cleaned with soap and methanol to remove the thin film of lubricant and were then photographed. Because of the compression of the specimens, the horizontal grid lines became thin, and the vertical ones became thick. The thin lines could not be effectively resolved by the camera because of the reflection of light from the shiny surface of the aluminum specimen. The specimen surface was therefore coated with carbon black in order to print the deformed grid on photographic paper for digitizing. The computer files containing the deformed and undeformed digitized data were used by a computer program to obtain the effective strains at various nodes.

A number of compression tests were performed. Figure 26 shows a plot of ram travel versus compression load for the two materials. It can be seen that the load increases with the amount of deformation, but the rate of increase is larger for 6061 aluminum than for 1100 aluminum. The deformed grid meshes for the two materials for various amounts of deformation are shown in Fig. 27. The ALPID code was then used to generate the distorted grid for both materials for the amount of deformation used in the experimental tests. In Fig. 27, the flow patterns as depicted by the grid meshes are almost identical in all cases; the difference in flow behavior is attributed to the estimated value of the die/workpiece friction used to generate the ALPID simulations.

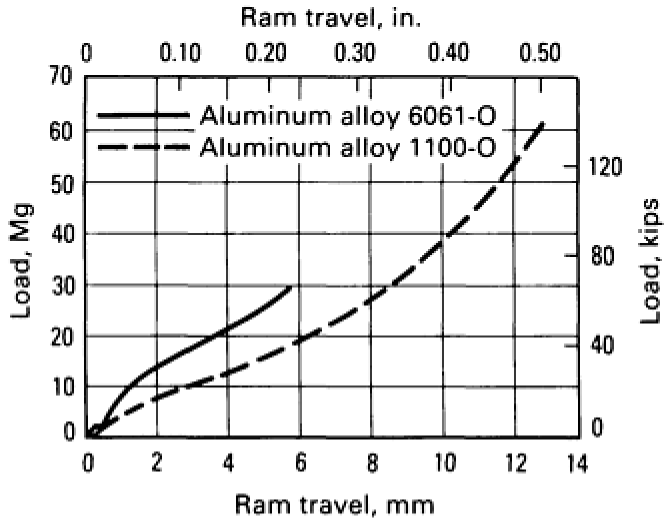

Fig. 26 Load versus ram travel for wedge specimens of aluminum alloys 1100-O and 6061-O

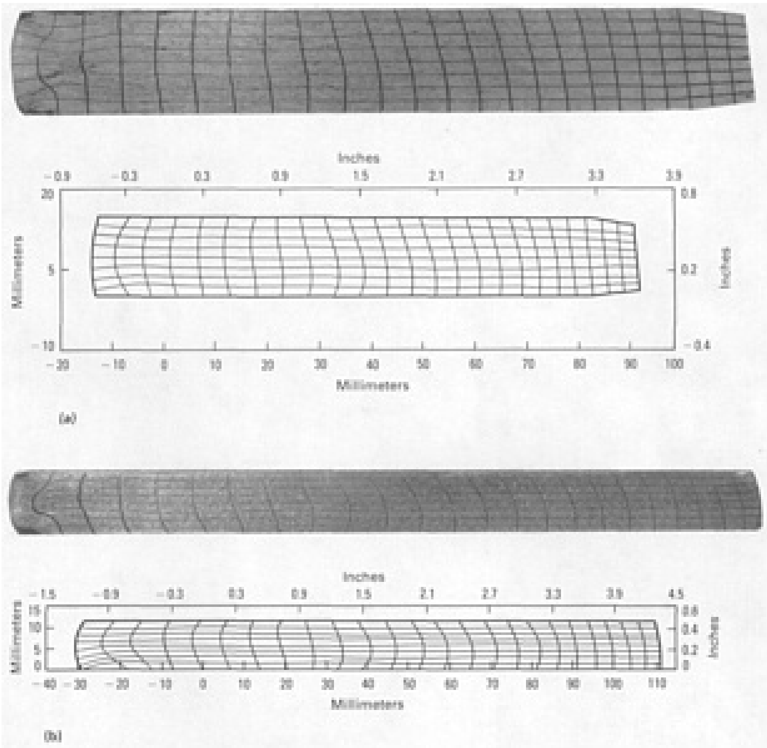

Fig. 27 Grid patterns showing metal flow in 6061-O (a) and 1100-O (b) aluminum alloy wedge specimens at 40% deformation. At top are experimental results; at bottom are ALPID simulations.

To quantify the verification of the ALPID code, the experimental and ALPID-generated values of effective true strain were used to plot the contour maps (Fig. 28). The ALPID-generated maps are very similar to the experimental ones.

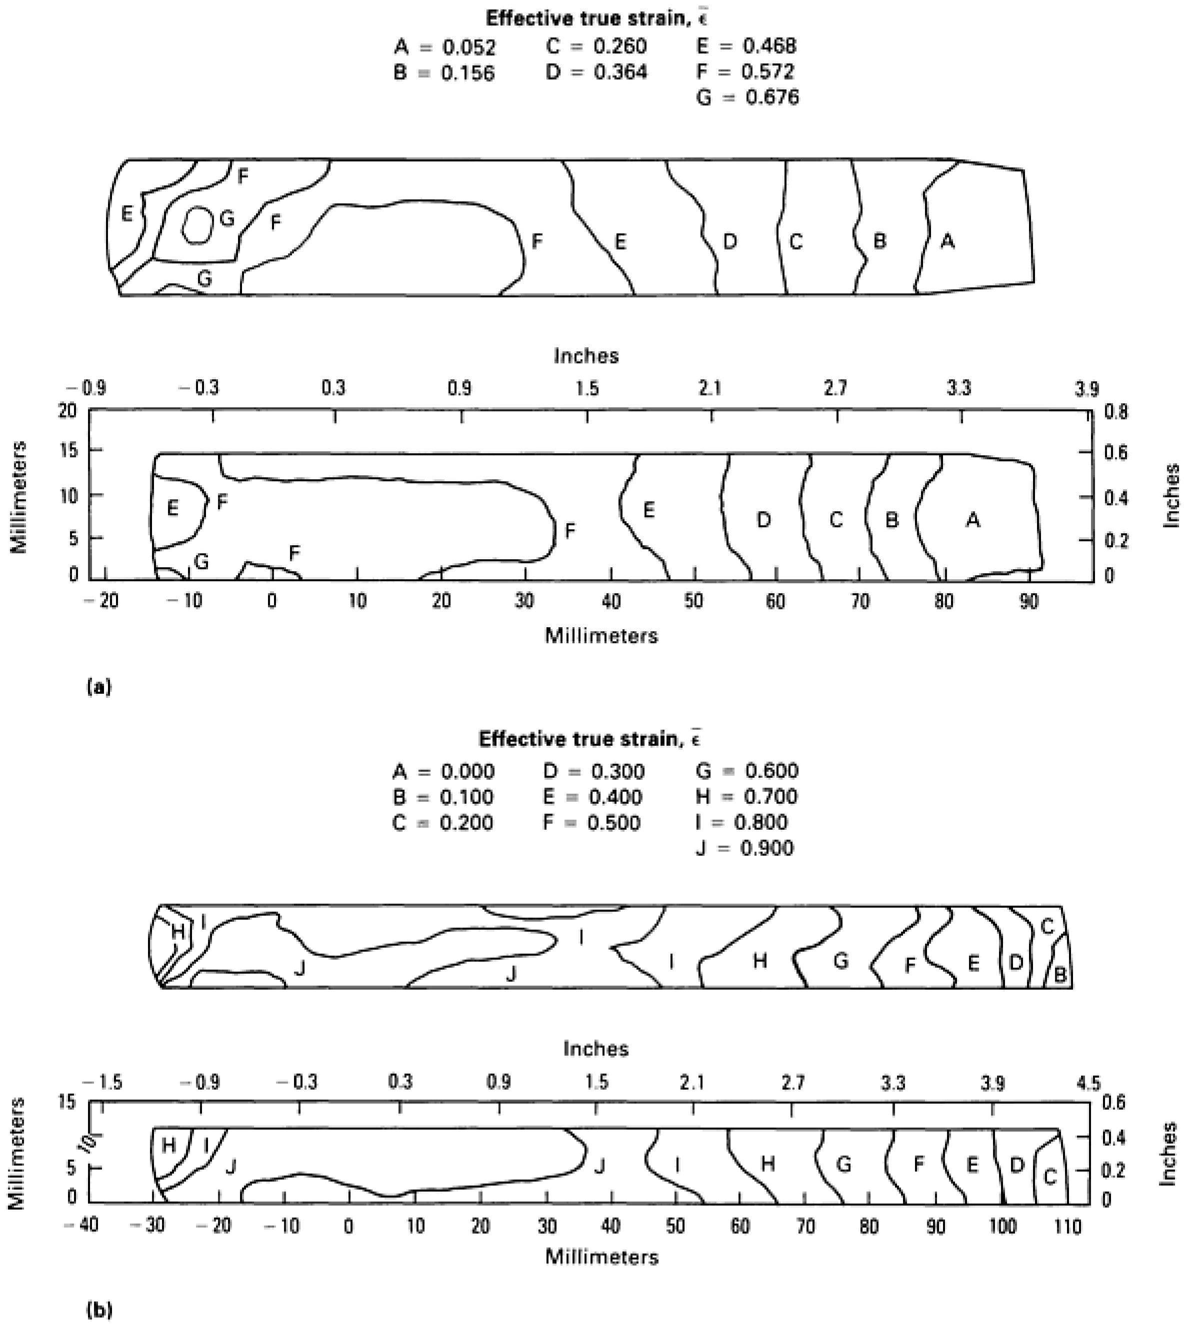

Fig. 28 Effective true strain contour maps for 6061-O (a) and 1100-O (b) aluminum alloy wedge specimens at 40% deformation. Experimental results are given at top; ALPID simulations are at bottom.

The reasons for the probable minor differences at some isolated locations in the experimental and ALPID-generated values of effective strains are:

- Error introduced in digitizing the deformed and undeformed grids on an electronic tablet
- Error in aligning the crosshairs of the cursor with the node points
- Error introduced in locating the grid node point precisely
- Distortion of the grid network during the printing process
- Undeformed grids not being identical on all specimens
- Imprecise constitutive equations for the materials under consideration
- Uncertainty in estimating the friction factor at the tool/specimen interface, which may vary from

specimen to specimen and with pressure and type of lubricant used

Development of Three-Dimensional Grid for Strain Calculation

To analyze the flow of material in deformation processing, it is necessary to determine the magnitude of strains in the deformed body. The formulas defining the strains are derived in terms of the position of an element before and after deformation with reference to a coordinate system. Therefore, the strains are computed by measuring the deformation of some geometrical pattern, for example, a grid mesh or an array of circles. Choice of the pattern depends on such factors as the type and accuracy of the information sought, the material, and the extent of specimen deformation.

Although in most plastic deformation processes the resulting strain is not homogeneous, the deformation will be assumed to be homogeneous. The rationale behind this assumption is that deformed material can be divided into numerous smaller regions where the deformation is homogeneous.

The Indirect Method. The development of a specimen shape to study metal flow in three dimensions is a tedious task. Therefore, an indirect approach has been developed (Ref 73). In this method, a rectangular block 19 × 12.7 × 6.4 mm (0.75 × 0.50 × 0.25 in.) thick with fine (0.38 mm, or 0.015 in., diam) through holes drilled and grid lines (2-2-2, 3-3-3, etc.) engraved at 1.27 mm (0.050 in.) intervals is used, as shown in Fig. 29. The holes are filled with 0.38 mm (0.015 in.) diam wires made of the same material. The specimen is then compressed between flat dies to a specified deformation, for example, 40%. The distance between the horizontal grids (1-1-1, 2-2-2, etc.) is measured to determine the strain in the *z* direction. The top surface (1-1-1-1) is photographed to obtain the flow pattern in the *x*-*y* plane. The specimen is machined to the level 2-2-2, and the hole pattern is photographed again. The process is repeated to the level 5-5-5. An indirect 3-D grid pattern is thus generated. This pattern is used to determine the true effective strain in each element.

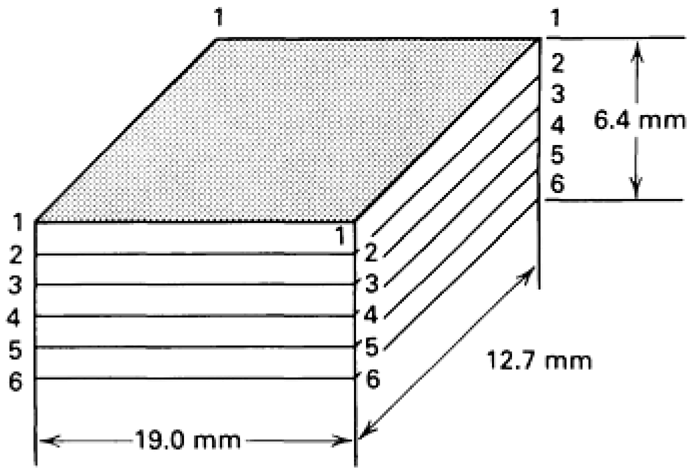

Fig. 29 Standard rectangular block specimen used to study three-dimensional material flow

The multicolored workpiece method was developed for determining the velocity field in true 3-D deformation (Ref 74). Figure 30 shows the workpiece. After every deformation, thin slices are removed from the workpiece, and each newly exposed surface is photographed.

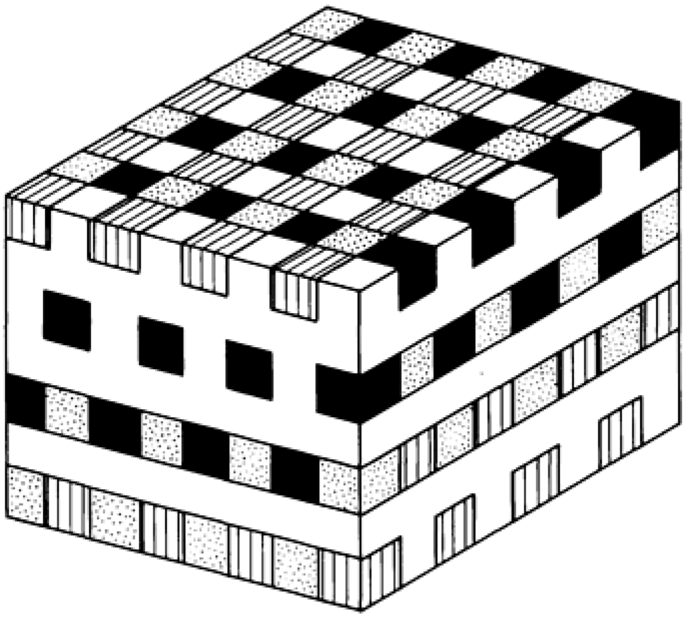

Fig. 30 Multicolored model material workpiece consisting of four-color checkerboard

Software has been developed that can compute the coordinates of each nodal point in the deformed workpiece from measurements of the above-mentioned photographs. The coordinates of these nodal points form the basis for determining strain rates. Two different methods for the strain calculations have been developed: the parallelepipedon method and the tetrahedron method. Figure 31 shows some results from an analysis of the upsetting of a cube with sticking friction between workpiece and tools. These results were obtained through application of the multicolored workpiece method.

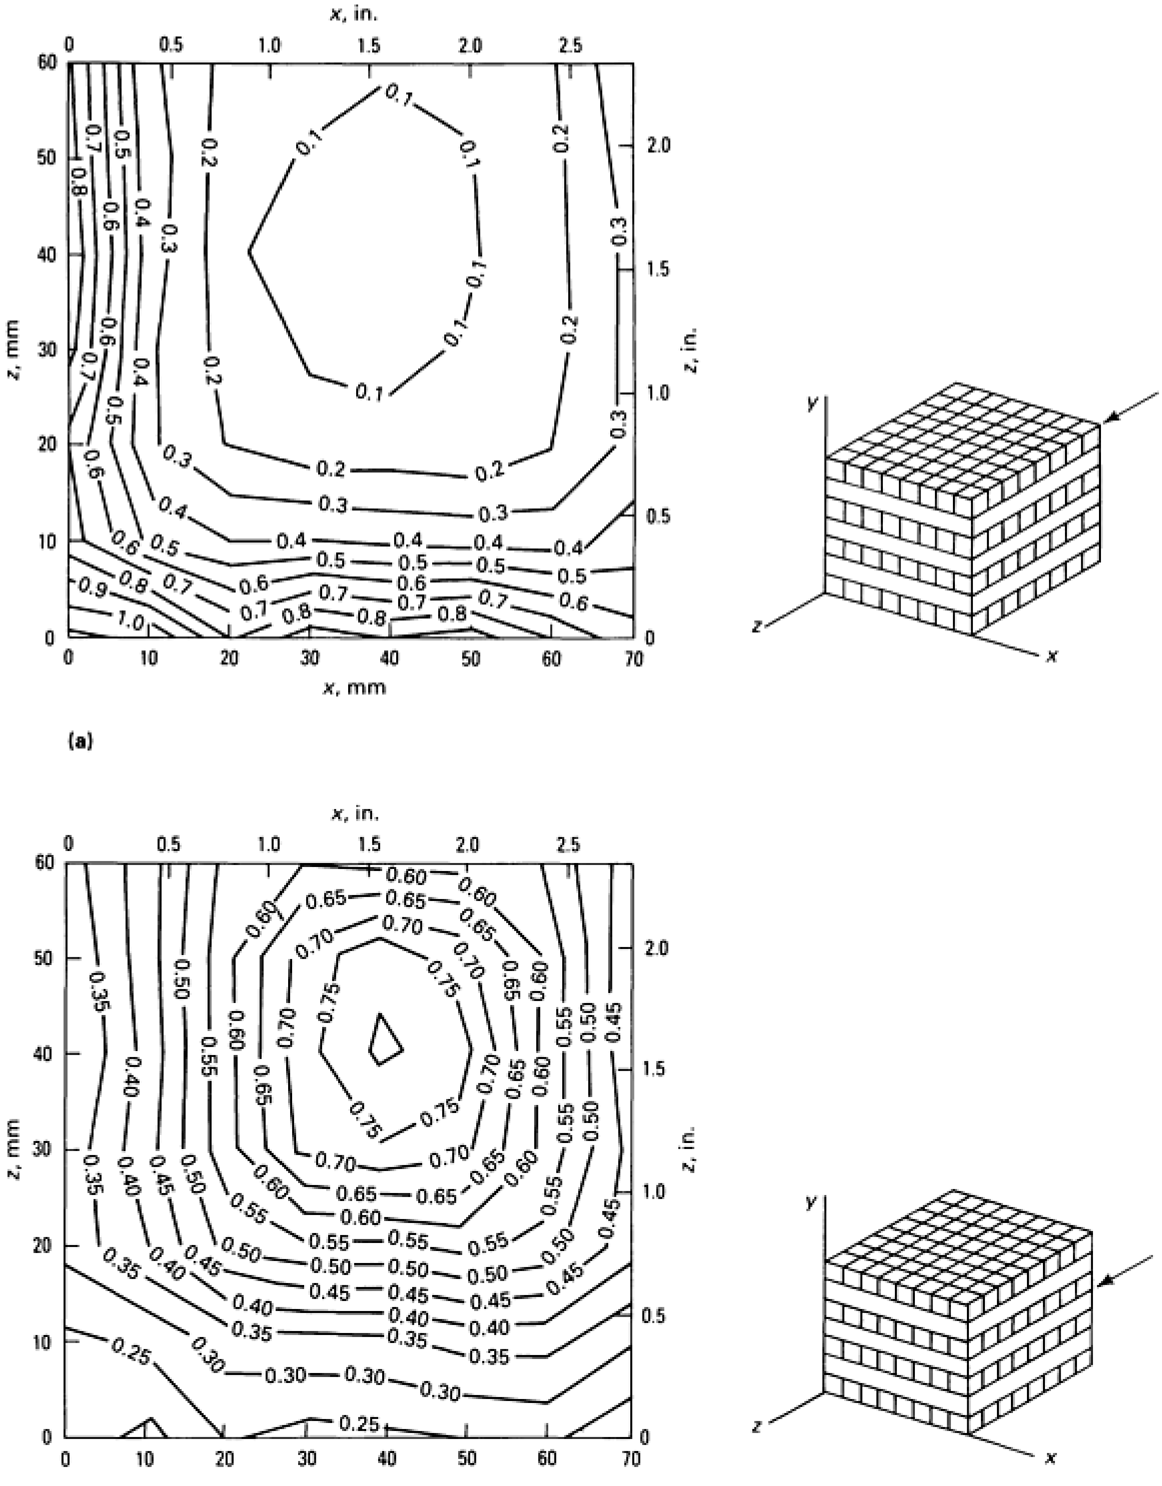

Fig. 31 Equivalent strain distribution in a cube after upsetting. (a) Distribution near the upper horizontal tool/workpiece interface (see arrow at right). (b) Distribution near the horizontal symmetry plane (see arrow)

Introduction

A number of experimental techniques are available for gathering necessary material-behavior data. These techniques include hot compression tests, hot torsion tests, hot tensile tests, and subscale metal-forming operations. These methods are reviewed in Ref 1 and 2 and are discussed in detail in the Section "Evaluation of Workability" in this Volume.

Hot Compression Testing

Hot compression testing has become increasingly popular for several reasons, in particular:

- Uniform deformation can be maintained to large strains with proper lubrication
- Isothermal conditions can be easily achieved
- The compressive state closely represents the conditions present in forging, extrusion, and rolling processes

Among the various types of hot compression tests, the constant strain rate test is preferred because it yields both the flow stress data required for finite-element method applications and the strain rate sensitivity and temperature sensitivity data needed for dynamic material modeling from the same set of tests (Ref 3).

Generation of Flow Curves. Compression testing is usually conducted on a servohydraulic computer-controlled load-frame with data acquisition instrumentation. Upon completion of the test, load-stroke data that have been written into microcomputer memory are converted from the resolution-step format generated by an analog-to-digital converter to the actual force (MPa) and displacement (mm) units. This new data set is written to disk for permanent storage and is also read for further analysis. Software is then used to calculate true stress and true strain, as discussed below.

First, plastic deformation is determined from the load-stroke curve by determining the elastic component and then subtracting it from the stroke. The true stress and true strain are then calculated. The resulting true stress-true plastic strain data are stored on disk for plotting the flow curves and for further analysis.

Software routines, which correct the true stress-true plastic strain curves for the temperature increase ΔT due to the heat of deformation, are based on:

$$\Delta T = \frac{h\bar{\sigma}\bar{\epsilon}}{\rho C} \quad \textbf{(Eq 1)}$$

where $\overline{\sigma}$ is the true stress, $\overline{\epsilon}$ is the true plastic strain, ρ is the density, C is the heat capacity, h is the deformation heat factor = (A/1 + m), m is the strain rate sensitivity, and A is the heat retention factor.

The calculated temperature increase is used to offset the pseudo flow softening by correcting the flow stress using:

$$\Delta\bar{\sigma} = \Delta T\left(\frac{d\bar{\sigma}}{dT}\right) \quad \textbf{(Eq 2)}$$

$$\Delta\bar{\sigma} = \left(\frac{h\bar{\sigma}\bar{\epsilon}}{\rho C}\right)\left(\frac{d\bar{\sigma}}{dT}\right) \quad \textbf{(Eq 3)}$$

The value of $d\overline{\sigma}/dT$ is determined from the uncorrected experimental data at small strains by plotting $\overline{\sigma}$ versus T at a particular strain rate. The slope of the least squares fit of this plot is taken as $d\overline{\sigma}/dT$.

Typically, several corrected flow curves are generated on a single plot, as shown in Fig. 1. Figure 2 shows the corrected flow curve and the uncorrected flow curve.

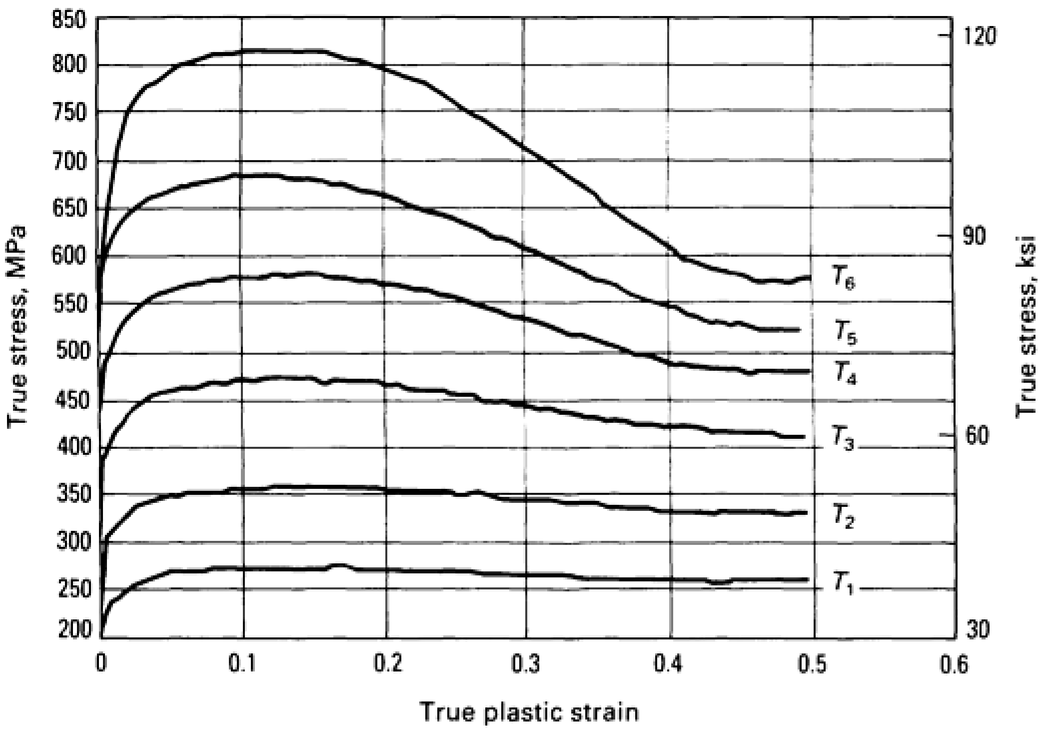

Fig. 1 Corrected flow curves at different temperatures with log $\dot{\epsilon}$ = 0.

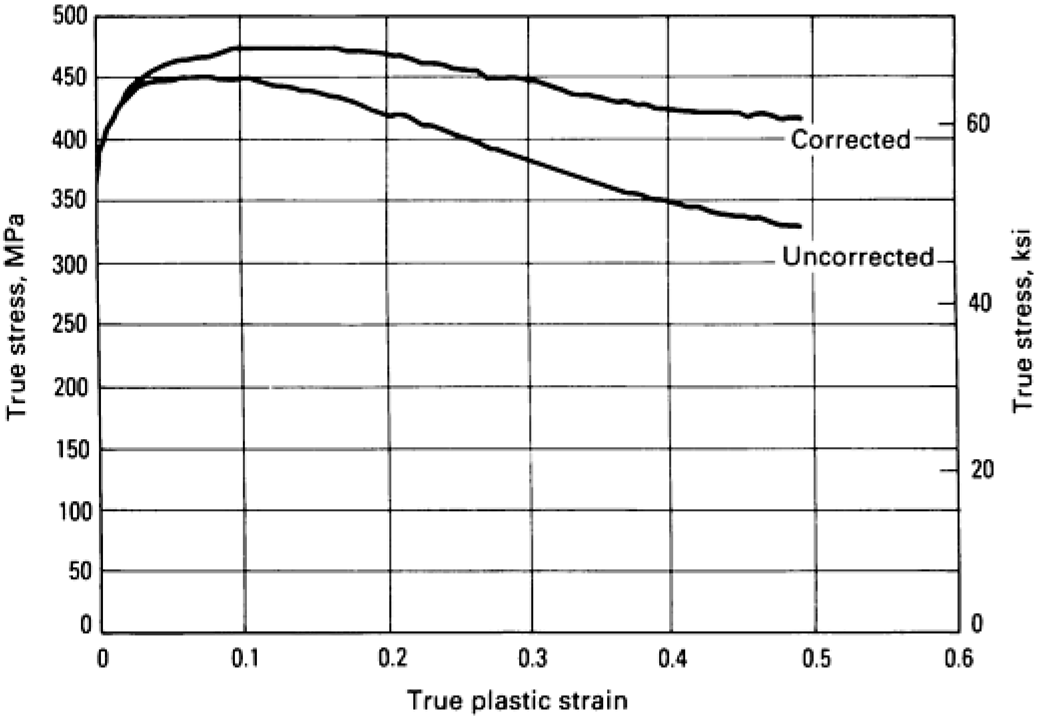

Fig. 2 Corrected and uncorrected flow curves at 1100 °C (2010 °F) and log $\dot{\epsilon}$ = 0.

Effective Stress/Effective Strain Rate/Temperature Relationships. Effective stress and effective strain rate values are extracted at various strain levels and test temperatures from the flow curves and are converted into log $\overline{\sigma}$ and log $\dot{\epsilon}$ The constitutive relationship is obtained by fitting data points to piecewise quadratic functions. Quadratic functions are selected to ensure that the convexity conditions is satisfied. At the intersection of two equations, suitable methods are used to obtain a smooth transition from one equation to another. In the region where two equations overlap, log $\overline{\sigma}$ values are generated by averaging the values obtained by two close equations. Therefore, a large number of log $\overline{\sigma}$ values are generated at very close intervals of log $\dot{\epsilon}$ values. These values can be used for representing flow stress as a function of log $\dot{\epsilon}$ and *T*, and they are also used as a subroutine in the finite-element analysis. Linear interpolation could be used if a value is required between the generated values. A similar procedure is used to generate intermediate points between the experimental data along the temperature axis. A minimum of 40 compression tests are generally recommended to obtain a good fit and accurate results.

Workability Data

Determination of m, η, and $\partial\eta/\partial \log \dot{\epsilon}$. The strain rate sensitivity parameter m is calculated by using the flow stress values generated as a function of log $\dot{\epsilon}$ at various test temperatures for a given effective strain. A pair of flow stress values taken at very close intervals of log $\dot{\epsilon}$ values are inserted into Eq 4, and the values of m are obtained as a function of log $\dot{\epsilon}$ at a given temperature and effective strain. This should be repeated at each test temperature to cover the entire range of test temperatures and strain rates for the given effective strain.

The efficiency parameter η can be determined by using the calculated m values and Eq 4:

$$\eta = \frac{2m}{m+1} \qquad \textbf{(Eq 4)}$$

The values of η as a function of temperature and log $\dot{\epsilon}$ can be output compatible with a graphics package such as MOVIE.BYU (the graphics software package used to generate the graph). A three-dimensional (3-D) plot of η as a function of temperature and log $\dot{\epsilon}$ and the corresponding efficiency contour plot can then be generated. A sample representation of a 3-D plot is shown in Fig. 3 (Ref 4).

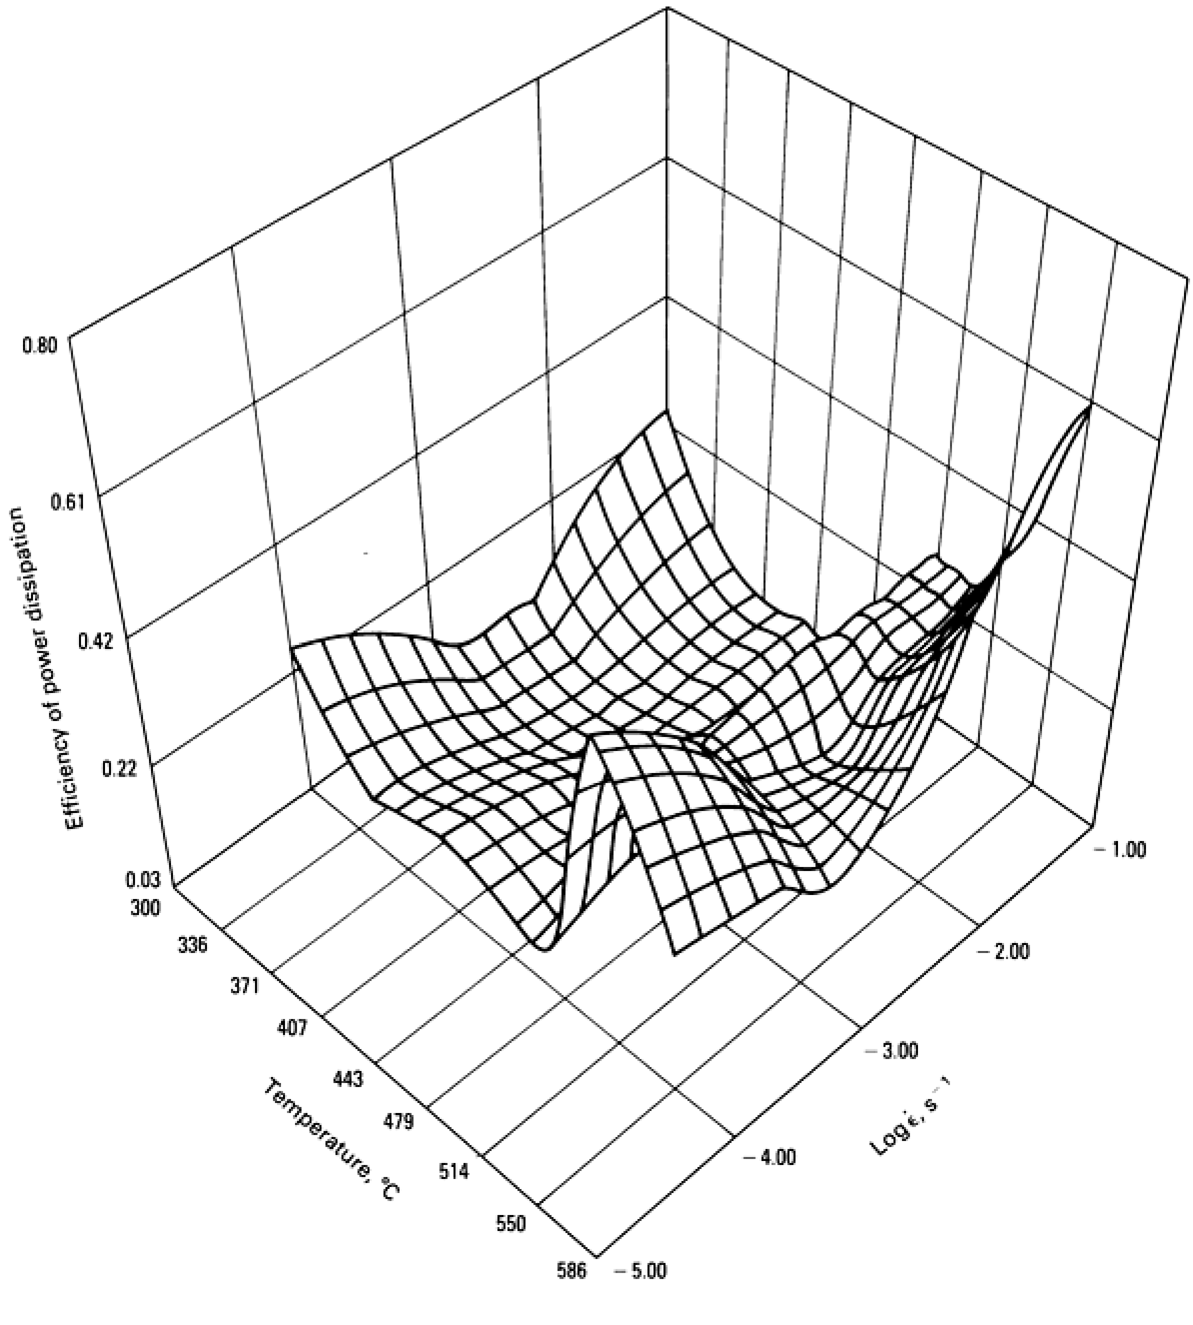

Fig. 3 Three-dimensional surface plot of efficiency of power dissipation as a function of strain rate and temperature of aluminum alloy 2024 with 20 vol% SiC.

Values of $\partial\eta/\partial \log \dot{\epsilon}$ are required to identify stable and unstable regions. The loci of all values of $\partial\eta/\partial \log \dot{\epsilon} = 0$ separate these regions. These values are calculated based on the values at very close intervals of log ε and using the formula $(\eta_2 - \eta_1)/(\log \dot{\epsilon}_2 - \log \dot{\epsilon}_1)$. The values can be plotted on a two-dimensional (2-D) efficiency contour plot.

Determination of *s* and $\partial s/\partial \log \dot{\epsilon}$ The entropy rate ratio, *s*, can be calculated by using the log $\dot{\epsilon}$ values generated from the experimental values at very close temperature intervals for a given effective strain rate and strain (see the section "Dynamic Material Modeling" in the article "Modeling Techniques Used in Forging Process Design" in this Volume). The following relationship is used for this calculation:

$$s = \frac{\partial \log \bar{\sigma}}{T\partial(1/T)} = \left.\frac{\log \bar{\sigma}_2 - \log \bar{\sigma}_1}{[(T_1 + T_2)/2][(T_2 - T_1)/T_1T_2]}\right|_{\dot{\epsilon},\epsilon} \quad \textbf{(Eq 5)}$$

This value will be represented at the temperature:

$$T = \frac{T_1 + T_2}{2} \quad \textbf{(Eq 6)}$$

Similarly, *s* is calculated at various temperatures and effective strain rates for a given effective strain, and these values will be subsequently used for the calculation of $\partial s/\partial \log \dot{\epsilon}$ The variation of *s* with strain rate is also calculated by using a pair of values and Eq 7:

$$\frac{(s_2 - s_1)}{(\log \dot{\epsilon}_2 - \log \dot{\epsilon}_1)} \quad \textbf{(Eq 7)}$$

For delineating the stable and unstable regions, the loci of all values of $\partial s/\partial \log \dot{\epsilon} = 0$ are used. These points can also be plotted on the same efficiency 2-D contour plot, along with the values of $\partial\eta/\partial \log \dot{\epsilon}$ for the development of processing maps. Such a map is shown in Fig. 4 (Ref 4).

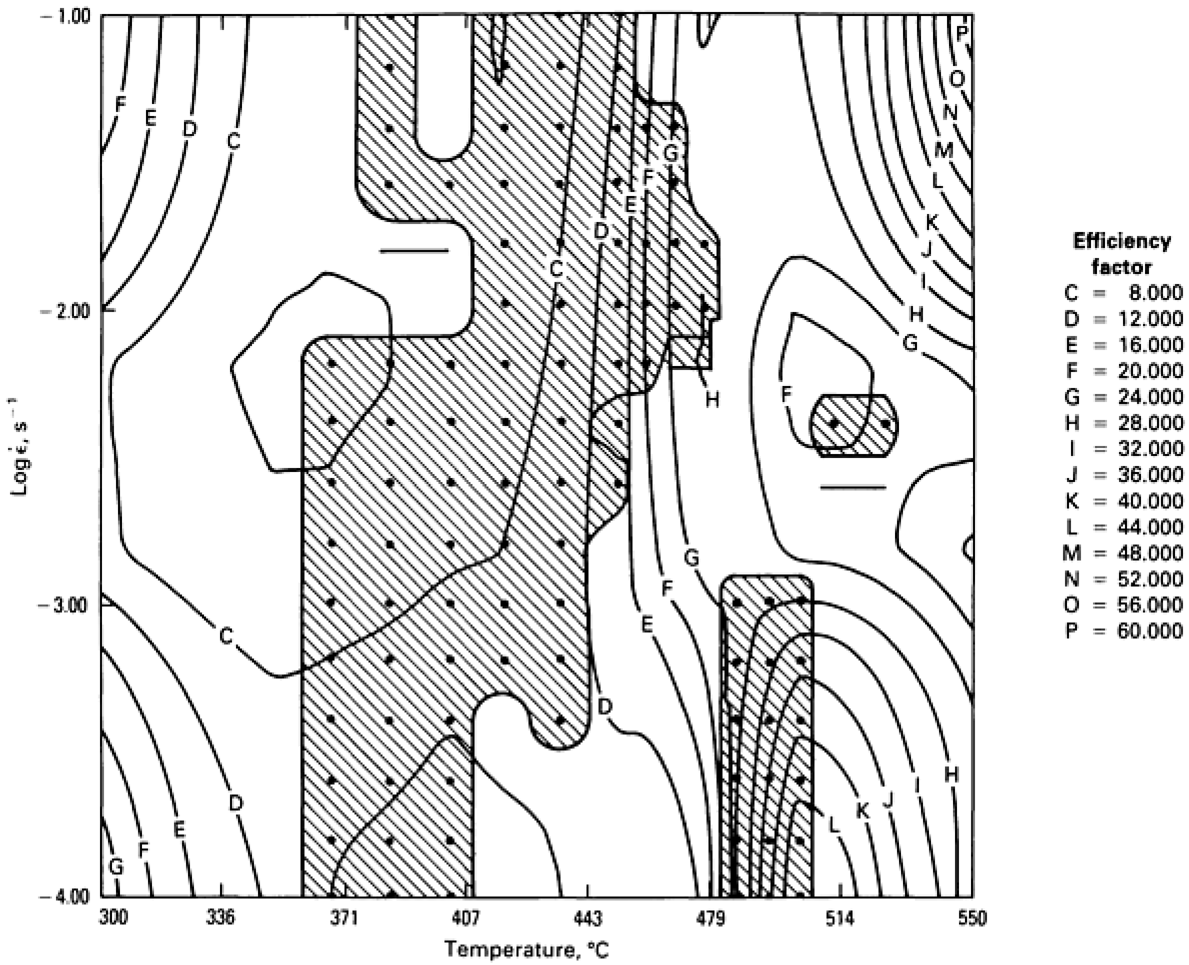

Fig. 4 Processing map showing areas of identical efficiency as a function of log $\dot{\epsilon}$ and temperature. The contour plot also shows stable regions (shaded areas) recommended for processing aluminum alloy 2024 with 20 vol% SiC.

Development and Interpretation of Processing Map. The processing map developed for each initial condition of the experiment provides stable and unstable regions in temperature and effective strain rate space. Stable regions are recommended for processing. In the stable region, the optimum combination of temperature and effective strain rate can be selected based on the required microstructure, the availability of equipment, and the ease with which processing parameters can be controlled.

On the 2-D efficiency contour map, the lines that represent the loci of all

$$\frac{\partial \eta}{\partial \log \dot{\epsilon}} = 0$$

and

$$\frac{\partial s}{\partial \log \dot{\epsilon}} = 0 \qquad \textbf{(Eq 8)}$$

values can be superimposed as shown in Fig. 4 to generate a comprehensive processing map.

Microstructural data should be incorporated into the processing map to correlate the types of microstructures and metallurgical processes. The aim of this evaluation is to identify dissipative processes such as the occurrence of dynamic recrystallization, microcracking, phase transformation, and primary and secondary grain growth. These can be correlated with different regimes on the processing maps in order to interpret the map and to arrive at an optimum range of temperature and strain rate for billet conditioning or hot working.

Interface Data

Determination of *m*' (Friction Factor). The ring compression test is commonly used for the measurement of the interface friction factor. Ring specimens of standard size are compressed between flat dies to a known reduction under optimum working conditions selected on the basis of dynamic material behavior modeling. The change in the internal diameter of the ring is measured to quantify the friction. The measured dimensions (reduction in height and variation in external diameter) are placed on the appropriate calibration curves to arrive at the friction factor. These analytical calibration curves are available in the literature.

The test can be conducted with different surface roughnesses of the flat dies, using a variety of lubricants. Thus, a complete variation of the friction coefficient is obtained as a function of temperatures, lubricants, surface conditions, and so on.

Determination of h (Heat-Transfer Coefficient). The thermal resistance of a contact is also a surface effect, coupled with the thermal and mechanical properties of the materials making up this contact as well as the interstitial fluid. The absence of either physical contact or an interstitial fluid results in poor contact. The most reliable contact involving metallic conduction results in the case of completely welded or brazed joints. All other cases fall in between these two extremes.

When two surfaces are held together under pressure, the effective contact area is a function of the contact materials, surface conditions, surface flatness, and the contact pressure. The thermal interface conductance is a function of the effective contact area, which is made up of many small points of contact and is only a small fraction of the nominal contact area. Figure 5 shows a representative view of the asperities that make up a contact. These contact points are distributed quite uniformly, so that an increase in pressure causes an increase in the number of points of contact, resulting in an increase in total true contact area.

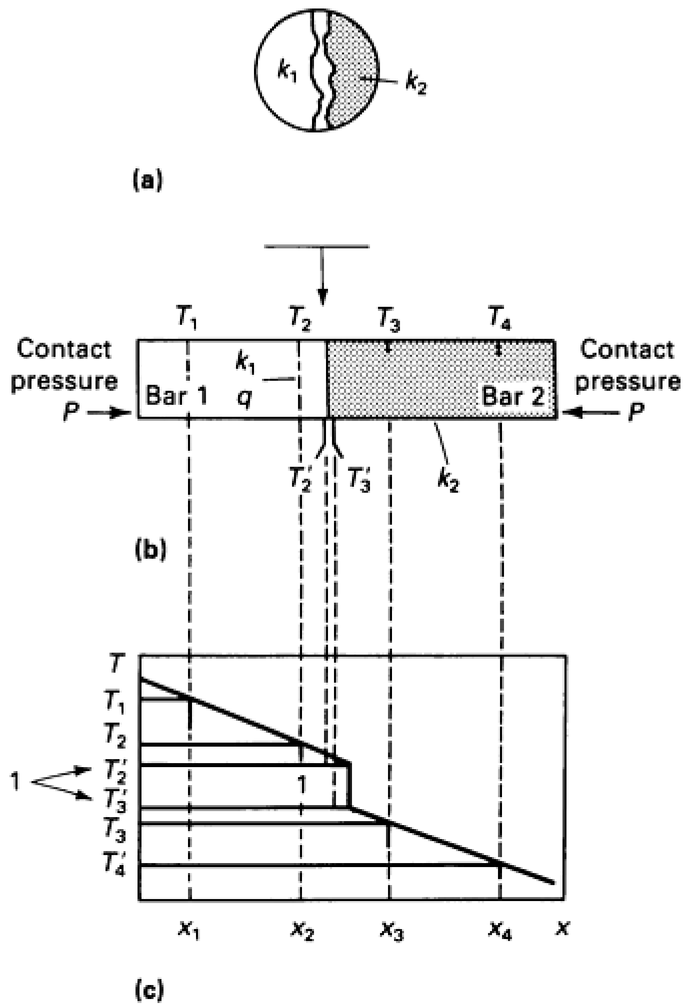

Fig. 5 Physical arrangement and temperature variation for the contact conductance phenomena. (a) Magnified view of contact cross section of bars. (b) Diagram of two bars jointed by contact pressure *P* with $T_1 > T_2$ and heat flowing from bar 1 to bar 2. (c) Temperature variations at points x_1 through x_4 used to extrapolate junction temperatures T'_2 and T'_3.

From the basic Fourier equation, the steady-state heat flow at any part of the heat path is given by:

$$q = k\frac{dT}{dx} \qquad \textbf{(Eq 9)}$$

If the thermal conductance of the interface is defined as:

$$h = \frac{q}{\Delta T} \qquad \textbf{(Eq 10)}$$

where q is the heat flow (in Btu/h/ft^2), k is the thermal conductivity (in Btu/h/ft/°F), T is the temperature (in °F), h is the conductance at interface (in Btu/h/ft^2/°F), and x is the distance in the direction of heat flow (in feet). Then:

$$h(\Delta T) = k\frac{dT}{dx} \qquad \textbf{(Eq 11)}$$

or

$$h = \frac{k(dT/dx)}{\Delta T} \quad \text{(Eq 12)}$$

The thermal resistance is defined as $r = 1/h$.

Figure 5 shows two bars held in position by a pressure, P. Under steady-state conditions, neglecting any losses when $T_1 > T_2$, the heat flux flows from left to right, and $q_1 = q_j = q_2$, where q_j is the heat flux through the junction of cross-sectional area A. If temperature measurements are made at locations x_1, x_2, x_3, and x_4 as shown in Fig. 5 and if the conductivities k_1 and k_2 are assumed to be independent of the temperature, the junction temperatures T'_2 and T'_3 can be obtained by extrapolation. The interface conductance, h, for the joint can then be determined by:

$$h = \frac{k_1[(T_1 - T_2)/(x_2 - x_1)]}{(T'_2 - T'_3)} \quad \text{(Eq 13)}$$

A test fixture, as shown in Fig. 6, is used to measure the thermal contact conductance between two dies. It consists of a hollow punch that is machined, ground, and then screwed onto a steel punch adaptor. The adaptor is fastened to the upper platen of the testing machine. A copper disk with cartridge heaters is used to heat the punch head.

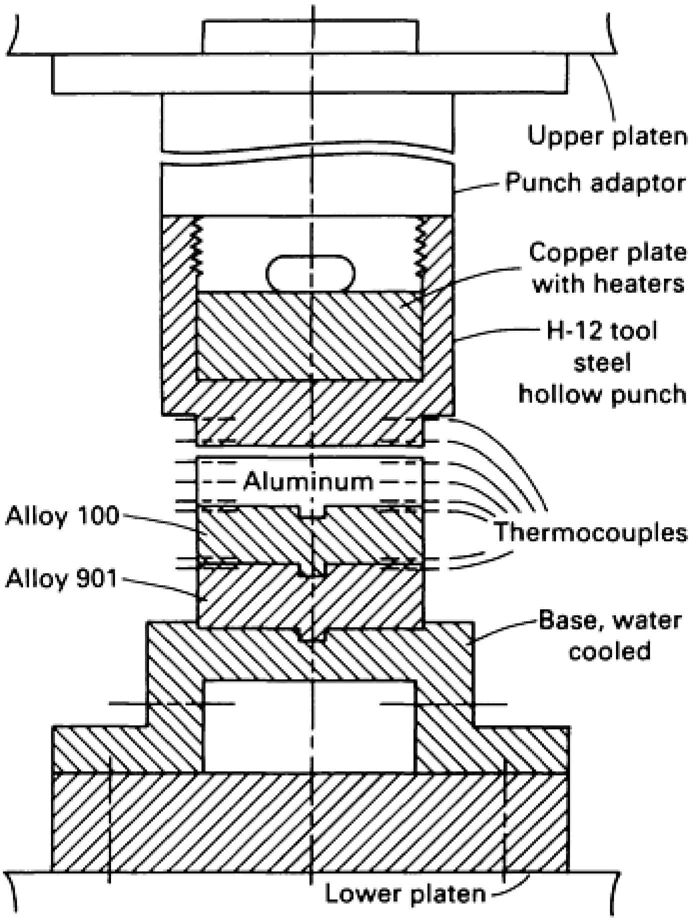

Fig. 6 Schematic of heat-transfer coefficient test fixture for measuring thermal contact conductance between two dies. The sample material tested is aluminum.

The punch is machined in two pieces to facilitate insertion of the copper plate. A voltage regulator is used to vary the heater output. The base of the fixture is mounted on the lower platen of the testing machine and can be cooled by water. A number of instrumented dies machined from various superalloys, such as Waspaloy, Alloy 901 (UNS N09901), Alloy 100 (Ni-15Co-10Cr-5.5Al - 4.7Ti - 3.0Mo - 1.0V - 0.6Fe - 0.15C-0.06Zr-0.015B), H-12 tool steel, and type 347 can be stacked on the base. This simulates the behavior of the stacked dies currently used by major forging companies. The punch head is heated to a high temperature and brought into contact with the lower dies. Each die disk is instrumented for temperature measurement. The temperature is measured at three different levels by thermocouples inserted in 0.51 mm (0.020 in.) diam holes machined by electrical discharge machining. Two thermocouples are used at each interface level. Therefore, temperature is measured at six different locations in each die to obtain temperature profiles and interface temperatures.

Acquisition of Data for Forging Process Design

Introduction

A BLANK is a shape cut from flat or preformed stock. Ordinarily, a blank serves as a starting workpiece for a formed part; less often, it is a desired end product. This article will discuss the production of blanks from low-carbon steel (such as 1008 and 1010) sheet and strip in dies in a mechanical or hydraulic press.

Improving the quality of blanked edges by shaving is discussed later in this article. Fine edge blanking is treated in the article "Fine Edge Blanking and Piercing" in this Volume. Shearing, a method of making blanks without using a die, is dealt with in the articles "Shearing of Plate and Flat Sheet" and "Slitting and Shearing of Coiled Sheet and Strip" in this Volume.

Methods of Blanking in Presses

Cutting operations that are done by dies in presses to produce blanks include cutoff, parting, blanking, notching, and lancing. The first three of these operations can produce a complete blank in a single press stroke. In progressive dies, two or more of these five operations are done in sequence to develop the complete outline of the blank and to separate it from the sheet, strip, or coil stock.

Trimming is defined as the cutting off of excess material from the periphery of a workpiece. It is usually done in dies and is similar to blanking. It is often the final operation on a formed or drawn part.

The applications of these methods are described in examples throughout this article. Other examples of these methods of producing blanks are provided in the articles "Piercing of Low-Carbon Steel," "Blanking and Piercing of Electrical Steel Sheet," "Press Forming of Low-Carbon Steel," "Press Forming of High-Carbon Steel," and "Deep Drawing" in this Volume.

Cutoff. This operation consists of cutting along a line to produce blanks without generating any scrap in the cutting operation, most of the part outline having been developed by notching or lancing in preceding stations. The cutoff line can take almost any shape--straight, broken, or curved. After being cut off, the blanks fall onto a conveyor or into a chute or container.

A cutoff die can be used to cut the entire outline of blanks whose shape permits nesting in a layout that uses all of the material (except possibly at the ends of the strip), as shown in Fig. 1. Alternating positions can sometimes be used in nesting (middle, Fig. 1) to avoid producing scrap except at strip ends. Cutoff is also used to cut blanks from strip that has already been notched to separate the blanks along part of their periphery, as described in the following example.

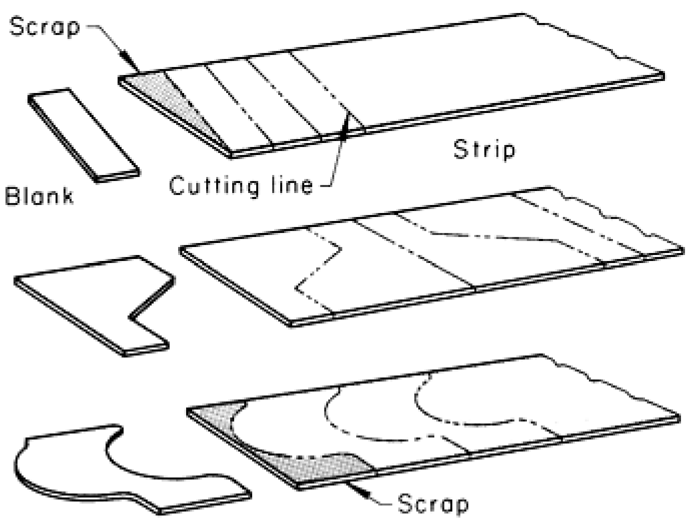

Fig. 1 Nested layouts for making blanks by cutoff

Example 1: Use of Cutoff to Separate Blanks Partly Outlined by Notching.

Figure 2 shows the layout for the cutoff of blanks for automobile body-bolt brackets. The brackets were completed by piercing and forming.

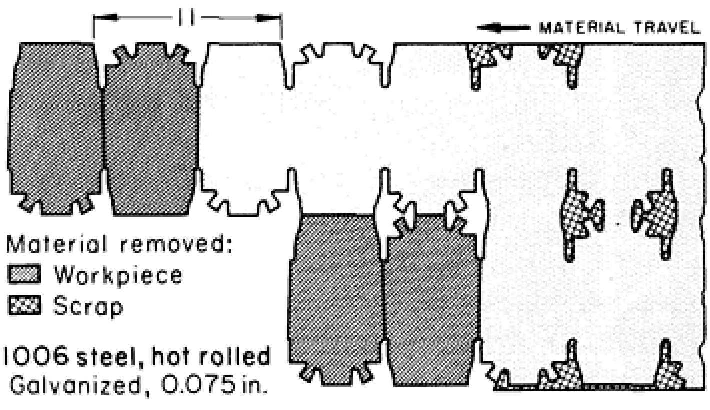

Fig. 2 Layout for the cutoff of four blanks at each press stroke from notched and seminotched strip. Dimensions given in inches

The coiled strip of galvanized hot-rolled 1006 steel was 1.90 mm (0.075 in.) thick by 495 mm (19.5 in.) wide. This was wide enough for two blanks, as shown in Fig. 2. The blanks were alternated in the layout to facilitate trimming and piercing.

The strip was notched and seminotched in the first stations of a progressive die (making a small amount of scrap). In the following stations, straight cutoff punches made four blanks at each stroke without producing any additional scrap.

The work was done in a 3.6 MN (400 tonf) single-action mechanical press with an air cushion. The press was equipped with a double roll feed and made 50 strokes (200 blanks) per minute.

Advantages of cutoff in making blanks include:

- The die has few components and is relatively inexpensive
- Waste of material in blanking is minimized or eliminated
- The die can be resharpened easily, and maintenance costs are low

Disadvantages of cutoff include:

- It can be used only to make blanks that nest in the layout without waste
- Cutting of one edge causes one-way deflection and stress
- Accuracy may be affected adversely by the method of feeding

Parting (Fig. 3) is the separation of blanks by cutting away a strip of material between them. Like cutoff, it can be done after most of the part outline has been developed by notching or lancing. It is used to make blanks that do not have mating adjacent surfaces for cutoff (Fig. 3) or to make blanks that must be spaced for ease of handling in order to avoid distortion or to allow room for sturdy tools. Some scrap is produced in making blanks by parting; therefore, this method is less efficient than cutoff in terms of material use.

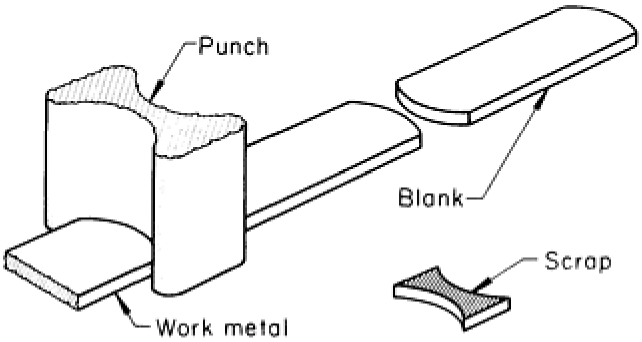

Fig. 3 Use of a parting punch to make blanks not having mating adjacent surfaces

Blanking (also called punching) is the cutting of the complete outline of a workpiece in a single press stroke. Because a scrap skeleton is usually produced, blanking involves some material waste. However, blanking is usually the fastest and most economical way to make flat parts, particularly in large quantities.

The skeleton left by blanking sometimes has only scrap-metal value, but many shops have organized programs to maximize the use of cutouts and sizable scrap skeletons in making other production parts. Material waste is completely avoided by using the scrap skeleton that remains from certain blanking operations to provide perforated stock for such items as air filters for forced-air furnaces.

Piercing (with a flat-end punch), also called punching or perforating, is similar to blanking except that the punched-out (blanked) slug is the waste and the surrounding metal is the workpiece. Piercing is discussed in the article "Piercing of Low-Carbon Steel" in this Volume.

Notching is an operation in which the individual punch removes a piece of metal from the edge of the blank or strip (Fig. 4). Notching is done for such reasons as the following:

- To free some metal for drawing (Fig. 4a) and for forming (Fig. 4b) while the workpiece remains attached to the strip
- To remove excess metal before forming (Fig. 4c)
- To cut part of the outline of a blank that would be difficult to cut otherwise (Fig. 2 and Fig. 28)

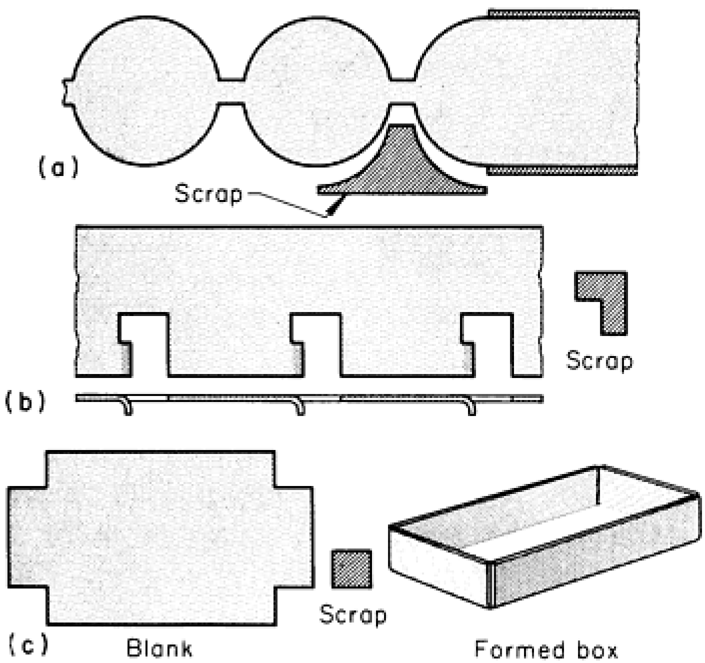

Fig. 4 Notched work illustrating the use of notching for freeing metal before drawing (a), and before forming (b), and for removing excess metal before forming (c)

The piercing of holes of any shape in a strip to free metal for subsequent forming or to produce surfaces that later coincide with the outline of a blanked part is sometimes called seminotching. The pierced area may outline a portion of one part or of two or more adjacent parts in a strip. Figure 2 illustrates a progressive-die layout incorporating seminotching.

Lancing is a press operation in which a single-line cut or slit is made part way across the strip stock without removing any metal. Lancing is usually done to free metal for forming (Fig. 5). The cut does not have a closed contour and does not release a blank or a piece of scrap. In addition to its use in freeing metal for subsequent forming, lancing is also used to cut partial contours for blanked parts, particularly in progressive dies.

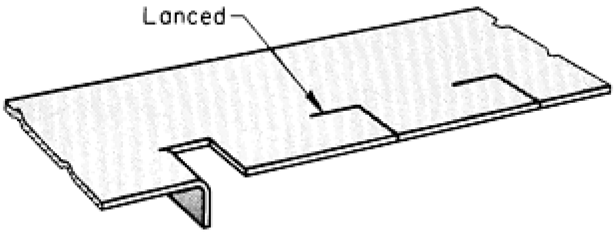

Fig. 5 Strip that was lanced to free metal for forming

Trimming is an operation for removing excess metal (such as deformed and uneven metal on drawn or formed parts) and metal that was used in a previous operation (such as a blankholding flange for a draw operation). Trimming is done in several ways, depending on the shape of the workpiece, the accuracy required, and the production quantity.

Figure 6 illustrates the tooling for trimming a horizontal flange on a drawn shell in a separate operation. The drawn shell is set on a locating plug for trimming. After scrap from a sufficient number of trimmed shells has accumulated, the piece of scrap at the bottom is severed at each stroke of the press by the scrap cutters shown in Fig. 6, and falls clear. Except that the die must be constructed to accept and locate the drawn shell, the operation is identical to the blanking of a flat workpiece and produces square edges of the same accuracy and quality. A drawn shell or formed part can be trimmed in a press without leaving a flange on the completed part by using one of three methods: pinch trim, shimmy trim, or trim and wipe-down.

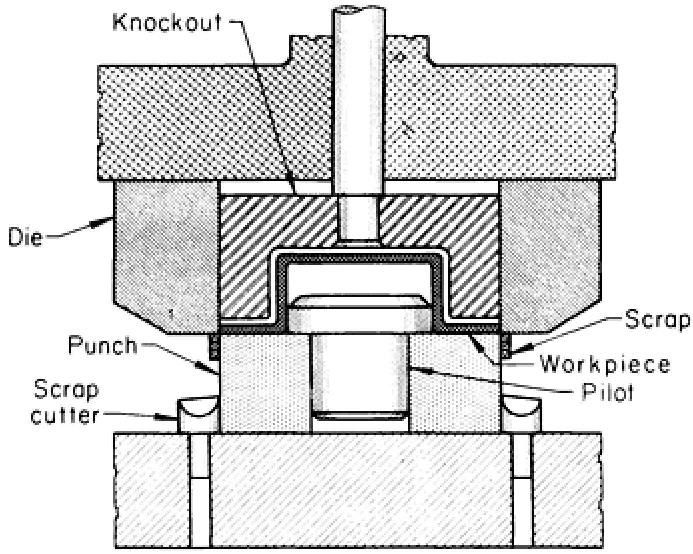

Fig. 6 Single-operation die for trimming a horizontal flange on a drawn shell

Pinch trimming, shown as a separate operation in a push-through die in Fig. 7, is done only on a part that has at least a narrow flange as-formed. The shell must be free from wrinkles at or near the trimming line. The trimmed edge is not square with the sidewall, but has the general shape shown in the lower right corner of Fig. 7. The accuracy of height resulting from pinch trimming is affected by variations in wall thickness and flange radius. To ensure an even pinch-off and to avoid sharp or rough edges, clearance between punch and die must be held to a minimum, and the punch must be kept sharp.

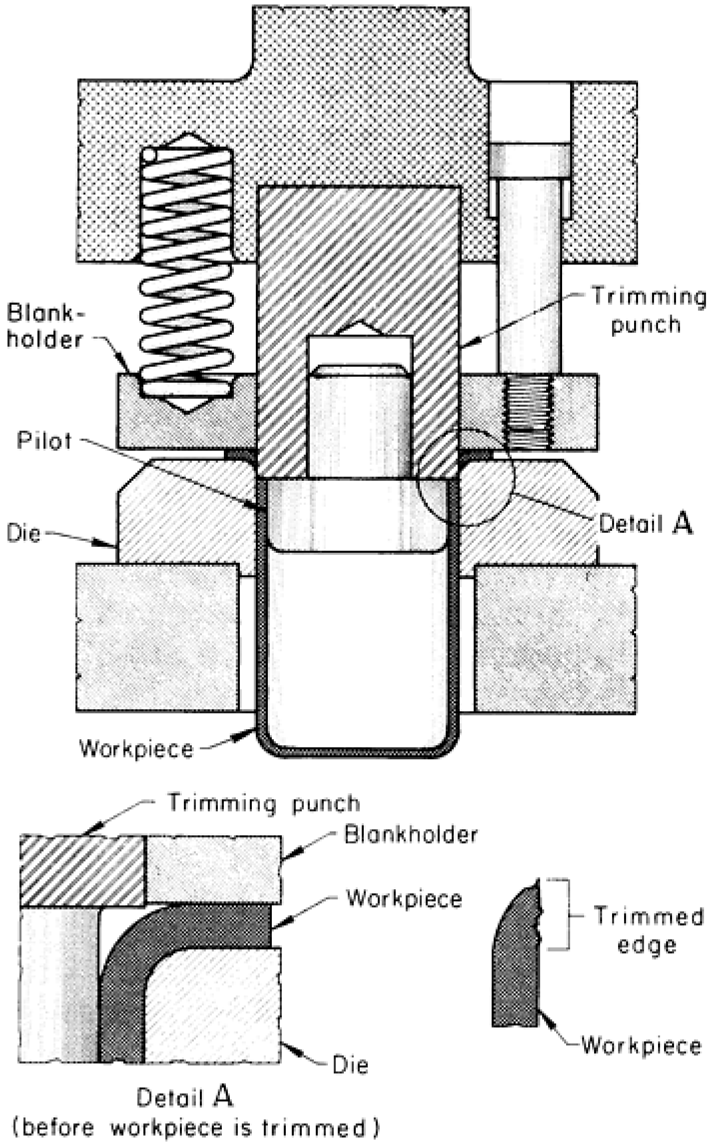

Fig. 7 Pinch trimming a drawn shell in a push-through die

Pinch trimming is also done without a blankholder or hold-down, using a die otherwise similar to that shown in Fig. 7. The scrap rings can be blown off the die at each stroke. In another method, the scrap rings climb the punch until they are severed by being compressed against a scrap cutter, after which they are spread apart and allowed to run out along a track for disposal. Pinch trimming without a blankholder is particularly well suited to the high-volume production of eyelets and other small parts.

Pinch trimming is primarily a mass production method. The production rate is high because only one stroke of the press is required to complete the trim. The method is often combined with drawing in a compound draw-and-trim die to reduce production costs further. The disadvantages of pinch trimming are excessive burrs, sharp cut edge, and high die maintenance.

Shimmy Trimming. In trimming with a shimmy die (also known as Brehm or model trimming), the drawn shell is held in a close-fitting die of the exact shell height and trimmed in segments by the successive horizontal oscillations of an internal cam-actuated punch toward the outside of the shell. The resulting trimmed edge is square and closely resembles the conventional blanked edge on a flat part. Shell height is more accurate than with pinch trimming. In addition to its application to shells that must have square, accurate edges, shimmy trimming is used on shells that have a wrinkled or otherwise nonuniform top edge as-drawn (cutoff is done below the defects) and on shells that cannot be produced economically with even the narrow flange needed for pinch trimming.

Tooling costs for shimmy trimming are much higher than those for pinch trimming. Shimmy trimming is also slower because it requires four or more oscillations of the punch in one press stroke and cannot be combined with other operations in a compound die. Shimmy dies are inexpensive to maintain because they remain in alignment and therefore are not likely to wear by shearing or chipping.

Trim and Wipe-Down. In this type of trimming, a flange is cut to width using a die such as that shown in Fig. 6 and then wiped or straightened into line with the sidewall of the shell or formed part. Because of narrow flange width, trimming and wiping down may be two operations.

The edge is square with the sidewall, but the shell height may be slightly irregular because of the forming characteristics of the metal. In addition, a ring may be visible at the original location of the flange radius.

Trimming, other than shimmy trimming, is frequently combined with one or more other operations in a compound die. Trim stock is often left on a drawn or formed workpiece so that it can be trimmed to size in a second operation. This is done to obtain the most accurate relationship of some other feature, such as a pierced hole, to the trimmed outline of the workpiece.

Characteristics of Blanked Edges

The sheared edges of a blank produced in a conventional die are not smooth and vertical for the entire thickness of the part, but exhibit the characteristics represented on an exaggerated scale in Fig. 8. The blank is shown in the position in which it would be cut from the work metal by the downward motion of the punch. A portion of the stock remaining after removal of the blank is shown at the top of the illustration.

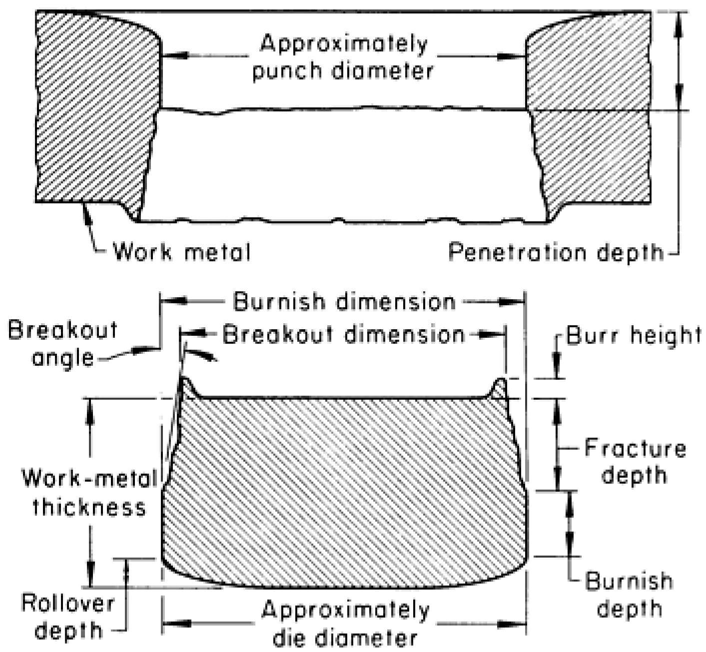

Fig. 8 Characteristics of the sheared edges of a blank. Curvature and angles are exaggerated for emphasis.

Rollover on the lower edges of the blank develops by plastic deformation of the work metal as it is forced into the die by the punch. Compression of the metal above the rollover zone against the walls of the die opening burnishes a portion of the edge of the blank, as shown in Fig. 8. As the punch completes its stroke, the remaining portion of the blank edge is broken away or fractured (resulting in die break), and a tensile burr is formed along the top of the blank edge.

The angle of the fractured portion of the edge is identified in Fig. 8 as the breakout angle. The breakout dimension of the blank and the burnish dimension of the hole in the scrap skeleton are approximately equal to the corresponding punch dimension, and the burnish dimension of the blank is very close to the corresponding die dimension. Therefore, the punch determines the hole size, and the die governs the blank size.

Penetration depth, or the amount of penetration of the punch into the work metal before fracture occurs, is shown on the edge of the remaining stock or scrap skeleton in Fig. 8. This depth is approximately equal to the sum of the rollover depth and the burnish depth on the blank, except when low die clearance produces secondary burnish. It is usually expressed as a percentage of the work metal thickness.

The percentage of penetration (before fracture) depends on the properties of the work metal, as shown in Table 1, which gives approximate values for various steels and nonferrous metals under typical blanking conditions. The percentage of penetration affects energy consumption and cutting force in blanking, as described in the section "Calculation of Force Requirements" in this article.

Table 1 Approximate penetration of sheet thickness before fracture in blanking

Work metal	Penetration, %
Carbon steels[a]	
0.10% C, Ann	50
0.10% C, CR	38
0.20% C, Ann	40
0.20% C, CR	28
0.30% C, Ann	33
0.30% C, CR	22

Zinc alloys	50

(a) Ann, annealed; CR, cold rolled

Die Clearance

The terms clearance, die clearance, and punch-to-die clearance are used synonymously to refer to the space between punch and die. Clearance is important for the reliable operation of the blanking equipment, the quality and type of cut edges, and the life of the punch and die. In general, the effects of clearance on these factors in blanking are the same as in piercing and are discussed in the article "Piercing of Low-Carbon Steel" in this Volume. The same article also describes the edge characteristics of slugs produced in piercing holes (see Fig. 2 of that article). The data in that illustration can serve as a guide for selecting clearances for blanking. All clearance values given in this article are per side, except where indicated.

Optimal blanking clearance may sometimes be less than optimal piercing clearance. This is partly because the blanked edge is generally close to the stock edge, and material expansion is therefore less restricted. A piercing tool must move a great deal of material away from its cutting edge, and for longest life, the clearance should be selected to eliminate as much compressive loading on the work metal as possible.

A part blanked using clearance much greater than normal may exhibit double shear, which is ordinarily evident only with extremely small clearance (see edge types 4 and 5 in Fig. 2 in the article "Piercing of Low-Carbon Steel" in this Volume). In addition, a part blanked using large clearances will be smaller than the die opening (except for a deeply dished blank), and it is difficult to correct the tooling to compensate for this. In some applications, retaining the blank becomes almost as great a problem as expelling the slugs into a die cavity after piercing, because of the increased clearance.

Relief in a blanking die (Fig. 9) is the taper provided so that the severed blank can fall free. The relief angle may range from $\frac{1}{2}$ to 2° from the vertical wall of the die opening. Relief in a die is sometimes called draft or angular clearance. In some dies, the relief may start at the top of the die surface and have a taper of only 0.002 in./in. (0.002 mm/mm) per side. In other dies, there is a straight, vertical wear land between the top of the die and the relief.

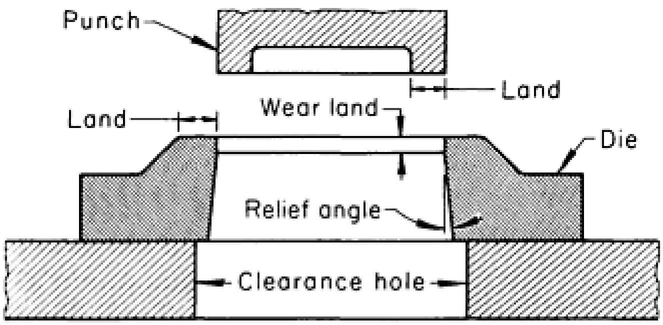

Fig. 9 Relief in a blanking die

Calculation of Force Requirements

Calculation of the forces and the work involved in blanking gives average figures that are applicable only when the correct shear strength for the material is used and when the die is sharp and the punch is in good condition, has correct clearance, and is functioning properly. The total load on the press, or the press capacity required to do a particular job, is the sum of the cutting force and other forces acting at the same time, such as the blankholding force exerted by a die cushion.

Cutting Force: Square-End Punches and Dies. When punch and die surfaces are flat and at right angles to the motion of the punch, the cutting force can be found by multiplying the area of the cut section by the shear strength of the work material:

$$L = S_s\, tl \qquad \textbf{(Eq 1)}$$

where L is the load on the press (in pounds) (cutting force), S_s is the shear strength of the stock (in pounds per square inch), t is the stock thickness (in inches), and l is the length or perimeter of the cut (in inches). The shear strengths of various steels and nonferrous metals are given in Table 2.

Table 2 Shear strengths of various steels and nonferrous metals at room temperature

Metal	Shear strength	
	MPa	ksi
Carbon steels		
0.10% C	241-296	**35-43**
0.20% C	303-379	**44-55**
0.30% C	358-462	**52-67**
High-strength low-alloy steels	310-439	**45-63.7**
Silicon steels	414-483	**60-70**
Stainless steels	393-827	**57-129**
Nonferrous metals		
Aluminum alloys	48-317	**7-46**
Copper and bronze	152-483	**22-70**
Lead alloys	13-40	**1.83-5.87**
Magnesium alloys	117-200	**17-29**
Nickel alloys	242-800	**35-116**

Tin alloys	20-77	**2.90-11.1**
Titanium alloys	414-483	**60-70**
Zinc alloys	**97-262**	**14-38**

Cutting Force: Dies With Shear. For cutting large blanks, shear can be applied to the face of the die by grinding it at an angle to the motion of the punch (Fig. 10), but shear is not used in cutting small blanks. Shear reduces shock in the press, as well as blanking noise and blanking force, but the same amount of work is done as with a flat die surface.

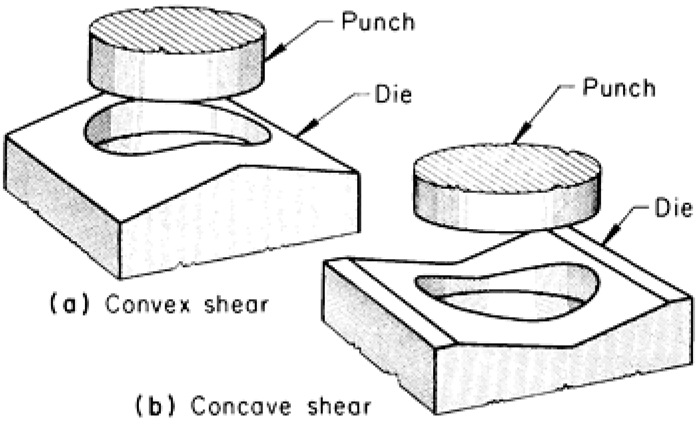

Fig. 10 Convex shear and concave shear on blanking dies. Angle and depth of shear are exaggerated for emphasis. Normally, depth of shear does not greatly exceed stock thickness.

The most common type of shear used on the die is convex (Fig. 10a). The apex of the die face is slightly rounded to avoid initiating a crack in the work metal. Concave shear (Fig. 10b) is somewhat more difficult to grind on the die, but holds the work metal more securely during blanking. A radius approximately equal to that of the grinding wheel is produced where the ground surfaces meet.

A third type of shear, sometimes used on a die for a large blank, consists of a wavy or scalloped surface around the die opening. This technique uses several convex and concave shear surfaces around the die opening. The punch load is distributed over the entire die surface, thus minimizing punch shift.

The amount of shear in a die can be less than or greater than stock thickness. Shear that is equal in depth or greater than the stock thickness is called full shear.

The cutting force for a die with shear can be calculated after first finding the work done (energy used) in blanking. The work done in blanking equals the force required in blanking (load on the press) multiplied by the distance that the force acted:

$$W = Ls \quad \textbf{(Eq 2)}$$

where W is the work done in blanking (in inch-pounds), L is the load (in pounds), and s is the distance the load acts (thickness multiplied by percentage of penetration before fracture) (in inches). To obtain accurate work values, the percentage penetration must be known accurately.

Cutting or blanking force is reduced by the use of angular shear in the die; the amount of reduction in force depends on the depth of the angular shear. The reduced average cutting force on the press is:

$$L_{sh} = \frac{W}{s + s_1} \quad \textbf{(Eq 3)}$$

where L_{sh} is the average cutting force (in pounds), with angular shear, W is the work done in blanking (in inch-pounds), s is the distance (in inches) that the load acts (thickness multiplied by percentage of penetration before fracture), and s_1 is the depth of angular shear (in inches).

In simplified practice, some plants ignore partial shear in calculating cutting force for blanking. When full shear is used, force is calculated as without shear and then reduced by 30%.

Stripping force is the force needed (when drop-through is not used) to free the blank from the die or the strip from the punch when they stick or jam because of springback. Stripping force can be calculated using:

$$L_{st} = kA \qquad \textbf{(Eq 4)}$$

where L_{st} is the stripping force (in pounds), k is a stripping constant (in pounds per square inch), and A is the area of the cut surface (in square inches) (stock thickness t multiplied by length or perimeter of cut l). Approximate values for the constant k (as determined by experiment for low-carbon steel) are:

- 1500 for sheet metal thinner than 1.57 mm (0.062 in.) when the cut is near an edge or near a preceding cut
- 2100 for other cuts in sheet thinner than 1.57 mm (0.062 in.)
- 3000 for sheet more than 1.57 mm (0.062 in.) thick

Factors That Affect Processing

Factors that affect the processing of blanks include the following:

- Size and shape of the blank
- Material for blanking
- Form in which the material is supplied
- Thickness of the blank
- Production quantity and schedule
- Quality specifications
- Availability of equipment and tools
- Number and type of subsequent operations required for completing the work

The size and shape of the blank affect the form and handling of the material blanked, the blanking method, and the handling of the completed blank. The thickness of the blank affects the press load required (see the section "Calculation of Force Requirements" in this article), the selection of equipment, and the choice of blanking and handling methods (see the section "Effect of Work Metal Thickness" in this article).

Production quantity and schedule determine the choice of equipment. A total production of fewer than 10,000 pieces is considered a short run; 10,000 to 100,000 pieces, a medium run; and more than 100,000 pieces, a long run.

Quality specifications and tolerances for thickness, camber, width, length, flatness, and finish affect the handling of the material. The availability of single-, double-, or triple-action presses (rated at various force capacities, sizes, speeds, lengths of stroke, strokes per minute, and shut heights) affects the selection of the processing method. The availability and capacity of auxiliary press equipment can have an effect on the selection of a tooling system and on whether a part can be made in-plant.

Operations that follow blanking also affect the choice of equipment, the processing method, and the handling procedures. Such subsequent operations may include piercing, bending, forming, deep drawing, machining, grinding, or finishing. Only rarely is the blank a final product.

Selection of Work Metal Form

Work metal for blanking in presses is usually in the form of flat sheets, strip, or coil stock. Less frequently, steel plate is blanked in presses (see the section "Effect of Work Metal Thickness" in this article). In some applications, the metal is preformed before blanking.

Special preparation of the work metal is usually not required for the blanking operation itself. However, annealing, leveling, or cleaning is often needed because of subsequent forming operations on the blank, as discussed in the article "Press Forming of Low-Carbon Steel" in this Volume.

Sheet or Strip. Flat sheet is usually the work metal for large blanks, such as automobile roofs. Square-sheared sheet can be used as a blank, or it can be blanked in a die. Small quantities of blanks, regardless of size, are usually made from straight lengths of sheet or strip.

Coil stock is used for mass production, whenever possible. In continuous production, the use of coil stock can save as much as one-third of the time needed for producing an equal quantity from flat stock. In addition, there are fewer scrap ends when coil stock is used.

Sheet metal is the least expensive when it is supplied in large coils from the mill. For most applications, the coil must be slit to the proper width for blanking, and some edge material must be trimmed off. Parts can sometimes be made most economically in a progressive die by using coil stock that is the width of the developed blank.

Blank Layout

In the medium and high production of medium-size blanks, the cost of material is 50 to 75% of the total cost of the blank; for large blanks, it may be more than 95% of the total cost of the blank. Substantial savings in net material cost can often be achieved by coordinating blank layout with the selection of stock form and width to minimize the amount of scrap produced.

Several trial layouts may be needed to find the width of stock and the layout that use the material most efficiently while taking into account the possible effects of orientation of parts on subsequent operations. The layout must include the minimum workable scrap allowance between blanks, providing just enough material to support or hold down the strip during blanking. Scrap allowances, based on the use of well-maintained equipment and good shop practice, are given in Table 3.

Table 3 Scrap allowance for blanking

Work metal	Scrap allowance when length of skeleton segment between blanks or along edge is:											
	2*t* or less						Greater than 2*t*

(a) Allowance between blanks in the same row and also between blanks of the first and second rows.

(b) Allow 1.52 mm (0.060 in.) between blanks at first and second rows.

(c) When the blank edge is parallel to the edge of the stock or when the length of the skeleton segment between blanks is more than 4*t*, scrap allowance is 1.8*t*.

The percentage of scrap in a strip layout can be calculated as:

$$100\left(1-\frac{A_B}{A_S}\right) \quad \textbf{(Eq 5)}$$

where A_B is the area of blanks produced in one press stroke and A_S is the area of strip consumed by one press stroke, or strip width times feed length.

Round blanks can be staggered in rows, at the same spacing as for hexagons (Fig. 11), for the most efficient blanking from a long strip. With such a layout, 20 to 40% more blanks can be made from a given amount of material than by blanking each circle from a separate square. With the layout shown in Fig. 11, each press stroke (after the third stroke) produces four blanks--spaced to provide enough room for mounting the punches and dies.

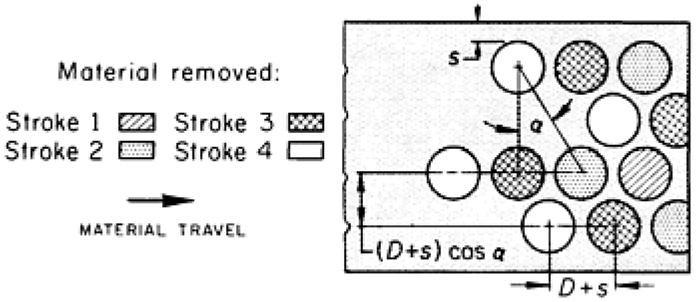

Fig. 11 Strip layout for blanking four circles per stroke with minimal material waste

The percentage of scrap loss for the layout of Fig. 11 can be calculated using Eq 5 and the following:

$$\begin{aligned} A_B &= \frac{n\pi D^2}{4} \\ A_S &= wl \\ l &= D + s \\ w &= (D + 2s) + (n - 1)(D + s)\cos\alpha \end{aligned} \qquad \textbf{(Eq 6)}$$

where n is the number of rows of blanks across the strip width, D is the blank diameter (in inches), l is the feed length (one blank made in each row per press stroke) (in inches), w is the strip width (in inches), s is the scrap allowance from the edge of the strip to the blank and between blanks (in inches), and α is the angular displacement between blanks (in degrees). The area of the holes pierced in a blank is not considered in these calculations, because it does not affect the efficiency of the layout.

Rectangular blanks can generally be laid out more easily than other shapes.

Odd-shape blanks are generally more difficult to lay out for the greatest economy.

Nesting, or the interlocking of blanks in the layout to save material, should be done wherever the shape of the blank permits. Nesting is possible with many irregular blanks.

Figure 12 shows a layout in which irregular blanks are nested so that an appreciable amount of material is saved. A double die can be used with such a layout, blanking two pieces per stroke. A single die can be used for short runs; the strip is turned around after the first pass and fed through the die again.

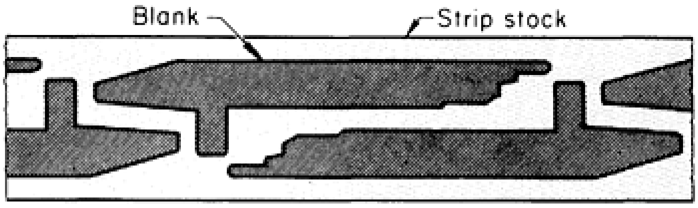

Fig. 12 Nesting of irregular blanks in layout to save material

Another way of nesting blanks is a layout such as that illustrated in Fig. 13. With this layout, three punches cut four pieces per stroke (after the third press stroke) in a shearing action that produces no scrap except at the ends of the strip. Other strip layouts in which the blanks have been nested are shown in the articles "Press Bending of Low-Carbon Steel" and "Press Forming of Low-Carbon Steel" in this Volume.

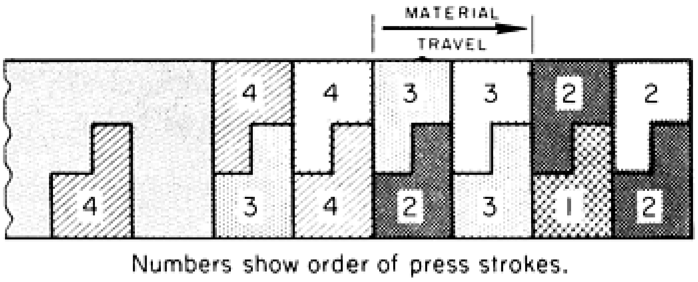

Fig. 13 Layout for the scrapless blanking of four blanks per press stroke, using three punches. The three shaded shapes for each press stroke denote the blanks produced directly by the three punches. The unshaded shape for each press stroke denotes a blank produced by the action of adjacent punches.

Use of Full Stock Width. Blanks that have two parallel sides can sometimes be made most economically in a layout that uses the full width of the stock. The remaining outline of the blank is produced by shearing, lancing, notching, parting, or a combination of these.

Effect of Rolling Direction. For blanks that must later be bent or formed, consideration must be given in layout to the orientation of the blanks with respect to the direction of rolling (grain direction). Ideally, blanks should be laid out so that severe bends are made with the bend axis at right angles to the direction of rolling or, if this is not practical, with the bend axis at an angle to the direction of rolling. Stretching should be in the direction of rolling, whenever possible. Examples and illustrations of blank layouts made to take advantage of the direction of rolling are provided in the articles "Press Bending of Low-Carbon Steel" and "Press Forming of Low-Carbon Steel" in this Volume.

Welded Blanks

Welded blanks are used when they have advantages over one-piece blanks, as in the following situations:

- The welded blank may cost less than an equivalent one-piece blank if scrap or other low-cost metal can be used to make the welded blank or if tooling and production for the one-piece blank cost more than for the welded blank.
- Stock for a welded blank may be more readily available than stock for an equivalent one-piece blank.
- The blank may have a shape that would waste more material if it were made in one piece instead of being welded. Material can sometimes be saved by welding projecting portions, such as tabs and ears, to simpler shapes.
- The welded blank, when used in subsequent forming operations, may reduce the cost of tooling. Flat or simple shapes are welded in a layout designed to avoid the presence of seams in certain portions of the blank and to permit automatic welding, if possible.

Large blanks that would cost extra because of width or for other reasons if they were made in one piece can sometimes be made at less cost by welding.

Difficult shapes that would waste a considerable amount of material if they were made in one piece can sometimes be made by welding two or more simple blanks together. In the application described in the following example, two developed blanks were welded and then formed into a bent channel.

Example 2: Use of Two Gas Metal Arc Welded Blanks to Form an Automobile-Frame Rail.

Figure 14 shows a side rail for an automobile frame that was formed from 5.05 mm (0.199 in.) thick hot-rolled commercial-quality 1008 steel. The blank for this rail had a shape that could be made in one piece only with excessive waste of metal in scrap. The two pieces used were blanked from nested layouts with little scrap waste.

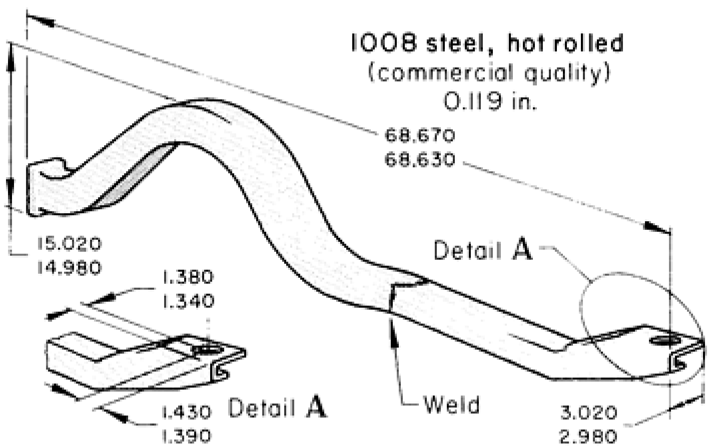

Fig. 14 Automobile-frame side rail that was formed from two blanks joined by gas metal arc welding. Dimensions given in inches.

Blanking was done in a die that made both pieces in a single press stroke. The two portions were butted and joined by high-speed automatic gas metal arc welding and then formed. Tolerance on all dimensions shown in Fig. 14 was ±0.51 mm (±0.020 in.).

The savings in metal exceeded the cost of welding, but if production needs had been fewer than 10,000 pieces, the savings in metal would not have paid for the welding and the blanking dies. The production quantity was 300,000 rails made in lot sizes of 20,000 pieces.

Open Shapes. A blank with a large cutout can sometimes be made at less cost than a one-piece blank by welding simpler pieces together.

Waste metal can sometimes be joined by welding to make a blank that costs less than a one-piece blank.

Welding methods used in making blanks include resistance welding methods (lap-seam, spot, foil butt-seam, mash-seam, flash, and high-frequency butt) and fusion welding.

Lap-seam welding (wheel electrodes) is a frequently used method. Tooling is simple if the components are joined first by tack welding. The disadvantages of lap-seam welding are loose edges, and joints that are double the thickness of the work metal.

Spot welding is fast and needs only simple, inexpensive tooling. The disadvantages of spot welding are loose edges, and joints that are not tight and are not as strong as those made by other methods.

Foil butt-seam welding is a fast method that makes smooth, tight joints with no loose edges. Its disadvantages include the cost of adding foil to one or both sides of the seam and the need to use starting tabs to make strong joints.

Mash-seam welding makes smooth joints that often need no grinding and tight joints that have no loose edges. Disadvantages include the short life of electrodes, and the high cost of tooling resulting from the difficulty in maintaining the small overlap.

Flash welding uses simple tooling; the joints are tight and free from loose edges. However, the length of joint that can be produced by flash welding is limited, and the joints are rough and therefore must be ground before the weldment can be worked in a die.

High-frequency butt welding is fast and can be used to join two dissimilar metals. Electrode life is good. However, costly equipment is required, and the technique is generally suitable only for mass production.

Fusion welding methods include gas metal arc welding and gas tungsten arc welding.

Presses

Most blanking is done in single-action mechanical presses. Some dies can be used only with a particular type of press; the die is usually made to suit a specific press. The force capacity rating must be adequate for the work and must be well above the calculated cutting force (see the section "Calculation of Force Requirements" in this article). Press capacities are given in kilonewtons (tons of force) at a certain distance above the bottom of the stroke. This distance must suit the die and the operation. Most blanking is done near the bottom of the stroke where the available force is greatest. In compound dies, blanking may be done near midstroke, where the available force is much lower than that at the bottom.

Size of bed, shut height, stroke length, and speed must all be suitable for the die and the work. Some types of dies can be run at high speeds, and some need moderate or slow speeds, as discussed in the following section in this article.

Construction and Use of Short-Run Dies

Small and medium quantities of blanks are often produced in punch presses by the use of inexpensive short-run dies. These include steel-rule dies, template dies (sometimes called plate dies or continental dies), and subpress dies. Although most applications of such dies are for production quantities of a few hundred to 10,000 pieces, suitably constructed dies of these types have been used for quantities of 100,000 pieces or more.

Short-run dies are used to a limited extent to blank initial quantities of parts that are to be mass produced. Because they can be made and put into operation more quickly than conventional dies, short-run dies make it possible to expedite the delivery of completed parts.

In addition, short-run dies are used to produce trial lots of parts that may be subject to extensive changes in design. If the trial lots show that die design changes are needed, the changes can be made at less cost before the conventional die is completed. After the conventional die has been set up, either the entire production can be transferred to it or both dies can be used.

For small quantities (<100 pieces), even the most inexpensive short-run blanking die may not be justified. Such small quantities of blanks are generally cut at less cost with standard tools, such as a nibbler, a squaring shear, or a rotary shear. Small quantities of blanks can also be made by contour band sawing, routing, gas cutting, filing, or machining.

Steel-rule dies are simple, inexpensive dies that are made by setting thin, bevel-edge strips of high-carbon tool steel on edge to outline the blank. The rule is set tightly into a slot in plain or impregnated plywood, and the plywood is backed by a steel subplate, as shown in Fig. 15. The die plate or template is attached directly to a steel subplate, and both upper and lower subplates are fastened to master die shoes, which are mounted in a conventional press.

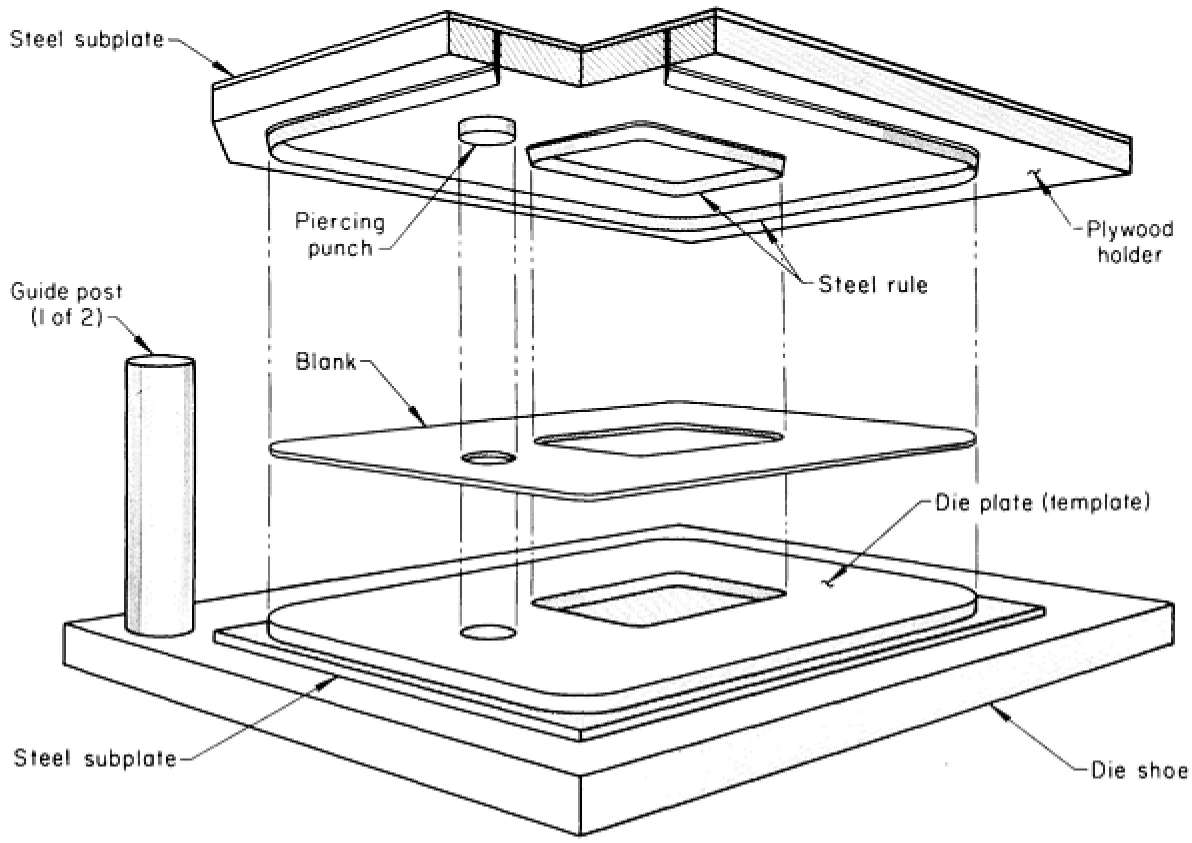

Fig. 15 Exploded view of a steel-rule die. See text for discussion.

Steel-rule dies are used for blanking, piercing, notching, and shallow forming. For work on flat blanks or on flat, sheared stock of low-carbon steel up to about 13 mm ($\frac{1}{2}$ in.) thick, a steel-rule die can usually be made more rapidly and at less cost than any other kind of die. Blanks as large as 1.2 × 2.1 m (4 × 7 ft) have been made in steel-rule dies.

Die. The steel rule that is used as the die is made of high-carbon steel or of a tool steel such as W1 or W2, in spring temper and other hardnesses. It is available in stock lengths in several thicknesses, ranging from 0.36 to 4.32 mm (0.014 to 0.170 in.), and in widths of 31.8 mm (1.25 in.) and narrower. Printers' rules of thickness from 1 to 12 points (0.36 to 4.32 mm, or 0.014 to 0.170 in.) are sometimes used. The finished rule usually has a square back edge, and a cutting edge that is ground to a 45° bevel or to a V-edge.

The back edge is fitted tightly into sawed slots in hard plywood as shown in Fig. 15 so that it will cut the outline of the blank. The steel subplate is used to back up the steel rule and to support the plywood.

Punch. For blanking low-carbon steel, a die plate (high-carbon or tool steel template) of the same shape as the required blank is used as the punch, opposing the steel rule. Other punch elements and die parts are added as needed to the die for piercing holes and slots at the same time that the blanking is done. Solid steel blocks, instead of a steel rule, can be used in the die to cut sharp corners and notches in the blank. For some work, including the cutting of paper and other soft materials, the punch can be a block of hard wood or a thick sheet of rubber or other soft material with a working surface that extends beyond the area enclosed by the steel rule.

Stripper. For cutting paper and leather, the steel-rule die is stripped by elastic material, such as sponge rubber, which is added to the die. In blanking low-carbon steel, blocks of tougher solid rubber can be used as strippers. Positive spring-loaded steel stripper plates are also used.

The accuracy of the blanks produced in steel-rule dies depends mainly on the skill of the diemaker and the care used in their construction. For noncritical parts blanked in steel-rule dies, the tolerance may be as large as ±0.8 mm ($\pm\frac{1}{32}$ in.); for more critical parts, the work can be located accurately to maintain a tolerance of ±0.13 mm (±0.005 in.). Closer tolerances on blanks can be obtained at increased cost by using rotary-head millers or jig boring machines in constructing the dies.

Because holes and slots made by steel-rule blanking are pierced with conventional punch and die elements that are added to the steel-rule die, they can be produced to the same tolerances as in conventional blanking. Steel-rule dies commonly blank laminations with burrs only 0.05 mm (0.002 in.) high.

Cost. A steel-rule die made to blank low-to-moderate quantities of low-carbon steel generally costs about 20% as much as a conventional die made for the mass production of similar work. The following example describes the use of a steel-rule die for stopgap and trial production of an automobile part. A die change was made inexpensively; after it was proved successful in the steel-rule die, the same change was then included in the design of the conventional die for production use.

Example 3: Use of a Steel-Rule Die for Temporary Production.

A steel-rule die was used to blank a part for an automobile frame in order to begin production without waiting until the conventional die could be delivered. It was expected that the steel-rule die would have to produce 325 blanks before production could be changed to the conventional die.

The die, shown in Fig. 16, was used in a 2.2 MN (250 tonf) straight-side press to blank annealed cold-rolled low-carbon steel, 3.96 mm (0.156 in.) thick by 229 × 229 mm (9 × 9 in.), with three 14 mm ($\frac{9}{16}$ in.) diam holes and three round-end slots 16 × 38 mm ($\frac{5}{8}$ × 1$\frac{1}{2}$ in.). Tolerances were ±0.81 mm (±$\frac{1}{32}$ in.) on the blank outline, and ±0.13 mm (±0.005 in.) on the pierced holes and slots. No burr limits were specified.

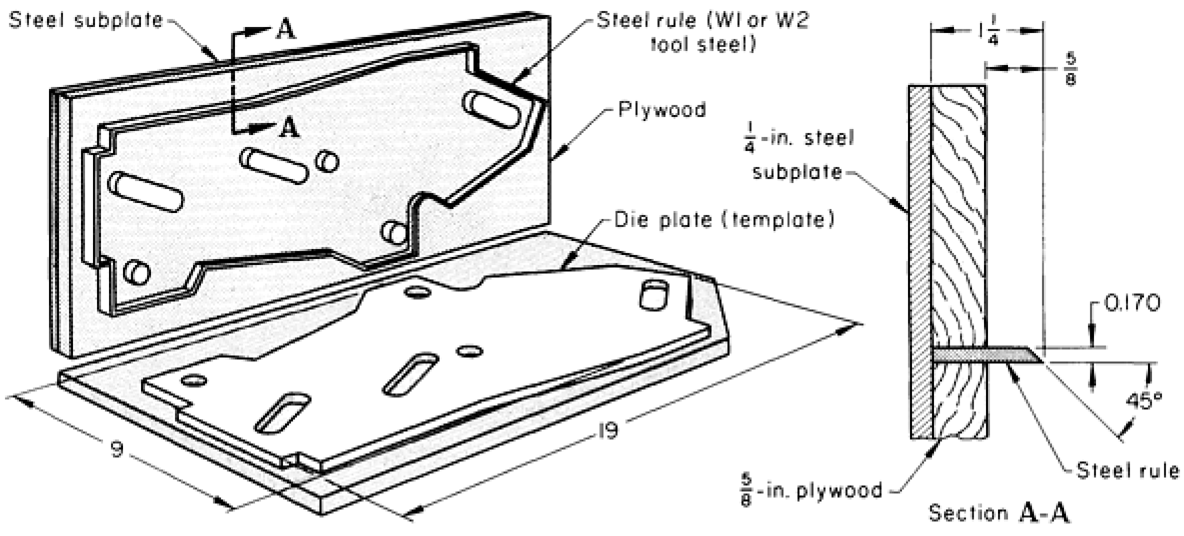

Fig. 16 Steel-rule die that was used as temporary tooling for the blanking of low-carbon steel sheet 3.96 mm (0.156 in.) thick. Dimensions given in inches

The steel rule was made of 12-point rule stock (4.32 mm, or 0.170 in., thick × 32 mm, or 1$\frac{1}{4}$ in., wide) set full depth into hard plywood 16 mm ($\frac{5}{8}$ in.) thick. A die plate of steel, which fit inside the rule, was used as the punch. The die was made by measuring a developed formed blank.

The ease and low cost of making a change in a steel-rule die proved important in this application because it was decided that one of the holes would not be needed. The punch that had been added for that hole was simply removed from the steel-rule die. After tryout, that hole was also eliminated in the conventional die before it was completed. The change, if made after the conventional die had been completed, would have cost much more.

The cost of the steel-rule die was 20% of the cost of the conventional die. Because the steel-rule die was fed and unloaded by hand, production was only a few pieces per minute. More than 1000 blanks were made in this steel-rule die.

Template dies (also called plate dies) are competitive with steel-rule dies in terms of cost and the quantity they can produce. Figure 17 shows an exploded view of the elements of a template die. Punches and die elements can be added, as in steel-rule dies, to combine piercing with blanking.

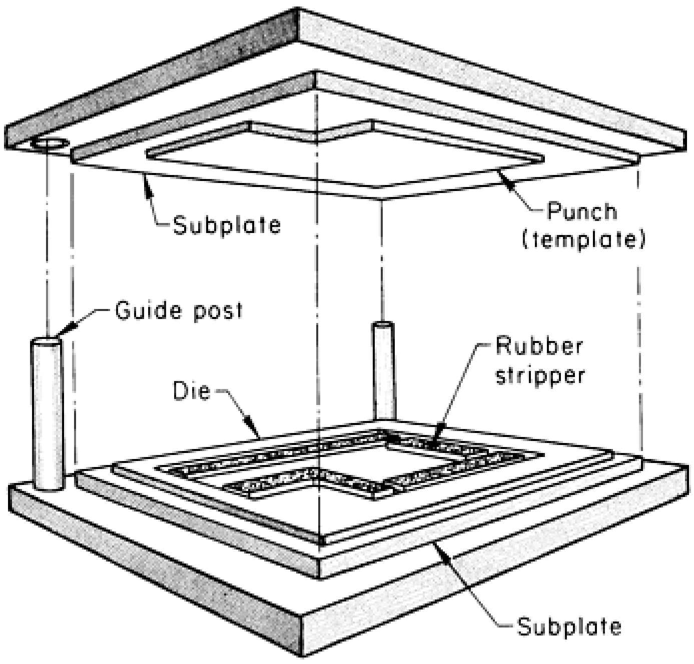

Fig. 17 Exploded view of a template die

Punch. The punch or template (Fig. 17) is made to fit the outline of the blank to be produced. The punch is usually made of medium-carbon steel plate (1040, 1050, or 4140) or of ground flat stock such as O2 tool steel, on which the edges may be flame hardened. In more difficult applications or where longer life is needed, the punch can be made of D2 or equivalent tool steel and hardened.

Die. The die is usually assembled of doweled, hardened blocks of steel, ground to fit the punch with proper clearance. The same materials are used as for the punch.

Construction. Typical clearance for template dies is 0.076 mm (0.003 in.). The construction shown in Fig. 17 is satisfactory for blanking low-carbon steel in the same types of applications as steel-rule dies. For severe blanking, a template die can be made stronger by using one-piece construction or adding pins to prevent the die blocks from spreading, and by nesting the die or die segments into a recess in the die backing plate (subplate).

Operation. A continuous strip of stock can be fed into a template die, feeding the stock against a stop for each press stroke and using a side guide for the stock. Blocks of tough rubber are usually used as strippers (Fig. 17), pushing the blank back into the strip so that the blank is removed from the die by the feed motion of the strip. A typical application of template dies is described in the following example.

Example 4: Blanking Laminations in a Template Die.

Motor laminations of 1.52 mm (0.060 in.) thick pickled hot-rolled low-carbon steel were blanked in a template die. The blank measured 318 × 140 mm (12.5 × 5.5 in.). The punch was made of a one-piece template, except for inserts that were provided where changes might be needed. The die was made with 0.076 mm (0.003 in.) clearance all around the punch (template).

The die was made of D2 tool steel. Rubber blocks were used for strippers, which pushed the blank back into the skeleton in the vertical press so that the blank was unloaded by the feeding of the stock. Hand feeding produced fewer than ten pieces per minute.

The burr was about 0.051 mm (0.002 in.)--well below the specified limit of 0.102 mm (0.004 in.). Estimated die life was 100,000 pieces.

Subpress dies are short-run die sets that are attached to the press bed, but in which the punch shoe is not attached to the ram. They require less setup time than conventional dies, but have a lower production rate. The length of stroke of a subpress die is limited because springs are used to raise the punch. Subpress dies are sometimes used to blank the precision parts used in instruments and timepieces.

Self-contained notching tools can be purchased ready to install as subpress tools. Notching units, consisting of both punch and die mounted in individual C-frame units, are available in a variety of standard-corner, V, and square-edge sizes for notching low-carbon steel in thicknesses to 6.4 mm ($\frac{1}{4}$ in.). Special shapes of irregular outline can be incorporated into standard notching units. The notching units can be used singly or in groups, and they can be used in combination with piercing tools of similar construction.

Each unit is self-contained and self-stripping by means of springs. The punches are held in close alignment and are not attached to the ram of the press. Each unit is located, pinned, and bolted to a die plate, template, or T-slot plate and is mounted on the bed of any type of press or press brake of adequate shut height.

This type of subpress tool can be used to make small blanks, but it is more commonly used to notch and pierce precut blanks. The units can be reused to produce parts of different shapes by relocating the tools.

Construction and Use of Conventional Dies

Conventional blanking dies consist basically of one or more mating pairs of rigid punches and dies and are the standard tooling for the production blanking of sheet metal in a press. Mating pairs of metal punches and dies are combined in various ways, and additional components are added to make up compound, progressive, transfer, and multiple dies.

Conventional dies are costly, specialized tools that are generally used for only one product, but they are so efficient, accurate, and productive that they are typically the best method of mass production at the lowest cost per piece. They are occasionally used for short-run production when tolerances are exceptionally stringent or when other reasons make the use of short-run dies impractical.

Conventional dies are more accurate than most short-run tooling, and they retain their accuracy for a greater number of pieces. They can also usually be resharpened after wear has affected their action or the quality of the work. Before dies are worn out, they have generally been resharpened many times. Conventional dies commonly produce several million blanks before replacement.

Tool materials used for blanking low-carbon steel sheet in conventional dies include (in order of increasing lot size for which they are recommended) 1020 steel; W1, O1, A2, and D2 tool steels; and, for extremely long runs, carbide. For long runs on steel thicker than about 6.4 mm ($\frac{1}{4}$ in.), M2 tool steel is often used instead of carbide because of the limited shock resistance of carbide. Type D2 tool steel is probably the most commonly used and most widely available tool material for the mass-production blanking of steel and other metals.

Cold-rolled sheet and hot-rolled pickled-and-oiled sheet are far less damaging to tools than gritblasted or hot-rolled unpickled surfaces. Tool materials that have a high resistance to abrasion, such as A2 or D2 tool steel, are recommended for use in tools for the blanking of sizable production lots of hot-rolled unpickled steel. Detailed information on the selection of tool materials and on tool life is available in the article "Selection of Material for Blanking and Piercing Dies" in this Volume.

Single-Operation Dies. The simplest conventional blanking dies are single-operation dies. They are used as separate units to produce blanks or as parts of more complex dies that perform several operations on a workpiece. The separate stations of a progressive die are similar to single-operation dies (although integrally constructed), and transfer presses use many single-operation dies.

The drop-through die is one of the commonest types (Fig. 18). In this die, the severed blank is forced through the die opening by the downward motion of the punch, and it drops through into a chute or container. This type of blanking die has a minimum number of parts and is relatively inexpensive. Another major advantage of drop-through blanking dies is their simple and reliable blank ejection system, which is usually compatible with the use of this type of construction in progressive or transfer dies. In other types of dies, the ejection system may be more complicated than the die itself.

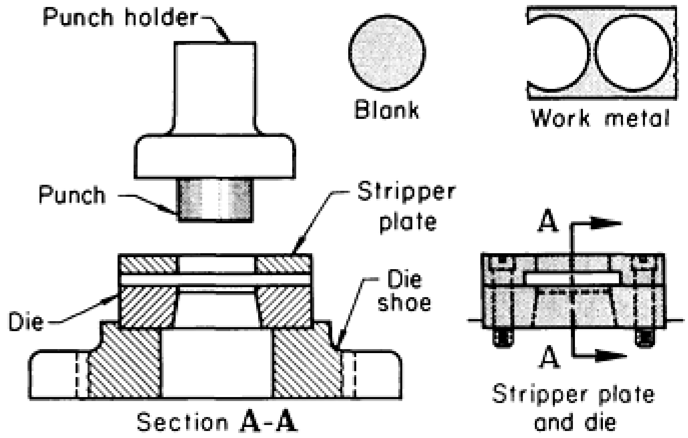

Fig. 18 Elements of a conventional drop-through blanking die

The disadvantages of drop-through dies for blanking include the following:

- Unless parallels are placed between the die and bolster, blanks must be small enough to go through the hole in the bed
- Blanks may distort by dishing
- Some shapes make drop-through difficult
- The die must be on the lower shoe and the punch on the upper shoe of the die set

Two other types of single-operation blanking dies--inverted and return dies--can be used when, because of size or susceptibility to damage, blanks or workpieces cannot be unloaded by dropping through the die, but can be removed between the die and punch faces.

Inverted dies (Fig. 19) have the punch on the lower shoe and the die on the upper shoe. A knockout pin releases the blank from the die, and the blank is removed mechanically or manually from the top of the punch. A scrap cutter is usually included so that the scrap can be blown or knocked away. The scrap is sometimes allowed to stack up in successive collars around the punch and is stripped off manually after a number of pieces have been blanked.

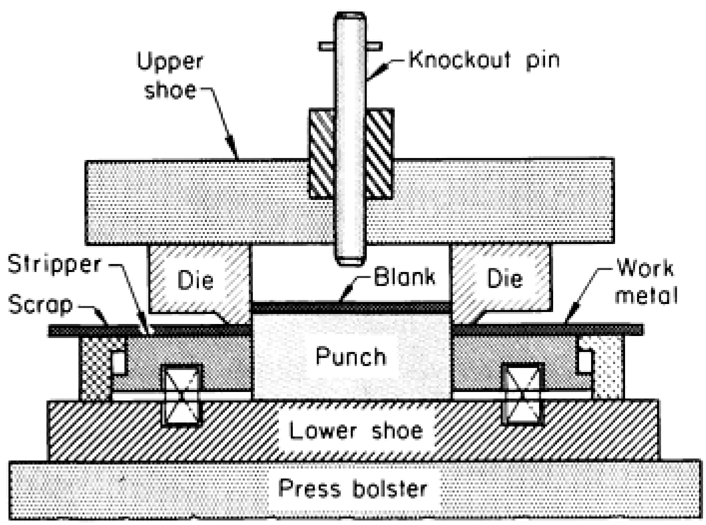

Fig. 19 Inverted blanking die with the punch on the lower shoe and the die on the upper shoe

Return dies (Fig. 20) are made in the usual way, with the punch on the upper shoe and the die on the lower shoe. The punch shears the blank and presses it into the die cavity, as with other types of blanking dies. A spring-loaded pressure plate or die cushion acts as an ejector for the die, returning the blank to the surface of the die, where it can be picked off manually or mechanically. A spring-loaded plate on the upper shoe acts as a blankholder on the downstroke and as a punch stripper on the upstroke. Like many inverted dies, a variation of the return die shown in Fig. 20 includes a scrap cutter (not shown in Fig. 20) that parts the ring of scrap so that it can drop away, can be blown away, or can be removed mechanically.

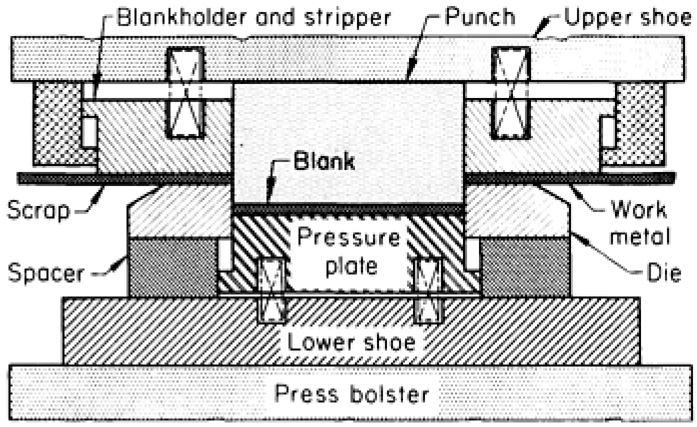

Fig. 20 Return blanking die with spring-loaded pressure plate that acts as a die cushion and an ejector for the die

Inverted and return dies have the advantage of not needing a clearance hole to let the workpiece or blank drop through. The main disadvantages of inverted and return dies are:

- They are more expensive than drop-through dies because they have more parts
- They may require careful adjustment and synchronization of external ejectors and air blasts, which adds to setup costs

Of the two types, inverted dies are generally simpler to construct and have less complicated knockout mechanisms than the pressure-plate or die-cushion ejectors in return dies.

Return dies are better suited to continuous strip operation because the strip remains in line and is not pressed down by the die over the punch. If the workpiece must be clamped before blanking, the blankholder or the pressure plate (or both) in a return die holds the workpiece or blank through the entire working stroke.

Instead of being removed by the methods described above, the severed blank is sometimes pushed back (completely or partly) into the strip to be removed later, as is sometimes done in a progressive die. Pushback can also be used for other purposes, such as to provide knockouts for fitting in electrical panels or junction boxes and in other sheet metal products. A flattening operation is sometimes added to assist pushback.

Compound dies perform several operations on the same workpiece in the same stroke of the press--such as blank and pierce, or blank, pierce, and form. Figure 21 shows the elements of a compound die for simultaneous blanking and piercing. In this die, the blanking punch is in the bottom; a hole in the punch is used as the piercing die. The piercing punch and the blanking die are in the top.

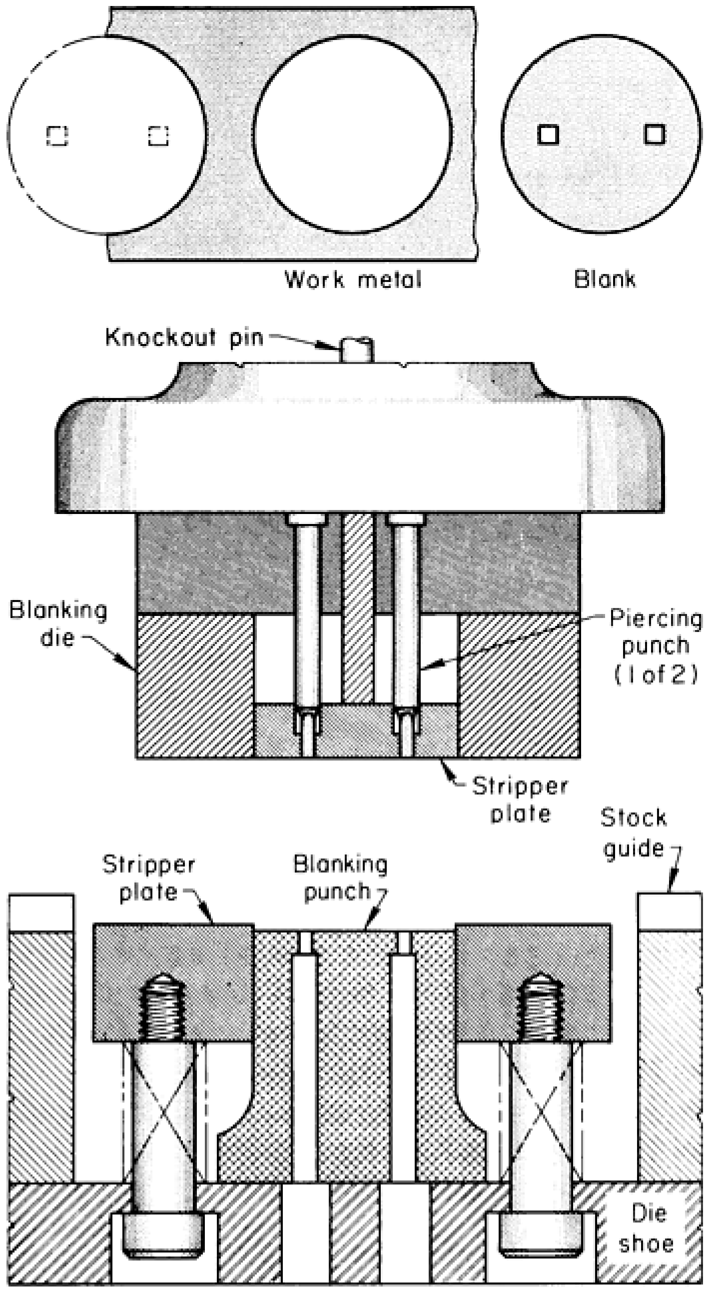

Fig. 21 Elements of a compound die for simultaneous blanking and piercing

Compound dies are generally more economical in mass production than a series of one-operation dies, and they are usually more accurate. For example, a compound die that blanks and pierces a workpiece can hold the spacing between pierced holes or the relation of the pierced hole to the edge of the blank more accurately than would be possible if the individual operations were done in separate dies. This is because of possible variation in locating the blank for piercing or in locating a prepierced strip for blanking.

Because the complexity of operation causes greater difficulties in unloading the workpiece, compound dies usually run slower than single-operation dies; the maximum speed of a compound die is about 250 strokes per minute. Other disadvantages of compound dies in comparison to single-operation dies are that they are more specialized (so that a change in the product is more likely to make the die obsolete) and that initial and maintenance costs are both higher. An advantage of compound dies is that, because of their slower operation, they generally produce more pieces per sharpening than single-operation dies.

A complex compound die can sometimes be more economical than two simpler compound dies in making the same part. This is illustrated in the following example.

Example 5: Replacing Two Two-Operation Dies With a Four-Operation Die.

The cup shown in Fig. 22 was originally produced from annealed cold-rolled low-carbon steel in two compound dies in separate press operations. The first die was a blank-and-draw die; the second was a pierce-and-pinch-trim die. Two separate dies were used on the assumption that the large pierced hole in the cup would not leave enough tool thickness to sustain all four operations. A 400 kN (45 tonf) open-back inclinable press was used for each of the two operations at a production rate of 500 pieces per hour.

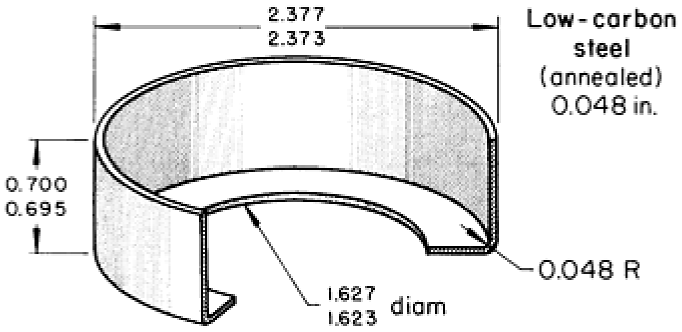

Fig. 22 Cup that was blanked, drawn, pierced, and trimmed in a compound die. This part was previously made in two compound dies: blank and draw, and trim and pierce. Dimensions given in inches

Examination of the procedure led to the design of a die to blank, draw, pierce, and trim--all in one press stroke. The same press was used at the same speed, thus cutting the labor cost per piece in half. Tooling cost also was reduced because the cost of the new die was less than the combined cost of the original two dies.

Production Applications. The following example describes production applications in which compound dies were used for blanking and other operations because of their inherent accuracy.

Example 6: Blanking, Forming, and Piercing a Brake-Drum Back in Compound Dies.

An automobile brake-drum back (Fig. 23) was formed from hot-rolled 1012 steel in two press operations. A compound die was used to blank and notch the part in a 1.8 MN (200 tonf) press at the rate of $17\frac{1}{2}$ strokes per minute, making one part per stroke. The tolerances shown in Fig. 23 were maintained in production with ordinary shop practice, as was the tolerance on the 14° 24' angle (±0° 30'). The die, made of vanadium tool steel, required reworking after 50,000 pieces. Chlorinated oils were used as lubricant.

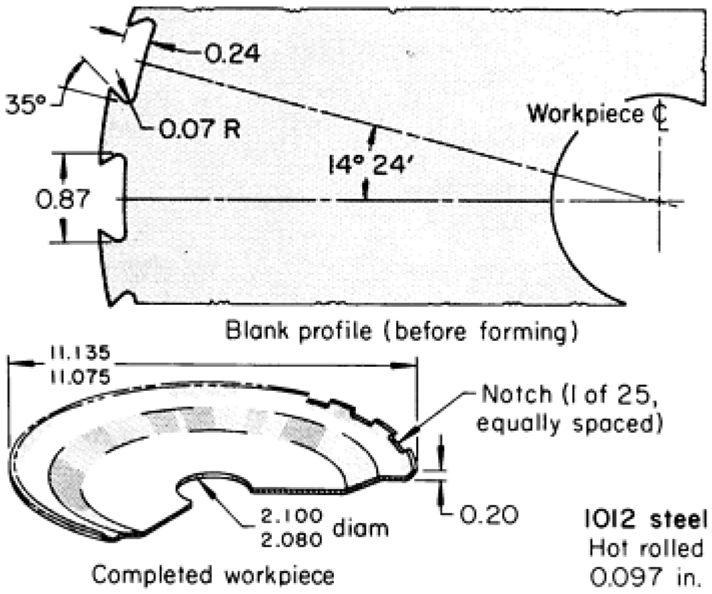

Fig. 23 Brake-drum back that was produced in two press operations, in a blank-and-notch die and in a restrike-and-form die. Dimensions given in inches

In the second press operation, a compound die in a 3.6 MN (400 tonf) press formed the workpiece, pierced the center hole, and flattened the workpiece at the notches. This die was made of tungsten oil-hardening tool steel. Production rates, lubrication, and die life were the same as in the blank-and-notch operation.

Progressive Dies. In a progressive die, the workpiece, while attached to the strip (or to the scrap skeleton), is fed from station to station at each stroke. At each stroke, the die performs work at some or all of the stations. The workpiece is cut off and unloaded at the last station. Each station can be simple or compound. Figure 24 shows the principal parts of a two-station blank-and-pierce progressive die.

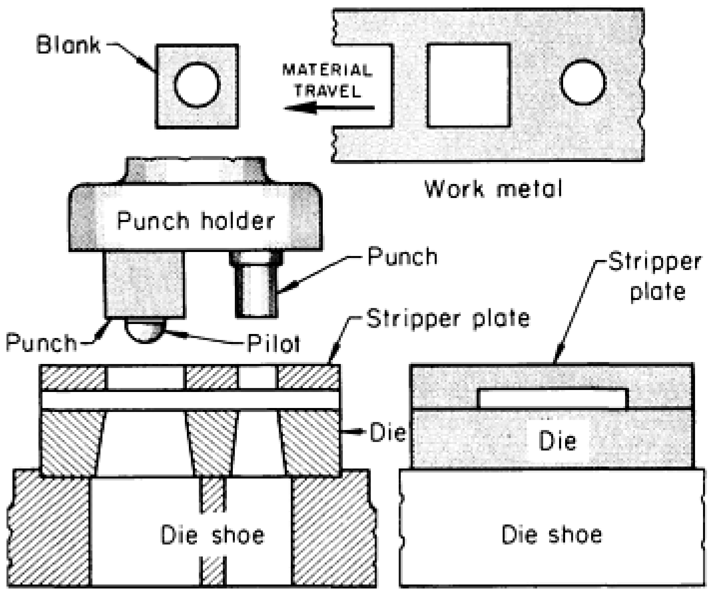

Fig. 24 Principal components of a two-station blank-and-pierce progressive die. Pierced blank and work metal (steel strip) are shown at top. The use of a pilot in the pierced hole ensures accuracy to within a few thousandths of an inch.

In producing the simple blank shown in Fig. 24 from coiled strip in a progressive die, the round hole is pierced at the first station. The strip is then fed left, to the next station. There the pilot enters the hole as the blanking punch moves down to complete the blank. Accurate relation of the hole to the outline of the blank depends on accurate fit of the pilot in the hole. The completed part is not separated from the strip until the last operation, regardless of the number of operations. After the first piece, one piece is completed at each stroke.

A progressive die is expensive, and because it is usually set up in an automatic press with scrap cutter, feeder, straightener, and uncoiler, the total cost of the auxiliary equipment is also high. Other disadvantages of progressive dies are:

- The part cannot be turned over between operations
- Material may be wasted because the workpiece may not nest well in the strip layout

Coil stock (or, less often, flat strip stock) is used. Many operations on parts of small and medium size can be done in conjunction with blanking in a progressive die, but the planning may be complicated. Soft or thin stock may be troublesome because the pilot may distort the locating holes. Setup and maintenance may be difficult.

The following example describes an application in which a progressive die was preferred to a compound die because it was too difficult to cut sharp corners in the compound die.

Example 7: Change From a Compound to a Progressive Die to Cut Sharp Corners.

Figure 25 shows a fast-idle cam on which the corners had to be sharp. A progressive die was used because it was difficult to make and maintain sharp corners in a compound die. The part was blanked from coiled 1010 steel strip, 3.05 × 60 mm (0.120 × $2\frac{3}{8}$ in.), with maximum hardness of 55 HRB. A seven-station progressive die cut the steps in the cam.

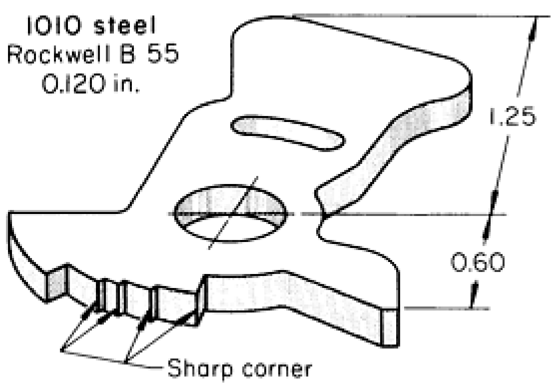

Fig. 25 Fast-idle cam on which sharp corners were cut in a progressive die. Dimensions given in inches

The punches were made of M2 tool steel and hardened to 60 to 63 HRC, and the die and the punch holders were made of O1 tool steel and hardened to 56 to 58 HRC. Approximately 10,000 to 15,000 cams were made between sharpenings of the progressive die, using a punch-to-die clearance of 0.10 mm (0.004 in.). This die was mounted in a 530 kN (60 tonf) press that was run at 76 strokes per minute.

In another operation, the steps in the cam were shaved to remove die break so that surfaces were flat across the thickness. Tools were of the same materials as in the progressive die and had a life of 5000 to 6000 pieces between sharpenings. The shaving was done at 16 strokes per minute in a 360 kN (40 tonf) press. Finally, the cam was liquid carburized 0.08 to 0.15 mm (0.003 to 0.006 in.) deep and oil quenched to file hardness. Zinc plating (0.005 mm, or 0.0002 in., minimum thickness) and a chromate postplating treatment followed.

Transfer dies, in which separate workpieces are fed from station to station by transfer fingers, are used for blanking only when coil stock is used. Blanking is done at the first station and is followed by other operations.

Transfer dies are typically used for additional operations on precut blanks made in a separate press (blanks that permitted close nesting for best use of the stock). When equally high utilization of stock can be obtained, coil stock can be used in a transfer die, with blanking done at the first station.

Like progressive dies, transfer dies and their related equipment (presses, special attachments, and feeding devices) are expensive and are best suited to mass production. Production rates are high.

Multiple dies (also called multiple-part dies) make two or more workpieces at each stroke of the press. The workpieces can be pairs of right-hand and left-hand parts, duplicate parts, or unrelated parts. Punch height can be staggered to reduce shock and blanking noise. Such dies are used in mass production.

Multiple dies can be multiples of single-operation dies or multiples of compound dies. They generally cost only slightly more than similar dies that make only one part per stroke. A die that makes two parts per stroke may cost only 5% more than a die that makes only one.

Such dies are primarily used for blank-and-form sequences. Draw operations are more difficult to combine with blanking or other operations because of blankholder needs and slower draw operation. Unloading of the work is sometimes difficult.

The use of multiple dies depends on the size and shape of the workpiece, size of the press, production quantity, possible savings in material and labor, and costs for setup and maintenance. Advantages of multiple dies include savings in material by better blank layout, reduced labor costs, and increased production. Disadvantages include increased setup and maintenance costs.

It is often better to increase the production of a single-part die by some simple change, such as putting the die in a faster press, rather than to replace the single-part die with a multiple die. A multiple die may also have to be run slower than the simpler die if a press of greater force capacity must be used to provide ample force. The use of a multiple compound die to blank, pierce, and form three pieces per stroke is illustrated in the following example.

Example 8: Blanking, Piercing, and Forming Three Pieces per Stroke in a Multiple Compound Die.

A multiple compound die was used to make a thick dished washer with three flats equally spaced on the edge circle, as shown in Fig. 26. The part was made of hot-rolled 1008 or 1010 steel, 2.36 ± 0.18 mm (0.093 ± 0.007 in.) thick.

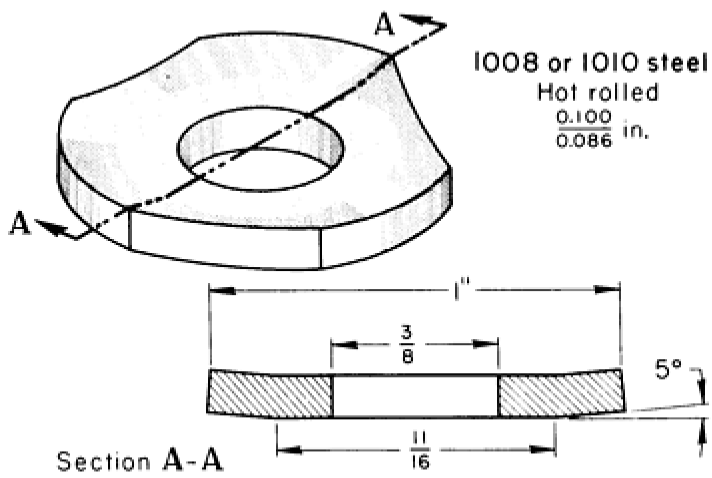

Fig. 26 Dished washer that was blanked, pierced, and formed, three pieces per stroke, in a multiple compound die. Dimensions given in inches

Operations in the compound die were blank, pierce, and form. The blanks were nested so closely in the stock layout that the pilot holes (half-circles) had to be notched in the edge of the stock. Three parts were made with each stroke of the die, and the parts were pushed partly back into the scrap skeleton so that they were carried out of the press for unloading. Production was 500,000 pieces per month. The die, made of D2 tool steel, needed to be resharpened after 150,000 strokes (450,000 pieces) and required reconditioning (replacement of some parts) after 3.5 million pieces.

Blanking of Low-Carbon Steel

Operating Conditions

To achieve high productivity and low unit cost, most blanking is done in high-speed mechanical presses. Speeds as high as 1200 strokes per minute are used. The equipment for high-speed blanking ordinarily includes a short-stroke press, automatic feed devices, and dies designed for bottom ejection.

In most blanking operations, press speed is limited by the length of feed, which is governed by blank size, or by the relationship between the force capacity of the press and the load. The combination of blanking with forming or drawing in compound dies also restricts press speed. Blanking speed may be as low as ten strokes per minute in producing blanks that are extremely large or that present handling problems for other reasons.

Regardless of the number of strokes per minute, the velocity of the punch always approaches zero near the bottom of the stroke. Within the usual range for production work in conventional blanking dies, the speed of the press has little practical effect on the speed of the punch during the blanking portion of the stroke. This effect, however, is critical for fine edge blanking, in which punch speed during the interval while the punch is cutting through the work metal is usually about 7.6 to 1.5 mm/s (0.3 to 0.6 in./s) (see the article "Fine Edge Blanking and Piercing" in this Volume).

Lubrication requirements are generally less critical for blanking than for forming or deep drawing; stock to be blanked is often fed into the press with no lubrication other than the residue remaining on the stock from the lubrication at the mill. The stock is sometimes coated with a light mineral oil or a light chlorinated oil. However, lubrication is important in dies that have close clearance between punches and stripper. At speeds of 40 strokes and more per minute, such dies must be lubricated constantly with a spray of light mineral oil to prevent galling of the punches in the stripper. Additional information on lubrication requirements in blanking is available in the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume.

Effect of Work Metal Thickness

Stock thickness affects the selection of material for dies and related components, as well as the selection of die type and design. The amount of shear and relief (angular clearance or draft) built into a blanking die and the amount of clearance between punch and die all depend on blank thickness.

Work metal thickness is also a factor in the selection of blanking method, handling procedure, and handling equipment. Blanking in a punch press is usually the fastest and most economical way of producing blanks thinner than about 6.4 mm ($\frac{1}{4}$ in.) in medium or large quantities.

Plate stock, in thicknesses of 6.4 to 25 mm ($\frac{1}{4}$ to 1 in.), is less frequently blanked in presses than sheet or strip. Blanks of such thick material are often made by gas cutting, sawing, nibbling, or routing instead of by shearing or by press operations; selection of the method depends primarily on plate thickness and production quantity.

Almost all blanks thinner than 3.2 mm ($\frac{1}{8}$ in.), except for intricate shapes chemically blanked from foil, are produced with conventional dies in mechanical or hydraulic presses. In only two of the examples of commercial practice presented in this article was work metal thicker than 3.2 mm ($\frac{1}{8}$ in.) (Example 3: 3.96 mm, or 0.156 in., and Example 9: 4.75 mm, or 0.187 in.).

Because of its strength and rigidity, material thicker than 3.2 mm ($\frac{1}{8}$ in.) is seldom blanked from coil stock or in a progressive die. On the other hand, because of its lack of strength and extreme flexibility, material thinner than 0.51 mm (0.020 in.) generally requires special handling techniques. The articles "Piercing of Low-Carbon Steel," "Blanking and Piercing of Electrical Steel Sheet," and "Press Forming of High-Carbon Steel" in this Volume contain additional information on the effect of work metal thickness on processing.

Distortion is often a problem in blanking complex shapes from thin low-carbon steel sheet by repeated strokes of a notching die. Distortion of such parts can be minimized by the use of hardened stock and by performing the entire blanking operation in one stroke in a single die.

Accuracy

Blanking in conventional dies readily produces parts within a total tolerance of 0.051 to 0.254 mm (0.002 to 0.010 in.), depending on the accuracy of the dies and the condition of the press. The tolerances given in Table 4 in the article "Piercing of Low-Carbon Steel" in this Volume generally also apply to blanks. The total tolerances listed under the column head "Location" apply to the relationship of a point on the periphery of the blank to a hole or other reference feature on the blank; the values listed under "Size" apply to a diameter for round blanks or to a similar control dimension for other blank shapes.

The production of blanks to these tolerances is illustrated by the examples in this article and the article "Piercing of Low-Carbon Steel." The following example describes the use of a compound die to maintain a total (envelope) tolerance of 0.13 mm (0.005 in.) on the relationship of a cam surface to a hole.

Example 9: Blanking and Piercing a Cam to 0.13 mm (0.005 in.) Total Tolerance on Cam Surface in Relationship to Hole Position.

A compound die was used to blank and pierce the cam shown in Fig. 27 so that the hole would be in accurate relationship to the cam surface. The die was made of A2 or equivalent tool steel and hardened to 62 HRC, and it had a clearance per side equal to 10% of the stock thickness.

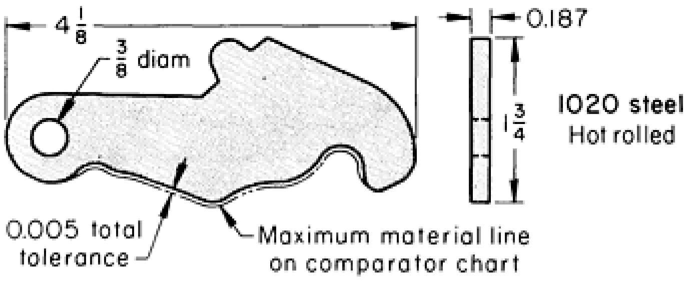

Fig. 27 Cam that was blanked and pierced in a compound die within an envelope tolerance of 0.13 mm (0.005 in.) TIR. Dimensions given in inches

The cam, used in the hinge mechanism of an automobile door, was blanked from hot-rolled 1020 steel 4.75 mm (0.187 in.) thick. Samples of the cam were inspected with an optical comparator, which compared the relationship of hole and cam surface to an outline that showed the full 0.13 mm (0.005 in.) tolerance, as illustrated in Fig. 27.

In another operation, the cam surface was machined to remove die break so that the edge would be square. The cam was then case hardened.

The part was produced in a 1.4 MN (160 tonf) open-back inclinable press at 60 strokes per minute. A sulfur-base lubricant was used. Die life was 40,000 pieces per sharpening.

Blanking and Piercing With Compound Dies. Example 6 in this article describes other applications of compound dies in blanking and piercing to conventional tolerances. For parts made in a progressive die, the relationship of the blank outline to features of the part produced in other stations of the die depends on the accurate fit of the pilot in the pilot hole. Transfer dies ordinarily provide better accuracy than progressive dies because the positive location of separate parts can be more precise than the roll feeding of coil stock with pilots.

Holding close tolerances on parts made in a progressive die is particularly difficult on soft or thin material because distortion of the locating holes by the pilot is more likely. Handling problems that might contribute to excessive variation in location or dimensions are not usually encountered in transfer dies, except with blanks of extremely thin material. Shaving (see the following section in this article) is used to improve the accuracy of blank outlines to meet close tolerances or to improve edge quality.

Short-run dies are generally less accurate than conventional dies. By using more accurate methods of constructing short-run dies, closer tolerances on blanked work can be obtained, but at some increase in die cost (see the section "Construction and Use of Short-Run Dies" in this article). Generally, making blanks by methods other than the use of dies in presses, except for machining or grinding, results in a lower level of accuracy.

Shaving

Shaving is an operation that can be performed after blanking to give a smooth, square edge and greater accuracy than can be achieved in ordinary blanking. Shaving removes only the blanked edge--cutting away the deformed, broken, and burred edge that was left in blanking. The elimination of these irregularities and the removal of locally work-hardened metal minimize breakage of the work metal during subsequent flanging, particularly the flanging of holes. The scrap produced in shaving is so thin that it resembles the chips produced in finish machining, rather than the usual scrap that is produced in a press.

When shaving is planned for, a small amount of extra stock is left on the workpiece to be removed in shaving. Shaving can be done in a separate operation, or it can be included in one station of a progressive die.

The shaving operation produces a straight, square edge, generally to about 75% of the metal thickness. Two shaves make a better, straighter edge (to about 90% of the metal thickness) than does a single shaving operation. To eliminate rollover from blank edges, which requires the removal of a greater amount of stock, it may be better to consider machining the workpiece rather than shaving.

Punch-to-die clearances range from 0 to $1\frac{1}{2}$% of stock thickness per side. Sturdy guideposts in a heavy die set are necessary to maintain the close alignment needed to prevent damage to the punch and die.

Shaving causes more wear on a die than ordinary blanking, so that the die produces fewer parts per grind and needs more frequent maintenance. Slivers of shaving scrap (chips) can jam feeding mechanisms, can become embedded in workpieces, or can mar the punch and die surfaces if not removed after each press stroke. Because of these problems, special attention must be given to die design when shaving is included among the operations done in a progressive die, as illustrated in the following example.

Example 10: Shaving in a Progressive Die.

In evaluating methods for high-volume production of the shaved low-carbon steel part shown in Fig. 28, the use of a single progressive die for all cutting and forming operations was projected as the most economical method, principally because this method would involve fewer operations and less handling than the other methods considered. However, two major problems were anticipated. First, the life of the shaving tools was expected to be much shorter than that of the other tools in the progressive die (which would have resulted in costly interruption of production to sharpen or replace the shaving tools), and, second, it appeared likely that misfeed could occur from jamming of the feeding mechanism by slivers of shaving scrap.

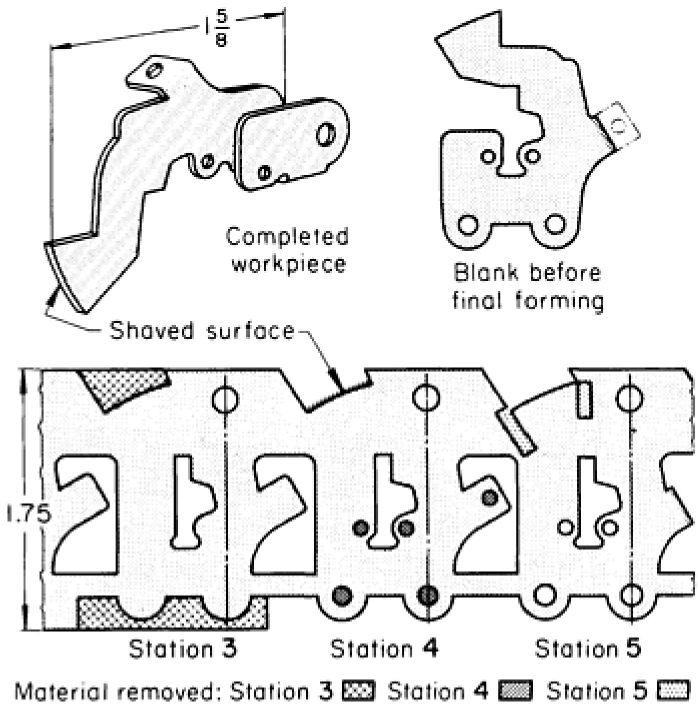

Fig. 28 Formed part on which a blanked edge was made smoother and more accurate by shaving (station 4) after notching (station 3) in a progressive die. Dimensions given in inches

By designing the die and feeding mechanism to eliminate difficulties from these two sources, efficient and economical production was obtained. The tools were of A2 air-hardening tool steel, hardened to 54 to 58 HRC for the forming sections and to 60 to 62 HRC for the cutting sections. The shaving section was made with a replaceable insert to minimize downtime when sharpening was needed. Damage to the progressive die from an accumulation of shaving scrap was prevented by including in the die a stock stop (station 3, Fig. 28) and misfeed and double-thickness protectors.

The shaving was done in station 4, as shown in Fig. 28. The production rate was 80 pieces per minute in a 530 kN (60 tonf) mechanical press with a 50 mm (2 in.) stroke. Tolerance on most sections of the part was ±0.13 mm (±0.005 in.). Additional information on the use of shaving to maintain close tolerances and to improve the quality of hole walls is available in the article "Piercing of Low-Carbon Steel" in this Volume.

Shaving allowance, or the amount of stock to be removed from the workpiece, depends on the hardness and thickness of the blank. Generally, the smallest amount of stock that will produce the desired result is left for the shaving operation. Table 4 lists shaving allowances recommended by one manufacturer. When shaving only one edge of a blank, shifting of the blank can be reduced by shaving the opposite edge as well, even if not required for function.

Table 4 Shaving allowances recommended by one manufacturer

Blank thickness		Allowance per side for steel with HRB hardness of:					
		50-66		**75-90**		90-105

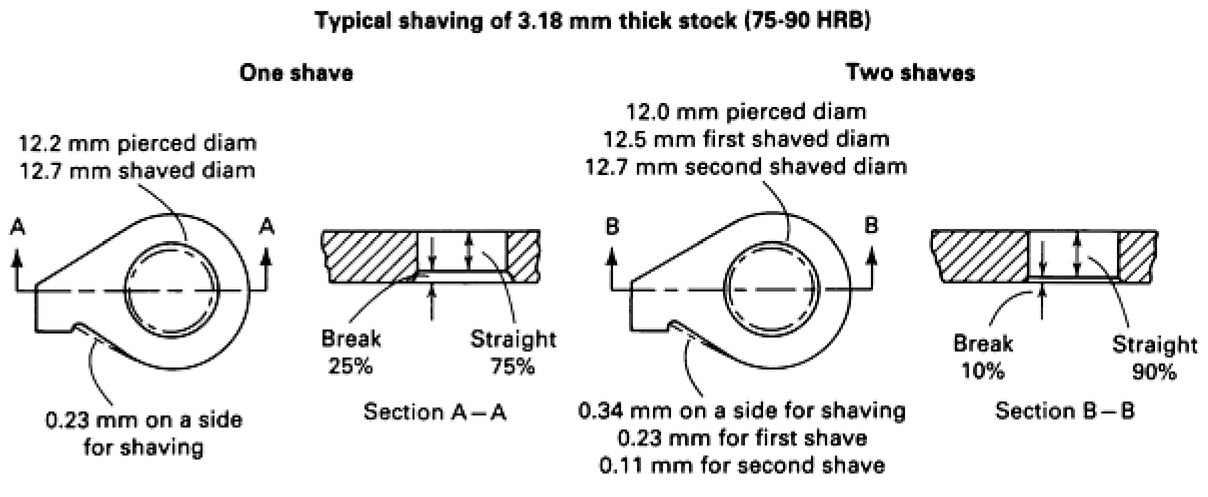
3.18	0.125	0.089	0.0035	0.114	0.0045	0.152-0.178	**0.006-0.007**



Setups or Shaving. Shaving requires that the blank be accurately located over the die or the punch, because only a few thousandths of an inch of metal is removed by the operation (Table 4). Piloting pins, projecting from the punch, can engage holes in the blank to ensure proper location. If the holes are not included in the original design, it may be permissible to add them for locating purposes only.

If adding holes is not permitted, a locating device such as that shown in Fig. 29 can be used. The clamping arms engage the blank at suitable nesting points. When the punch descends, the shaved blank falls through the die. The position of the clamping arms is fixed by the two stop pins.

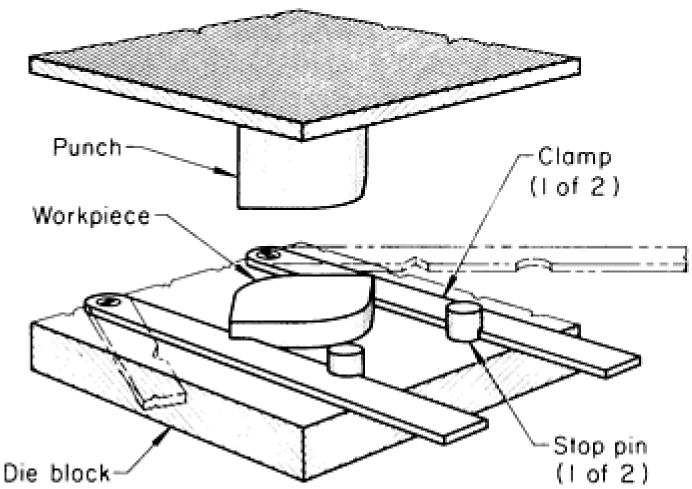


Fig. 29 Shaving die with a device for locating a blank with no holes for piloting.

Operation of this die can be improved by he use of a spring-loaded ejector and pressure pad within the die opening. As the punch ascends, the ejector lifts the shaved workpiece above the die face, thus eliminating the fall through the die block, which may result in dents or other surface defects.

Burr Removal

The shape, height, and roughness of burrs must be controlled to some degree in nearly all blanking operations. Complete elimination of burrs is not possible, but their formation can be minimized by the use of proper clearance between punch and die and by good maintenance.

Exposed burrs on the finished part can be unsafe and unsightly. Burrs on some blanked work can cause difficulties in forming and can increase the rate of workpiece breakage and die wear. Burrs can be removed by grinding, which generally removes the burr and a portion of the work-hardened edge. Tumbling in a barrel is a common method of deburring small parts. Other deburring methods include chemical and electrolytic deburring, belt grinding, polishing and ultrasonic methods, as described in *Surface Engineering*, Volume 5 of the *ASM Handbook.* Hand scrapers can be used to remove burrs from irregular shapes or soft metal parts.

Blanking In Presses Versus Alternative Methods

Fine edge blanking is primarily used where die break is unacceptable and would require removal by subsequent shaving if conventional blanking were used. In fine edge blanking, there is no die break, and the entire wall surface of the cut is burnished. Additional information is available in the article "Fine Edge Blanking and Piercing" in this Volume.

Milling is applicable mainly for cutting stacked parts, for short runs, and for making parts that are subject to frequent design change. It substitutes an inexpensive template for a conventional punch and die.

Chemical blanking may be competitive with blanking in presses for intricate parts that are only a few thousandths of an inch thick. Combs for electric shavers, for example, are more frequently made by the chemical blanking of stainless steel than by mechanical blanking methods.

Contour band sawing and gas cutting may be competitive with blanking for stacked parts and thick material.

Safety

In all blanking operations, as in all press operations, there are hazards to operators, repairmen, and personnel in the vicinity. No press, die, or auxiliary equipment should be considered operable until these hazards are eliminated by installing necessary guards and other safety devices. The operator and all persons working around the blanking operation should be instructed in all precautions for safe operation before work is started. Additional information is available in the article "Presses and Auxiliary Equipment for Forming of Sheet Metal" in this Volume.

Introduction

PIERCING is the cutting of holes in sheet metal, generally by removing a slug of metal, with a punch and die. Piercing is similar to blanking, except that in piercing the work metal that surrounds the piercing punch is the workpiece and the punched-out slug is scrap, while in blanking the workpiece is punched out.

The term piercing is used in this article, and in related articles in this Volume, to denote the production of a hole by removing a slug of metal with a punch and die. However, some prefer the terms punching or perforating, limiting the term piercing to the use of a pointed punch that tears and extrudes a hole without cutting a slug of metal. The term perforating is also sometimes used in the special sense of cutting many holes in a sheet metal workpiece by removing slugs with several punches.

Piercing is ordinarily the fastest method of making holes in steel sheet or strip and is generally the most economical method for medium-to-high production. Pierced holes can be almost any size and shape; elongated holes are usually called slots. The accuracy of conventional tool steel or carbide dies provides pierced holes with a degree of quality and accuracy that is satisfactory for a wide variety of applications.

Additional information on piercing is available in the articles "Blanking of Low-Carbon Steel," "Fine Edge Blanking and Piercing," "Press Forming of High-Carbon Steel," and "Blanking and Piercing of Electrical Steel Sheet" in this Volume.

Characteristics of Pierced Holes

Pierced holes are different from through holes that are produced by drilling or other machining methods. A properly drilled or otherwise machined through hole has a side-wall that is straight for the full thickness of the work metal, with a high degree of accuracy in size, roundness, and straightness. The sidewall of a pierced hole is generally straight and smooth for only a portion of the thickness, beginning near the punch end of the hole; the rest of the wall is broken out in an irregular cone beyond the straight portion of the hole, producing fracture, breakout, or die break (Fig. 1).

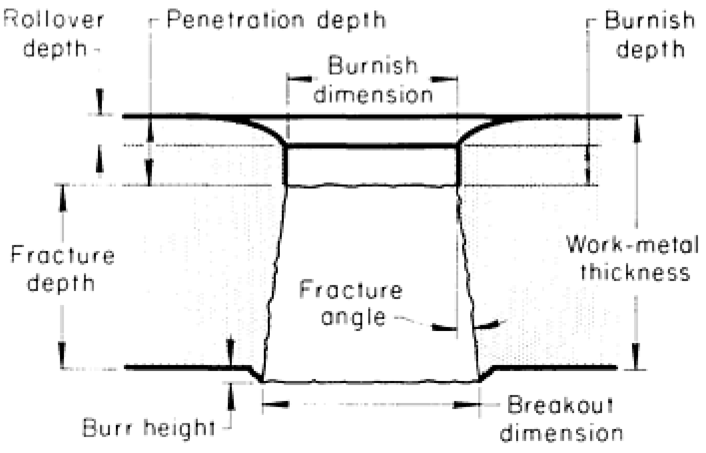

Fig. 1 Characteristics of a pierced hole. Curvature and angles are exaggerated for emphasis.

The piercing operation typically begins as a cut that produces a burnished surface on the hole wall and some rollover (curved surface caused by deformation of the workpiece before cutting begins), as illustrated in Fig. 1. The punch completes its stroke by breaking and tearing away the metal that was not cut during the beginning of the piercing operation.

The combined depth of rollover and burnish is a measure of the penetration depth of the stroke, also shown in Fig. 1. This is the part of the stroke during which the cutting force is exerted, before the metal fractures or breaks away (Fig. 1).

The amount of penetration before fracture is commonly expressed as a percentage of the stock thickness. In general, the percentage of penetration depends more on the material than on other factors, such as punch-to-die clearance. Table 1 in the article "Blanking of Low-Carbon Steel" in this Volume shows the average percentage of penetration (before fracture) in various metals under typical piercing or blanking conditions. The percentage of penetration affects energy consumption and cutting force in blanking or piercing, as described in the article "Blanking of Low-Carbon Steel" in this Volume.

Quality of Hole Wall

If the sidewall of a pierced hole is not smooth or straight enough for the intended application, it can be improved by shaving in a die or by reaming. When done in quantity, shaving is the least expensive method of improving the sidewall of a pierced hole. Shaving in one or two operations generally makes the sidewall of a hole uniform and smooth through 75 to 90% of the stock thickness.

Superior accuracy and smoothness of hole walls can be obtained by fine edge piercing. With this method, one stroke of a triple-action press pierces holes with smooth and precise edges for the entire thickness of the material. Additional information is available in the article "Fine Edge Blanking and Piercing" in this Volume.

Burr height is an important element in hole quality, and a maximum burr height is usually specified. For most applications, the limit on burr height is between 5 and 10% of stock thickness. Burr height in piercing a given workpiece is primarily governed by punch-to-die clearance and tool sharpness.

Burr condition and limits usually determine the length of run before the punch and die are resharpened. With good practice, burr height generally ranges from 0.013 to 0.076 mm (0.0005 to 0.003 in.), but may be much greater, depending on workpiece material and thickness, clearance, and tool condition. As an alternative to limiting the length of run to control burr condition, unacceptable burrs can be removed by shaving or deburring, as described in the article "Mass Finishing" in *Surface Engineering*, Volume 5 of the *ASM Handbook.*

Selection of Die Clearance

Clearance, or the space between the punch and the sidewall of the die, affects the reliability of operation of piercing (and blanking) equipment, the characteristics of the cut edges, and the life of the punch and die. Published recommendations for clearances have varied widely, with most suggesting a clearance per side of 3 to 12.5% of the stock thickness for steel.

Establishment of the clearance to be used for a given piercing or blanking operation is influenced by the required characteristics of the cut edge of the hole or blank and by the thickness and the properties of the work metal. Larger clearances prolong tool life. An optimal clearance can be defined as the largest clearance that will produce a hole or blank having the required characteristics of the cut edge in a given material and thickness. Because of differences in cut-edge requirements and in the effect of tool life on overall cost, clearance practices vary among plants and for different applications.

No single table or formula can specify an optimal clearance for all situations encountered in practice. Starting with general guidelines, trial runs using several different clearances may be needed to establish the most desirable clearance for a specific application. The following general principles are useful in making adjustments:

- Rollover (plastic deformation) and burnish depths are greater in thick material than in thin material and are greater in soft material than in hard material
- Clearance (in decimal parts of an inch) needed to produce a given type of edge should vary directly with material thickness and hardness, and inversely with ductility

All clearance values given in this article are for clearance per side, except where indicated.

Edges

More specific guidance in selecting die clearances is provided by considering the types of edges produced with different clearances.

Edge Types. The acceptability of a punched hole or a blank is generally based on the condition of the cut edge and its suitability for the application. Usable holes and blanks can be obtained over a broad range of punch-to-die clearances, each resulting in a different edge condition. Figure 2 shows five types of edges that result from the use of different clearances in piercing or blanking low-carbon steel at a maximum hardness of 75 HRB. The tabular data accompanying Fig. 2 include approximate ranges of fracture or breakout angles, rollover, burnish and fracture depths, and burr characteristics for the five edge types. Table 1 lists the clearance ranges that will produce these edges when piercing or blanking various metals.

Table 1 Punch-to-die clearances for piercing or blanking various metals to produce the five types of edges shown in Fig. 2

For clearances that produce type 1, 2, and 3 edges, it is ordinarily necessary to use ejector punches or other devices to prevent the slug from adhering to the punch.

Work metal	Clearance per side, % of stock thickness				
	Type 1[(a)]	**Type 2**	**Type 3**	**Type 4**	Type 5

Burr	**Large, tensile plus part distortion**	**Normal, tensile only**	**Normal, tensile only**	**Medium, tensile plus compressive[(g)]**	**Large, tensile plus compressive[(g)]**

(a) Rollover plus burnish approximately equals punch penetration before fracture.

(b) Burnish on edge of slug or blank may be small and irregular or even absent.

(c) With spotty secondary shear.

(d) In two separate portions, alternating with fracture.

(e) With rough surface.

(f) In two separate portions, alternating with burnish.

(g) Amount of compressive burr depends on die sharpness.

Fig. 2 Effect of punch-to-die clearance per side (as a percentage of stock thickness, *t*) on characteristics of edges of holes and slugs (or blanks) produced by piercing or blanking low-carbon steel sheet or strip at a maximum hardness of 75 HRB. Table 1 lists clearances for producing the five types of edges in various metals. See text for additional discussion and for applicability of the five types of edges.

Type 1. This type of edge has a large rollover radius and a large burr that consists of a normal tensile burr in addition to bending or deformation at the edge. Burnish depth is minimal. Fracture depth is about three-fourths of stock thickness, and the fractured surface has a large angle. This edge is satisfactory for noncritical applications in which edge quality and part flatness are not important.

Type 2. This edge, which has a moderate rollover radius, normal tensile burr, and a small fracture angle, provides maximum die life and a hole or blank that is acceptable for general work in which a large burnish depth is not required. Burnish depth plus rollover depth is about one-third of stock thickness; fracture depth, about two-thirds.

Type 3. This edge has a small rollover radius, a normal tensile burr, and a small fracture angle. It has low residual stress and is therefore particularly desirable for use in parts made of work-hardenable material that will undergo severe forming. The clean stress-free edge reduces the possibility of edge cracking during forming. Burnish depth plus rollover depth is one-third to one-half of stock thickness.

Type 4. This is a desirable edge for stampings used for mechanisms or parts that must receive edge finishing such as shaving or machining. The edge has a very small rollover radius, a medium tensile and compressive burr, and a small fracture angle. Burnish depth plus rollover depth is about two-thirds of stock thickness. This edge type can be recognized by the spotty appearance of secondary shear on the fractured surface.

Type 5. This edge has a minimum rollover radius and a large tensile and compressive burr, and it can be recognized by the complete secondary shear on the cut surface. It is useful in applications in which edges must have a maximum of straight-wall depth without secondary operations. On steel and other hard metals, die life is extremely short. The edge can be useful on some of the softer metals, which allow a reasonable die life.

Edge Profiles. The exact profile of the edge varies somewhat for different work metals, depending on the properties of the metal. Results are also slightly affected by:

- Face shear on punch or die
- Punch-to-die alignment
- Proximity to adjacent holes
- Distance to adjacent blanked edges
- Orientation of the different portions of the cut edge with respect to the rolling direction of the stock
- Ratio of hole size to stock thickness
- Internal construction of the die cavity
- Lubrication

The edge profiles illustrated in Fig. 2, as well as the estimates of fracture angles and the relative amounts of rollover, burnish, fracture, and burr given in the accompanying table, are intended to represent production conditions, allowing for the normal range of tool sharpness encountered in piercing and blanking low-carbon steel sheet.

The clearance values given in Table 1 for piercing and blanking various metals to produce the five types of edges were obtained in laboratory tests. The cutting edges of the punches were stoned to a radius of 0.05 to 0.15 mm (0.002 to 0.006 in.) to simulate an amount of wear corresponding to the approximate midpoint of a production run. No lubricant was used on the work metal.

As clearance is increased from the low values used for type 5 edges to those used for type 1 edges, several effects are evident. The edge profile deviates more and more from straightness and perpendicularity as rollover, fracture angle, and fracture depth increase, while burnish depth decreases proportionately. Total burr height initially decreases as its compressive component decreases, leaving only the essentially constant tensile burr on type 2 and 3 edges (usually in the range of 0.013 to 0.076 mm, or 0.0005 to 0.003 in., depending on the work metal and the tool condition).

With further increase in clearance (edge type 1), bending or deformation at and near the edge adds an additional burr component, increasing the total burr height. This part distortion immediately adjacent to the cut edge is usually accompanied by a more gradual curvature, or dishing, on blanks or slugs; the corresponding curvature is much less pronounced on the stock around a hole, which is usually restrained by a stripper (curvature of blanks or stock strip is not shown in Fig. 2). At extremely large clearances (substantially above those shown for type 1 edges), double-shear characteristics are sometimes observed on the cut edge.

Effect of Tool Dulling

The sharpness of punch and die edges has an important effect on cut-edge characteristics in piercing and blanking. At the beginning of a run, with punch and die equally sharp, the hole profile is the same as that of the slug or blank. As the run progresses, dulling of the punch increases the rollover and the burnish depth on the hole wall and increases the burr height on the slug or blank. Dulling of the die increases burnish depth and burr height on the hole edge. The punch dulls faster than the die; therefore, the changes in hole characteristics related to punch dulling proceed more rapidly than those related to die dulling.

On average, the following differences between hole edge and blank edge are observed in production work on sheet metal:

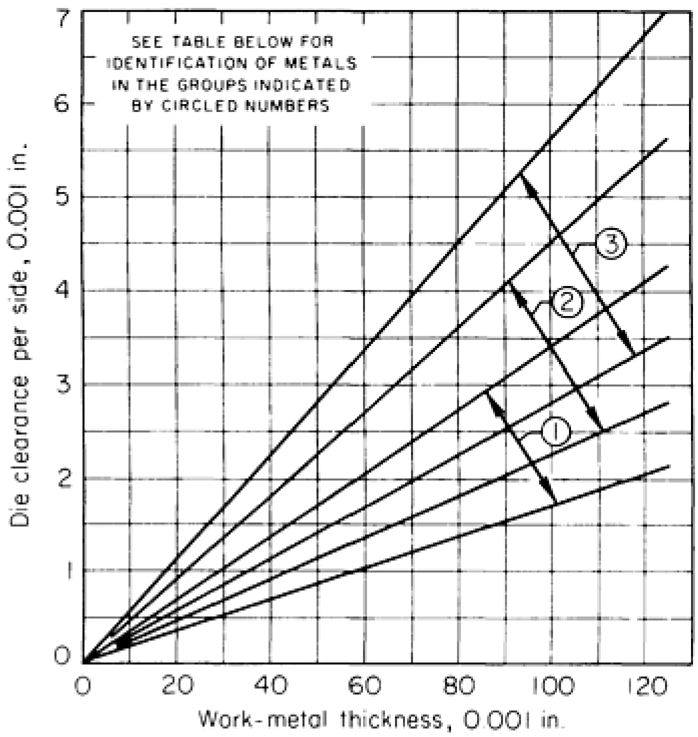
- Rollover is greater on hole edge than on slug or blank edge
- Burnish depth is greater on hole edge than on slug or blank edge
- Fracture depth is smaller (and fracture angle greater) on hole edge than on slug or blank edge
- Burr height on hole edge is less than that on slug or blank edge, and varies with tool sharpness

These differences are illustrated in Fig. 2.

Use of Small Clearance

Where relatively square edges are required, small clearances can be used to produce holes with type 4 edges. Although tool life is shorter than when larger clearances are used, this may not be an important factor in the overall costs for short or medium production runs.

Figure 3 shows the ranges of die clearance per side used by one electronics manufacturer in piercing and blanking three groups of metals up to 3.18 mm (0.125 in.) thick. The groups and the percentages of stock thickness on which these ranges of clearance were based are listed with Fig. 3. For stainless steel (not included in Fig. 3), nominal clearance per side was 2.5% of the thickness for stock thicknesses up to 4.75 mm (0.187 in.), and 4% for thicknesses between 4.75 and 6.35 mm (0.187 and 0.250 in.).



Group	Clearance per side, % of stock thickness[(a)]	
	Average	Range
1. Aluminum alloys 1100 and 5052, all tempers	2.25	**1.7-3.4**
2. Aluminum alloys 2024 and 6061, T4 and T6 tempers; brass, all tempers; cold-rolled steel, dead soft	3.0	**2.25-4.5**
3. Cold-rolled steel, half hard	**3.75**	**2.8-5.6**

Note. Incorrect clearance values twice as large as those shown here have appeared with charts of this type in some publications, apparently because of confusion between clearance per side and total clearance. Also, stainless steel has erroneously been included with the metals in groups 2 and 3 in those publications.

(a) Percentages of stock thickness on which the ranges of acceptable clearance in chart are based. See text for clearances used in piercing or blanking of stainless steel.

Fig. 3 Ranges of punch-to-die clearance per side recommended by one manufacturer for piercing and blanking of various metals up to 3.18 mm (0.125 in.) thick

The data plotted in Fig. 3 were used by the manufacturer to determine whether a given punch and die could be used interchangeably for a metal different in thickness or type from the one for which it had been designed. If the point of intersection of a vertical line for the thickness of the new material with a horizontal line for the existing die clearance was within the range shown for the new material, the punch and die were normally satisfactory for use on the new material.

Piercing of Low-Carbon Steel

Use of Large Clearance

Studies of die operation under both laboratory and production conditions have indicated that large clearances can be used to obtain maximum tool life in numerous piercing (and blanking) applications. Table 2 indicates the effect of clearance on force requirements for piercing and stripping, presenting data on the test piercing of 6.53 mm (0.257 in.) diam holes in cold-rolled low-carbon steel of various thicknesses and hardnesses. Although individual results show some inconsistency, as would be expected because of the difficulty in obtaining accurate measurements of this type, the trend toward lower stripping force with an increase in clearance is evident from these data. The amounts of punch penetration into the die needed to release the slug are also given in Table 2. Table 3 lists production data on the effect of increased clearance on tool life for piercing and blanking common metals in various thicknesses.

Table 2 Effect of clearance on piercing and stripping force required for piercing 6.53 mm (0.257-in.) diam holes in cold-rolled low-carbon steel

No lubricant was used.

(f) Soft.

(g) Eliminated die breakage.

(h) Run completed without regrind.

(i) Half hard.

On the basis of these studies and production experience, clearance per side equal to 12.5% of stock thickness has been recommended by some toolmakers and sheet metal fabricators for the general-purpose piercing (and blanking) of cold-rolled steel 0.51 to 3.18 mm (0.020 to 0.125 in.) thick in all tempers. This practice produces type 2 cut edges (Fig. 2).

The advantages observed when using a clearance of 12.5%, instead of substantially smaller clearances (as for a type 4 edge), include the following:

- Total tool life and tool life between regrinds are considerably increased (Table 3). Punch wear, normally two or three times die wear, is greatly reduced because the hole is larger than the punch size and because stripping wear is minimized
- Load on the press may be slightly reduced (Table 2)
- Burr height is smaller at the beginning of a run and increases at a slower rate during the run
- Distortion or waviness of the work surface is reduced, especially with closely spaced holes
- Stripping force is reduced (Table 2), which partially accounts for the reduced punch wear

The factors that must be considered in applying the 12.5% clearance include the following:

- A different clearance may be required for steel outside the thickness range of 0.51 to 3.18 mm (0.020 to 0.125 in.), for metals other than steel, or to meet critical edge-quality requirements
- A spring-loaded stripper should be used instead of the positive or fixed type, and the slug or blank must be prevented from adhering to the end of the punch. These precautions are especially important in transfer dies
- Hole size is larger than punch size, particularly with hard or thin materials
- With clearance above 15%, slugs of some materials (for example, 1.3 mm, or 0.050 in., thick type 410 stainless steel at a hardness of 50 HRC) may be ejected from the die at high velocity--possibly requiring special safety precautions

Clearance and Tool Size

In blanking, the die opening is usually made to the desired size of the blank, and the punch size is then equal to the die opening minus twice the specified clearance per side. Conversely, in piercing, the punch is usually made to the desired size of the hole, and the die opening is then equal to the punch size plus twice the specified clearance per side.

Clearance per side for blanking dies is ordinarily calculated from the desired percentage of clearance and the nominal thickness of the stock. However, to keep the inventory of piercing tools from becoming too large, some manufacturers use a modified practice for stocking piercing punches and die buttons in commonly used diameters. Punches are ordered to size. Work metal thickness is classified into several ranges, and die buttons are ordered to the specified clearance per side for the median stock thickness of the range to which the work metal for the given application belongs.

Hole dimensions are slightly affected as the clearance is changed. When using clearances that produce a type 4 edge, the diameter of the pierced hole is about 0.013 mm (0.0005 in.) less than that of the punch used to produce it. By increasing the clearances to those for a type 2 edge, the hole size will be equal to, or approximately 0.013 mm (0.0005 in.) larger than, the punch diameter.

With tight clearances, the slug is wedged into the die cavity. As the clearance is increased, the wedging action decreases; consequently, the slug may be as much as 0.013 mm (0.0005 in.) smaller than the die cavity.

Force Requirements

The force needed to pierce a given material depends on the shear strength of the work metal, the peripheral size of the hole or holes to be pierced, stock thickness, and depth of shear on the punch. The calculation of piercing force is the same as that for cutting force in blanking (see the article "Blanking of Low-Carbon Steel" in this Volume).

Effect of Punch Shear. Shear is the amount of relief ground on the face of a punch (Fig. 5). It is used to reduce the instantaneous total load on the tool and to permit thicker or higher-strength materials to be pierced in the same press. It distributes the total piercing load over a greater portion of the downstroke by introducing the cutting edge in increments rather than instantaneously.

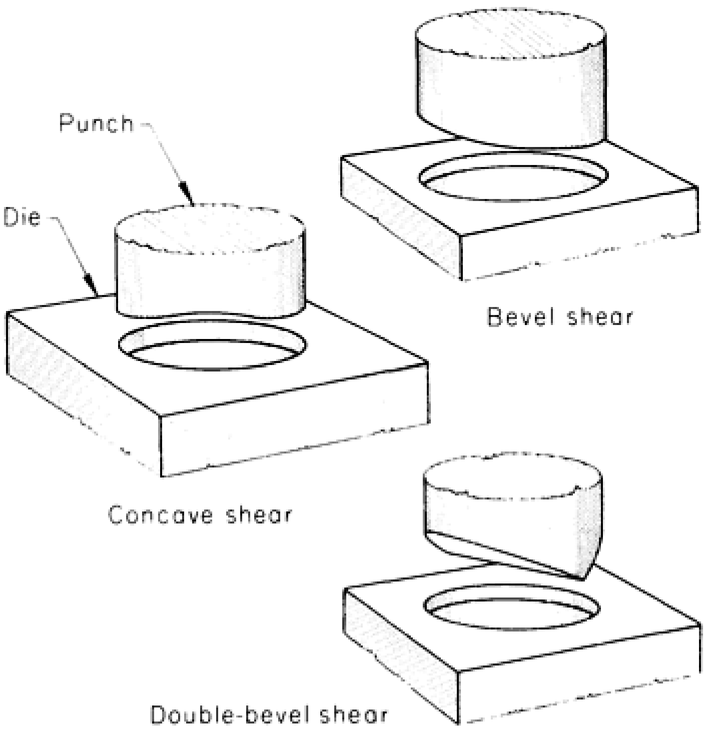

Fig. 5 Three types of shear on piercing punches. Angle and depth of shear are exaggerated for emphasis.

Piercing force (but not contact edge pressure or total work done) varies with the amount of shear on the punch face. With the bottom of the punch flat and parallel to the face of the die, piercing takes place on the entire periphery at once, requiring maximum force. The load on the press and tools increases rapidly to a maximum after impact and then releases suddenly when piercing is completed. By grinding shear on the punch as shown in Fig. 5, the maximum load is decreased, but the punch travels correspondingly farther to complete the piercing. Load release is also somewhat less sudden.

Shear location is ordinarily selected so as to confine distortion to the scrap metal (slug). Thus, in piercing, shear is ground on the punch because the punched-out metal is to be scrap. Concave shear and double-bevel shear (Fig. 5) provide a balanced load on the punch. Scalloped shear, sometimes ground on round punches, also provides a balanced load on the punch. An unbalanced load may cause deflection and tool breakage or excessive wear.

The amount of shear is determined by trial. However, shear equal to one-third of stock thickness (t/3) will reduce piercing force about 25%, and shear equal to stock thickness will reduce piercing force about 50%. Shear can be applied to punches for large holes but not to small-diameter punches, because they lack column strength.

When a number of small holes are being pierced and the press load must be reduced, the punches can be ground to different lengths. This enables the punches to start cutting at different times and reduces the maximum load. In selecting a press, it should be noted that the reduction in maximum impact load on the press achieved by staggering punch length or by using shear is not sufficient to enable the use of a press that is significantly lower in tonnage rating, strength, or rigidity.

Piercing of Low-Carbon Steel

Presses

Presses used in piercing are the same as those used in other pressworking operations. Open-back gap-frame presses of the fixed upright, fixed inclined, or inclinable type are common. The stock can be fed from the side with minimal interference from the press frame, and the parts can be removed from the front by the operator or ejected out the back by gravity or air jets.

Adjustable-bed or horn presses are used for piercing holes in tubing and in the sides of drawn or formed shells and boxes. Adjustable-bed and gap-frame presses are generally rated at capacities of less than 1.8 MN (200 tonf).

Straight-side presses are commonly used for compound-die and progressive-die operations. Increased accuracy, speed, and stability are required for these operations.

The turret punch press is a special machine in which the punches and dies are mounted in synchronized indexing tables. Several sets of punches and dies are mounted in the table, which can be manually or automatically indexed into operating position. A flat blank is pierced and notched in a turret punch press by positioning it under the operating punch and tripping the punching mechanism. The blank is secured to a free-floating table on which a template containing the hole pattern is also attached. Each hole size and shape is coded so that all such holes can be pierced before indexing a new punch-and-die set under the press ram. The table is moved so that a pin will drop into a hole in the template; this places the blank in the proper position for piercing a hole. After the holes of one size and shape have been pierced, a new punch and die are indexed into operating position, and piercing continues in this manner until the part is finished. Almost any size or shape of hole can be pierced, within the capacity of the machine.

Turret punch presses can be programmed for tape control for increased production. Turret movement can also be controlled semiautomatically or automatically, on numerical control (NC) or computer numerical control (CNC) punch presses. A closed-loop direct or alternating current drive connected to both the upper and lower turret assemblies provides the automatic turret with either unidirectional or bidirectional movement. Selected CNC presses even offer an optimization feature that automatically determines the most efficient and most cost-effective punching sequence for a specific workpiece.

Piercing of Low-Carbon Steel

Tools

A typical piercing die consists of:

- Upper and lower die shoes, to which punch and die retainers are attached
- Punches and die buttons
- A spring-actuated guided stripper (Fig. 6)

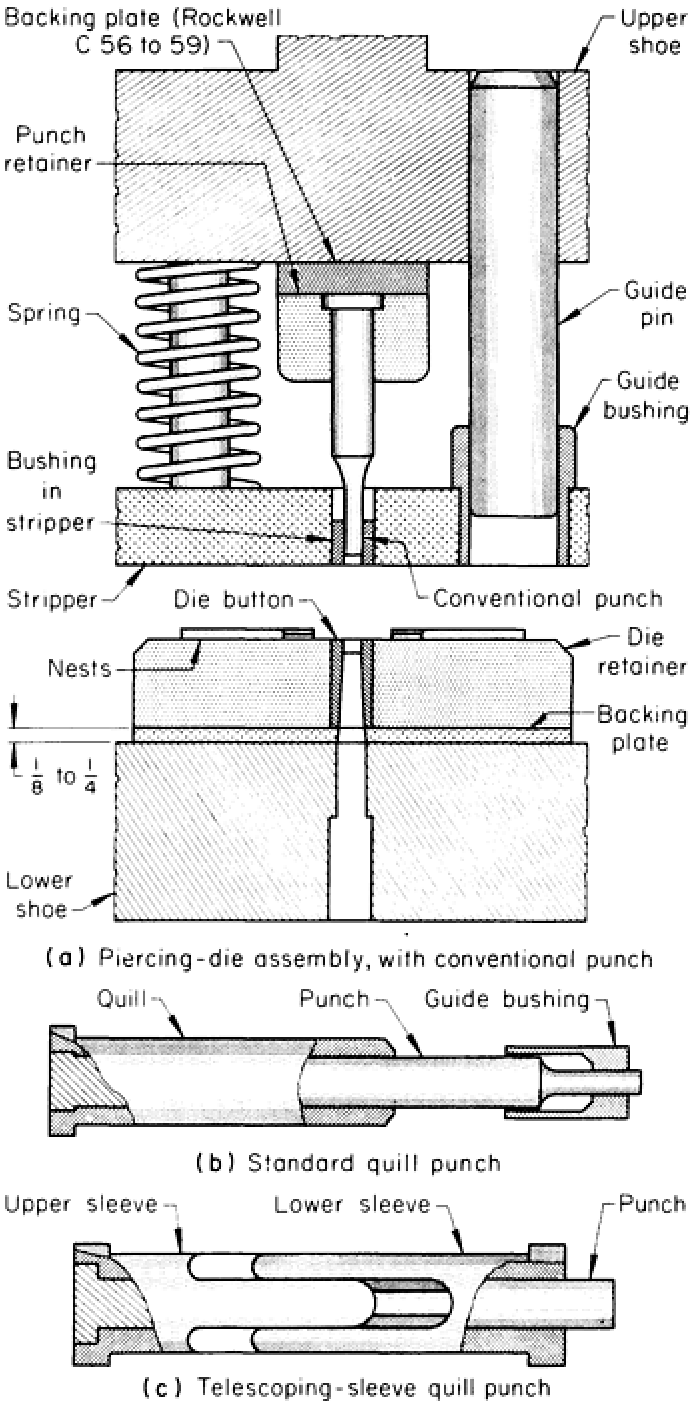

Fig. 6 Typical piercing die, and three types of punches used. See text for discussion. Dimensions given in inches

Small workpieces are generally pierced in compound dies that blank and pierce in the same stroke. Piercing is also done in the stations of a progressive die or a transfer die.

Any of these dies can be constructed as multiple dies, in which two or more workpieces are pierced at each stroke of the press. Additional information on dies is available in the article "Blanking of Low-Carbon Steel" in this Volume.

Punches. Figure 6 shows three types of punches used for piercing: conventional, standard quill, and telescoping-sleeve quill. Conventional punches are generally available with a standard maximum shank diameter of 25 mm (1 in.), and they can be used to pierce round, square, oblong, or rectangular holes that have a size and shape not exceeding 25 mm (1 in.)

in diameter or a size and shape that can be machined or ground on the end of the shank, as shown in Fig. 6(a). Punch shanks are also available in other sizes and shapes. Standard-size punch retainers, backing plates, die buttons, and die button retainers are also generally available.

The head-type punch shown in Fig. 6(a) is held by a carefully positioned and ground punch retainer. This type of punch cannot be replaced without removing the retainer. Headless punches are available with locking devices that permit replacement without retainer removal.

A spring-loaded and guided stripper is incorporated into the die design. Conventional punches for small-diameter holes and accurately spaced holes are supported and guided by hardened bushings pressed into the guided stripper plate. Piloting punches can also be guided in the same manner. For larger punches that do not need guidance or support, clearance holes are drilled in the stripper plate, and guide bushings for both the punch and the plate are omitted.

Figures 6(b) and 6(c) show two types of quill punches that replace conventional punches when piercing conditions are more severe or when more support is required for the punch when piercing small-diameter and accurately spaced holes to close tolerances. The type shown in Fig. 6(b) was designed to hold and align a small-diameter punch. The quill containing a close-fitting punch is pressed into the punch retainer. The punch can easily be changed and still maintain the original alignment and fit in the retainer. A punch guide bushing is used in the stripper plate, and a hardened backup plate supports the head of the punch. Quills are available for punches with body diameters ranging from 1.0 to 9.52 mm (0.040 to 0.375 in.). The nib or end can be ground to a smaller diameter if desired.

The telescoping-sleeve quill punch shown in Fig. 6(c) provides complete support to small-diameter punches and eliminates the weaknesses encountered in other punch-mounting designs. The upper part of the sleeve is press fitted into the punch retainer; the lower part, into the guided stripper plate. The inside diameter of the sleeve will accommodate punch bodies ranging from 0.38 to 9.52 mm (0.015 to 0.375 in.) in diameter. However, a punch body at the larger end of the range and with a ground nib is suggested for best results. When piercing holes in printed circuit boards, a 2° cone-type taper is ground on the bottom surface of the lower sleeve to concentrate the holding and stripping force at the edge of the hole.

Quill punches have been used to pierce holes in low-carbon steel having a thickness up to twice the punch diameter. Supporting sleeves or quills can be used for long, narrow punches of rectangular, oblong, or other shape.

Piercing dies can be ground into a hardened die block, or they can be die buttons that are press fitted into a die retainer, as shown in Fig. 6(a). To coordinate the quill, guide bushing, and die button, the punch retainer, stripper plate, and die retainer can be clamped together and jig bored and ground at the same time. This is possible because the quill, guide bushing, and die button are available with the same body diameters.

Guided Strippers. For all three types of punches, the function of the guided stripper is threefold. On the downstroke, the spring-actuated stripper contacts the work metal ahead of the punches and acts as a hold-down. On the upstroke, the metal is stripped from around the punches. The third function is to guide small punches. To ensure that the force at the points of contact and release is sufficient to accomplish the stripping, stripper springs must exert the calculated force in the open-die position (not just in the closed-die position).

Self-Contained Tools. Piercing tools can also be purchased as individual units consisting of frame, punch, die, and spring or hydraulic strippers. The self-contained unit is not attached to the press ram, but is located, pinned, and bolted to a die plate, template, or T-slot plate mounted on the bed of any type of press having adequate shut height. The units can be reused by relocating, pinning, and bolting. They can be used singly or in groups and with notching units of the same construction. Punch and die sizes can be replaced as desired, and standard sizes and shapes are available for piercing thicknesses up to 19 mm ($\frac{3}{4}$ in.). The units are available in various styles for the horizontal and vertical piercing of flat or flanged workpieces.

Tool Materials. The materials used for piercing punches and dies are selected to suit the service requirements. In general, the materials used are the same as those for blanking (see the article "Blanking of Low-Carbon Steel" in this Volume).

Piercing involving unusual shock and high impact may require a shock-resistant tool steel such as S7. As in blanking, M2 high-speed steel is used for long punch life, particularly in piercing thicker steel, or where high abrasion resistance is required. In Example 7 in this article, a cam-actuated punch made of an air-hardening tool steel was replaced by a punch made of low-carbon steel, carburized and hardened. This change increased tool life tenfold.

Information on the selection of tool material and data on tool life are given in the article "Selection of Material for Blanking and Piercing Dies" in this Volume.

Use of Single-Operation Dies

Single-operation piercing dies are used:

- When piercing is the only operation to be performed
- When the holes to be pierced are so close to the edge of the work that the incorporation of a piercing operation into a compound die would weaken the die elements
- When the required accuracy or the sequence of operations prevents the inclusion of piercing in compound, progressive, or transfer dies

In large work, such as panels for automobiles, holes are often pierced in a separate operation for numerous reasons. For example, the holes may distort during forming, accuracy of position may be impaired if holes are pierced before forming, or separate operations may provide a more balanced work load and reduce maintenance.

As an example, when a hole is pierced and coined to a bevel with the same punch, coining extrudes an excessive burr between the punch and the die unless a close punch-to-die clearance is maintained. Die maintenance can be reduced by using separate piercing and coining dies.

Use of Compound Dies

Compound dies are used for most piercing operations in which accuracy of position is important. Except for the production of small lots, the use of a compound die is usually the most economical method for making a pierced and formed part to commercial tolerances. The following example describes the use of a compound die to blank and pierce a U-shaped bracket before it was formed.

Example 1: Piercing Five Holes with a Compound Blank-and-Pierce Die.

The mounting bracket shown in Fig. 7 was made of 4.55 mm (0.179 in.) thick hot-rolled 1010 to 1025 steel strip, 200 mm ($7\frac{7}{8}$ in.) wide, in two operations: blank and pierce, then U-form. A compound die was used to blank the outline and pierce three round holes and two slots. The holes were reamed to size in a secondary operation to hold the 0.025 mm (0.001 in.) tolerance on the diameter. The compound die was made of oil-hardening tool steel (O2) hardened to 58 HRC. Punch-to-die clearance was 5% of stock thickness per side.

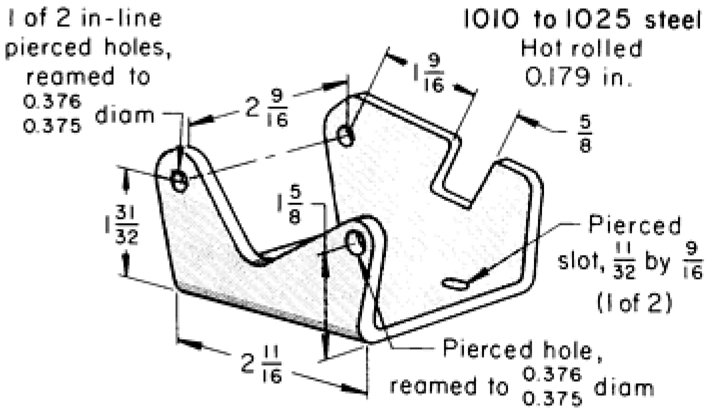

Fig. 7 Bracket that was blanked and pierced in a compound die before being formed. Dimensions given in inches

The blank was located by pins in the 8.7 × 14 mm ($\frac{11}{32} \times \frac{9}{16}$ in.) slots for the forming operation. A spring-loaded pressure pad held the blank firmly against the punch during forming. To overcome springback, the flanges were overbent by 2 to 3°. The forming die was made of air-hardening tool steel (A2).

Total tolerance on location of the in-line holes was 0.25 mm (0.010 in.). Production lots were 50 to 100 pieces. Expected die life was 15,000 to 20,000 pieces before regrinding.

Piercing of Low-Carbon Steel

Use of Progressive Dies

Progressive dies perform blanking, piercing, and other operations in successive stations of a die. Each station in a progressive die is similar to a simple die or a compound die. The workpiece in a progressive die remains connected to the strip of work metal until the last station in the die, so that the feeding motion carries the work from station to station.

In a progressive die, piloting holes and notches are pierced in the first station. Other holes can be pierced in any station if they are not affected by subsequent cutting or forming. Holes for which the relative position is critical are pierced in the same station; other holes are distributed among several stations if they are close together or near the edge of a die opening. Tolerances on hole shape, size, or location dictate whether holes are pierced before or after the part is formed.

It is often advisable to add idle stations or to distribute the work over one or two additional stations, so that holes will not be pierced near the edge of a die block. The die block is therefore stronger, and there is less chance of the die cracking in operation or fabrication. Adding stations also allows better support for the piercing punches and increases strength to the strip.

Progressive dies are more expensive than a set of single-operation dies for the same part; therefore, progressive dies are generally used for high production. However, because one part is made at each press stroke, direct labor costs are greatly reduced, and one operator can often attend to more than one progressive die. Manufacturing costs can also be reduced by making a pierced and formed part in a progressive die, rather than in two separate dies (one compound and one single-operation die).

The amount of scrap produced in progressive dies is generally high because the nesting of parts is somewhat limited and because material must be provided for connecting tabs and carrier strips. A fully automatic press with cutoff, feed, straightener, and coil cradle or reel is normally used with a progressive die; therefore, press costs are high. Pierced parts can sometimes be made most economically in a progressive die by using coil stock that is the exact width of the developed blank. In the following example, the high-volume production of a bracket in a progressive die is compared with the production of smaller quantities in separate operations in utility tooling.

Example 2: Producing a Bracket in Large Quantities in a Progressive Die and in Small Lots with Utility Tooling.

Figure 8 shows a bracket and the strip development for producing it in a five-station progressive die in a 670 kN (75 tonf) mechanical press that had a 102 mm (4 in.) stroke, an air-actuated stock feeder, and an automatic oiler. Material for the bracket was coiled cold-rolled low-carbon steel strip, 2.41 mm (0.095 in.) thick by 13 mm ($5\frac{1}{4}$ in.) wide, in the No. 2 (half-hard) temper.

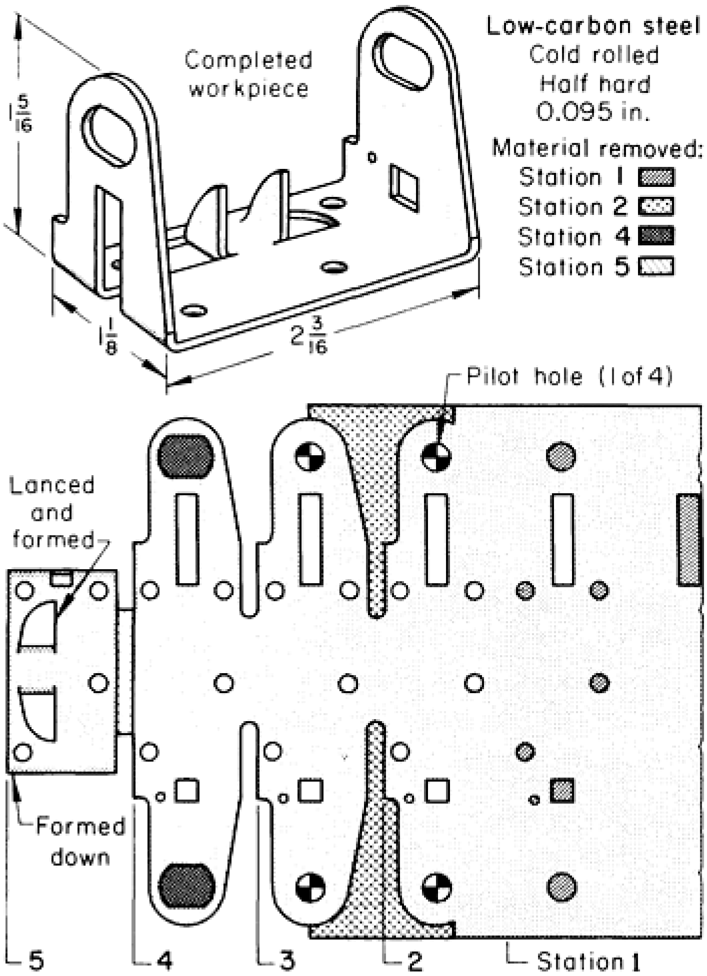

Fig. 8 Bracket that was produced more economically and more accurately in a progressive die (strip layout shown) than by the separate-operation method used for small quantities. Dimensions given in inches

The die was made of D2 tool steel and hardened to 59 to 60 HRC. Setup time was 1.5 h, and the press was stopped for die maintenance at intervals of 15,000 pieces. Production rate was 1200 pieces per hour. A light paraffin oil was the lubricant. The tolerance on the dimensions of all of the pierced holes was +0.051, -0.025 mm (+0.002, -0.001 in.), and the tolerance on the position of the square hole and the two rounded slots was ±0.13 mm (±0.005 in.).

Small quantities of the brackets were made from coil stock 29 mm ($1\frac{1}{8}$ in.) wide in the following operations, using utility tooling:

- Cut stock into 13 mm (5 in.) lengths (3500 pieces per hour)
- Trim end in a single-operation die, two strokes per piece (1000 pieces per hour)
- Pierce two holes 10.1 × 13.3 mm (0.398 × 0.523 in.), one at each end, in a single-operation die, two strokes per piece (1000 pieces per hour)

- Pierce a 4.88 mm (0.192 in.) wide slot and a 5.11 mm (0.201 in.) square hole, and lance and form two ears, all in a compound die for accurate relative position (2000 pieces per hour)
- Bend the ends down, locating on the ears (1000 pieces per hour)
- Drill four holes 4.90 mm (0.193 in.) in diameter in a multiple-spindle drilling machine (500 pieces per hour)
- Drill small hole next to square hole (500 pieces per hour)

The short-run method required eight times as many man-hours per 1000 pieces as the progressive-die method, and the brackets produced were less accurate.

Piercing of Low-Carbon Steel

Use of Transfer Dies

Transfer dies are used for piercing in applications that are similar to those for which progressive dies are used. A number of operations are done in successive stations of the transfer die.

Blanking, cutoff, lancing, notching, forming, and drawing (as well as piercing) can be done in transfer dies. The method differs from progressive-die operation in that the workpiece does not remain attached to the strip for feeding, but is fed from station to station by transfer fingers. Production quantities must be large enough to justify the cost of tooling and equipment.

Piercing of Low-Carbon Steel

Accuracy

Accuracy in the dimensions between pierced holes is highest for holes that are pierced by the same die in one press stroke. Accuracy in the location of holes relative to an edge or some other feature is highest when the workpiece is blanked and pierced (or pierced and trimmed) in the same stroke in a compound die.

When the above procedures are used, total tolerances of 0.25 mm (0.010 in.) on hole location and 0. 13 mm (0.005 in.) on hole size are readily met in normal production, and closer tolerances can be met with suitable tools, as indicated in Table 4. Tooling cost and per-piece cost usually increase in piercing to closer tolerances. Accuracy is typically somewhat lower for holes pierced by different dies or in different stations of a progressive or transfer die because of piloting and nesting tolerances.

Table 4 Typical accuracy in piercing

For holes that are pierced with a conventional die in the same press stroke. Location will be less accurate for holes that are pierced with different dies, or pierced in different stations of a progressive die or a transfer die.

Finish on tools	**Die retainers used**		Total tolerance on pierced holes			
			Location[a]		Size[b]	
	Typical material	**Locating holes for tools**	**mm**	**in.**	**mm**	in.
Commercial ground	1020 or 4130[c]	Drilled in a drill press	0.25	0.010	0.13	**0.005**
Commercial ground	1020 or 4130[c]	Jig bored and jig ground	0.10	0.004	0.13	**0.005**

Precision ground	**4130(d)**	**Jig bored and jig ground**	**0.05**	**0.002**	**0.03**	**0.001**

(a) Relationship between hole centers or between hole center and edges or other reference points on the workpiece.

(b) Diameter for round holes, or other control dimension for holes of other shapes.

(c) Can be hardened; other grades of steel also can be used.

(d) Hardened and tempered before being jig ground

Tolerances smaller than the lowest given in Table 4 can be met with the use of special tooling and gaging and close control over the press operations, but only at increased cost and a lower production rate. The use of shaving to produce holes to a tolerance of less than 0.025 mm (0.001 in.) in size is described in Example 11. The use of fine-edge blanking for improved accuracy and edge quality is discussed in the article "Fine Edge Blanking and Piercing" in this Volume.

Accuracy of hole location is increased by the use of a rigid stripper, precisely aligned on guideposts, to guide the punches. Typical clearance of round punches in the stripper (using drill bushings as guides) is 0.005 to 0.013 mm (0.0002 to 0.0005 in.) total. Lubrication is important in dies that have such close clearance between punches and stripper. At speeds of 40 strokes and more per minute, the die must be lubricated constantly with a spray of light machine oil to prevent galling of the punches in the guides.

Accuracy often requires that holes be pierced after forming. In some cases, it may be necessary to pierce a hole after forming in order to avoid distortion of the hole. In Example 8, holes on opposing flanges were cam pierced in one stroke after forming for accurate alignment. In Example 7, two slots were pierced in flanges after forming, instead of being machined, for accurate alignment and location.

Noncritical holes, for which there are no close tolerances on size or spacing, can be pierced for venting (to provide for free passage of air or other fluids), for lightening, for improved bond with a molded plastic cover, for increased flexibility of a workpiece, and even to provide controlled strength. In the following example, noncritical holes were pierced to weaken a part so it would deflect under impact or shock loading.

Example 3: Piercing Noncritical Holes.

The workpiece shown in Fig. 9 is a wheel spider that was designed to be enclosed in molded plastic and to deflect under impact load. The spider was made of hot-rolled 1008 or 1010 steel, dead soft, pickled and oiled. The steel strip, 3.2 mm ($\frac{1}{8}$ in.) thick by 406 mm (16 in.) wide, was hand fed into a two-stage progressive die in a 4 MN (450 tonf) mechanical blanking press. In the first stage, noncritical holes were pierced to make the spider deflect upon impact and to provide a better bond with the molded plastic. The piece was blanked in the second stage. The pierced blanks were then fed into a 5.3 MN (600 tonf) mechanical forming press, where the part was formed. The forming die was sprayed with soluble oil.

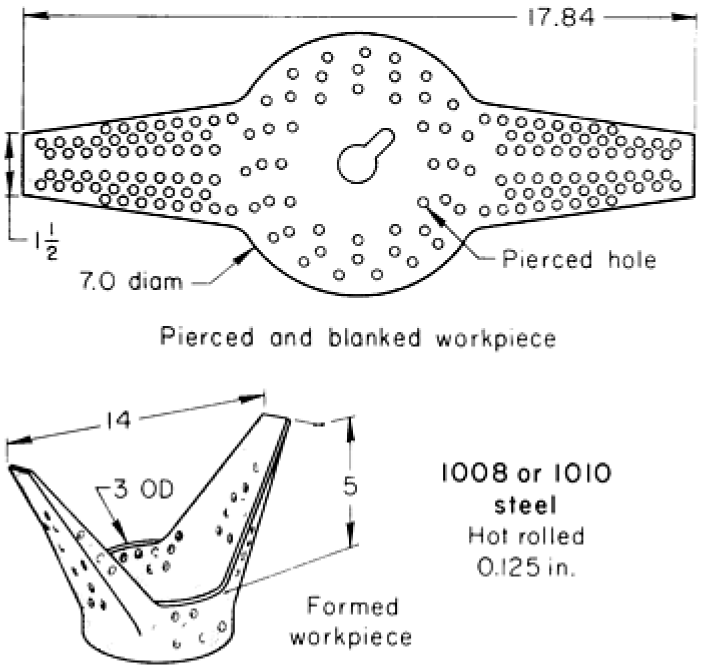

Fig. 9 Wheel spider in which noncritical holes were pierced for deflection under impact and to improve bonding to plastic. Dimensions given in inches

Hole Size

Pierced holes can be of almost any size, ranging from holes as small across as the thickness of the stock to the largest size that can be adapted to the equipment available. Some holes can be pierced that are smaller across than the stock thickness, but such piercing is not common.

Small holes and slots are pierced in much the same manner as large holes, but small holes are more difficult to pierce because slender punches are comparatively weak. To minimize deflection and breakage, punch length is limited to that needed for the operation, and punches are specially stiffened and guided (Fig. 6). The minimum hole size that can be pierced in a specific application is ordinarily found by trial.

Piercing of Thick Stock

The effects of work metal thickness on piercing are generally the same as on blanking. Cutting force increases with thickness; consequently, tool design and material, press selection, and operating conditions are influenced by work metal thickness. The relationship between die clearance and work metal thickness is discussed in the sections on die clearance in this article. The minimum pierced hole size is usually expressed as a function of work metal thickness, as described in the preceding section. The following example illustrates the piercing of unusually thick flat workpieces prior to forming.

Example 4: Piercing a Square Hole in 19 mm ($\frac{3}{4}$ in.) Plate.

A hole 17 mm ($\frac{11}{16}$ in.) square was pierced through high-strength low-alloy steel plate 19 mm ($\frac{3}{4}$ in.) thick in a die in a 1.1 MN (120 tonf) open-back inclinable press. The die was made to pierce holes one at a time in any of several flat workpieces. A typical workpiece size was 19 × 305 × 940 mm ($\frac{3}{4}$ × 12 × 37 in.).

The production rate for piercing in D2 tool steel dies was 300 to 360 pieces per hour. Maximum yearly production was 1000 pieces.

After the holes were pierced, the workpiece was heated to 815 °C (1500 °F) and formed into a curved shape. The shape was used as a digger bucket--one of many that were bolted to a large wheel (digger rim) of a machine used for digging trenches for sewers and pipelines.

Radial Piercing of Curved Surfaces. The radial piercing of thick curved workpieces is done in the same manner as the piercing of flat workpieces, except that the die must be designed to accommodate the curved parts. The piercing of a hole through round stock, such as a radial hole through a cylinder, is done by using a die with a heavily loaded stripper, both of which fit the round shape of the workpiece. The round hole is then readily pierced with little bulging of the workpiece, even though the hole can be as large as 40% of the diameter of the workpiece. The center of the hole should be at a distance from the end of the workpiece that is at least equal to the work thickness (diameter of the rod).

Piercing of Thin Stock

Because of its strength and rigidity, material thicker than 3.2 mm ($\frac{1}{8}$ in.) is seldom blanked or pierced from coil stock or in a progressive die. On the other hand, material thinner than 0.51 mm (0.020 in.), because of its lack of strength and extreme flexibility, generally requires special handling techniques. The following example describes the blanking of steel shims from thin coil stock in a compound die.

Example 5: Piercing of Shims from 0.25 mm (0.010 in.) Strip in a Compound Die.

The shim shown in Fig. 10 was made from coil stock of cold-rolled 1008 steel, 19 mm ($\frac{3}{4}$ in.) wide by 0. 25 mm (0.010 in.) thick, in a pierce-and-cutoff compound die. Thickness tolerance was +0, -0.025 mm (+0, -0.001 in.). The coiled strip was fed automatically from a stock reel by an air-operated slide feed into a 220 kN (25 tonf) open-back inclinable press that operated at 150 strokes per minute.

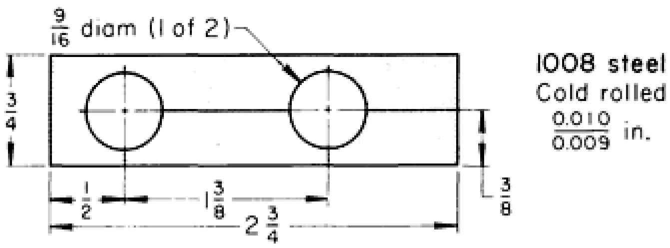

Fig. 10 Shim that was pierced and cut off from thin coiled strip in a compound die. Dimensions given in inches

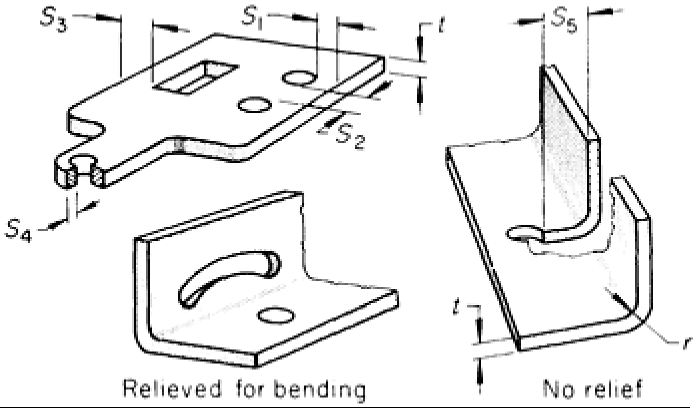
The die, made of oil-hardening D3 tool steel, produced 230,000 shims before it needed sharpening. Die life was indefinite because a thickness of 38 mm ($1\frac{1}{2}$ in.) had been provided for grinding allowance in repeated sharpenings in order to restore the cutting edge.

Hole Spacing

Recommended minimum spacings for pierced holes are given in Table 5. These minimum spacings apply when ordinary pressworking practices are followed, without confinement of the workpiece in the die or other special procedures to prevent distortion.

Table 5 Recommended minimum spacings for pierced holes in flat and formed steel and nonferrous metal workpieces



Dimension	Work metal thickness (t), mm (in.)	Minimum distance, mm (in.)
S_1 and S_2	<1.57 (0.062)	**3.05 (0.120)**
	1.57-9.65	
	(0.062-0.380)	**3.05 (0.120) (but at least 1.5*t*[(a)]**
S_3 and S_4	<0.81 (0.032)	**1.52 (0.060)**
	0.81-3.18	
	(0.032-0.125)	**2*t***
	3.18-9.65	
	(0.125-0.380)	**2.5*t***

(a) For steel. Minimum for nonferrous metals, 2*t*.

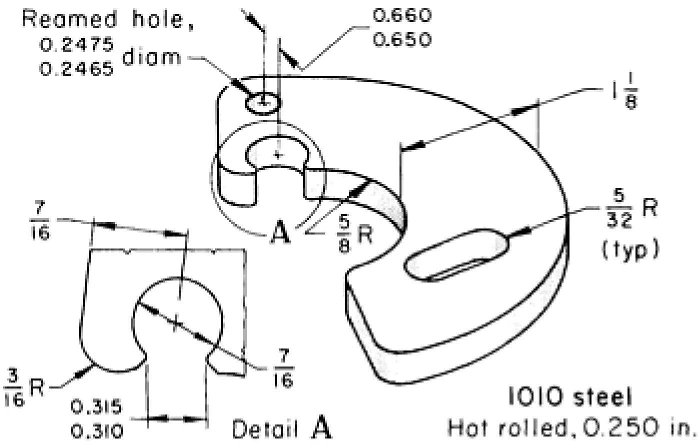
(b) For flanges with no relief. Value for S_5 can be reduced when work metal is relieved for bending (as shown at lower left above) to prevent distortion of the pierced hole in forming.

As noted in Table 5, S_5 (the distance from the edge of a hole to the inside of a flange) can be reduced when the metal is relieved near the pierced hole (as by a slot) to prevent distortion of the hole in forming. Accuracy in the shape and location of pierced holes often demands that the holes be pierced after the workpiece has been formed.

When a round hole must be pierced so as to leave almost no metal between the edge of the hole and the edge of the part, the hole can be cut through the edge in a keyhole shape that minimizes bulging and does not leave sharp points. In the following example, spacing between the keyhole and the end of the part was only 58% of the recommended spacing given in Table 5, and spacing for the round hole and the slot was only 50% of the recommended spacing. Confinement of the blank in the die prevented distortion at the keyhole and the slot.

Example 6: Piercing Holes at Less Than Recommended Minimum Edge Distance.

The flyweight shown in Fig. 11 was part of a centrifugal device used to release pressure. The part was made of hot-rolled 1010 steel, pickled and oiled, 6.4 mm ($\frac{1}{4}$ in.) thick. Preliminary design had a wall thickness of 2.4 mm ($\frac{3}{32}$ in.) between the 11 mm ($\frac{7}{16}$ in.) diam hole and the edge of the part. The original tooling called for a compound die to pierce and blank the part completely in one press stroke. However, with the fragile punch required, it was impossible to hold the 8.00/7.87 mm (0.315/0.310 in.) dimension on the keyhole opening (Detail A, Fig. 11).



Sequence of operations	
Shear 1-2 m (4-8 ft) long by 100 mm (3 $\frac{7}{8}$ in.) wide Blank outline; pierce round hole (1000 pieces/h) Ream and deburr round hole (300 pieces/h) Pierce keyhole and oval slot (770 pieces/h)	
Operating conditions	
Type of press	**670 kN (75 tonf) mechanical**
Press speed	**55 strokes per minute**
Die material	**A2 tool steel at 58-60 HRC**
Lubricant	**Sulfur-base, EP type[(a)]**
Production rate[(b)]	**300 pieces per hour**

Die life per grind	**20,000 pieces**
Total die life	**1 million pieces**

(a) Applied to strip by roller.

(b) Lot size was 2500 pieces; annual production, 10,000 pieces.

Fig. 11 Flyweight in which holes were pierced at less than recommended minimum distances from the edge. Overall length of the flyweight was 90 mm ($3\frac{1}{2}$ in.). Dimensions given in inches

Production was successful when the part was made in three separate dies, using the sequence of operations shown in the accompanying table. A keyhole punch was used to pierce the 11 mm ($\frac{7}{16}$ in.) diam hole. The hole-to-edge spacing was increased from 7.9 to 11.1 mm ($\frac{5}{16}$ to $\frac{7}{16}$ in.).

Distortion was minimized by confining the blank in a nest during piercing. In the compound die, the hole shown in Detail A and the edge of the part were connected with a radius tangent to both. When the keyhole punch was used, the punch surface intersected the outer edge at a 45° angle--a change that did not interfere with the function of the part but avoided difficulty in making a transition radius tangent to the outer edge.

The hole to be reamed was pierced with a 5.74 mm (0.226 in.) diam punch and a 6.25 mm (0.246 in.) diam die. The hole was later reamed to 6.29/6.26 mm (0.2475/0.2465 in.) in diameter for nearly its full length and then deburred. This hole was perpendicular to the part surface within +0° 45'.

Effect of Forming Requirements

It is simpler to pierce holes in a flat sheet than in a part that has been formed. Holes near a bend radius (see the illustration in Table 5) are usually distorted when the part is formed. If distorted holes are unacceptable or if an accurate relation of holes to other features in a workpiece is specified, piercing must be done after forming.

Dies for piercing after forming are generally more complex, more expensive, and require more maintenance than dies for flat blanks. These dies often have cam-actuated punches.

In Example 9, when the part was U-formed after piercing, one hole closed in during forming, resulting in an elongated hole. This deformation was taken into consideration during product design. The following two examples describe applications in which it was necessary to pierce holes after forming.

Example 7: Piercing of Accurately Located Slots after Forming.

Figure 12 shows a formed part that, because of close tolerances, should not be slotted before forming. The original procedure was to drill the holes and mill the slots to hold the alignment of the slots to the end radii and to the tongue within 0.08 mm (0.003 in.). Results from machining were unsatisfactory, and it became necessary to pierce the slots after forming in order to hold tolerances.

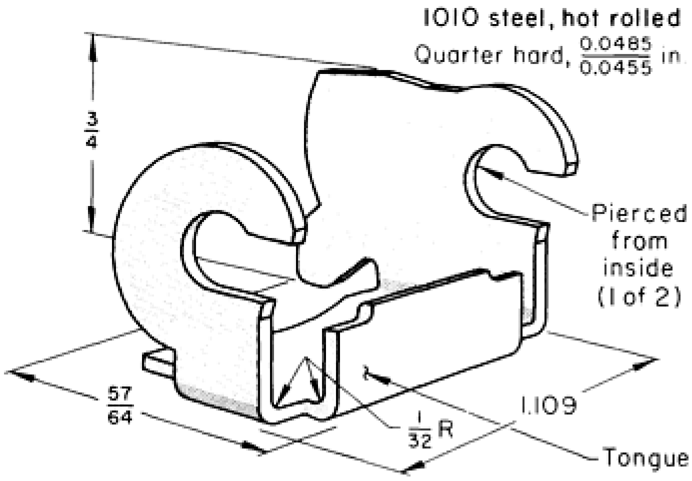


Fig. 12 Part in which accurately aligned slots were pierced (after forming) by two punches that were cam operated from the inside. Dimensions given in inches

The size and shape of the part and the location of the slots precluded piercing from the outside. Piercing was done from the inside by two punches split on the centerline of the part and moved outward by cam action.

The original punches were made of air-hardening tool steel hardened to 58 to 60 HRC. Because of breakage, the maximum punch life was 10,000 pieces. Changing the punch material to carburized and hardened 1025 steel increased the average punch life to 100,000 pieces. Annual production was about 240,000 pieces in lots of 50,000 to 60,000.

Example 8: Cam-Piercing Holes in Opposing Flanges of a Formed Part for Accurate Alignment.

To maintain alignment of the two opposing holes in the automobile-frame control-arm bracket shown in Fig. 13, the holes were cam pierced in one press stroke after the part was formed. Tolerance on hole alignment was ±0.13 mm (±0.005 in.).

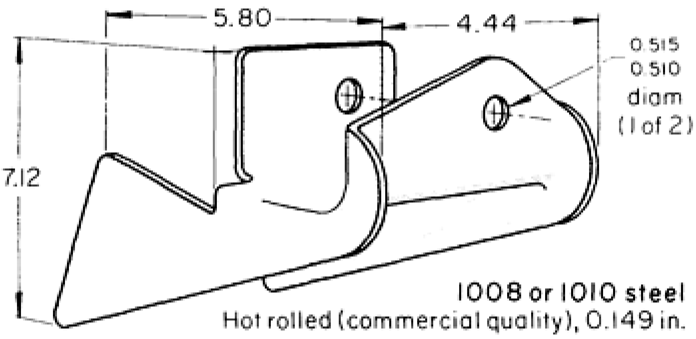

Fig. 13 Bracket in which accurately aligned holes on opposing flanges were cam pierced in one press stroke after forming. Dimensions given in inches

The bracket was made of commercial-quality 1008 or 1010 steel, as-rolled, 3.78 mm (0.149 in.) thick, in five operations:

- Blank two workpieces per stroke
- Prebend, form, and re-form in three separate dies, side by side
- Form ear
- Trim in two stages
- Restrike and campierce

Blanking was done at 1800 pieces per hour in a 4.4 MN (500 tonf) coil-fed automatic blanking press. The remaining operations were done at 135 pieces per hour in a 2.7 MN (300 tonf) or a 3.6 MN (400 tonf) mechanical press.

The use of high-production equipment, including the cam-operated piercing die, was economical for the annual production of 350,000 pieces in 20,000-piece lots. Drilling would have been used for making the holes if 10,000 or fewer pieces had been needed per year to meet production requirements.

Piercing Holes at an Angle to the Surface

For piercing holes that are not perpendicular to the surrounding surface, the workpiece is securely clamped to the die with a pressure pad, and the dies are usually ground to fit the contour of the part. The shape of the punch nose depends on the angle of contact with the workpiece and on the stock thickness.

In one application, holes 7.9 mm ($\frac{5}{16}$ in.) in diameter were pierced in 6.35 mm (0.250 in.) thick 1090 steel at an angle of 83° to the surface. The holes were pierced by using sleeved punches and clamping the work tightly to the die with a pressure pad. In the following example, holes were pierced at an angle of 40° 30' to the surface of a flat workpiece, which was later formed by bending.

Example 9: Piercing Holes at an Angle to the Work Surface.

Two 12.8 mm (0.505 in.) diam holes were pierced at an angle of 40° 30' to the surface in the 2.67 mm (0.105 in.) thick cold-rolled 1010 steel flat blank for the lamp-bracket base shown in Fig. 14. To pierce the compound-angle holes, the blank was placed in a nest, which held it at the proper angle and position for piercing. By repositioning the blank in a second nest, it was possible to pierce both of these holes with one punch and die.

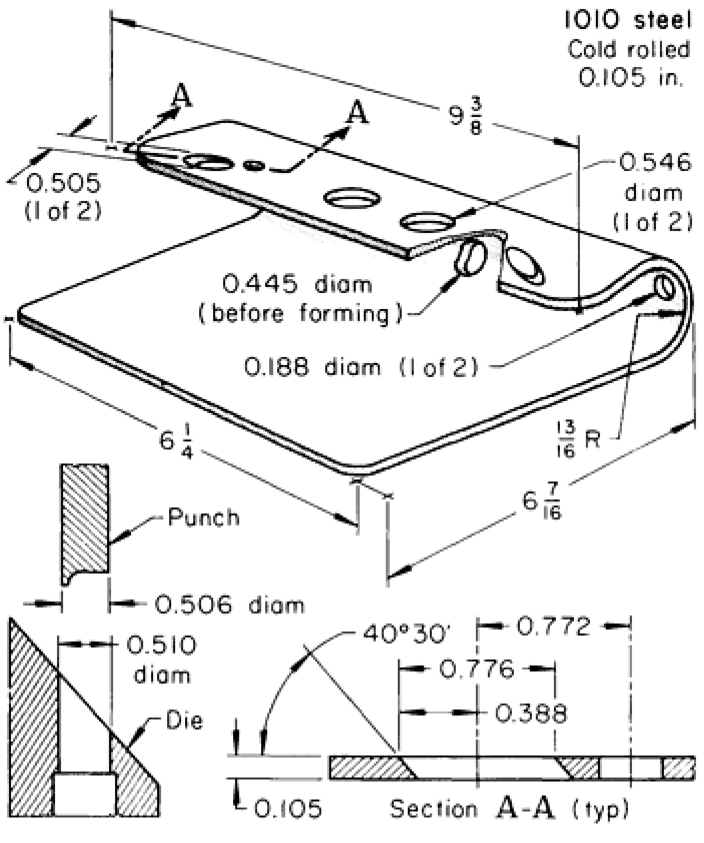

Fig. 14 Lamp-bracket base in which two holes were pierced at an angle to the surface using the punch shown at lower left. All holes were pierced before the part was formed. The 90° hole in the U-bend zone deformed to an elliptical shape during forming. Dimensions given in inches

The face of the die button was ground flush with the surface of the nest. The die had a straight land with a minimum length of 9.5 mm ($\frac{3}{8}$ in.). There was a 16 mm ($\frac{5}{8}$ in.) diam relief below the land. The punch was ground with a step, as shown in Fig. 14. This step curled the slug, permitting the use of a long straight land in the die. The punch and die were made of M2 high-speed steel, hardened to 58 to 59 HRC. Punch-to-die clearance was 0.05 mm (0.002 in.) per side. Die life was 15,000 holes per grind.

The punch was mounted in a heavy quill designed for quick changing, which proved unnecessary. A spring-loaded pressure pad guided and added support to the punch and held the blank securely in the nest. The pressure pad was interlocked with the die so that shifting could not take place after piercing started. The die was run in a 90 kN (10 tonf) mechanical press, which produced 300 pieces per hour.

Before the angle holes were pierced as described above, the outline of the part and seven 90° holes had first been produced in a compound blank-and-pierce die. The blanking die and punch, as well as the punches and die buttons for the 90° holes, were made of O1 tool steel and hardened to 59 to 60 HRC. The die was mounted in a 900 kN (100 tonf) mechanical press producing 300 pieces per hour. Die life was 40,000 pieces per grind.

When the workpiece was bent through 180° after all of the holes had been pierced, the 11.3 mm (0.445 in.) diam hole changed in shape, assuming final dimensions of 10.4 × 11.3 mm (0.411 × 0.443 in.). This deformation did not affect the function of the hole.

Special Piercing Techniques

Piercing operations that require special tooling and techniques include the piercing and forming of flanged holes, piercing with a fastener and with a pointed punch, and tube piercing.

Flanged holes (sometimes called extruded, countersunk, dimpled, or burred holes) are generally used for assembly purposes, such as providing more thread length for a tapped hole, greater bearing surface, or a recess for a flathead screw or rivet. The flanged hole can be produced by forcing a punch of the desired hole diameter through a smaller prepierced hole or by using a shouldered or pointed punch that both pierces the hole and flanges it.

The depth of flange that is formed depends on the elongation of the metal, and the flange is thinnest at its outer edge. A deeper flange can be made by extruding metal into the flange. Such flanging is done by first piercing a smaller lead hole and then using a punch that extrudes metal around the hole into the die clearance to produce a flange and simultaneously coins or forms a slight chamfer (depressed cone) or other shape of recess into the hole (see also the article "Press Bending of Low-Carbon Steel" in this Volume). This kind of extruded flange has uniform wall thickness. Such extrusion causes more metal flow and greater work hardening than ordinary piercing of flanged holes.

Piercing with a fastener (self-piercing) is primarily used as an assembly technique. A rivet, for example, can be used as a punch to pierce a hole through the material that it will join. The following example describes an application in which a square nut with a sharp face served as a piercing tool and then became part of an assembly.

Example 10: Automatic Assembly of Self-Piercing Nut into a Bracket.

A square nut was automatically assembled into a body-bolt bracket, as shown in Fig. 15. The nut served as the piercing punch to make a 17.4 mm (0.687 in.) square hole in the embossed portion of the bracket. The bracket was made of galvanized, hot-rolled 1006 steel, 1.9 mm (0.075 in.) thick. After being pierced, the metal sprang back into two grooves in the nut, locking the nut into the pierced square hole. The nut was fed from a special installing head that was loaded from a rotary hopper.

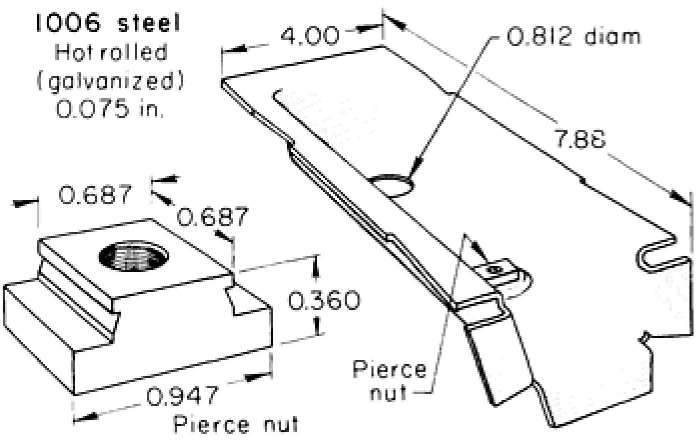

Fig. 15 Bracket with a square nut that pierced a hole for itself. Dimensions given in inches

Two assemblies were completed (pierced and installed) at each stroke of a 640 kN (72 tonf) open-back inclinable press running at 45 strokes per minute. Maximum daily production was 12,000 assemblies. The bracket was fed by a gravity-slide feed at the front of the press and was unloaded at the rear with the help of an air blast.

The 20.6 mm (0.812 in.) diam hole was pierced at the same time the nut was inserted. Commercial punches and die buttons were used.

A standby unit for piercing a square hole was available in case a supply of the square nuts was not on hand when the part was scheduled to run. The nuts were later inserted and clinched using pneumatic equipment.

Holes made with a pointed punch, such as a cone-point, nail-point, or bullet-nose (ogive) punch, have rough or torn flanges. Such a hole is satisfactory for holding a sheet metal screw, acting as a spacer, or providing a rough surface.

Tube piercing and slotting are done in dies when production lots are large enough to pay for special tooling. Simple dies, as well as more complex tooling such as cam dies, are designed to hold, locate, and pierce tubes, drawn cups, and other round parts.

A mandrel can be used in a horn die for work on tubing and other round parts as well as for piercing, slotting, and notching. One version of a die that uses a mandrel permits piercing two opposing holes in a tube in one stroke, with the slug from one wall going through a hole in the mandrel to act as the punch for the hole in the opposite wall.

Tubes can also be pierced with opposing holes without using a mandrel. The bottom half of the tube is supported by the die, which has a nest with the same diameter as the outside diameter of the tube. A similar nest for the upper half of the tube is in a combined hold-down and punch guide. Therefore, the tube is completely surrounded during piercing. Because the bottom side of the tube is supported by the die, the lower hole is pierced without any distortion. The tube will collapse slightly around the hole in the top side of the tube. The amount of distortion of the top hole varies with the size of the tube and the hole.

Holes on opposite sides of a tube can be pierced simultaneously, using the tool shown in Fig. 16, which does not require a mandrel. The tool consists of identical upper and lower assemblies--one attached to the press ram and the other to the press bed. Each assembly consists of a punch and a spring-loaded combined nest, stripper, and punch guide. When used for multiple-hole piercing, the assemblies are usually mounted to upper and lower plates having tapped holes or T-slots. There will be a slight indentation around each hole, as shown in Fig. 16.

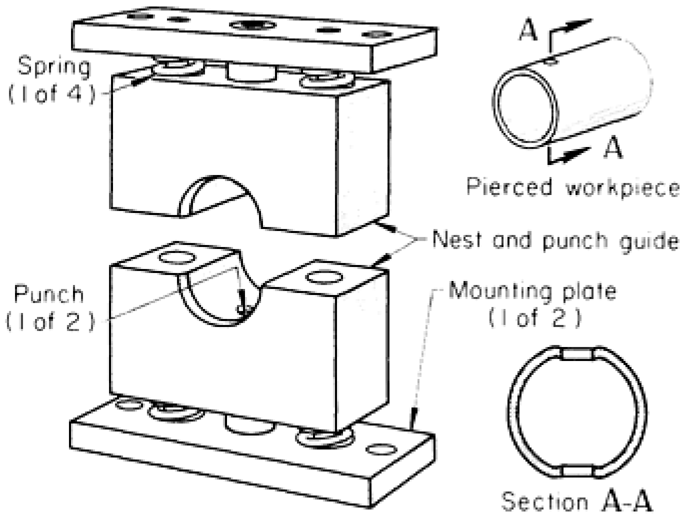

Fig. 16 Tool for tube piercing without a mandrel, and a pierced tube showing the indentations around the holes

---

Piercing of Low-Carbon Steel

Shaving

Shaving is done in a separate operation or is included in one station of a progressive die (see the article "Blanking of Low-Carbon Steel" in this Volume for more information on shaving). The inclusion of a shaving operation in a progressive die generally increases the need for die maintenance, and the slivers of shaving scrap can jam the feeding mechanism. A replaceable insert can be used in a shaving die for easier maintenance.

Shaving allowance depends on the workpiece material and on its thickness.

Shaving plus burnishing is used to produce greater accuracy in a pierced hole than can be obtained by shaving alone, as shown in the next example.

Example 11: Use of Blanking, Piercing, Shaving, and Burnishing in Making Gear Blanks to Close Tolerances.

The small gear blank illustrated in Fig. 17 was produced from a 50 mm (2 in.) wide strip of cold-rolled 1010 steel of No. 2 temper in a five-station progressive die to the following specifications:

- Critical tolerance of +0.013, -0.010 mm (+0.0005, -0.0004 in.) on the center hole
- Finished blanks flat within 0.05 mm (0.002 in.)
- Surface finish of 0.70 μm (28 μin.) or smoother for 70% of the center-hole surface

These specifications were met by piercing, shaving, and burnishing the center hole in the sequence of operations indicated by the strip progression. A sulfurized and chlorinated extreme-pressure (EP) lubricant was applied to the coil stock by roller coating.

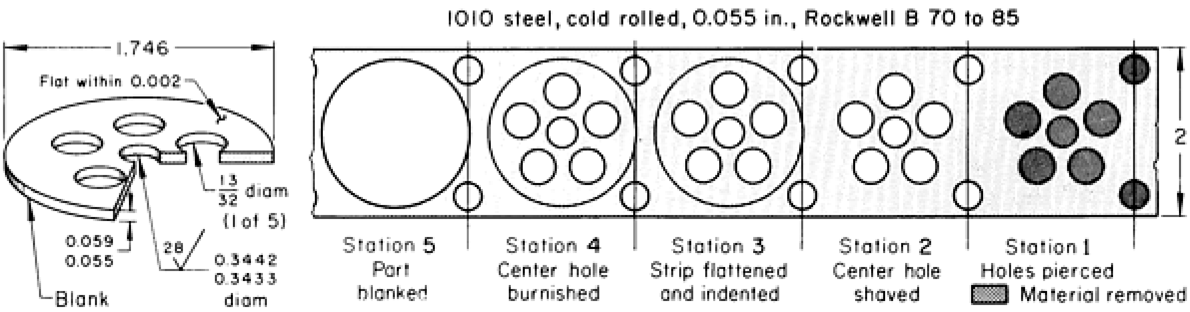

Fig. 17 Gear blank that was produced with an accurate center hole by piercing, shaving, and burnishing in a five-station progressive die. Dimensions given in inches

Annual production was 2 million pieces in four lots. The gear blanks were made at 150 pieces per minute in a 530 kN (60 tonf) press. The dies, made of M2 high-speed tool steel, had a life of about 100,000 pieces before regrinding and a total life of about 10 million pieces.

Piercing Versus Alternative Methods

Piercing is primarily used when accurate holes are required and when the production lot is large enough to justify the tooling costs. Alternative methods are used for smaller production lots or for holes that have a diameter less than stock thickness. Examples of alternative methods are drilling (including electrochemical machining), milling and sawing, and electric-arc and gas cutting. For increased efficiency, all of these methods can be applied to work that is stacked or nested.

Safety

Piercing, like other press operations, involves potential hazards to operators, maintenance people, and others in the vicinity. The articles "Presses and Auxiliary Equipment for Forming of Sheet Metal" and "Blanking of Low-Carbon Steel" in this Volume contain information and literature references on safe operation.

Introduction

FINE-EDGE BLANKING (also known as fine blanking) is a process developed in Switzerland to produce precise blanks in a single operation with smoother edges and closer tolerances than are possible with conventional blanking. In fine-edge blanking, a V-shaped impingement ring (Fig. 1) is forced into the stock to lock it tightly against the die and force the work metal to flow toward the punch, so that the part can be extruded out of the strip without fracture or die break. Die clearance is extremely small, and punch speed is much slower than in conventional blanking.

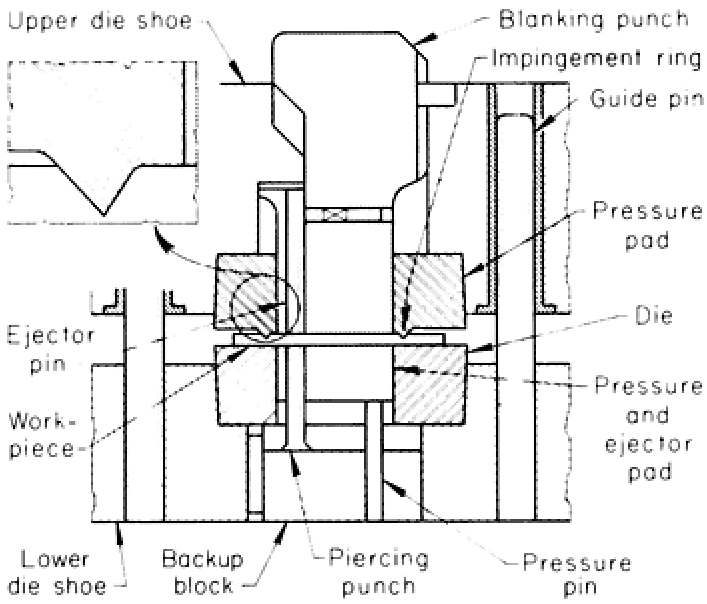

Fig. 1 Typical tooling setup for fine-edge blanking a simple shape

Fine-edge piercing can be done either separately or at the same time as fine-edge blanking. In piercing small holes, an impingement ring may not be needed.

No further finishing or machining operations are necessary to obtain blank or hole edges comparable to machined edges, or to those that are conventionally blanked or pierced and then shaved. A quick touch-up on an abrasive belt or a short treatment in a vibratory finisher may be used to remove the small burr on the blank. Specially designed single-operation or compound blanking and piercing dies are generally used for the process.

Comparison With Conventional Blanking

Fine-edge blanking and piercing (Fig. 2) are actually more akin to cold extrusion than to a cutting operation. They are similar to conventional blanking using a compound die (see the articles "Blanking of Low-Carbon Steel," "Piercing of Low-Carbon Steel," "Blanking and Piercing of Electrical Steel Sheet," and "Selection of Material for Blanking and Piercing Dies" in the Section "Blanking and Piercing of Steel Sheet, Strip, and Plate" in this Volume), but with several important differences.

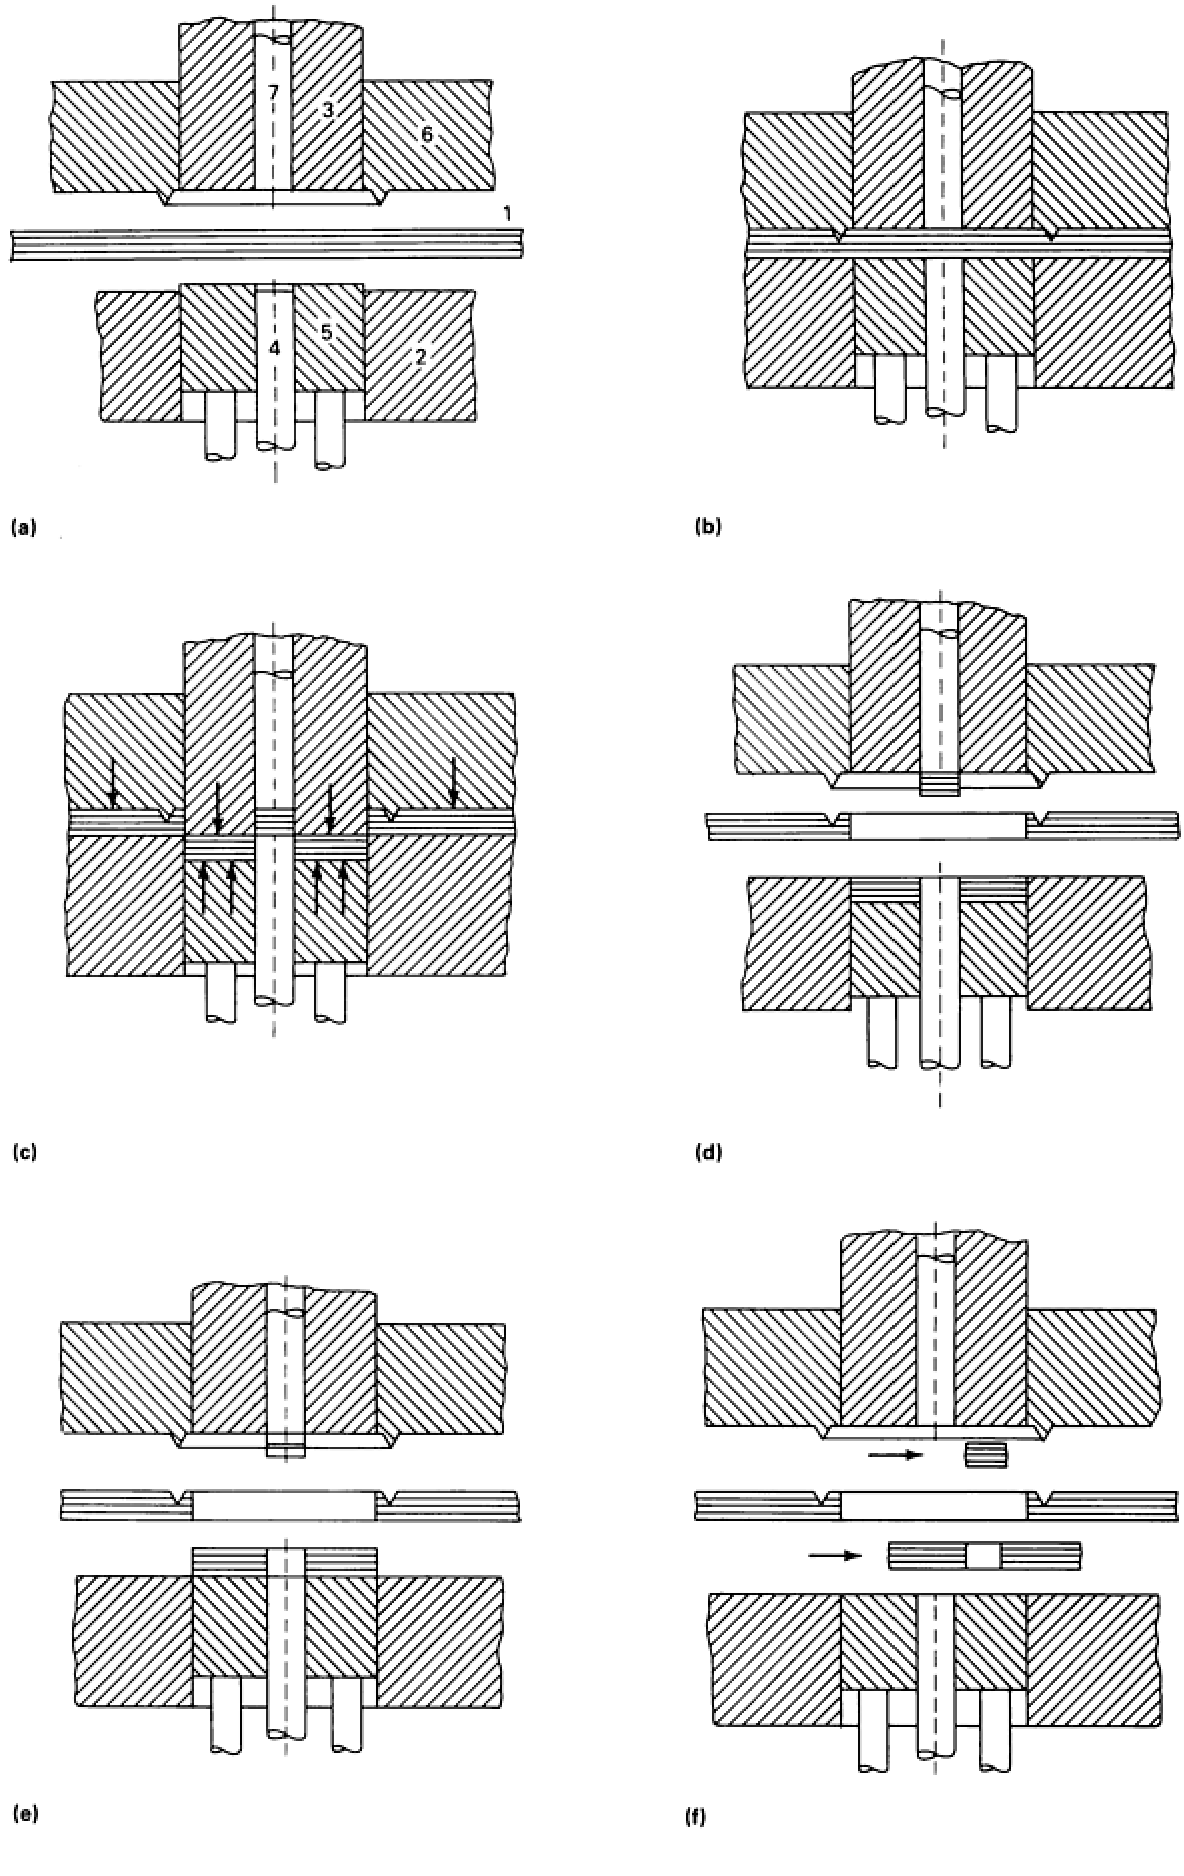

Fig. 2 The fine-edge blanking process. (a) Work material is fed into the die. 1, work material; 2, die plate; 3, punch; 4, piercing punch; 5, ejector/counterpunch; 6, impingement ring; 7, slug ejector. (b) The die closes,

and the V-shaped impingement ring is embedded into the work material. (c) The part is blanked. The impingement ring maintains pressure while blanking pressure and counterpressure are exerted against the part. (d) Slugs are ejected from the top down. (e) Part is ejected from the bottom up by reversing counterpressure. (f) Parts and slugs are removed from the die area.

First is the V-shaped impingement ring, which restricts the flow of metal away from the cutting edge and presses the material to be cut against the punch. Another important difference is the independent control of the three forces acting on the workpiece (clamping, counterpressure, and blanking) obtained through the use of a triple-action press (see the section "Presses" in this article).

The very small clearance between punch and die is another difference between fine-edge blanking and conventional blanking. Combined with correspondingly tighter tolerances on both punch and die and the fact that the punch enters the die only a slight amount if at all, this feature prevents cracking of the workpiece and results in smooth blanked and pierced edges.

Process Capabilities

Holes with diameters as small as 50% of stock thickness can be pierced in low-carbon steel. In high-carbon steel, the smallest hole diameter is about 75% of stock thickness. Holes can be spaced as close to each other, or to the edge of the blank, as 50 to 70% of stock thickness. Total tolerances obtainable are 0.013 mm (0.0005 in.) on hole diameter and for accuracy of blank outline; 0.025 mm (0.001 in.) on hole location with respect to a datum surface; and 0.025 mm (0.001 in.) on flatness.

No die break shows on the sheared surface of the hole. Blank edges may be rough for a few thousandths of an inch of thickness on the burr side of the part when the width of the part is about twice the stock thickness or less. Finish on the sheared edge is governed by the condition of the die edge and the land within the die. Parts fine-edge blanked from stainless steel will have a surface finish of 0.8 μm (32 μin.) or better. Smooth edges also are produced on spheroidize-annealed steel parts. Burr formation increases rapidly during a run, necessitating frequent grinding of the cutting elements.

Chamfers can be coined around holes and on edges. Forming near the cut edge, or forming offset parts with a bend angle up to 30°, is possible under restricted conditions.

Metals up to 3.18 mm (0.125 in.) thick having a tensile strength of 586 to 793 MPa (85 to 115 ksi) are easily blanked. Parts up to 13 mm ($\frac{1}{2}$ in.) thick can be blanked if press capacity is available. Material thicker than 3.18 mm (0.125 in.), especially steel having a carbon content of 0.25% or more, requires an impingement ring on the die so that the corners on the part will not break down. The edges of parts made of 1018 steel work harden as much as 7 to 12 points Rockwell C during blanking.

In tests on 0.60% C spring steel with a hardness of 37 to 40 HRC, the surface finish on the sheared edges was 0.8 μm (32 μin.) or better, but punch life was only 6000 pieces.

The cutting speed for fine-edge blanking is 7.6 to 15.2 mm/s (0.3 to 0.6 in./s).

Work Materials

Any material suitable for cold forming can be fine-edge blanked, including low- and medium-carbon steels, some alloy and stainless steels, copper and brass, and aluminum alloys (Table 1).

Table 1 Materials for fine-edge blanking

Material	Condition
Carbon steels	
1008-1024	**Up to fully hard**
1025-1095	**Spheroidize annealed**
Alloy steels	
AISI 4000 series, 8000 series	**Spheroidize annealed**
Stainless steels	
AISI types 301, 302, 303, 304, 316, 430, 416	**Fully annealed; shorter tool life than for plain carbon steels**
Aluminum alloys	
1*xxx*, 3*xxx*, 5*xxx* series	**H (strain hardened) temper; O (annealed) temper**
6061, 7075	**T3 or T4 for thinner gages**
Copper alloys	
C26000 (cartridge brass, 70%), C26800 (yellow brass, 66%)	**Annealed, quarter hard, or half hard**
C27400 (yellow brass, 63%)	**Fully hard in thin gages**
C17*xxx* (beryllium copper alloys)	**Annealed only**
Other nonferrous metals and alloys	
Monel alloy 400	**Annealed**
Soft bronzes	**Annealed**
Silver, gold	**Excellent results**

Carbon and Alloy Steels. The easiest materials to fine-edge blank are low-carbon steels (<∼0.25% C). Thin parts, however, have been fine-edge blanked from plain carbon steels containing up to about 0.95% C. Alloy steels can be fine-edge blanked only in the fully annealed, spheroidized condition (Table 1).

Stainless Steels. Austenitic stainless steels, such as AISI types 301 to 304 and 316, can be fine-edge blanked in the fully annealed condition. These materials, as well as the ferritic type 430 and martensitic type 416 (both fully annealed), have good blanked edges but cause higher tool wear than do plain carbon steels.

Most aluminum alloys, with the exception of alloy 2024, can be fine-edge blanked in the O (annealed) temper. Wrought alloys of the 1*xxx*, 3*xxx*, and 5*xxx* series can be fine-edge blanked in the H (strain hardened) temper with excellent results. In thinner gages, alloys 6061 and 7075 can be fine-edge blanked in the T3 or T4 condition.

Copper alloys are easily fine-edge blanked. The most workable alloys, such as alloy C27400 (yellow brass, 63%) can be fine-edge blanked even in the full hard condition. Other brasses, such as C26000 (cartridge brass, 70%) and C26800 (yellow brass, 66%) can be worked in the annealed, quarter-hard, or half-hard condition. Beryllium-copper alloys can be fine-edge blanked in the annealed condition, as can pure copper, soft bronzes, Monel alloys, nickel-silvers, and silver and gold.

Blank Design

Limitations on blank size depend on the thickness, tensile strength, and hardness of the work metal and on available press capacity. For example, perimeters of approximately 635 mm (25 in.) can be blanked in 3.18 mm (0.125 in.) thick low-carbon steel (1008 or 1010). It is possible to blank smaller parts from low-carbon or medium-carbon steel that is about 12.7 mm ($\frac{1}{2}$ in.) thick.

Sharp corner and fillet radii should be avoided when possible. A radius of 10 to 20% of stock thickness is preferred, particularly on parts over 3.18 mm (0.125 in.) thick or those made of alloy steel. External angles should be at least 90°. The radius should be increased on sharper corners or on hard materials.

Parts with tiny holes or narrow slots to be pierced or with narrow teeth or projections to be blanked may be unsuited to fine-edge blanking. Hole diameter, slot width, or projection width should be at least 70% of metal thickness for reasonably efficient blanking, although features as small as 50% of stock thickness have been successfully formed.

These limitations have been exceeded. For instance, a 16 mm ($\frac{5}{8}$ in.) diam hole was pierced in each end of a 1018 steel link 25 mm (1 in.) wide and 7.9 mm ($\frac{5}{16}$ in.) thick. Because the part had a 13 mm ($\frac{1}{2}$ in.) radius on each end, the wall thickness was 3.92 mm ($\frac{3}{16}$ in.). The part was offset 2.54 mm (0.100 in.) in the same die. Holes 3.18 mm (0.125 in.) in diameter were pierced in a part made of 4 mm (0.156 in.) thick aluminum alloy 5052-H34, leaving a wall thickness of 1.0 mm (0.040 in.). A 1.6 mm (0.062 in.) diam hole was pierced in the same part.

The sheared faces of holes pierced during fine-edge blanking are usually vertical, smooth, and free from die break, provided the maximum hole dimensions are not more than a few times the stock thickness. As in conventional piercing, there is a slight radius around the punch side of the hole, but there are no torn edges on the die side of the blank. A rough-sheared surface on the blank may be caused by too great a punch-to-die clearance, or improper location and height of the impingement ring for the material being blanked. On parts blanked to a small width-to-thickness ratio, a small, rough surface may be noticeable, but may not be detrimental.

Presses

Triple-action hydraulic presses or combination hydraulic and mechanical presses are used for fine-edge blanking. The action is similar to that of a double-action press working against a die cushion. An outer slide holds the stock firmly against the die ring and forces the impingement ring into the metal surrounding the outline of the part. The stock is stripped from the punch during the upstroke of the inner and outer slides. An inner slide carries the blanking punch. A lower slide furnishes the counter-action to hold the blank flat and securely against the punch. This slide also ejects the blank.

The stripping and ejection actions are delayed until after the die has opened at least to twice the stock thickness to prevent the blank from being forced into the strip or slugs from being forced into the blank. Because loads are high and clearance between punch and die is extremely small, the clearance between the gibs and press slides must be so close that they are separated only by an oil film.

Force requirements for fine-edge blanking presses are influenced not only by the work metal and the part dimensions, but also by the special design of the dies and pressure pads used for fine-edge blanking (Fig. 3). Depending on part size and shape, an 890 kN (100 tonf) press can blank stock up to 8 mm (0.315 in.) thick; a 2.2 MN (250 tonf) press can blank stock up to 11.94 mm (0.470 in.) thick; and a 3.6 MN (400 tonf) press can blank stock up to 12.7 mm (0.500 in.) thick.

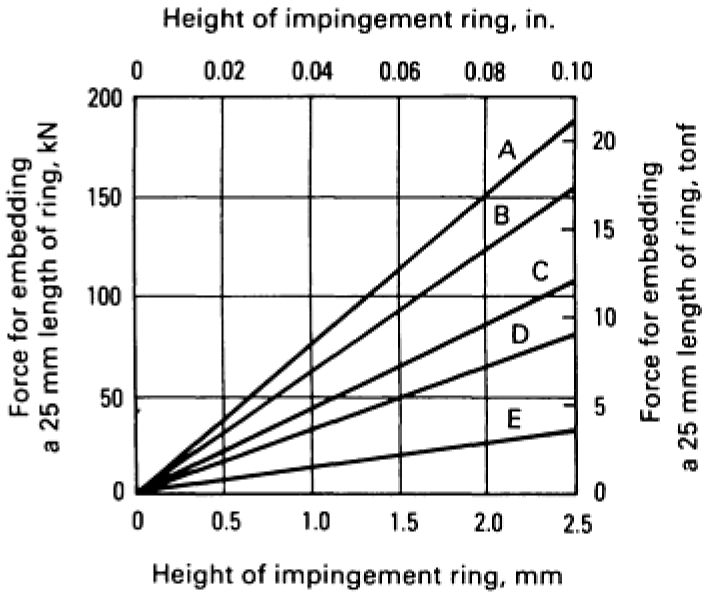

Fig. 3 Force required for embedding impingement rings of various heights into several different work metals. A, stainless steel; B, prehardened alloy steel; C, mild steel, half-hard brass, hard copper, 6*xxx* aluminum alloys in the H temper; D, soft copper; series 6000 aluminum alloys, half hard; E, commercially pure aluminum, H temper

When impingement rings are used on both the pressure pad and the die, the calculation of force is still based only on the pressure pad impingement ring. The reduced height of impingement rings when used in pairs allows the use of a lower clamping force, thereby reducing the overall load on the press. This is because the lower impingement ring is pressed into the workpiece by the reaction force. If coining, embossing, or other forming is done during the blanking, the additional force required for those operations must be added to the force requirements.

Press Safety. Blanking and piercing are potentially dangerous operations. Information and references on the safe operation of presses for sheet metal forming is available in the article "Presses and Auxiliary Equipment for Forming of Sheet Metal" in this Volume.

Fine-Edge Blanking and Piercing

Tools

The design of tools for fine-edge blanking is based on the shape of the part, the method of making the die, the required load, and the extremely small punch-to-die clearance. The considerable loading and required accuracy dictate that the press tools be sturdy and well supported to prevent deflection. The small clearance presupposes precise alignment of the punch and die.

Design. A basic tool consists of three functional components, the die, the punch, and back-pressure components. To produce high-quality blanks, the punch-to-die clearance must be uniform along the entire profile and must be suitable for the thickness and strength of the work metal. Clearance varies between 0.005 and 0.01 mm (0.0002 and 0.0004 in.).

The components of a typical tooling setup for fine-edge blanking of a part of simple shape are shown in Fig. 1. The profile part of the blanking punch is guided by the pressure pad. A round punch is prevented from rotating by a key fastened to the upper die shoe. The hardened pressure pad is centered by a slightly conical seat in the upper die shoe; this pad contains the V-shaped impingement ring.

Some diemakers put a small radius on the cutting edge of the die. This causes a slight bell-mouth condition, which produces a burnishing action as the blank is pushed into the die, improving the edge finish.

If holes are to be pierced in the part, the blanking punch will contain the piercing die. The slug is ejected by ejector pins or through holes in the punch.

The die is centered in the lower die shoe by a slightly conical seat, as is the upper pressure pad. Both the die and the upper pressure pad are preloaded to minimize movement caused by compression. The pressure and ejector pad is guided by the die profile, and is supported by pressure pins and the lower slide. The backup block for the piercing punch also guides the pressure pins.

The die components are mounted in a precision die set with precision guide pins and bushings. Some designers prefer pressing the guide pins into the upper shoe.

Materials and Life. Because of the high loads, close tolerances, and small clearances involved in fine-edge blanking, the die elements are made of high-carbon high-chromium tool steels, such as AISI D2 or D3, or of A2 tool steel heat treated to about 62 HRC.

Punch and die life vary with tool material and hardness, punch-to-die clearance, type of work metal, and workpiece dimensional and surface finish requirements.

For most work metals under the usual operating conditions, punch life for fine-edge blanking of 3.2 mm ($\frac{1}{8}$ in.) thick stock is 10,000 to 15,000 blanks between regrinds--assuming that the blanks are of simple shape and that punch wear is such that only 0.05 to 0.13 mm (0.002 to 0.005 in.) of metal must be removed to restore the punch to its original condition.

The effect of work material on punch and die life can be illustrated by the following data. In one application, after blanking 33,000 pieces made of 1010 cold rolled steel, 0.23 mm (0.009 in.) was ground from the punch and 0.15 mm (0.006 in.) was ground from the die. Production rate was 35 pieces per minute. When blanking 8617 and 8620 steel, it was necessary to grind 0.23 mm (0.009 in.) from the punch after 12,000 pieces and 0.18 mm (0.007 in.) from the die after 23,000 pieces. The production rate was 27 to 30 pieces per minute.

In another instance, 15,000 to 30,000 pieces per punch grind were produced when blanking annealed 1040 and 1050 steel; 25,000 to 50,000 pieces were produced for 1010 steel. Punch life for blanking fine-tooth gears made of annealed high-carbon steel was 10,000 to 15,000 pieces, and for steel with a hardness of 32 to 34 HRC was 5000 to 15,000 pieces. The reason for grinding the punch was to remove the small radius on the edge of the punch, which must be kept sharp and flat to obtain a good edge on the part.

Total die life may be 200,000 to 300,000 blanks per tool. The die is usually sharpened once for each two or three punch sharpenings. It may be necessary to remove from the die an amount of metal up to half the work metal thickness to restore the die to its original condition.

In some production applications of blanking simple shapes from 2.5 mm (0.100 in.) thick 1010 steel, life between regrinds was about 40,000 blanks for punches and about 80,000 blanks for dies, when punch and die wear of 0.13 to 0.18 mm (0.005 to 0.007 in.) was allowable and the surface finish of the cut edge was 1.6 μm (63 μin.) or better.

Lubrication

The work metal must have a film of oil on both sides to lubricate the punch and die during fine-edge blanking. The lack of a lubricant on either side can reduce punch or die life between sharpenings by as much as 50%. Oils used for conventional blanking are usually satisfactory. In severe applications, a wax lubricant may be used. More information on lubricants is available in the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume.

Applications

Initially, most applications of fine-edge blanking were in the production of components for instruments, watches, and office machines. These included levers, gears, fingers, tooth segments, and similar parts.

Fine-edge blanking is now being applied to a wider variety of materials, as well as to thicker stock, in the automotive, farm equipment, ordnance, machine tool, printing machine, household appliance, and textile machine industries. Gears, racks, sprockets, and other toothed forms are easily produced and are common applications.

Introduction

ELECTRICAL STEELS are used for various static and rotating electrical devices. They are magnetically soft materials; that is, they are not permanent magnets but have properties that make them useful in electrical applications. Most of the parts produced from electrical steels must be laminated. A lamination consists of flat blanked sheets of a particular shape that are stacked to a given height and fastened together by riveting, bolting, or welding. Electrical steel sheet is available in coils or cut-to-length. For most applications, stock thickness ranges from 29 to 24 gage (0.343 to 0.607 mm, or 0.0135 to 0.0239 in.).

The properties and selection of electrical steel sheet are discussed in detail in the article "Magnetically Soft Materials" in *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials*, Volume 2 of the *ASM Handbook.* Information on the metallography and microstructure of electrical steels and other types of magnetically soft materials is available in the article "Magnetic and Electrical Materials" in *Metallography and Microstructures*, Volume 9 of the *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

Materials

The general category of magnetically soft materials encompasses many types of materials, including iron-nickel, iron-cobalt, and iron-aluminum alloys; ferrites; and austenitic stainless steels. The discussion in this article, however, will be limited to the most commonly used magnetically soft materials: low-carbon electrical steels and oriented and nonoriented silicon electrical steels. Table 1 lists some of the characteristics and applications of these materials.

Table 1 Silicon contents, densities, and some applications of electrical steel sheet

AISI type	**Nominal Si + Al content, %**	**Assumed density, Mg/m^3**	Characteristics and applications
Low-carbon steel			
. . .	0	7.85	**High magnetic saturation; magnetic properties may not be guaranteed; intermittent-duty small motors**
Nonoriented silicon steels			

M47	1.05	7.80	**Ductile, good stamping properties, good permeability at high inductions; small motors, ballasts, relays**
M45	1.85	7.75	**Good stamping properties, good permeability at moderate and high inductions, good core loss; small generators, high-efficiency continuous-duty rotating machines, ac and dc**
M43	2.35	7.70	
M36	2.65	7.70	**Good permeability at low and moderate inductions, low core loss; high reactance cores, generators, stators of high-efficiency rotating machines**
M27	2.80	7.70	
M22	3.20	7.65	**Excellent permeability at low inductions, lowest core loss; small power transformers, high-efficiency rotating machines**

Low-Carbon Steels. For many applications that require less than superior magnetic properties, low-carbon steels (AISI 1010, for example) are used. Higher-than-normal phosphorus and manganese contents are often used to increase electrical resistivity. Such steels are not purchased to magnetic specifications. Although low-carbon steels exhibit power losses higher than those of silicon steels, they have better permeability at high flux density. This combination of magnetic properties, coupled with low price and excellent formability, makes low-carbon steels especially suitable for applications such as fractional-horsepower motors, which are used intermittently.

Nonoriented Silicon Steels. Except for saturation induction, the magnetic properties of iron containing a small amount of silicon are better than those of pure iron. Few commercial steels contain more than 3.5% Si because the steel becomes brittle and difficult to cold roll at silicon levels above 4%.

The commercial grades of silicon steel in common use (0.5 to 3.5% Si) are made primarily in electric or basic-oxygen furnaces. Nonoriented grades are melted with careful control of impurities; better grades have sulfur contents of about

0.01% or less. Continuous casting and vacuum degassing can be used. After hot rolling, the hot bands are annealed, pickled, and cold rolled to final thickness as continuous coils.

Semiprocessed grades of strip are not sufficiently decarburized for electrical use; therefore, decarburization and annealing to develop potential magnetic quality must be done by the user. This procedure is practical for small laminations accessible to the annealing atmosphere. Fully processed grades are strand annealed in moist hydrogen at about 825 °C (1520 °F) to remove carbon. The final annealing operation is very important and is carried out at a higher temperature (up to 1100 °C, or 2000 °F, for continuous strip) to cause grain growth and the development of magnetic properties. Use of a protective atmosphere is vital. The steel often is coated with organic or inorganic materials after annealing to reduce eddy currents in lamination stacks.

Most finished nonoriented silicon steel is sold in full-width coils (860 to 1220 mm, or 34 to 48 in.) or slit-width coils, but some is sold as sheared sheets. All coils are sampled and tested according to ASTM A 343 and graded as to quality.

Oriented Silicon Steels. Grain size is as important in silicon steel as in iron with regard to core losses and low-flux-density permeability. For high-flux-density permeability, however, crystallographic orientation is the deciding factor. Like iron, silicon steels are more easily magnetized in the direction of the cube edge: <100>. For special compositions, rolling and heat-treating techniques are used to promote secondary recrystallization in the final anneal at about 1175 °C (2150 °F) or higher, which results in a well-developed texture with the cube edge parallel to the rolling direction {110} <001>. Conventional oriented grades contain about 3.15% Si.

About 1970, improved {110} <001> texture was developed in silicon steel through the modification of composition and processing. The high-permeability material usually contains about 2.9 to 3.2% Si. Conventional oriented 3.15% Si steel has grains about 3 mm (0.12 in.) in diameter. The high-permeability silicon steel tends to have grains about 8 mm (0.31 in.) in diameter. Ideally, grain diameter should be less than 3 mm (0.12 in.) to minimize excess eddy-current effects from domain-wall motion. Special coatings provide electrical insulation and induced tensile stresses in the steel substrate. These induced stresses lower core loss and minimize noise in transformers.

Size and Shape. Flat laminations of a wide variety of shapes and sizes are blanked and pierced from electrical sheet. However, most are shaped like those shown in Fig. 1. Laminations similar to those shown in Fig. 1(a) can range in diameter from less than 25 mm to 1.3 m (1 to 50 in.) or more, and laminations similar to those shown in Fig. 1(b) can range in length from less than 25 to 305 mm (1 to 12 in.) or more.

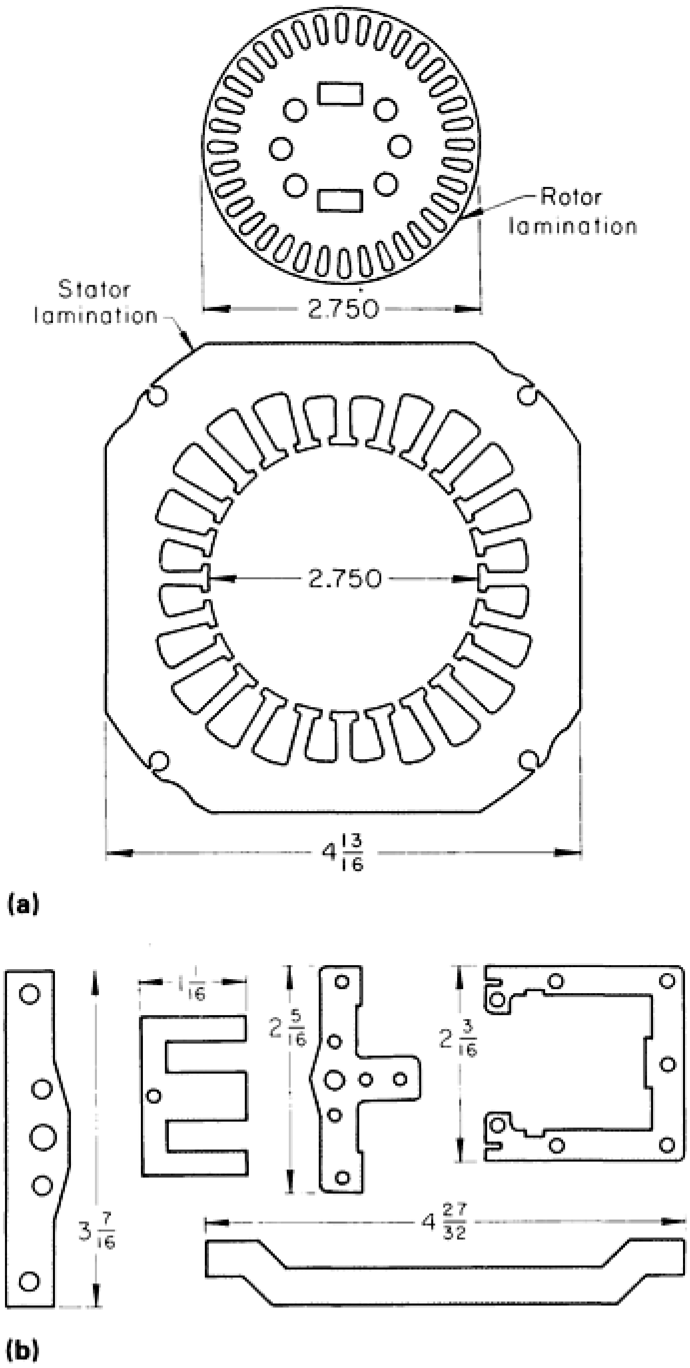

Fig. 1 Typical laminations blanked and pierced from electrical sheet. (a) Laminations for rotating electrical machinery are blanked and pierced in single-station dies (Fig. 3) or progressive dies (Fig. 4). Slots can also be made in precut blanks, one at a time, with notching dies. (b) Typical laminations blanked and pierced from electrical sheet for application in units other than rotating machines. Dimensions given in inches.

Punchability. Materials used for electrical sheet can be classified in the following order with respect to decreasing ease of blanking, piercing, and notching:

- Conventional flat-rolled low-carbon steels such as 1008
- Nonoriented silicon steels
- Oriented silicon steels

To a large extent, applications also follow the above classification (Table 1). Each group has certain distinct characteristics that affect punchability. In addition, differences in composition and hardness within any specific group cause considerable variation in punchability (see the section "Effect of Work Metal Composition and Condition" in this article).

Presses

A general-purpose punch press in good mechanical condition is acceptable for stamping laminations, but large-volume production of laminations by progressive-die methods requires the use of high-productivity presses (see the article "Presses and Auxiliary Equipment for Forming of Sheet Metal" in this Volume). Most high-productivity presses have heavy bed and crown members to minimize deflection and vibration. Bed deflection for lamination presses should be no more than 0.006 mm/mm (0.006 in./in.) of bed length (measured left-to-right between uprights), with a load equal to the rated capacity of the machine distributed over two-thirds of the bed area between tie rod centers. Deflection of the slide should not exceed 0.006 mm/mm (0.006 in./in.) of the length between the pitman centers, with rated load evenly distributed between those centers. Bending deflection and shear deflection are both considered in these standards. Double-crank presses with two or four points of suspension are preferred for progressive-die applications because of their better resistance to off-center die loads. Parallelism of the bed and slide should be 0.012 mm/mm (0.012 in./in.) of bed dimensions, both left-to-right and front-to-back.

Presses designed for producing laminations have heavy connections, large diameters of the mainshaft and connection bearings, close gib clearances, and thick bolsters. Because of the close gib fits (needed for accurate vertical motion), recirculating oil systems must be used to provide forced-feed lubrication of bearings and slides.

The fact that a die was built with uniform punch-to-die clearance at all cutting edges does not necessarily mean that the clearance is uniform at the instant the punch begins to enter the work metal. The act of applying the load to the work metal can cause lateral deflections in the die and press, which can change the clearances. To minimize these undesirable deflections, the mechanical condition of the press and die must be maintained at a high level. The total force capacity exerted at each stroke must be in proper relation to the force capacity of the press and to the type of press frame (some types of press frames will deflect laterally more than others). Close-fitting gibs and bearings are essential in minimizing lateral deflection. The die should be built with large guideposts and close-fitting bushings.

A preventive maintenance program must be established to ensure that all presses are kept in top condition. Special attention should be given to bearing clearances, the condition of the counterbalance springs or cylinders, and the parallelism of the slide.

Auxiliary Equipment

When producing motor laminations in individual dies for each operation with upright or inclined presses, blanks can be loaded and unloaded manually. However, when individual dies are used for the simultaneous production of stator and rotor laminations, feeding and stacking equipment is necessary for optimal efficiency. The use of an inclined press is preferred because gravity assists in loading the die and removing the laminations. When progressive dies are used, automatic feeding and scrap-cutting equipment is required.

Stock reels, cradles, and straighteners are required when coil stock is used. Several types and sizes are available (see the article "Presses and Auxiliary Equipment for Forming of Sheet Metal" in this Volume).

Feed Mechanisms. In progressive-die operations, the common types of feed mechanisms, for example single-roll or double-roll, hitch, grip, and slide, are used to feed strip or coil. Cam feed, which has a fixed feed length, is widely used for large-volume production. This method is accurate at high speeds because it eliminates the slippage that usually occurs in the overriding clutch-and-brake mechanisms of roll feeds.

Magazine feeds have a mechanism that ejects the blank from the bottom of a stack into the die or onto a magnetic belt or a chain feed. In inclined presses, the blank may slide by gravity into the die nest after leaving the magazine.

Stacking. Figure 2 shows a method that can be used for stacking laminations when each operation is done in an individual die. Blanks are fed to the press (inclined 35 to 45° to the rear) from a magazine feeder. Laminations drop from the press into a chute, where they are picked up by a driven elevating belt that conveys them to the stacking chute, from which they fall onto a stacking mast. Stacking masts are usually 380 to 915 mm (15 to 36 in.) high. The tops of the masts are either threaded or have tapped holes so that they can be picked up by handling machines and moved to subsequent operations. The bases of the stacking masts are large or weighted to prevent the masts from tipping or falling when being loaded or moved to the assembly floor.

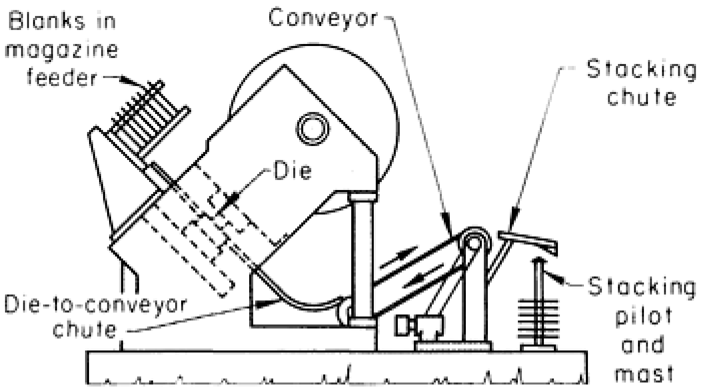

Fig. 2 Method for stacking laminations stamped in individual dies.

Scrap disposal is a major consideration in producing laminations. The removal of scrap from a trimming operation or the removal of slugs from piercing holes and slots requires consideration during die design. Scrap is discharged through holes in the die shoe onto chutes. The chutes convey the scrap into containers or into automatic scrap-conveying systems below the floor. When the die is in the upper shoe, a mechanically operated pan can be used to catch the slugs on the upstroke. The slugs are then ejected into a container on the downstroke.

Blanking and Piercing of Electrical Steel Sheet

Dies

Single-station and progressive dies are both used for making laminations.

Single-Station Dies. Each single-station die performs one operation, and a set of dies for a lamination can be mounted in one press or in different presses. Simple laminations such as those shown in Fig. 1(b) are usually produced in one operation. More complex parts may require several operations. Figure 3 shows a typical sequence for the production of stator and rotor laminations in four operations.

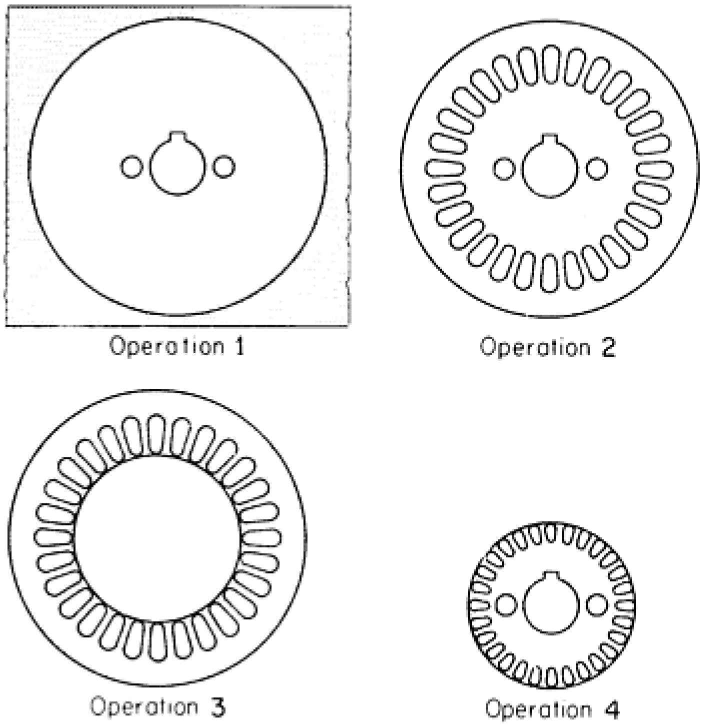

Fig. 3 Sequence of operations for producing stator and rotor laminations using single-station dies. Operation 1, stock blanked and pierced; operation 2, stator lamination notched; operation 3, rotor lamination separated from stator lamination; operation 4, rotor lamination notched. Compare with Fig. 4.

Single-station dies can be used for punching any lamination, regardless of the size, composition, shape, or quality requirements. However, because production with single-station dies is relatively slow, the cost per piece is high for mass production. Laminations such as those shown in Fig. 1 can be produced in large quantities at a lower cost in progressive dies.

The size of the workpiece and the quantity required influence the degree to which operations can be combined and the complexity of any one die. For example, in Fig. 3, the slots made in operations 2 and 4 can be punched in one stroke in a multiple die for each operation if the die sections are strong enough. An alternative method is to punch the slots in 28 strokes with a single-notch die in a high-speed notching press equipped with an indexing mechanism. Single-notch dies are used in the production of laminations for the following reasons:

- Tool costs are lower, and the single-notch die can be used on several different laminations. The cost is sometimes less than 5% of that for a multiple die that can pierce all the holes and slots in one press stroke
- Laminations more than about 380 mm (15 in.) in diameter are sometimes too large to be notched by any other method because of tool and equipment costs. However, many larger-diameter laminations are multiple pierced
- Limited production does not warrant the cost of a multiple die
- Available equipment must be used

Progressive dies perform a series of operations at two or more die stations during each stroke of the press. Each working, or active, station in the die performs one or more operations. The work material progresses through successive stations until a completed part is produced (Fig. 4). Idle stations, in which no work is performed, are added to provide strength to the die, to facilitate material travel through the die, to simplify construction, or to increase flexibility for die changes.

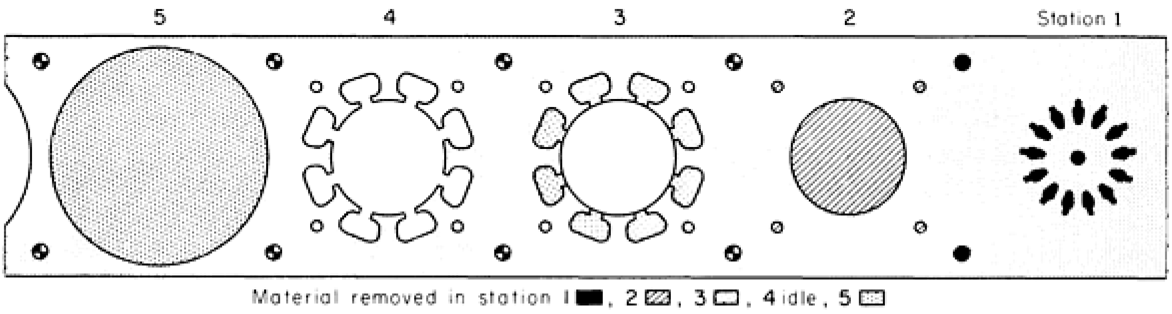

Fig. 4 Blanking and piercing sequence for rotor and stator laminations in a five-station progressive die. Two pilot punches were used at each station. Station 1, pierce pilot holes, rotor slots, and rotor-shaft hole; station 2, pierce stator rivet holes and blank rotor; station 3, pierce stator slots; station 4, idle; station 5, blank stator. Compare with Fig. 3.

One of the more common progressive dies used in the electric-motor industry is a five-station die that produces a rotor lamination and a stator lamination with each stroke of the press (Fig. 4). This die can be provided with carbide inserts for the punch and die sections. It has a spring-actuated guided stripper. The die components are mounted on a precision die set with ball bearing guide bushings and hardened guide pins. Slender punches are guided through the stripper by bushings. Such a die usually has four active stations and one idle station.

The progressive die described above is the blanking or scrap-all-around type. For the most efficient use of material, the cutting-off or parting methods of severing the blank from the strip are used where layout permits.

The principal advantages of progressive dies for blanking laminations are:

- Handling between operations is eliminated; therefore, cost per piece is lower
- Laminations from progressive dies are generally stacked in chutes that allow the press to be operated at uninterrupted maximum capacity. Stacking chutes fastened to the bottom of the bolster or die shoe keep the laminations oriented in a smooth, uninterrupted flow from the die. Therefore, laminations are better controlled with regard to burr direction and are easier to handle for assembly

Two disadvantages of progressive dies for blanking laminations are:

- A progressive die is, to a great extent, a single-purpose die. Even a minor change in part design can necessitate an expensive die alteration or can make the die obsolete
- Progressive dies are more susceptible to damage from accidents than single-station dies. Progressive dies run at high speed and may make many strokes before the press can be stopped. Misfeed detectors built into the die can help prevent damage. Die damage can halt production in progressive operations. In single-station operations, if the inventory of processed material is sufficient to keep other dies running, a breakdown of a die does not interrupt production

The minimum size of lamination that can be made depends on the slot size and spacing, work metal thickness, and tolerances on the slot dimensions. The die must be strong enough to withstand the blanking pressure. Figure 5 shows some very small laminations that were made in progressive dies. The 6.48 mm (0.255 in.) diam rotor was made in three stations in order to have the necessary die strength. Part tolerances were such that piercing in three stations produced acceptable parts.

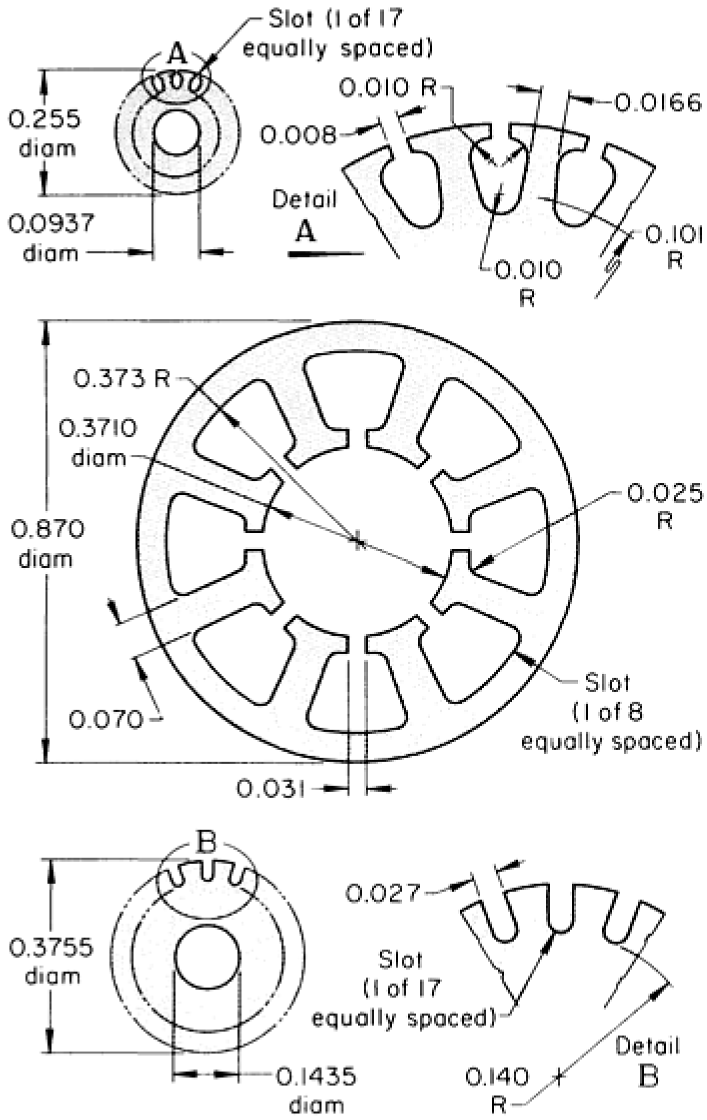

Fig. 5 Small-diameter laminations produced in progressive dies. Dimensions given in inches.

The dies for producing laminations are usually of segmented construction, which provides maximum accuracy. However, electrical discharge or electrochemical machining methods have been used to produce satisfactory dies.

There is no agreement as to the maximum size of lamination that can be efficiently produced in progressive dies. However, progressive dies are seldom used for laminations larger than 380 mm (15 in.) in major dimension. The factors that limit the maximum practical size are as follows:

- Progressive dies for making laminations more than 380 mm (15 in.) in major dimension represent a large investment (and a significant loss if damaged)
- Quantity demands are usually lower for large laminations; therefore, the investment is not warranted
- Extremely large dies may require a press capacity that is so large as to be impractical
- Problems from camber and lack of flatness in the stock are magnified in stamping large laminations in progressive dies

Blanking and Piercing of Electrical Steel Sheet

Selection of Die Materials

Almost any hardened tool steel is satisfactory as die material for making a small quantity of laminations. However, for production blanking and piercing, either a high-carbon high-chromium cold-work tool steel, such as AISI D2, or carbide must be used to resist the abrasiveness of electrical steels.

The shape or size of the lamination seldom affects the choice of die material. Dies ranging from the smallest to the largest and from the simplest to the most complex have been made from both high-carbon high-chromium tool steel and carbide. In addition, both die materials have been used to blank and pierce all compositions and thicknesses of electrical sheet. The composition and thickness of the stock rarely affect the choice between carbide and tool steel.

Production Quantity. If the dies are of the same design and construction, the total quantity of parts to be produced is the major factor in choosing die material. If the run is so short that it can be made with tool steel dies without sharpening, tool steel is more economical. However, for longer runs, carbide dies have 10 to 20 times as much life per grind as tool steel dies.

Uniform quality of cut edges and minimum burr height will be retained over a much longer run by carbide dies than by tool steel dies. In some cases, the edge condition of the lamination is not critical. However, when automatic stacking and core assembly equipment is used after blanking and piercing, burr height is important. Excessive burr height can cause short circuiting of the laminations in the core.

Cost. Depending on size and design, a die with carbide cutting edges will cost at least $1\frac{1}{2}$ times as much as a steel die. However, in terms of cost per piece, carbide dies may be more economical. Press downtime and die maintenance affect cost per piece; carbide dies can run about ten times as long per sharpening as tool steel dies.

Press condition is important in the operation of blanking and piercing dies. To achieve the maximum potential usage of carbide dies, press condition must be maintained at a high level. Although tool steel punches and dies can chip and shear because of misalignment, carbide punches and dies are more likely to break. Therefore, the presses used for tool steel dies can be in less than top level condition and continue to produce quality laminations.

Effect of Stock Thickness

Electrical sheet that is to be blanked and pierced usually ranges in thickness from 29 to 24 gage (0.343 to 0.607 mm, or 0.0135 to 0.0239 in.). Thinner or thicker stock is used for special applications. The blanking and piercing of extremely thin electrical sheet requires close control of equipment and technique. The processing of thick sheet (>1.27 mm, or 0.050 in.) can also cause difficulty, although the force-capacity rating of the press is the major factor that determines the maximum thickness of sheet that can be blanked and pierced.

Punch-to-die clearance for electrical sheet generally ranges from 3 to 7.5% of stock thickness per side, with clearances as large as 20% reported for grain-oriented stock. These values are similar to those used for low-carbon steel, but the stock thicknesses are thinner than those commonly used for the low-carbon steels. This results in close die clearance and requires good diemaking practice and accurate press equipment.

Thin Sheet ($\leq$0.254 mm, or 0.010 in.). Under carefully controlled conditions, laminations can be blanked and pierced from sheet as thin as 0.051 mm (0.002 in.), but the press must be in top condition. Further, the feeding mechanism must be capable of feeding within ±0.076 mm (±0.003 in.) total error per stroke at a feed rate of 23 m/min (900 ft/min).

Punches and dies of hardened tool steel, such as D2, or carbide are satisfactory, although carbide dies and punches will have at least ten times the life of their tool steel counterparts. The punches must be rigidly supported and guided. The entire tool must be made rugged and accurate enough to maintain alignment. To avoid shearing the punch and die during press setup, it is important that the die be handled carefully to prevent the possibility of some of the components moving out of alignment. The press bed, the bottom of the die shoe, the face of the press slide, and the top of the punch holder must be clean and free of any irregularities that would cause a deviation from parallelism.

The punch and the die as a unit should be aligned square with the centerline of the press. The press slide should then be brought down slowly to meet with the top of the punch holder, and the punch holder should be fastened to the face of the slide. The slide should then be adjusted downward so that the punches enter the die cavities. Finally, the die shoe should be fastened to the bolster or press bed.

Dies with this close clearance are often designed as a unit, and the die is not fastened to the press ram. Therefore, the tool is not subject to the inaccuracies of the press.

A back taper of 0.002 mm/mm (0.002 in./in.) per side is commonly used in the die. Because of this angular clearance in the die, total die life is limited by the maximum punch-to-die clearance that can be tolerated. Each time a die having a back taper of 0.002 mm/mm (0.002 in./in.) per side is sharpened, the hole diameter will increase 0.1 μm (4 μin.) for each 0.0254 mm (0.001 in.) ground from the top of the die. After grinding 2.54 mm (0.100 in.) from the die, the punch-to-die clearance will increase 0.005 mm (0.0002 in.) per side.

If this amount of clearance is too great, the original clearance can be restored by installing new die sections or, if the dimensional tolerance permits, by using an oversize punch. The amount that can be removed from the die depends on the amount of back taper in the die, the stock thickness, and the maximum punch-to-die clearance permissible. Dies sometimes have a straight land that is 1.6 to 3.2 mm ($\frac{1}{16}$ to $\frac{1}{8}$ in.) wide before beginning the back taper.

Lubricant is applied to the stock during blanking and piercing to keep wear on the cutting edges of the punch and die at an acceptable level. Use of a water-thin lubricant with rapid evaporation and low residue makes it unnecessary to perform a burn-off operation before hydrogen annealing. Difficulties in producing acceptable laminations from thin sheet are magnified as the plan area of the lamination increases.

Effect of Work Metal Composition and Condition on Blanking and Piercing

Each of the three most widely used electrical sheet materials (low-carbon steels and nonoriented and grain-oriented silicon steels) has distinctive punching characteristics. These characteristics often necessitate specific procedures to produce laminations of the desired quality at the lowest cost.

Low-carbon steels such as 1008 are used as electrical sheet when their electrical properties can meet requirements, primarily because they cost less than silicon steels and the cost is lower for blanking and piercing. More pieces per die sharpening are usually obtained in blanking these steels than in blanking silicon steels. One study of die wear in making stator and rotor laminations similar to those shown in Fig. 1 and ranging in diameter from 92 to 149 mm ($3\frac{5}{8}$ to $5\frac{7}{8}$ in.) showed that, with tool steel cutting edges, 120,000 to 150,000 pairs were punched per sharpening when stamping 1008.

The condition of the low-carbon steel stock influences power requirements and punching characteristics. When annealed, this steel has a tensile strength of 380 to 414 MPa (55 to 60 ksi), but the strength of full-hard material may be over 690 MPa (100 ksi). Therefore, the material condition must be known before the force-capacity requirements of the presses can be determined. Low-carbon low-silicon steels in the annealed condition are soft, and they are likely to roll at the edges and form excessive burrs. Therefore, punch-to-die clearances must be as close for these steels as for electrical sheet of the same thickness. An annealed product is usually specified, but whether annealed stock is stamped or individual laminations are annealed after stamping is often a matter of convenience, because of press capacity, annealing facilities, or other factors.

Nonoriented silicon steels are available with silicon contents ranging from 0.5 to 3.25%. As silicon content increases, the sheet becomes more brittle and more abrasive. As a result, the edges of higher-silicon steel are less likely to roll and make excessive burrs, but die wear is increased because of abrasion.

Many nonoriented silicon steels are coated with an organic or inorganic material (core plating) to insulate one lamination from another. This organic core plating also improves the punchability of electrical sheet. In one application, carbide dies produced about 3.5 million laminations from core-plated M-36 (2.5% Si) between resharpenings. When similar laminations were produced from uncoated M-36, dies required sharpening after each 1.2 million parts. Heating of the coated blanks by welding or die casting may destroy the organic coating. Additional information is available in the section "Core Plating" in this article.

General practice is to use approximately the same punch-to-die clearances for all silicon steels. The tensile strength of the particular steel must be considered in determining press capacity because silicon steels may vary in strength, depending on whether they are fully annealed at the time of stamping.

Oriented silicon steels are relatively high in silicon (3.15% Si + Al) and have most of their grains (crystals) oriented with the cube edges parallel with the rolling direction and face diagonals at 90° to the rolling direction ({110} <001>). Because of this orientation, these steels have blanking and piercing characteristics that are different from those of nonoriented steels. Tensile strength will vary as much as 20% between the rolling direction and the transverse direction (strength is greater parallel with the rolling direction).

A magnesium hydroxide coating is applied to grain-oriented steel after normalizing. This coating prevents the coiled strip from welding together during annealing. Magnesium hydroxide, in contrast to the organic coatings, is highly abrasive and greatly increases die wear; therefore, it is not recommended for stamped laminations. Tool steel dies wear so rapidly under these conditions, because of the high silicon content of the steel, that carbide cutting edges are almost always used for the blanking and piercing of grain-oriented steel.

Because mechanical properties vary with direction, cutting properties also vary in grain-oriented steels. Cutting across the rolling direction results in a clean break, but the edges are smeared when cutting is parallel with the rolling direction. Therefore, punch-to-die clearance is more critical on the sides parallel with the rolling direction.

Camber and Flatness

Camber in electrical sheet is the deviation (parallel to the stock surface) of a side edge from a straight line that extends to both ends of the side, and it is customarily limited to 6.4 mm ($\frac{1}{4}$ in.) for any 2.5 m (96 in.) length or fraction thereof. Flatness, or the degree to which a surface of a flat product approaches a plane, is expressed in terms of the deviation from a plane. Flatness tolerances have not been established for electrical sheet; the operations employed to flatten other steel products cannot be used because of their effect on magnetic quality. Flatness requirements should be specified for a particular application.

Camber and flatness are interrelated; the edge of a 2.5 m (8 ft) section of sheet may come within the 6.4 mm ($\frac{1}{4}$ in.) tolerance while lying freely on a flat surface. However, the seemingly flat sheet may have a number of faint waves (sometimes called oil cans). If this sheet is then flattened (as it is in dies), the flattening of these waves causes multidirectional elongation of the sheet, and the edge of the sheet may then be forced into a camber different from that when the sheet is not under flattening pressure. Minimum camber and maximum flatness are desirable for blanking electrical sheet and are especially important in progressive-die operations.

Effect on Progressive-Die Operation. If there is no camber, it is easy to start the stock through the die correctly by aligning the straight edge of the sheet against a straight-edge starting guide, with the end of the material covering the first die stage. Feed rolls are then engaged, and the blanking and piercing can begin.

Even though the edge of the sheet is cambered, it must still be used in the starting alignment. Therefore, the material may be misaligned to some degree as it enters the die. A small degree of misalignment is not readily apparent to the press operator.

Minor misalignment in starting the material through a progressive die may not cause immediate problems. Operating difficulties result from various misalignments, which have a cumulative effect.

In the first stage of the die, pilot holes are pierced into the sheet, often into a portion that will later be scrap. At subsequent die stations, bullet-nose pilots engage the pilot holes as the die closes. The piloting action may cause the sheet to move slightly into true position before the cutting edges of the die meet the sheet. Powered feed rolls move the sheet between press strokes to an approximate position for the next die station. The feed rolls then open, releasing the sheet so that there is no conflict between the locating action of the pilots and the feed rolls.

When the original lineup is not correct or when there are cumulative effects of camber against the stock guides, the sheet may wander from side to side on the die face. Stock guides are provided in progressive dies to limit wandering due to camber and misalignment.

Interference between the pilots and the stock guides may cause the stock to distort and jam in the die, preventing proper flow of the stock. If the stock jams, the press must be stopped at once.

Camber can cause other difficulties. For example, a change in camber or multidirectional elongation of the sheet as the press flattens the waviness may cause the pilots to distort the piloting holes; thus, misaligned rotor and stator laminations are made. This leads to misalignment of the slots in the stacked core. As slots are blanked out, stresses are released that also can change the amount of camber and flatness.

There is no single solution to the problem of camber in the production of laminations in progressive dies, because no two shipments of material are exactly alike. Some manufacturers of laminations use less efficient single-station dies because of difficulties with camber, even though production volume could justify the use of progressive dies. Other manufacturers use progressive dies only for laminations below a certain size.

Burr Height

It is impossible to blank and pierce laminations without producing some burr along the cut edges (Fig. 6). The amount of burr (measured as burr height) depends on the composition and condition of the electrical sheet, the thickness of the sheet, the clearance between punch and die, and the edge condition (sharpness) of the punch and die.

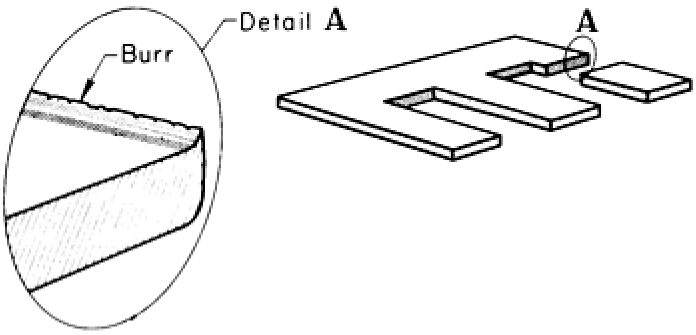

Fig. 6 Burr (exaggerated) produced along the edges of a blanked lamination.

The amount of burr that can be tolerated depends on end use. Burr height influences the stacking factor, which in turn influences magnetic characteristics. Maximum burr height is usually limited to 0.05 to 0.13 mm (0.002 and 0.005 in.).

Length of Die Run. A die is usually run until the maximum allowable burr height is reached, at which time the punch and die are removed for sharpening. Close control is required with this method of determining the length of the die run.

Optimal Die Run. For the greatest economy and convenience of operation, die maintenance requirements and die life (in addition to maximum burr height) should be considered in determining the optimal die run. A die should not be run too long before resharpening; otherwise, excessive stock must be removed from both the punch face and the die face to restore the cutting edges. As a result, fewer laminations can be made during the life of a die.

A common method of determining the optimal die run is to establish an arbitrary number of pieces to be run before die sharpening. At the end of this run, the punch face is sharpened. By knowing the number of pieces run and the amount removed from the die during sharpening, the number of pieces produced per unit of length removed from the die can be established. Using this procedure, the number of pieces run between sharpenings can be varied, an optimal die life between sharpenings can be determined.

Lubrication

Although uncoated electrical sheet is sometimes blanked and pierced without lubrication, the use of some type of lubricant is preferred. Organic core plate (used on nonoriented silicon steels) serves as a lubricant, and no further lubrication is needed when blanking and piercing sheet that has core plating.

Tool life will be greatly improved by using a lubricant in the blanking and piercing of electrical sheet that has no coating or has been coated with magnesium hydroxide, which acts as an abrasive rather than a lubricant. Oil-type lubricants, such as those used in blanking and forming operations, are not ordinarily used for blanking and piercing electrical sheet, because removal is too expensive.

Some plants purchase nonoriented silicon steel sheet without core plate and then subject the punched laminations to an oxidizing anneal, in which the lubricant is burned off; the only requirement is to select a lubricant that will leave the least residue when it is burned off. Water-soluble oils (1 part oil to about 20 parts water) have been used when annealing follows punching. Other low-viscosity low-residue oils, such as the aliphatic petroleums, also burn off with little residue.

Liquid lubricants can be applied in several ways. In low-production operations, the work metal can be dipped into the lubricant just before punching. In high-production operations, in which the stock is continuously fed, the lubricant can be brushed on just before it enters the press, or it can be dripped onto the sheet a few feet from the press. The top of the sheet is then rubbed with a felt wiper that spreads the lubricant over the entire surface. The bottom of the sheet can be coated with lubricant by having a trough under the sheet that catches the excess drip. A piece of felt or similar material in the trough acts as a wick to wet the underside of the moving sheet. A more complete discussion of lubricants is available in the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume.

Molybdenum disulfide is a good lubricant for the blanking and piercing of electrical sheet. The amount used is usually so small that no removal is required. When there is an excess, it can be removed by immersing the sheet for 4 to 5 min in a dilute solution of stripper-type cleaner at 80 °C (180 °F).

Molybdenum disulfide is the basic ingredient of several compounds that are available as dry powder, paste concentrate, and dispersion in liquid. A common method of applying dry molybdenum disulfide is shown in Fig. 7. The sheet passes through a box containing the dry powder, and felt wipers remove the excess. A slurry can be used instead of the dry powder. Sheets can also be coated by a spray timed with the stroke of the press; either powder or a liquid suspension can be sprayed. In low-production operations, a liquid suspension of molybdenum disulfide can be applied to the sheet by brush.

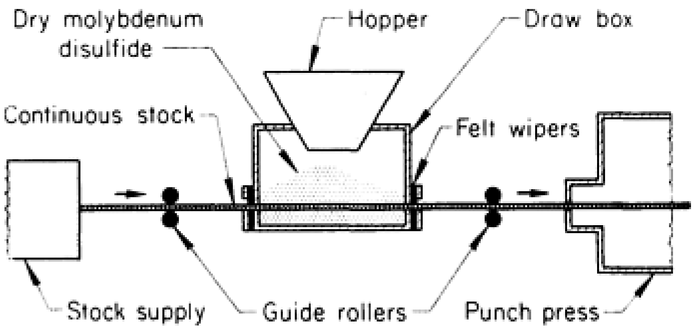

Fig. 7 Setup for applying dry molybdenum disulfide to both sides of electrical sheet.

Core Plating

Core plating, or insulation, is a surface coating or treatment applied to electrical steel sheet to reduce interlaminar loss and sometimes to increase punchability. This treatment does not reduce eddy currents within the laminations. Interlamination resistance is usually improved by annealing the laminations under slightly oxidizing conditions and then core plating. Core plating can be classified as organic or inorganic.

Organic insulation generally consists of enamels or varnishes applied to the steel surface. Steels having organic coatings cannot be stress relieved without impairing the insulating value of the coating, but the coating will withstand normal operating temperatures. Coatings are about 0.0025 mm (0.0001 in.) thick.

Inorganic insulation usually includes chemical or thermal treatments; it has a high degree of electrical insulation and can withstand stress relieving. Inorganic coatings form a very thin surface layer on the steel and increase lamination thickness only slightly.

Introduction

BLANKING AND PIERCING DIES, as discussed in this article, include the punches, dies, and related components used to blank, pierce, and shape metallic and nonmetallic sheet and plate in a stamping press. The primary measure of the performance of die materials in blanking and piercing service is the number of acceptable parts produced.

Sectional views of the blanking dies and the blanking and piercing punches used for making simple parts are shown in Fig. 1. Parts that are more complex require notching and compound dies.

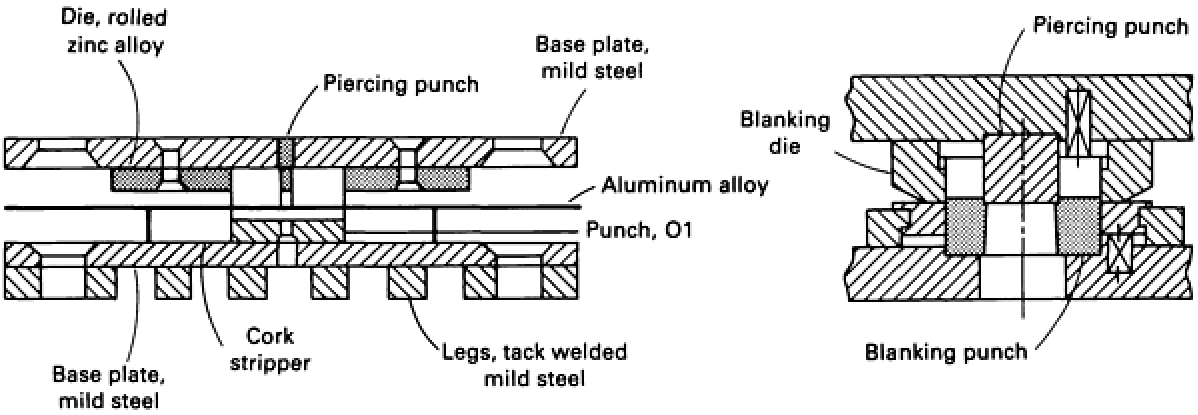

Fig. 1 Sectional views illustrating typical tools used for blanking and piercing simple shapes. Tooling at left is for short-run production of parts similar to parts 1 and 2 in Fig. 2 made from relatively thin-gage metal. Tooling at right is for longer production runs.

A common indication of tool deterioration is the production of a burr along the sheared edge of the workpiece. When tools are new, there is minimal clearance between punch and die, and the cutting edges are sharp. Under these conditions, the break in the stock begins at the underside (the side not in contact with the punch) because there the stock is subjected to the greatest tensile stress from stretching of the outer fiber. As more and more parts are produced, the cutting edges of the punch and the die become rounded by wear, and the stress distribution in the stock is changed. Stress on the underside is reduced, breaking at that point is delayed, and deformation accompanied by work hardening occurs. When breaking starts, it nucleates from both sides simultaneously, and a burr develops on both the slug and the surrounding area of the sheet from which it was cut. The height of this burr increases with tool wear. Acceptable burr height varies with the application, but is usually between 0.025 and 0.125 mm (0.001 and 0.005 in.).

Materials for Specific Tools

The compositions and properties of the tool materials referred to in this article are presented in *Properties and Selection: Irons, Steels, and High-Performance Alloys*, Volume 1 of the *ASM Handbook.*

Punches and Dies. Table 1 lists typical materials for punches and dies used for blanking parts of different sizes and degrees of severity from several different work materials about 1.3 mm (0.050 in.) thick in various quantities. Illustrations of typical parts are presented in Fig. 2. Typical materials for the punches and dies used to shave several work materials of this same thickness in various quantities are listed in Table 2.

Table 1 Typical punch and die materials for blanking 1.3 mm (0.050 in.) sheet

See Fig. 2 for illustrations of typical parts.

Work material	Tool material for production quantity of:				
	1000	**10,000**	**100,000**	**1,000,000**	10,000,000
Part 1 and similar 75 mm (3 in.) parts

Stainless steel, austenitic, over quarter hard	A2	D2	D2	D2, D4, CPM 10V	**Carbide**

Spring steel, hardened, 52 HRC max	A2	A2, D2	D2	D2, D4, CPM 10V	**Carbide**
Electrical sheet, transformer grade, 0.64 mm (0.025 in.)	A2	A2, D2	D2	D2, D4, CPM 10V	**Carbide**
Paper, gaskets, and other soft materials	W1[(b)]	W1[(b)]	W1[(l)]	W1, A2	**D2, CPM 10V**
Plastic sheet, not reinforced	A2	A2	A2	A2, D2, CPM 10V	**Carbide**
Plastic sheet, reinforced	**A2[(f)]**	**A2[(f)]**	**D2[(f)]**	**D2[(f)], CPM 10V**	**Carbide**

Note: Although carbide is recommended in this table only for 10 million pieces, it should usually be considered also for runs of 1-10 million pieces.

(a) Zn refers to a die made of zinc alloy plate and a punch of hardened tool steel.

(b) For punching up to 10,000 parts, the W1 punch and die would be left soft and the punch peened to compensate for wear if necessary.

(c) For punching 10,000-1,000,000 pieces, the W1 punch can be soft so that it can be peened to compensate for wear, or it can be hardened and ground to size.

(d) Of the two alternatives listed, A2 tool steel is preferred if compound tooling is to be used for quantities of 10,000-1,000,000.

(e) This O1 punch may have to be cyanided 0.1 to 0.2 mm (0.044 to 0.008 in.) deep to make even 1000 pieces.

(f) For the application indicated, the punch and die should be gas nitrided 12 h at 540-565 °C (1000-1050 °F).

(g) Soft.

(h) Working edges are flame hardened in this application.

(i) May be soft or flame hardened.

(j) For punching 10,000-1,000,000 pieces, the punch would be W1, left soft so that it can be peened to compensate for wear, and the die would be O1, hardened.

(k) Cyaniding of the punch is advisable, even for 1000 pieces.

(l) For punching 10,000-1,000,000 pieces, the W1 die would be hardened and the W1 punch would be soft, so that it can be peened to compensate for wear.

Table 2 Typical punch and die materials for shaving 1.3 mm (0.050 in.) sheet

Work material	Tool material for production quantity of:			
	1000	**10,000**	**100,000**	1,000,000
Aluminum, copper, and magnesium alloys	O1[(a)]	A2	A2	**D4[(b)], CPM 10V**
Carbon and alloy steel, up to 0.30% C, and ferritic stainless steel	A2	A2	D2	**D4[(b)], CPM 10V**
Carbon and alloy steel, 0.30-0.70% C	A2	D2	D2	**D4[(b)], CPM 10V**
Stainless steel, austenitic, up to quarter hard	A2	D2	D4[(b)]	**D4[(b)], CPM 10V**
Stainless steel, austenitic, over quarter hard, and spring steel hardened to 52 HRC	**A2**	**D2**	**D4[(b)]**	**M2[(b)], CPM**

(a) Type O2 is preferred for dies that must be made by broaching.

(b) On frail or intricate sections, D2 should be used in preference to D4 or M2. Carbide shaving punches may also be practical for this quantity.

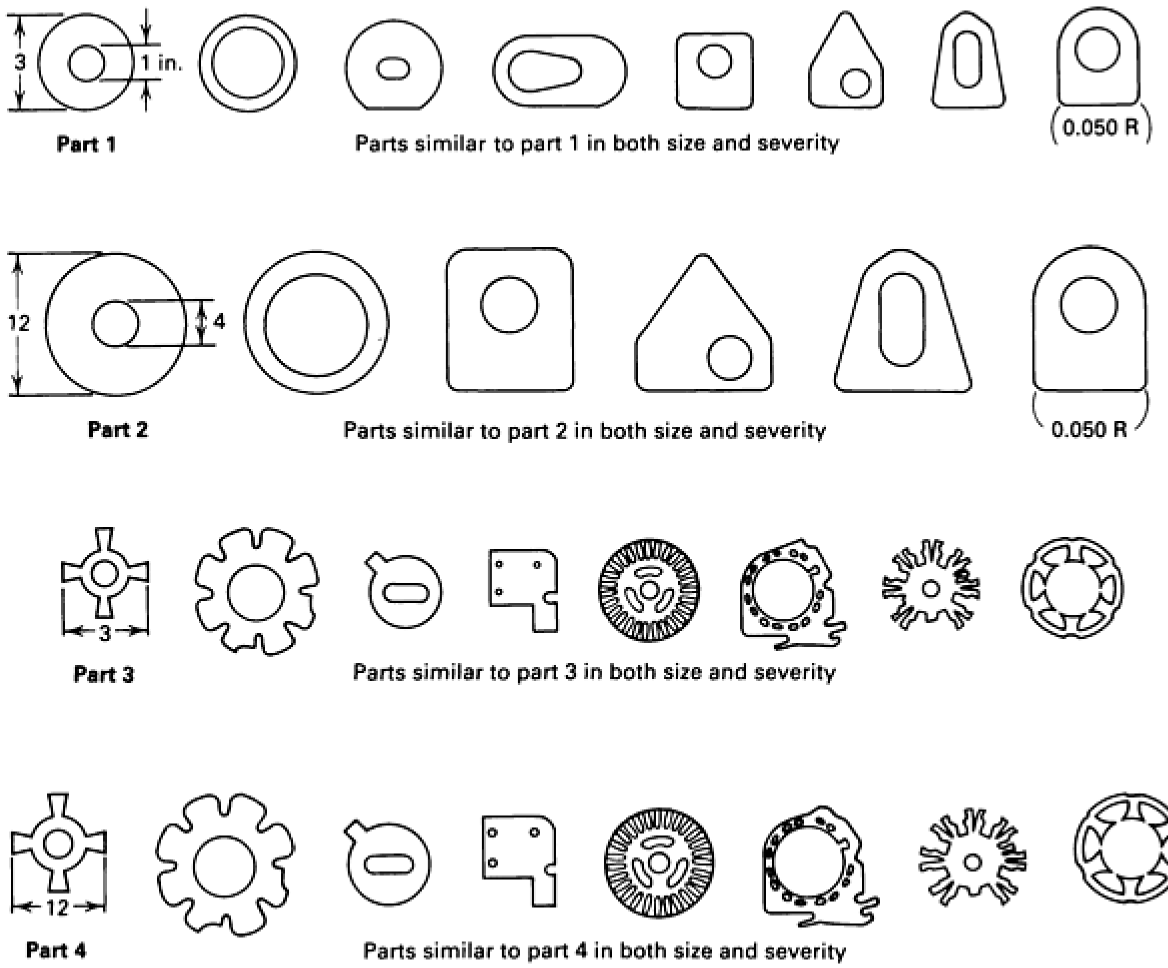

Fig. 2 Typical parts of varying severity that are commonly produced by blanking and piercing. Parts 1 and 2 are relatively simple parts that require dies similar to those illustrated in Fig. 1. Parts 3 and 4 are more complex, requiring notching and the use of compound or progressive dies. Dimensions given in inches

Tables 1 and 2 can be used to select punch and die materials for parts made of sheet that is thicker or thinner than the 1.3 mm (0.050 in.) used for the parts illustrated in Fig. 2. For thicker sheet, the punch and die material recommended for the next greater production quantity should be used instead of the material recommended for the production quantity that will actually be made (in Tables 1 and 2, the column to the right of the production quantity that will actually be made). For thinner sheet, the punch and die material recommended for the next lower production quantity should be used instead of the material recommended for the production quantity that will actually be made (in Tables 1 and 2, the column to the left of the production quantity that will actually be made).

Table 3 lists typical materials for perforator punches used on several different work materials. The usual limiting slenderness ratio (punch diameter to sheet thickness) for piercing aluminum, brass, and steel is 2.5:1 for unguided punches and 1:1 for guided punches. For piercing spring steel and stainless steel, this ratio ranges from 3:1 to 1.5:1 for unguided punches and from 1:1 to 0.5:1 for accurately guided punches. Typical hardnesses for these perforator punches are given in Fig. 3.

Table 3 Typical materials for perforator punches

Work material	Punch material for production quantity of:		
	10,000	**100,000**	1,000,000

Punch diameters up to 6.4 mm ($\frac{1}{4}$ in.)			
Aluminum, brass, carbon steel, paper, and plastics	M2	M2, CPM 10V	**M2, CPM 10V**
Spring steel, stainless steel, electrical sheet, and reinforced plastics	M2	M2, CPM 10V	**M2, CPM 10V**
Punch diameters over 6.4 mm ($\frac{1}{4}$ in.)			
Aluminum, brass, carbon steel, paper, and plastics	W1	W1	**D2, CPM 10V**
Spring steel, stainless steel, electrical sheet, and reinforced plastics	**M2**	**M2, CPM 10V**	**M2, CPM 10V**

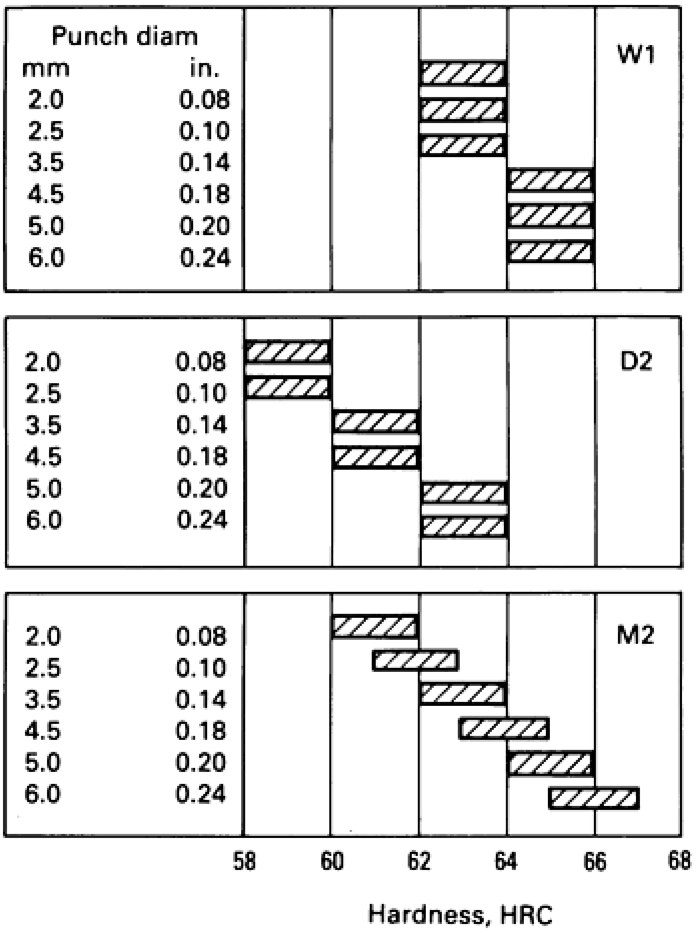

Fig. 3 Typical hardnesses for tool steel perforator punches. Regardless of material, punches should be tempered back to 56 to 60 HRC if they are to be subjected to heavy shock or used to pierce thick material.

Table 4 lists typical materials for perforator bushings of all three types (punch holder, guide or stripper, and perforator or die). These recommendations are particularly applicable to precision bushings--for example, where the outside diameter is ground to a tolerance of -0, +0.008 mm (-0, +0.0003 in.) and is concentric with the inside diameter within 0.005 mm (0.0002 in.) total indicator reading. The hardness of W1 bushings should be 62 to 64 HRC, and that of D2 bushings, 61 to 63 HRC.

Table 4 Typical materials for perforator bushings

Work material	Bushing material for production quantity of:		
	10,000	**100,000**	1,000,000
Aluminum, brass, carbon steel, paper, and plastics	W1[(a)]	W1[(a)]	**D2**

(a) When bushings are of a shape that cannot be ground after hardening, an oil- or air-hardening steel is recommended to minimize distortion.

Die plates and die parts that hold inserts are usually made of gray iron, alloy steel, or tool steel. For stamping thick sheet or hard materials, either class 50 gray iron or 4140 steel heat treated to a hardness of 30 to 40 HRC should be used. For long-run die plates for stamping thick or hard materials, steels such as 4340 and H11 are preferred when inserts are pressed into the die plates, and 4340 is nearly always used when inserts are screwed in. Die plates for stamping thin or soft sheet can be made of class 25 or class 30 gray iron or carbon steel.

Secondary Tooling. Punch holders and die shoes for carbide dies are made of high-strength gray iron or low-carbon steel plate. Yokes for retaining carbide sections are usually made of O1 tool steel hardened to 55 to 60 HRC. Backup plates for carbide tools are preferably made of O1 hardened to 48 to 52 HRC. Strippers can usually be made of low- or medium-carbon steel (1020 or 1035) plate. Where a hardened plate is used for medium-production work, 4140 flame hardened, W1 conventionally hardened, or W1 cyanided and oil quenched are often preferred. Hardened strippers for carbide dies and high-production D2, D4, or CPM 10V dies are made of O1 or A2, hardened to 50 to 54 HRC.

Custom-made hardened guides and locator pins are usually made of W1 or W2 for most medium- or long-run dies or of alloy steels such as 4140 for low-cost short-run dies. Commercial guide pins are often made of SAE 1117 and then carburized, hardened, and finished to a surface roughness of 0.4 μm (16 μin.) rms.

Applications of Specific Materials

Rolled zinc alloy tooling plate is available in the form of 6.4 mm ($\frac{1}{4}$ in.) plate from the principal suppliers of zinc-base die-casting alloys. Dies of this material are sheared in with a flame-hardened O1 punch, and strippers of 9.5 mm ($\frac{3}{8}$ in.) sheet cork are invariably used with them.

Tools of hot-rolled low-carbon steel plate (0.10 to 0.20% C) can be used for short runs of small parts if these tools have been surface hardened, either by carburizing to a depth of 0.25 to 0.50 mm (0.010 to 0.020 in.) or by cyaniding to a depth of 0.1 to 0.2 mm (0.004 to 0.008 in.). Because of distortion in heat treatment, use of this material is limited to the blanking of small, symmetrical shapes.

For the long-run blanking of soft materials, various sizes of aircraft-quality 4140 steel plate have been used. In this application, 4140 is normally flame hardened to about 50 HRC. Flame hardening the working edge of a large die has an advantage over through hardening in that very little warping or change of size occurs. However, tools with inside or outside corners may have soft spots after flame hardening and, if so, will perform poorly.

The tool steels in Table 1 are assumed to have been hardened and tempered by conventional methods to their maximum usable hardness (58 to 61 HRC. In addition to these tool steels, type O6 has given satisfactory service in multiple-stage progressive dies, and type A10, because of its low austenitizing temperature, high dimensional accuracy, and good dimensional stability, is often used to make large dies for stamping laminations.

In some applications, M2 high-speed steel tools may produce smaller burrs than D2 tools (for equal numbers of parts). In addition, steel-bonded carbides and high-vanadium-carbide powder metallurgy tool materials such as CPM 10V should be considered for critical applications. Steel-bonded carbides belong to the cemented carbide family and are also produced by the powder metallurgy process, but differ from cemented carbides in that they have variable physical properties (specifically hardness) obtained by heat treatment of their matrices. Crucible particle metallurgy tool steels and their applications are described in the article "Particle Metallurgy Tool Steels" in *Powder Metal Technologies and Applications*, Volume 7 of the *ASM Handbook.*

Cemented tungsten-carbide tooling should be considered where production life must be four or more times that possible with D4 tool steel. Partial or complete carbide inserts in tool steel dies may be considered for lower quantities, especially where close tolerances and minimum burr height are desired or where tool life between resharpenings needs to be extended. However, brazed inserts are hazardous, and the cost of dovetailed or mechanically held inserts approaches that of complete carbide dies.

Composition and hardness of carbides frequently used in blanking and piercing dies are as follows:

Composition, %			Hardness, HRA
W	**C**	**Co**	
75.1	4.9	20.0	**86**
78.9	5.1	16.0	**86**
81.7	5.3	13.0	**88**

The first material listed above should be used where shock is appreciable. The second material combines toughness and wear resistance and is preferred for heavy-duty service, such as the piercing of silicon steel. Where close tolerances must be held in piercing silicon steel laminations, the third material is useful. The fourth material is best for guides and guide rolls and for applications involving very light shock. The data in Fig. 4 show that the difference in wear life between two different tool steels at the same hardness is negligible compared with the difference between the average life of conventional tool steel dies and the life of a carbide die or a CPM 10V die.

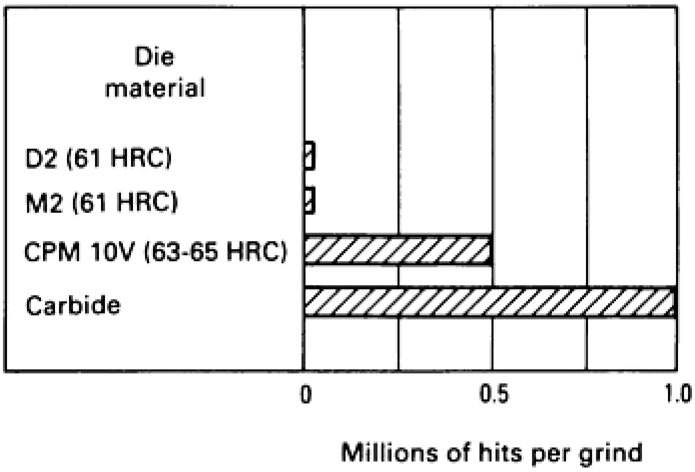

Fig. 4 Relative service lives of three steel dies and one carbide die. Die life was obtained under the same operating conditions; that is, the blanking of 3.25% Si electrical steel sheet 0.36 mm (0.014 in.) thick. Dies were reground when they had worn sufficiently to produce a burr 0.13 mm (0.005 in.) high.

Introduction

THE PRESSES described in this article are mechanically or hydraulically powered machines used for producing parts from sheet metal. Forging equipment is described in the article "Hammers and Presses for Forging" in this Volume.

Power presses can be classified according to the following characteristics: source of power, type of frame, method of actuation of slides, and number of slides in action. Presses in any of these classes are available in a range of capacities (tonnage or bed area), although the range is not necessarily the same for all types of presses. Characteristics of 18 types of presses are summarized in Table 1.

Table 1 Characteristics of 18 types of presses

Type of press	Frame type							Frame position				Action			Actuation method

The Joint Industry Conference (JIC), a committee of press builders and large-press users formed some years ago, set guidelines for uniformity with respect to nomenclature, bed and ram sizes, force ranges, and symbols for presses. Although JIC is no longer in existence, most press builders adhere to the standards either completely or in part. Under the JIC press classification system with respect to the number of slides, the first letter in the designation is *S* for single-action, *D* for double-action, and *T* for triple-action presses. Other designations used for visible identification of presses suggested under the JIC classification system are given in Fig. 1. Most press builders place these markings in a prominent position on the fronts of the presses.

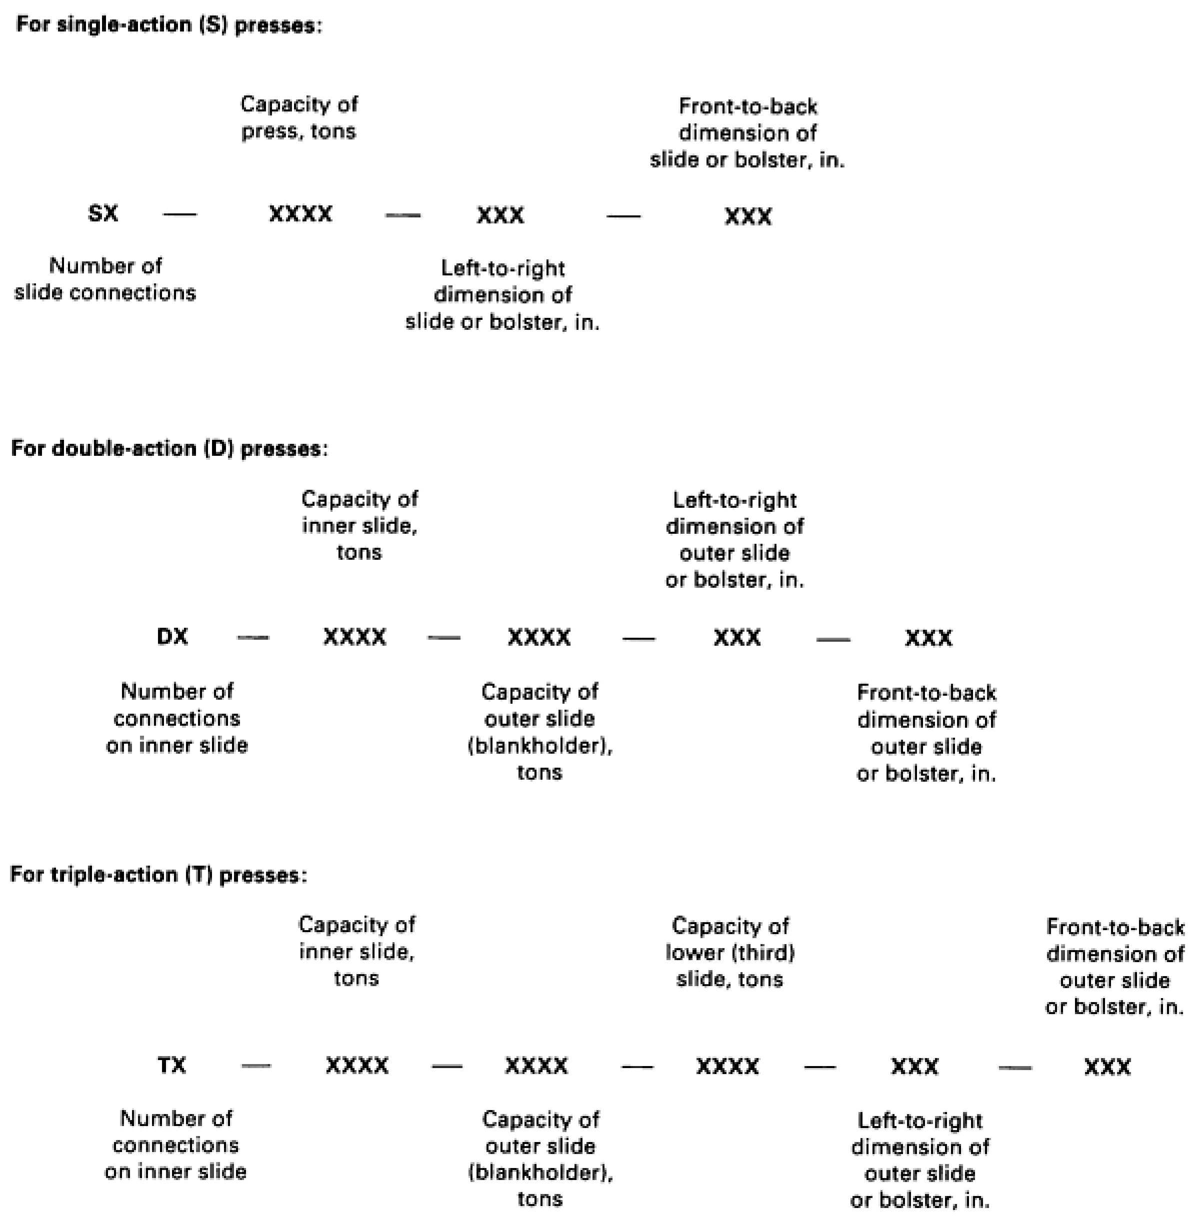

Fig. 1 Designations used for press identification under the JIC classification system.

Source of Power

Power presses for sheet metal forming can be driven either hydraulically or mechanically. The performance characteristics and other operational features of hydraulic and mechanical presses are compared in Table 2.

Table 2 Comparison of characteristics of mechanical and hydraulic presses

Force	**Capacity**	**Stroke length**	**Slide speed**	**Control**	Preferred uses
Mechanical					
Varies depending on slide position	Practical maximum of ~54 MN (6000 tonf)	Limited	Higher than hydraulic, and can be varied. Highest at midstroke	Full stroke is usually required before reversal.	**Preferred for operations requiring maximum pressure near the bottom of the stroke. Preferred for cutting operations such as blanking and piercing, and for relatively shallow forming and drawing (depths to about 102 mm, or 4 in.). Good for high-production applications and progressive and transfer die operations**
Hydraulic					
Relatively constant (does not depend on slide position)	**445 MN (50,000 tonf) or more**	**Capable of long (2.5 m, or 100 in.) strokes**	**Slower pressing speeds, with rapid advance and retraction. Speed is uniform throughout the stroke.**	**Adjustable; slide can be reversed at any position.**	**Good for operations requiring steady pressure throughout the stroke. Preferred for deep drawing, die tryout, flexible-die forming, drawing of irregular-shape parts, straightening, operations requiring high and variable forces, and operations requiring variable or partial strokes**

Mechanical Presses

In most mechanical presses, a flywheel is the major source of energy that is applied to the slides by cranks, gears, eccentrics, or linkages during the working part of the stroke. The flywheel runs continuously and is engaged by the clutch only when a press stroke is needed. In some very large mechanical presses the drive motor is directly connected to the press shaft, thus eliminating the need for a flywheel and a clutch.

Two basic types of drive, gear and nongeared, are used to transfer the rotational force of the flywheel to the main shaft of the press.

Nongeared Drive. In a nongeared drive (also known as a flywheel drive), the flywheel is on the main shaft (Fig. 2a), and its speed, in revolutions per minute, controls the slide speed. Usually press speeds with this type of drive are high, ranging from 60 to 1000 strokes per minute. The main shaft can have a crankshaft, as shown in Fig. 2(a), or an eccentric.

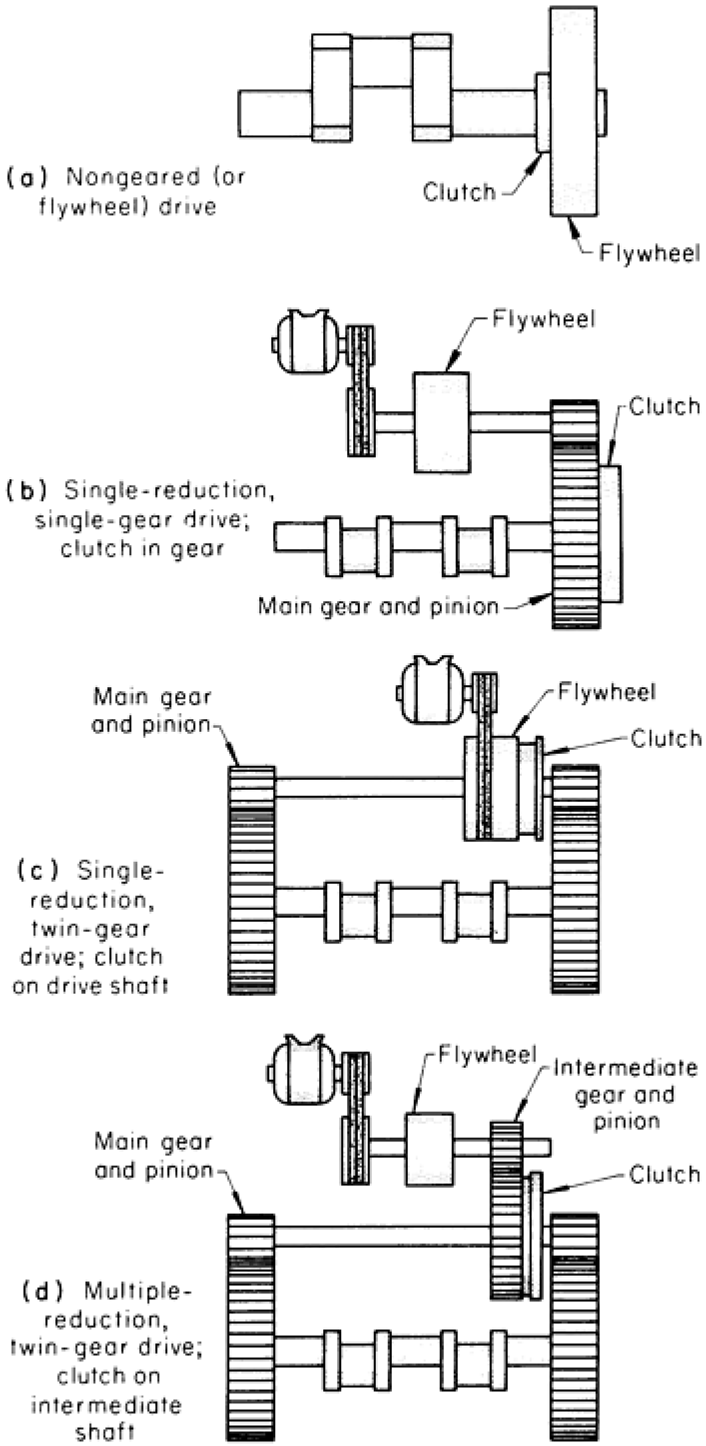

Fig. 2 Four types of drive and clutch arrangements for mechanical presses.

Energy stored in the flywheel should be sufficient to ensure that the reduction in the speed of the flywheel will be no greater than 10% per press stroke. If the energy in the flywheel is not sufficient to maintain this minimum in speed reduction, a gear-driven press should be used.

Gear drives (Fig. 2b, c, and d) have the flywheel on an auxiliary shaft that drives the main shaft through one or more gear reductions. Either single-reduction or multiple-reduction gear drives are used, depending on size and tonnage requirements. In gear-driven presses, there is more flywheel energy available for doing work than there is in the nongeared presses, because the speed of the flywheel is higher than that of the main shaft. The flywheel shaft of a gear-driven press often is connected to the main shaft at both ends (Fig. 2c), which results in a more efficient drive.

A single-reduction gear drive develops speeds of 30 to 100 strokes per minute. Speed for a multiple-reduction twin gear drive (Fig. 2d) is usually 10 to 30 strokes per minute, which provides exceptionally steady pressure.

Hydraulic Presses

Hydrostatic pressure against one or more pistons provides the power for a hydraulic press. Most hydraulic presses have a variable-volume, variable-pressure, concentric-piston pump to provide them with a fast slide opening and closing speed. It also provides a slow working speed at high forming pressure.

The principal components of a typical hydraulic press are shown in Fig. 3. A bolster plate is attached to the bed to support the dies and to guide the pressure pins between the die cushion and the pressure pad.

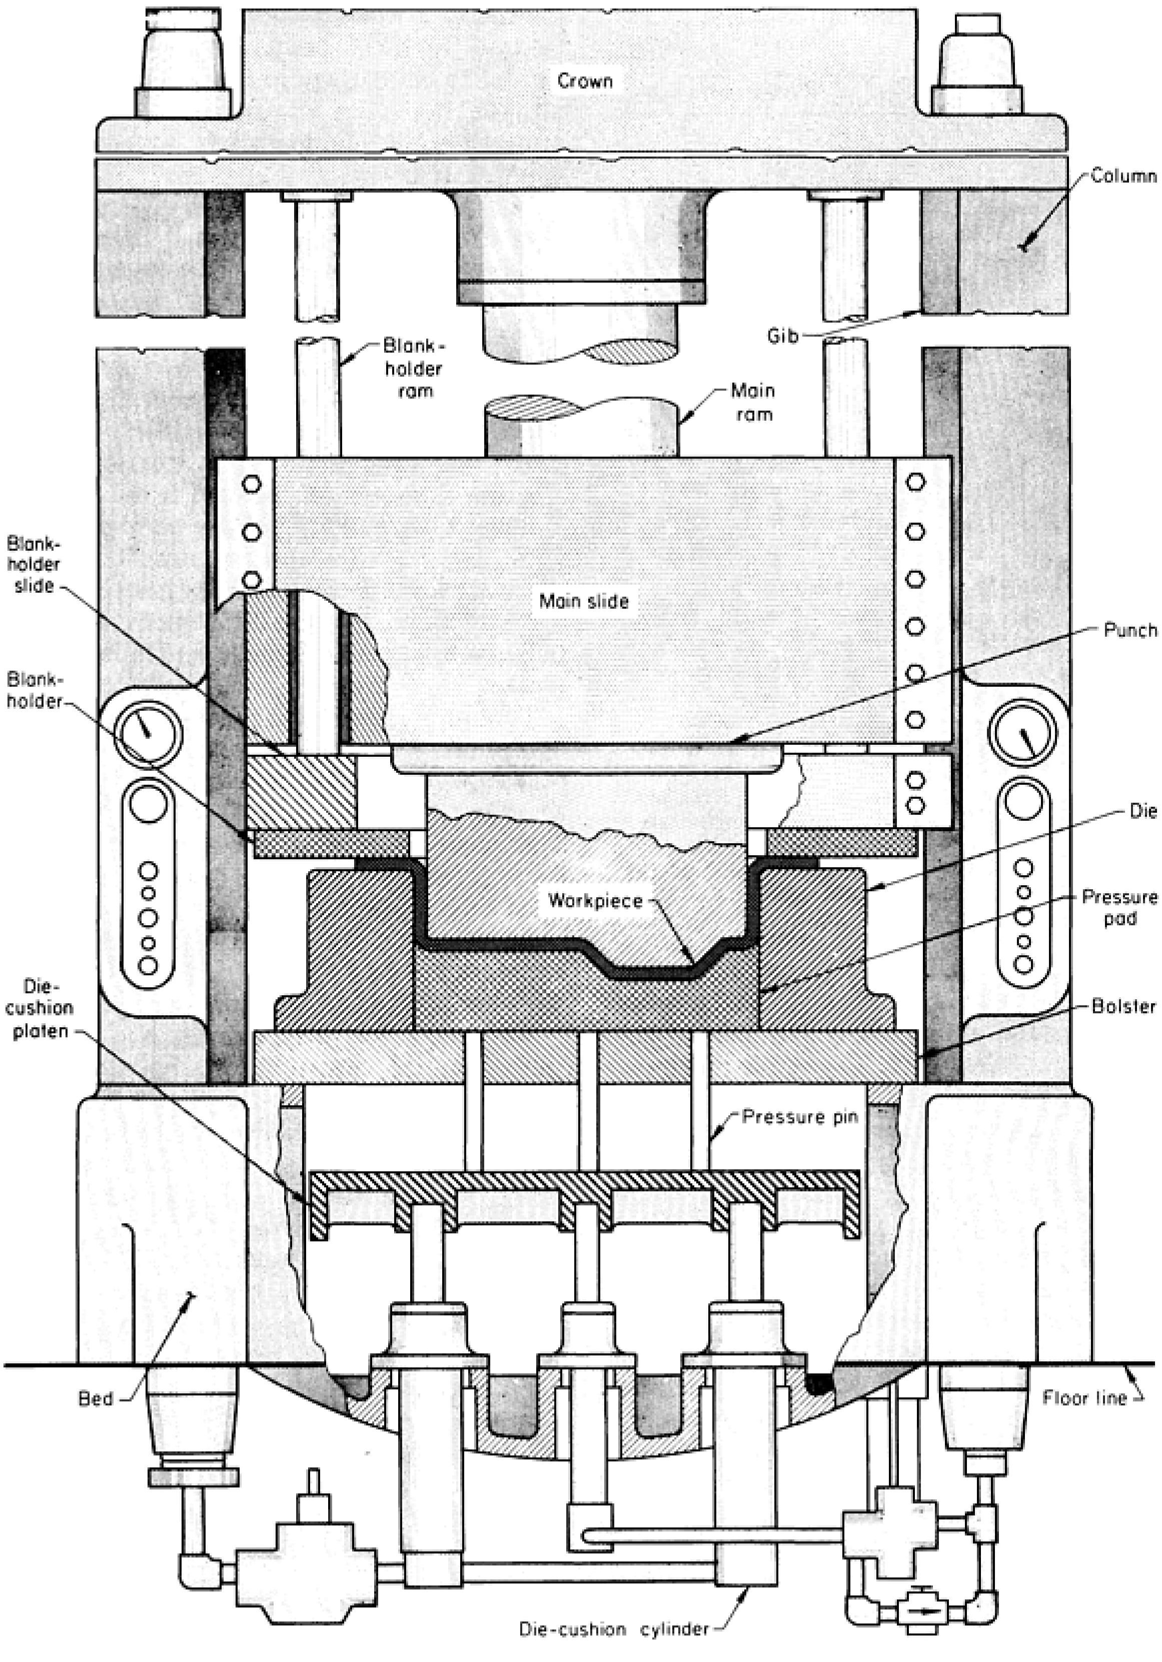

Fig. 3 Principal components of a double-action hydraulic press with a die cushion.

The capacity of a hydraulic press depends on the diameter of the hydraulic pistons and on the rated maximum hydraulic pressure, the latter being a function of the pump pressure and related mechanisms. Hydraulic presses with capacities up to 445 MN (50,000 tonf) have been built, but most have a capacity of less than 133 MN (15,000 tonf). The typical hydraulic press is rated at 900 kN to 9 MN (100 to 1000 tonf). Gap-frame presses are rated at 45 to 450 kN (5 to 50 tonf).

Because of their construction, hydraulic presses can be custom designed at a relatively low cost. They can be designed with a number of slides and motions, or separate hydraulic circuits can be used for various independent actions. In addition, side action can be provided within the frame of the press by means of separate cylinders. Such side action in a mechanical press is usually provided by cams and is complex and expensive. Most hydraulic presses are straight-side models, but small, fast, gap-type presses designed to compete with mechanical open-back inclinable presses have been developed.

Hydraulic press slides, or platens, are actuated by numerous combinations of hydraulic drives. Hydraulic presses usually have a longer stroke than mechanical presses, and force can be constant throughout the stroke. Hydraulic presses have an adjustable stroke for one or more slides. Accumulators or large-volume pumps can provide fast motion for a slide to open and close. High-pressure pumps provide the working force at a slower speed.

Usually all slides are operated by one pumping system. The relation of each action to the others, interaction, and timing all depend on the controls.

Press Selection

Proper selection of a press is essential for successful and economical operation. The purchase of a press represents a substantial capital investment, and return on investment depends upon how well the press performs the job required. No general-purpose press exists that can provide maximum productivity and economy for all applications. Compromises usually must be made to permit a press to be employed for more than one job. Careful consideration should be given to both present and future production requirements.

Important factors influencing the selection of a press include size, force, energy, and speed requirements. The press must be capable of exerting force in the amount, location, and direction, as well as for the length of time, needed to perform the specified operation or operations. Other necessary considerations include the size and geometry of the workpieces, the workpiece material, operation or operations to be performed, number of workpieces to be produced, production rate needed, accuracy and finish requirements, equipment costs, and other factors.

Size, Force, and Energy Requirements. Bed and slide areas of the press must be large enough to accommodate the dies to be used and provide adequate space for die changing and maintenance. Space is required around the dies for accessories such as keepers, pads, cam return springs, and gages; space is also needed for attaching the dies to the press. Shut height of the press, with adjustment, must also be suitable for the dies.

Presses with as short a stroke as possible should be selected because they permit higher-speed operation, thus increasing productivity. Stroke requirements, however, depend upon the height of the parts to be produced. Blanking can be done with short strokes, but some forming and drawing operations require long strokes, especially for ejection of parts.

Size and type of press to be selected also depend upon the method and direction of feeding; the size of sheet, coil stock, blank, or workpiece to be formed; the type of operation; and the material being formed and its strength. Material or workpiece handling and die accessibility generally determine whether the press should be of gap-frame or straight-side construction, and whether it should be inclined or inclinable.

Physical size of a press can be misleading with respect to its capacity. Presses having the same force rating can vary considerably in size depending upon differences in length of stroke, pressing speed, and number of strokes per minute.

The force required to perform the desired operations determines press capacity, expressed in tons or kilonewtons (kN) (see the section "Press Capacity" in this article). The position on the stroke at which the force is required and the length of stroke must be considered.

Energy or work (force times distance), expressed in inch-tons or joules (J), varies with the operation. Blanking and punching require the force to be exerted over only a short distance; drawing, forming, and other operations require force application over a longer distance. The major source of energy in mechanical presses is the flywheel, the energy varying with the size and speed of the flywheel. The energy available increases with the square of the flywheel speed.

Possible problems are minimized by selecting a press that has the proper frame capacity, drive motor rating, flywheel energy, and clutch torque capacity.

Speed Requirements. Press speed is a relative term that varies with the point of reference. Fast speeds are generally desirable, but they are limited by the operations performed, the distances above stroke bottoms where the forces must be applied, and the stroke lengths. High speed, however, is not necessarily the most efficient or productive. Size and configuration of the workpiece, the material from which it is made, die life, maintenance costs, and other factors must be considered to determine the highest production rate at the lowest cost per workpiece. A lower speed may be more economical because of possible longer production runs with less downtime.

Simple blanking and shallow forming operations, however, can be performed at high speeds. Mechanical presses have been built that operate to 2000 strokes/min with 25 mm (1 in.) stroke, but applications at this maximum speed are rare. Speeds of 600 to 1400 strokes/min are more common for blanking operations, and thick materials are often blanked at much slower speeds. For drawing operations, contact velocities are critical with respect to the workpiece material, and presses are generally operated at slide speeds from 10 to 300 strokes/min, with the slower speed for longer stroke drawing operations.

Mechanical Versus Hydraulic Presses. Mechanical presses are the most frequently used for the blanking, forming, and drawing of sheet metal, but hydraulic presses are being increasingly applied. There are applications for which hydraulic presses offer certain advantages and, in some cases, are the only machines that can be used. For example, very high force requirements can only be met with hydraulic presses. A comparison of characteristics and preferred uses for both mechanical and hydraulic presses is presented in Table 2.

Type of Press Frame

Presses are broadly classified, according to the type of frame used in their construction, into two main groups: gap-frame presses and straight-side presses. Details of construction vary widely in each group.

Gap-frame presses (Fig. 4) are sometimes called C-frame presses because the frame resembles the letter C when viewed from the side. The gap makes the die area accessible from either side, as well as from the front, for ease in die setting or for feeding stock. Coil stock often is supplied to gap-frame presses by feeders from stock reels and straighteners.

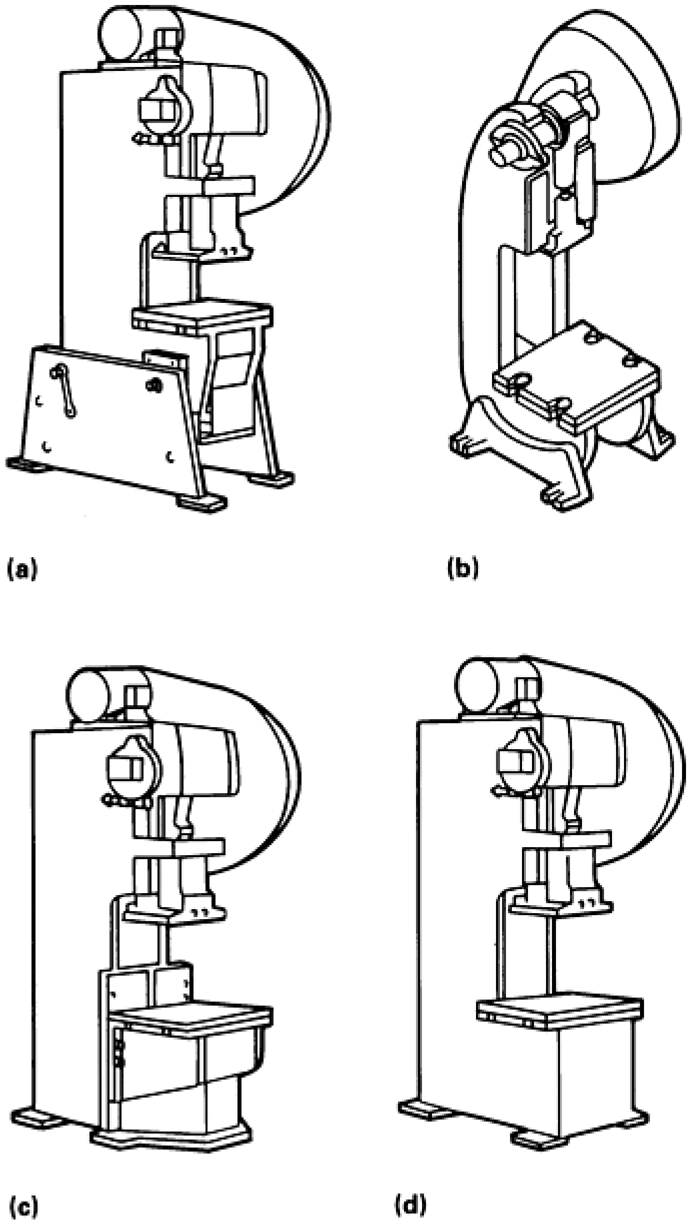

Fig. 4 Four types of gap-frame presses. (a) Open-back inclinable. (b) Bench press. (c) Adjustable-bed stationary. (d) Open-back stationary.

Workpieces usually are ejected through an opening in the press bed, or through the back of an open-back press. (A few gap-frame presses with solid backs are in service, but solid-back presses are coming into increasing disfavor because work cannot be ejected through the back of the press and because the design in general is less convenient than is the open-back type).

Gap-frame construction has one disadvantage: The gap opens under load, thus causing angular deflection. (A straight, vertical deflection would be less critical.) Gap deflection resulting from overload causes misalignment of punches and dies, which is a major cause of premature die wear.

Tie rods extending from the top of the frame to the front corners of the bed can be used to minimize deflection. Because the tie rods close the gap, the accessibility to the die area and the width of parts fed into the die are limited. Tie rods can be removed for die setup.

Straight-side presses have a frame made up of a base, or bed; two columns; and a top member, or crown. In most straight-side presses, steel tie rods hold the base and crown against the columns. Straight-side presses have crankshaft, eccentric-shaft, or eccentric-gear drives (see the section "Slide Actuation in Mechanical Presses" in this article).

A single-action straight-side press is shown in Fig. 5. The slide in this illustration is equipped with air counterbalances to assist the drive in lifting the weight of the slide and the upper die to the top of the stroke. Counterbalance cylinders provide a smooth press operation and easy slide adjustment. Die cushions are used in the bed for blank-holding and for ejection of the work.

Fig. 5 Principal components of a single-action straight-side mechanical press. The press shown has a large bed, four-point suspension, and an eccentric drive with counterbalance cylinders. Slide adjustment is motorized.

The straight-side design permits the use of an endless variety of bed and slide sizes. Presses range from 180 kN (20 tonf) capacity and a bed of 510 × 380 mm (20 × 15 in.), to 36 MN (4000 tonf) capacity with a bed as large as 915 mm (360 in.) left-to-right by 455 mm (180 in.) front-to-back. The size and shape of the slide usually determine the number of points of suspension, or connections between the main shaft and the slide, that are needed.

The straight-side design also can provide high pressures with minimum deflection. A straight-side press deflects less under off-center loads than does a gap-frame press.

Presses and Auxiliary Equipment for Forming of Sheet Metal

Slide Actuation in Mechanical Presses

Rotary motion of the motor shaft on a mechanical press is converted into reciprocating motion of the slides by a crankshaft, eccentric shaft, eccentric-gear drive, knuckle lever drive, rocker arm drive, or toggle mechanism, each of which is discussed below.

Crankshafts. The most common mechanical drive for presses with capacities up to 2.7 MN (300 tonf) is the crankshaft drive (Fig. 6). A crankshaft is used in both gap-frame and straight-side presses. The crank-shaft drive is used most often in the single-suspension design, although some double-crank (two-point suspension) presses, particularly in the 900 to 1800 kN (100 to 200 tonf) range, also have crankshafts.

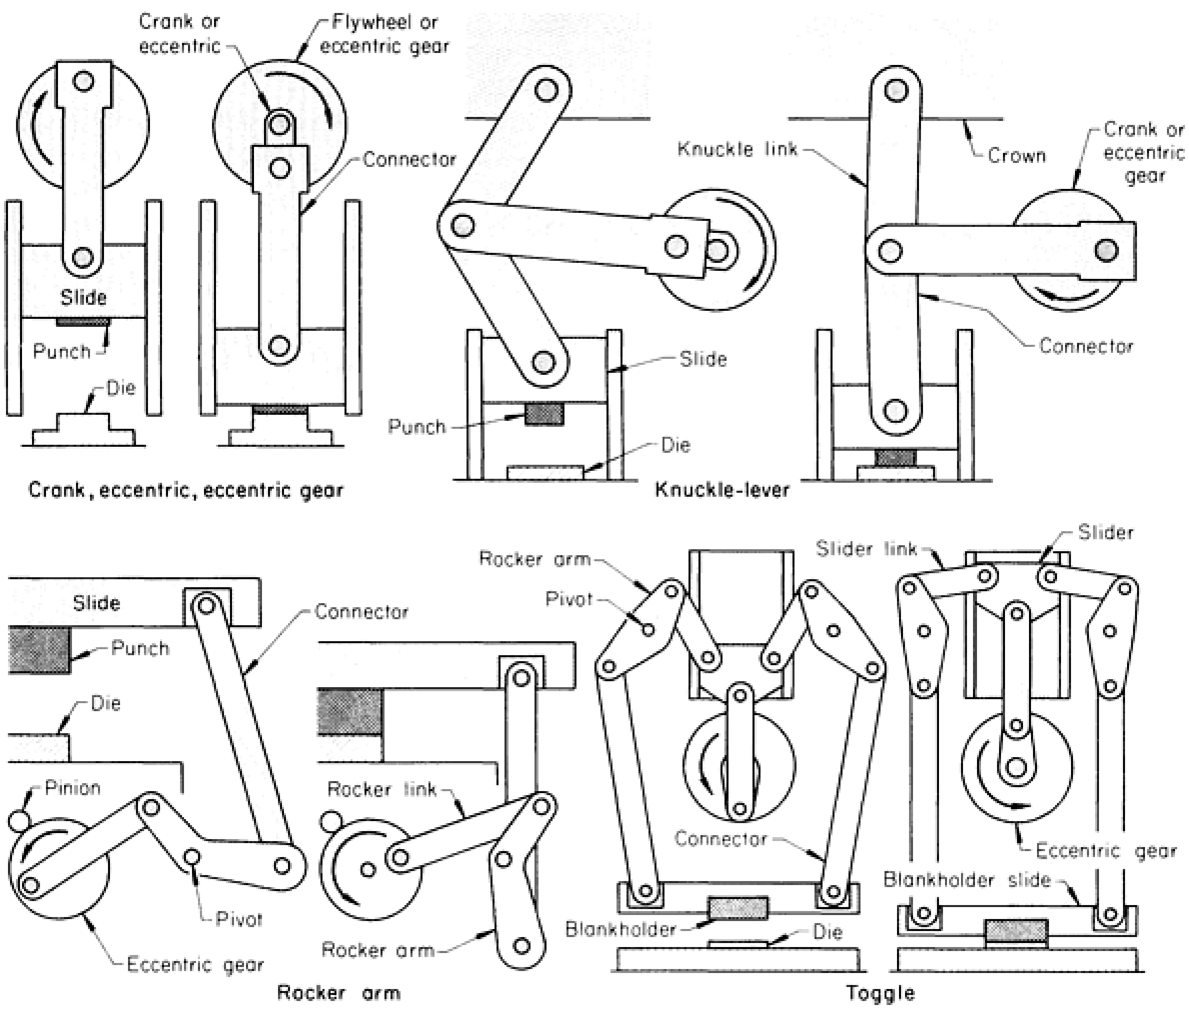

Fig. 6 Operating principles of various drive systems for mechanical presses.

The crankshaft imparts a sine-curve speed relation to the press slide. The stroke of a crankshaft-actuated press can be as short as 25 mm (1 in.), in a small gap-frame press, or as much as 760 mm (30 in.), in a straight-side press. However, most mechanical presses with longer strokes are actuated by an eccentric gear, because it provides greater strength. Crankshaft drives are usually limited to strokes of 152 to 305 mm (6 to 12 in.).

The main advantage of a crankshaft-driven press is its lower cost, particularly when capacities do not exceed 2.7 MN (300 tonf).

Points of suspension refer to the number of connections between the slide and the actuating mechanism. Presses can have single-point, two-point, or four-point suspension, depending on the number of points at which the slide is pushed or pulled. The simplest mechanical presses have a pitman that connects the eccentric shaft or the crankshaft to the slide at only one point.

Many wide mechanical presses are built with two-point suspension by connecting the slide to the crankshaft (or eccentric) with two pitmans instead of one, for better distribution of force on the slide.

The largest straight-side mechanical presses usually have four-point suspension, for more uniform loading of large slides. Four-point suspension is usually accomplished by two interconnected crankshafts or eccentrics and four pitmans; each pitman is connected near a corner of the slide.

Hydraulic presses also can have one, two, or more points of suspension by operating the slide with as many rams as desired.

Eccentric shafts are similar to crankshafts. The eccentric completely fills the space between the supporting bearings of the press crown, thereby eliminating the deflection commonly caused by the unsupported portion where the crank cheeks normally would be. Eccentric drives (Fig. 6) often are used in high-speed, short-stroke, straight-side presses with progressive dies.

The height of the workpiece is the main limitation of the eccentric-shaft drive, because the stroke is always equal to twice the eccentricity. When eccentricity is increased, the space available in the press crown determines the maximum stroke that can be used. In most presses of this type, the maximum stroke is usually limited to 152 mm (6 in.). A few presses have been built and used for high-speed operations in which strokes longer than 152 mm (6 in.) were needed. This was accomplished in the press by balancing the eccentric shaft to minimize vibration.

Eccentric-gear drives (Fig. 6) are used almost universally for large, straight-side presses that operate at speeds under 50 strokes per minute. In place of a crankshaft, an eccentric is built as an integral part of the press drive gear. The eccentric gear permits strokes as long as 1.3 m (50 in.); however, with such long strokes, speeds are usually only 8 to 16 strokes per minute. With the eccentric as part of the gear, accuracy of alignment of the slide is determined by accuracy and alignment of the gears. In a two-point suspension, the parallel condition of the ram is determined by the alignment of the driving gears. The principal advantage of the eccentric gear is that it permits greater torque loads at points above the bottom of the stroke. It also permits multiple-point construction with greater versatility and range of stroke length than is possible with a crankshaft.

The chief limitation of the eccentric-gear design is that it usually requires an overhung flywheel. In addition, a single-gear eccentric press usually costs more than a crankshaft or eccentric-shaft press of equal capacity. A further limitation is that eccentric-gear presses are more likely to stick at the bottom of the stroke than are crankshaft presses. Sticking is caused by greater friction in the connector, which is inherent in the large-diameter eccentrics needed for an equal press stroke. Sticking usually occurs during setup, if the press is moved slowly until the bottom of the stroke is reached. At this point, a skilled setup man can usually detect whether the press is likely to stick.

Knuckle lever drives combine the motions of a crank and knuckle lever to drive the press slide (Fig. 6). Their use is limited to operations such as coining or embossing, in which the work is done almost entirely at the bottom of a short stroke. The knuckle lever mechanism permits large capacity in a relatively small press. High mechanical advantage is inherent at the bottom of the stroke. These presses are rated to deliver full capacity at 1.6 to 6.4 MM ($\frac{1}{16}$ to $\frac{1}{4}$ in.) above the bottom of the stroke. The very quick increase in force as the slide nears the bottom of the stroke is the reason its usefulness is limited to operations performed at the bottom of the stroke. Knuckle lever presses usually have capacities of 1.4 to 8.9 MN (150 to 1000 tonf).

Rocker arm drives apply crank or eccentric motion to a rocker arm that is connected to the press slide (Fig. 6). In this mechanism, the linkage is driven by an eccentric gear and a connecting rod. The rocker arm drive is a variation of the knuckle lever drive. However, a press with rocker arm drive is not limited to coining operations; it can also be used for drawing or forming operations.

The rocker arm drive is used mainly in large-bed underdrive presses. The linkage operates from below the press bed and pulls the slide into the work by a link running up through each of the press columns. In most rocker arm drives, the rocker pin and the connecting eccentric pin do not stop in a vertical plane; thus, the load on the eccentric shaft is relieved at the point of maximum load on the slide, and sticking at the bottom of the stroke is prevented. In addition, a high press capacity is obtained because of the mechanical advantage.

Toggle mechanisms are the most widely used means of providing the second action in double-action mechanical presses. The toggles operate an outer slide, which clamps the blank against the die, while the punch, operated by the inner slide directly from the crankshaft, performs the draw operation. Principal components of a toggle mechanism are shown in Fig. 6.

Number of Slides

Mechanical (and hydraulic) presses have one, two, or three slides and are referred to as single-, double-, or triple-action presses. Each slide can be moved in a separately controlled motion.

A single-action press has one reciprocating slide (tool carrier) acting against a fixed bed. Presses of this type, which are the most widely used, can be employed for many different metal-stamping operations, including blanking, embossing, coining, and drawing. Depending on the depth of draw, single-action presses often require the use of a die cushion for blankholding. In such applications, a blankholder ring is depressed by the slide (through pins) against the die cushion, usually mounted in the bed of the press (see the section "Die Cushions" in this article).

A double-action press has two slides moving in the same direction against a fixed bed. These slides are generally referred to as the outer (blankholder) slide and the inner (draw) slide. The blankholder slide is a hollow rectangle, while the inner slide is a solid rectangle that reciprocates within the blankholder.

Double-action presses are more suitable for drawing operations, especially deep drawing, than are single-action presses. In single-action presses, force is required to depress the cushion. In double-action presses, the blankholder slide has a shorter stroke and dwells at the bottom of its stroke before the punch mounted on the inner slide contacts the work. As a result, practically the entire capacity of the press is available for drawing. Another advantage is that the four corners of the blankholder are individually adjustable so that nonuniform forces can be exerted on the work when required. A double-action press equipped with a die having an open bottom permits pushing the stamping through the die to perform other operations, such as ironing, after drawing.

Deep-drawing operations and irregularly shaped stampings generally require the use of a double-action press. Most operations performed on double-action presses require a cushion either for lift-out or for reverse drawing of the stamping.

A triple-action press has three moving slides: two slides moving in the same direction as in a double-action press and a third, or lower, slide moving upward through the fixed bed in a direction opposite to the blankholder and inner slides. This action permits reverse drawing, forming, or beading operations against the inner slide while both upper actions are dwelling.

Cycle time for a triple-action press is necessarily longer than it is for a double-action press because of the time required for the third action. Because most drawn stampings require subsequent restriking and/or trimming operations, which are done in faster, single-action presses, most stamping manufacturers consider the triple-action press too slow.

Press Accuracy

Suggested criteria for the accuracy of a press are:

- Maximum tolerances for parallelism between slide and bed; 0.08 mm/m (0.001 in./ft) at the bottom of the stroke for all slides; 0.24 mm/m (0.003 in./ft) at midstroke for punch slides; and 0.4 mm/m (0.005 in./ft) at midstroke for blankholder slides
- Feed, if used, should be accurate within ±0.076 mm (±0.003 in.) at 23 m/min (75 ft/min) (see the section "Press Feeds" in this article)
- Gib clearance should be set as close as required to do the job

Parallelism. In a single-point press, the slide guides basically determine parallelism of the slide face with respect to the bed or bolster, both in the front-to-back and right-to-left directions. In a two-point press, slide guides determine parallelism only in the front-to-back direction. Out-of-parallel conditions in the right-to-left direction because of faulty adjusting-screw timing, variations in throw between the cranks or eccentrics, or bicycling (periodic tilting of the slide in opposite directions) due to timing errors in the drive cannot be corrected by adjusting the slide guides.

In a four-point press, parallelism is determined strictly by the press-drive and adjusting-screw accuracy and timing. Out-of-parallel conditions at midstroke, however, can be caused by improper centering of the slide guide adjustment.

Gib Clearance. Clearances between press slide guides and gibs are required to compensate for inaccuracies in machining and in the throw and timing of two- and four-point presses, and to allow for expansion and contraction of the guides and gibs. With the bronze-to-cast iron or cast iron-to-cast iron gibbing normally used, some slight clearances must also exist for the oil or grease lubricant.

If sufficient clearance is not provided, excessive pressure on the guides occurs at some point during the stroke, resulting in galling of the mating surfaces. The amount of clearance also affects the repetitive registry of punch with die. If the clearance between punch and die is less than the clearance between the press guides, the punch can mount the die, thereby causing premature wear. Clearance between the press guides also depends upon the length of the gibs. A reasonable allowance can be 0.08 to 0.15 mm (0.003 to 0.006 in.), the exact amount varying with gib length. For high-speed presses, the clearance between a gib-type guide and the press slide at normal operating temperature is generally no more than 0.038 mm (0.0015 in.).

Clearances between the mating surfaces of press guides can be reduced by using self-lubricating reinforced-phenolic liners. The modulus of elasticity of this material is about $\frac{1}{50}$ that of steel. As a result, deformation of the liners due to the inaccuracies discussed does not raise excessive compressive stresses in the liners, providing the liners are of sufficient thickness.

Near-zero clearances can be achieved by using preloaded rolling-contact (ball or roller) bearing guides. When offset or lateral loads are encountered, however, tending to cause the press slide to tilt, only a few rolling-contact members at the top and bottom of the guides take the loads. As a result, stresses exerted on the balls or rollers can be very high.

Press Capacity

Capacity, or rating, of a press is the maximum force that the press can apply. Hydraulic presses can exert maximum force during the full press stroke. Mechanical presses exert maximum force at a specified distance above the bottom of the stroke (usually 1.6 to 13.0 mm, or $\frac{1}{16}$ to $\frac{1}{2}$ in.), and the force decreases to a minimum at midstroke.

The tonnage rating of a press may have little relation to the bed area. This is especially true in the automotive and appliance industries, where presses have large bed areas and die spaces but relatively low tonnage ratings. Coining presses have small bed areas and high tonnage ratings.

Overloading of the press can cause damage to both the die and the press. Several devices based on the strain-gage principle have been developed for accurately measuring the load on a mechanical press with a given die. Misfeeds or double blanks are common causes of press overloading. Detectors built into the die stop the press before overloading occurs.

The capacity of a mechanical press involves consideration of the frame capacity, drive capacity, flywheel energy, and motor size.

Frame Capacity. The press frame must be able to work at its rating without deflecting beyond predetermined standard limits. For general-purpose applications, the bed deflection should not exceed 0.17 mm/m (0.002 in./ft) between tie rod centers (or per foot of left-to-right bed dimension on presses without tie rods) when the rated load is evenly distributed over the middle 60% of the distance between tie rod centers (or of the left-to-right bed length). Slide deflection should not exceed 0.17 mm/m (0.002 in./ft) between pitman centers when the rated load is evenly distributed between pitmans. Both bending and shear deflections are considered. These specifications can be revised to suit more precise applications.

Drive capacity is the capacity a mechanical press develops through the gear train and linkage. The capacity can vary because of the mechanical advantage developed by different types of press linkage, and generally is expressed in distance above the bottom of the stroke.

Variation in the capacities of presses with eccentric-gear, crankshaft, or eccentric-shaft drive at any point in the stroke is almost equal. However, the capacity decreases between the bottom of the stroke and mid-stroke. The capacity of both the knuckle lever drive and the rocker arm drive, however, is much less above the point of rating on the stroke than is that of the crank drives, because the knuckle lever drive loses mechanical advantage more rapidly than do crank drives. In addition to loss in capacity, velocity of the slide in the knuckle lever drive and the rocker arm drive is considerably greater at points high above the bottom of the stroke than is the case in the eccentric-gear or crankshaft drives.

Flywheel energy for a given job may be insufficient, although the press frame and shaft may be adequately strong. For a greater working distance or for faster operation, more energy and power must be provided.

Blanking operations are completed in a brief portion of the press cycle. The flywheel instantly supplies practically all of the energy required by its resistance to deceleration. The motor may take the remainder of the press cycle to restore lost energy to the flywheel by bringing it back up to speed. Draw operations may take up to one-fourth of the press cycle.

For intermittent operation, 20% is arbitrarily considered the maximum the flywheel may be slowed when energy from it is being used. For continuous operation, 10% is considered the limit, because of the short time available to restore lost energy. The low-speed torque characteristics of the press drive motor greatly affect the amount the flywheel can be safely slowed, because the ability of the motor to restore lost kinetic energy is a function of these characteristics.

The amount of energy, *E,* available at 10% slowdown can be calculated from the following equation:

$$E = \frac{N^2 D^2 W}{5.25 \times 10^9} \quad \textbf{(Eq 1)}$$

where E is expressed in inch-tons, N is the rotary speed of the flywheel (rpm), D is flywheel diameter (inches), and W is flywheel weight (pounds). The metric version of Eq 1 is:

$$E = \frac{N^2 D^2 W}{6.8 \times 10^6} \quad \textbf{(Eq 2)}$$

where E is given in kilojoules, N remains rpm, D is given in meters, and W is expressed in kilograms.

If calculation indicates that the flywheel will not furnish the necessary energy, it may be necessary to increase the weight, diameter, or speed of the flywheel, or to use different type of drive or motor.

To change the press speed, devices are used to change the speed of the flywheel. The energy of the flywheel is directly proportional to the square of the flywheel speed of rotation. Therefore, the standard energy of a variable-speed press is calculated at its slowest speed. The intended operating speed should be used in checking the suitability of a press for a specific operation.

Motor Selection. The primary function of the main drive motor on most mechanical presses is to restore energy to the flywheel. During flywheel slowdown, most of the energy is derived from the flywheel, with some contribution from the motor. Following the working stroke, the motor must restore the energy expended by the flywheel while returning the wheel to speed. If the capacity of the press is not adequate to satisfy the operation, slowdown of the flywheel during the working portion of the stroke becomes excessive, resulting in overloading of the motor. Stoppage of the press can occur if there is insufficient time between production strokes to permit recovery of flywheel speed.

When slowdown is rapid and the working stroke is long, it is desirable to use a high starting torque with relatively low starting current, good heat-dissipating capacity, and sufficient slip (slowdown). The slip designation of a motor is the amount of motor slowdown at rated full-load torque. Under conditions of moderate slowdown and short working strokes, general-purpose motors can be satisfactorily used.

Many presses employ alternating current (ac) induction motors having slip ratings of 3 to 5%, 5 to 8%, or 8 to 13%, the choice depending upon flywheel design, press speed, and other parameters. For short-stroke presses operating at speeds above 40 strokes/min, general-purpose motors with a slip rating of 3 to 5% are often satisfactory. Motors with a slip rating of 5 to 8% are often used for press speeds of 20 to 40 strokes/min. For long-stroke presses operating at speeds less than 20 strokes/min high-slip (8 to 13%) motors are usually required.

Clutches and Brakes in Mechanical Presses

Both clutches and brakes are essential to the operation of mechanical presses. No other part must work more perfectly if the press is to operate successfully. The clutch must deliver and control the surge of force that is required to shape the work metal. When the press runs continuously, the clutch transmits power from the flywheel to the main shaft. In a single-stroke press, the clutch must accelerate the rotating parts of the drive from stop to full speed at each stroke of the press. The brake must decelerate this moving mass in order to stop the slide at the end of each upstroke. The brake must be large and efficient enough to stop the press in an emergency, or during inching.

Clutches and brakes in presses that are stopped at the end of each stroke need more maintenance than do those in presses operating continuously or that are stopped only a few times a day.

Positive clutches are mainly used on presses of less than 900 kN (100 tonf) capacity. Positive clutches always are on the main shaft and use pins, keys, or jaws to lock the shaft and flywheel together. They usually are engaged by a foot treadle or an air cylinder.

Positive clutches can be engaged or disengaged only once during each press stroke. Usually a throw-out cam disengages the keys, pins, or jaws near the top of the stroke. These clutches can be arranged for one-stroke or continuous operation.

Positive clutches accelerate the slide very rapidly, because there is no slip. Because they are shaft mounted, they have a minimum mass to move.

Mechanical positive clutches (Fig. 7) cost less than other types and are compact and easy to operate, but are limited in many respects and usually require excessive maintenance. They are not recommended for one-stroke work, because wear on the clutch would be severe.

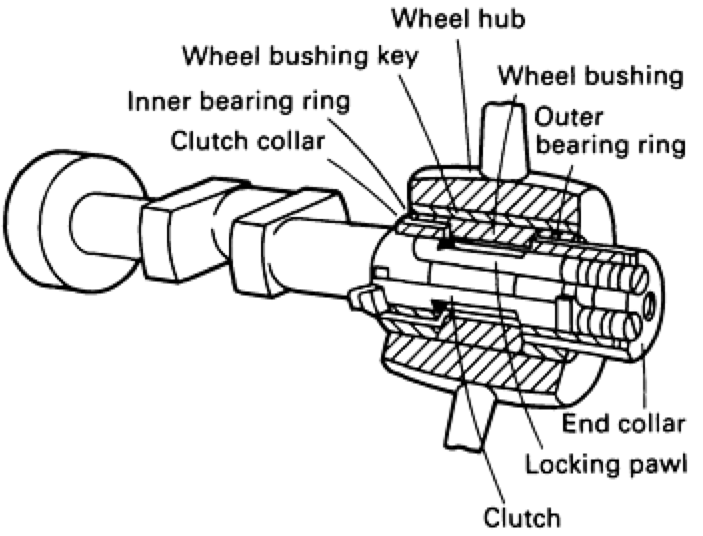

Fig. 7 Mechanically actuated positive clutch mounted on press crankshaft.

Pneumatic positive clutches are much more efficient than their mechanical counterparts. A pneumatic positive clutch is usually a jaw clutch with 16 or more points of engagement. The jaws are engaged by an air cylinder or a diaphragm and are disengaged by springs. No throw-out cams are used. The clutches have electric controls like those used with friction clutches. A press with a pneumatic positive clutch can be used for a single stroke, operated continuously, jogged in either direction, and stopped for emergencies. The brake used with this type of clutch is usually spring operated and air released as a fail-safe measure.

Friction clutches are preferred to positive clutches for most press applications. They are mounted on the crankshaft, eccentric shaft, intermediate gear shaft, or drive shaft, as shown in Fig. 2. The location of the clutch brake unit is determined by factors such as press size, press speed, type of clutch brake unit, and inertia of the press drive.

Friction clutches allow the slides to be stopped or started at any point in the stroke. This makes setting and adjusting dies convenient, especially in large presses. With a well-designed air friction clutch, sudden power failure causes the press to stop immediately. Friction clutches using high-pressure oil or magnetic attraction have been employed to some degree.

Most friction clutches are air engaged and spring released. Brakes are spring engaged and air released. Some clutches are combined with integral brakes; others are constructed as individual units for separate mounting. The brakes for presses equipped with friction clutches are a drum type or single- or multiple-disk type and are operated in unison with the clutches. Some designs use diaphragms or air tubes for actuation instead of pistons with packings.

One of the greatest advantages of friction clutches is their compatibility with electric and electronic controls. In this respect, they are superior to the positive clutch, with the exception of the pneumatic type.

Eddy Current Clutches. A high degree of control over the press is the major advantage of eddy current clutches, which are, in reality, press drives. Ram speed at any point on the stroke can be programmed.

Eddy current drives consist of a constant-speed flywheel, a variable-speed clutch-and-brake rotor, and a stationary brake field assembly. The clutch-and-brake rotor is directly connected to the press drive shaft.

Clutching and braking are controlled by the current in the coils. In practice, the press drive is usually controlled automatically to speed up the motion of the slide during the idle portion of the stroke, and to slow it down just before the tooling contacts the work.

Presses and Auxiliary Equipment for Forming of Sheet Metal

Press Accessories

The setup and operation of a mechanical press are made more versatile through the use of built-in accessories. Included are bolster plates, rolling bolster assemblies, speed change mechanisms, shut height adjusters, and slide counterbalances.

Bolster plates are used in most hydraulic and mechanical presses, between the bed and the die. They provide a flat surface on which to mount the dies and can be remachined to remove nicks and worn areas. T-slots in the top surface facilitate clamping of the die to the bolster plate. Clearance holes in the bolster plate permit pressure pins to extend from the die cushion to the die. Some press beds have a large hole through the top surface for drop through of parts or for mounting of die cushions. For this reason, bolster plates are thick, to minimize deflection and support the die properly. When parts are ejected through the die, holes of the proper size and location are cut in the bolster.

The width, length, and thickness dimensions of bolster plates have been standardized for each bed size, as have the size and location of T-slots, pressure pin holes, and holes for fastening to the bed. Standardization facilitates interchangeability of dies between presses. Filler plates can be used either above or below the bolster to reduce the shut height of the press. This is in addition to the normal slide adjustment.

Rolling bolster assemblies are made for some large straight-side presses for fast tooling change. Dies are set up on an assembly outside the press. When a press run is finished, the punch and blankholder are undamped from the slides and the assembly is moved out of the press. Then another assembly is moved into place, the punch and blankholder are clamped to the sides, adjustments are made, auxiliary equipment is set up, and the press is made ready to run.

Speed change drives are used mostly to change the number of strokes per minute, but some drives also can be used to change speeds during the press stroke for fast approach to the work, slower working stroke, and quick return. Changing speed during the stroke permits an increase in production without increasing the working speed. Press builders commonly supply charts that show the slide speed at any point on the press stroke.

In simple blanking operations the speed of the working stroke is not critical. In drawing and in some forming operations, the plastic-flow characteristics of the material being formed impose specific speed limitations.

A two-speed drive is combined with clutching and braking in some presses. A clutch can have planetary gears for a two-speed drive. Some two-speed drives have two flywheels with a common brake. With a two-speed gearbox and two speeds from the clutch, a press can have four speeds.

Variable-speed drives may incorporate a speed change belt with adjustable cone pulleys connecting the motor to the flywheel or a steplessly variable electric drive. The eddy current drive, originally developed for inching of mechanical presses, also provides variable speed.

Shut height adjustment is provided in mechanical presses to change the distance between the slide and the bed to fit dies of different sizes. Small, single-point presses have a screw arrangement to provide this adjustment. In heavier presses, a gear drive makes it easier for the operator to move the massive slide. As press size increases, this gear drive is motorized. Motorized slide adjustment is used also in many smaller presses. Air counterbalances on most large presses relieve the load of the slide and die from the adjusting mechanism.

Some presses have dials that indicate the shut height in thousandths of an inch. If the dies to be used in the press are similarly marked, die-setting time will be greatly reduced. Other presses have a motorized adjustment with a dial control. The operator sets the desired shut height, and the slide automatically positions itself.

Counterbalances in press slides provide smooth cycling and reduce backlash and gear wear by:

- Counteracting the moving weight of slides, components, and die members attached to the slides
- Reducing the load on the press brake, thus providing faster stopping
- Taking up clearance on the main bearings, reducing the breakthrough shock for cutting operations
- Reducing backlash in the drive gearing
- Easing the adjustment of slides by reducing the load on the adjusting screws

Excessive counterbalance pressure can prevent the normal breathing of bearings and consequently prevent good lubrication of the bearings.

Most presses manufactured with slide counterbalances use pneumatic cylinders as a means of counterbalance, although springs have been used. To prevent too great an increase of pressure through the full range of press stroke, a surge tank is used in conjunction with the cylinders. The tanks are of such a size that the pressure does not increase more than 20 to 25%. A pressure control valve allows the counterbalance pressure to be adjusted to take care of variation in die weights.

The counterbalance cylinder is attached to the press frame, and the cylinder rod to the press slide. Usually the cylinders are attached to either the crown or the press uprights.

Die Cushions

Die cushions, often referred to as pressure pads, are used to apply pressure to flat blanks for drawing operations. They also serve as knock-out or ejection devices to remove stampings from the dies.

Single-action presses do not have an integral means for blankholding and require the use of cushions or other means of applying uniform pressure to the blanks for drawing operations, except for shallow draws in thick stock. The most common means of pressure control for drawing operations on single-action presses are pneumatic and hydropneumatic die cushions. Figure 8(a) shows a single-action press set up for use with a die cushion.

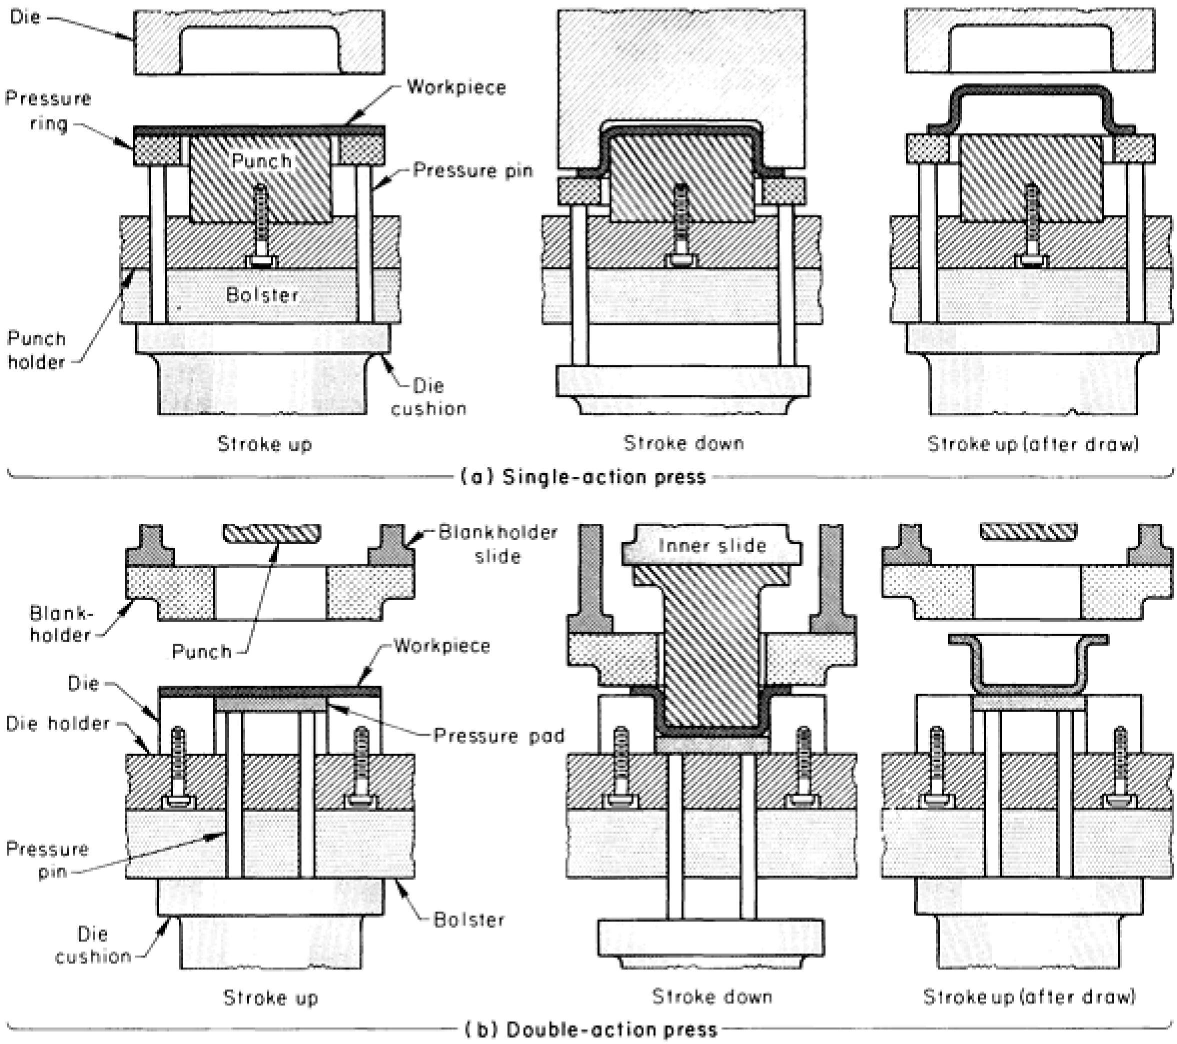

Fig. 8 Setups incorporating die cushions in single-action and double-action presses.

Double- and triple-action presses feature integral blankholders and do not require cushions for drawing operations. Cushions are sometimes employed on double-action presses, however (Fig. 8b), for ejection of triple-action draws, for keeping the bottoms of the stampings flat or ensuring that they hold their shapes, or for preventing slippage while drawing. For such applications, the cushions must be equipped with locking devices to hold the cushions at the bottom of stroke for a predetermined length of the return stroke of the press slide.

Most die cushions are located in the press beds, but there are applications that require installation within or on the press slides. In either case, the functions are similar, and the operations are the same. The recommended capacity of a die cushion (the amount of force it is capable of exerting) is generally about 15 to 20% of the rated press force. Strokes of the cushions are usually one-half the strokes of the press slides, but should not exceed bolster thickness less 13 mm ($\frac{1}{2}$ in.).

Cushions with different strokes and higher capacities are available, but the size of the press bed opening limits the size, type, and capacity of the cushions. Consideration must be given to the press capacity at the point at which the draw is to begin, because the force and energy required to depress the cushion is added to that required to draw the stamping. As a result, the force and energy needed for a high-capacity cushion may not leave enough for the operation to be performed.

In pneumatic cushions, the maximum pressure is controlled by the diameter and number of cylinders and the available air pressure. Shop line pressure is generally used, but it is possible to use a booster or intensifier to increase the air pressure. Most cushions are normally rated at a pressure of 690 kPa (100 psi), and it is generally recommended that the pressure not exceed 1380 kPa (200 psi). Surge tanks, if required, must conform to local codes and are generally approved for a maximum pressure of 860 kPa (125 psi).

A pneumatic die cushion for a single-point press normally uses one cylinder and one piston. Two or more cushions may be stacked, however, when a high-capacity unit is required in a limited bed area in which vertical space is available. For multiple-point presses, when the pressure pad area requirement is too large for one cushion, multiple cushions can be arranged alongside one another. The cushions may be individually adjustable or tied together. A multiple-die cushion is often preferable to a hydropneumatic die cushion because of the speed restrictions of the latter. Presses to be used with progressive dies can be equipped with a cushion whose position may be changed from right to left in the press bed.

Hydropneumatic Cushions. These die cushions are used when higher forces are required or when space does not permit the use of double- or triple-stage cushions. Hydropneumatic cushions are slower acting than the pneumatic cushions; therefore, they are usually used on large presses and on slow presses. They can be adjusted to hold a large, light blank for deep drawing or shallow forming or to grip heavy-gage material as tightly as is required for curved-surface or flat-bottom forming.

A typical hydropneumatic cushion is connected to a surge tank, as shown in Fig. 9. Two individually controlled air lines are required: one connected to the operating valve of the cushion and the other connected to the top of the surge tank. The air pressure supplied to the operating valve determines the capacity of the cushion on the downstroke. The pressure of the air in the surge tank determines the stripping force available on the upstroke. The surge tank may be separate from or integral to the cushion, depending upon the space available beneath the press bed.

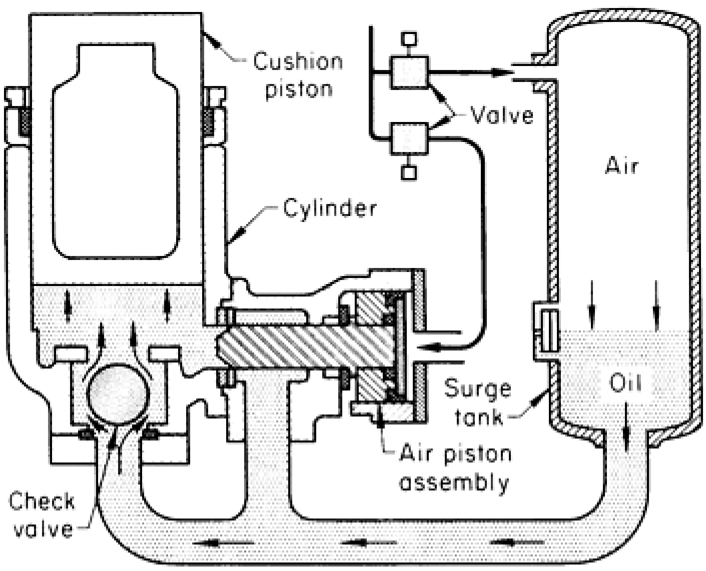

Fig. 9 Components and operating principle of a hydropneumatic die cushion.

The pressure of the air in the surge tank is transmitted to the hydraulic fluid, which is free to pass upward through the check valve and force the cushion piston upward. Pressure is also exerted against the face of the operating valve stem, but it is not sufficient to overcome the opposing air pressure working on the operating air piston.

When a downward force is applied to the cushion, the check valve is immediately closed and the pressure of the fluid that is trapped beneath the piston begins to rise. When the pressure against the small face of the operating valve stem reaches a predetermined point, it exceeds the magnitude of the air pressure on the larger area of the air piston and opens the operating valve. As long as the cushion piston continues its downward movement, the fluid beneath it is maintained under constant pressure by the throttling action of the operating valve; the additional fluid replaced by the piston is forced through the valve to the surge tank. Oil pressures are generally limited to about 6.9 MPa (1 ksi).

When the stroke has been completed and the downward force on the cushion piston is removed, the pressure of the fluid beneath the piston is immediately lessened, reducing the air pressure on the air piston and thereby closing the operating valve. Fluid from the surge tank under pressure from the air behind it passes upward through the check valve and raises the cushion piston to top stroke.

Auxiliary Equipment

Most primary press operations are automated, so that equipment for feeding and unloading is used even for fairly short runs. Hand feeding, with its attendant hazards, is often confined to secondary operations on partly completed workpieces. Goals for planning automated operations should include:

- Maximum safety to the operator and to the equipment
- High or nearly continuous production
- Improved quality of the product and minimum scrap
- Reduction in cost of the finished parts

The shape and position of the part before and after each operation must be carefully studied to determine whether design changes, such as adding tabs or extra stock to the blank, will facilitate handling.

Automatic handling equipment can be divided into the following categories: feeding equipment, unloading equipment, and transfer equipment.

Coil-handling equipment moves coiled stock to the press area and uncoils it with a minimum of damage to the stock and danger to the tools and operator. Reliable coil handling is important, because coil stock is being increasingly used to supply material to presses.

Other auxiliary equipment discussed in this section includes lubricant applicators, straighteners, and revelers.

Press Feeds

Mechanical feeds are important for high production, combined operations, and operator and press safety. Some feeds supply the presses with stock from a strip or coil; others feed blanks or partly completed workpieces. Either kind, with or without auxiliary hand feeding, can be used with almost any kind of press. For progressive-die work, the feed length should be accurate and should repeat within ±0.076 mm (±0.003 in.). The stock must advance accurately so that the pilot pin can easily enter the piloting hole and position the strip. Too great a variation in feed length could result in distorted pilot holes and scrap parts.

Feeds for coil stock feed the work metal from a coil to the press. Choosing the optimum type of feed depends mainly on the type of press, strokes per minute, length of feed per stroke, accuracy needed, and the kind of strip (width, thickness, stiffness, and surface condition). The two most common kinds of feeds are slide and roll feeds.

Slide feeds are made in a variety of sizes and capacities. The basic principle of a slide feed is the use of a feed block that is moved between positive stops to advance the material the distance required at each stroke. Slide feeds are very accurate and are particularly suitable for use with coil stock. When strip stock is used, the ends of the strip must be hand fed into the press.

Some slide feeds are powered by the press through an eccentric mounted on the crankshaft extension (Fig. 10). The eccentric can be a simple one-piece unit keyed to the crankshaft, or it can be adjustable to vary the feed in relation to the rotation of the crankshaft. When changes in feed length are frequent, the adjustable type is usually warranted.

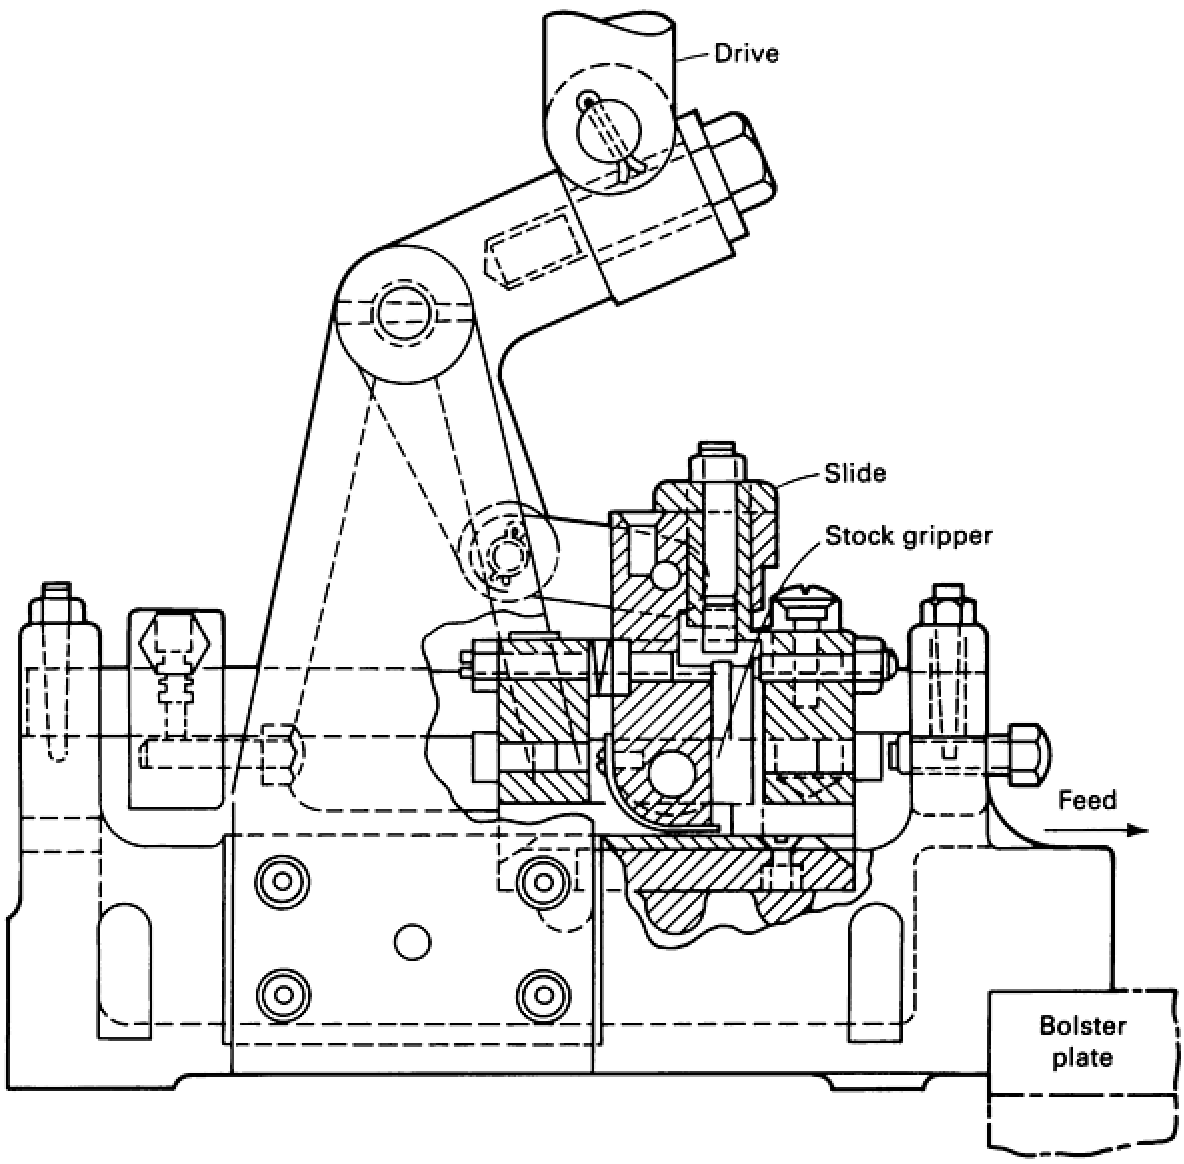

Fig. 10 Press-driven slide feed.

The feed block is mounted on hardened slides and either has a feed-blade holder with an adjustable feed blade (usually carbide-tipped) or a pair of eccentric gripping cylinders. The material is gripped during the feed stroke and released on the return stroke. Accurate control of feed length is obtained by the use of adjustable stops.

The direction of feed--left to right, right to left, or front to back--is governed by the location of the crankshaft extension on the press and the arrangement of the die. A mechanical slide feed, feeding from left to right on a press with a front-to-back crankshaft, can be provided by using an appropriate linkage. Slide feeds also can be powered by air cylinders or cams on the press slide.

Roll feeds are available in sizes suitable for use with almost any width and thickness of stock and are used in every type of presswork, from blanking to complex operations in progressive dies.

A roll feed essentially consists of a pair of rolls that can turn in one direction only. The rolls exert pressure on the stock by the use of springs or some other device and are rotated by the motion of the press crankshaft.

Roll feeds are suitable for extremely thin material and material with highly polished surfaces. If hard chromium-plated rolls are substituted for standard ground-steel rolls, polished surfaces will not be scored or marked during feeding. Rubber-coated or plastic-coated rolls can be used on soft finished or prepainted stock.

There are two advantages to using roll feeds for feeding thin stock. With patterned rolls, a flange can be formed on a waste edge of the stock as a stiffener. With a single-roll feed, the stock usually is pulled through the die.

The best method of feeding extra-thin stock is the use of double-roll feeds (Fig. 11), in which roll feeds at each side of the die are set so that the stock between them is always under slight tension. Double-roll feeds eliminate manual feeding of end sections when strip stock is processed, and are suitable only when a substantial scrap skeleton remains.

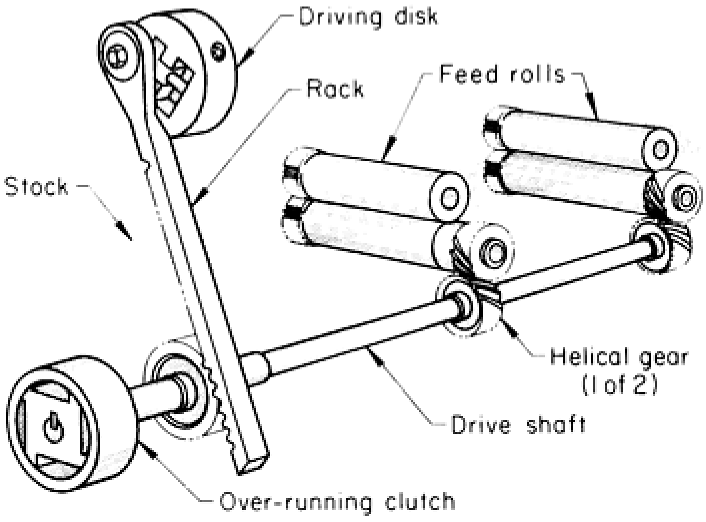

Fig. 11 Components of a double-roll feed.

Rack-and-pinion-actuated roll feeds are available in almost all sizes but are used most in relatively heavy stamping and drawing operations. In larger presses it is common to use double-roll feeds of the rack-and-pinion type that are attached to the press bolster.

Feeding of blanks or previously formed stampings to presses is accomplished in several ways. Selection of a specific method depends upon many factors, including safety considerations, production requirements, and cost.

Manual Feeding. Feeding of blanks or stampings by hand is still a common practice, but this method is generally limited to low-production requirements which do not warrant the cost of automatic or semiautomatic feeds. Manual feeding, however, requires the use of a guard or, if a guard is impossible, hand-feeding tools and a point-of-operation safety device. The use of tools and a safety device eliminates the need for the operator to place hands or fingers within the point of operation and safeguards the operator who inadvertently reaches into the point of operation (see the section "Press Safety" in this article).

Chute Feeds. Simple low-cost chutes are often used for feeding small parts, with the blanks or stampings generally sliding by gravity along skid rails in the bottoms of the chutes. Side members guide the workpieces, and rollers are sometimes added to facilitate sliding. Production rates to 1800 parts per hour are not uncommon for gravity chute feeds.

Blanks or stampings are generally placed in the inclined chutes manually, but the setup can be automated by using hoppers, prestacked magazines, or other means to supply the chutes. Windows are provided at the point at which the workpieces enter the chutes when proper orientation is required.

Push feeds are used when blanks must be oriented in a specific relation to the die, or when irregularly shaped parts are fed that do not slide down a chute and orient themselves properly in the die nest. Workpieces can be manually placed in a nest in a slide, one at a time, and the slide pushed until the piece falls into the die nest. An interlock is generally provided so that the press cannot be operated until the slide has correctly located the part in the die. Slide length should be sufficient to allow placement of workpieces in the pusher slide nest outside a barrier guard enclosure. Strippers, knockouts, or air can be used to eject finished parts from the die. In some cases, holes can be provided in the bottom plates of the slides through which finished pieces fall on the return stroke of the pusher.

Transfer Feeds. In some automated installations, blanks are lifted one at a time from stacks by vacuum or suction cups and moved to the die by transfer units. Separation of the top blank from a stack is usually done magnetically, pneumatically, or mechanically. The top level of a stack can be controlled by a height detection system that regulates a stack-elevating cylinder. Two or more stacks can be arranged to be automatically moved into the elevating station when the previous stack has been used up.

Dial feeds are another method of feeding secondary operations that is being increasingly applied because of improved safety provisions and increased productivity. Such feeds consist of rotary indexing tables having nests or fixtures for holding workpieces as they are carried to the press tooling. Parts can be placed in the nests or fixtures at the loading station (away from the point of operation) either manually or by other means, such as with the use of hoppers, chutes, magazines, vibratory feeders, or robots. Dial feeds can be built into or added to presses.

Industrial robots are being used extensively for press loading and other industrial applications. These mechanical arms, manipulators, or universal transfer and positioning units are more sophisticated versions of the mechanical hands or swinging arms long used for press loading and unloading (see the section "Press Unloading" in this article). The main difference between these devices and true robots is that true robots can be programmed to perform different operations. Various types of tooling can be attached to the arms to handle different sizes and shapes of workpieces. Not only do such units increase safety, but they also substantially boost production rates. Robots are particularly suitable for low-volume production requirements and for operations in which there are large differences in the size and geometry of the workpieces to be handled.

Press Unloading

Methods used to unload stampings from presses vary depending upon workpiece size, weight, and geometry; production requirements; material from which the stamping is made; press and die design; surface quality requirements; and safety considerations.

Gravity and Air Ejection. Gravity is the simplest and least expensive method of unloading presses, but it is not applicable for many operations. In some cases, dies can be designed so that the stampings fall through a hole in the press bed. The use of open-back inclinable presses facilitates unloading by means of gravity when there are no holes in the beds; stampings fall out of the open backs of the presses. When press inclination is not practical, chutes are sometimes provided to carry the stampings away. Air ejection is still common for light-weight parts but is expensive and noisy.

Kickers, Lifters, and Shuttle Extractors. Kickers consist of pivoted levers, generally air actuated, that are mounted in the dies and throw stampings out of the dies when the dies open. Lifters are similar devices, but simply move vertically and require other means for stamping ejection. Pan shuttle-type extractors swing to and from the die area, catching stampings as they are stripped from the punches or upper dies and dropping them outside the presses. Actuation of the pans can be from either the press rams or the independent drives.

Mechanical hands, often called iron hands, are actuated by air or electrical mechanisms commonly used to remove stampings from presses. Gripping fingers or jaws are mounted on arms that swing or reciprocate into the die area to lift the stampings and place them on a mechanism for transfer to the next press or operation site. Standard units are available as swing arm or straight-path types.

Interchangeable jaws or fingers are designed to grip the flanges of stampings. Vacuum cups or electromagnetic elements are used in place of jaws or fingers for curved surfaces and fragile or easily damaged workpieces.

Industrial robots, discussed previously in this article, are also used for press unloading. An important advantage of robots is their programmability to suit various workpieces and requirements.

Transfer Equipment

Several methods are used to automatically transfer stampings from press to press for high-production requirements. When applicable, the use of chutes on which the stampings slide provides the lowest-cost method. Power-driven slat or belt conveyors are commonly used. Adjustable-speed drives for the conveyors are often desirable to accommodate various cycle times.

Shuttle-type transfer devices are extensively used. With some units, the stampings are pushed by reciprocating fingers that extend and retract as required; other units use the lift-and-carry (walking-beam) method. Shuttle units are driven by hydraulic, pneumatic, or electric power, or they are driven mechanically from the press. Adjustable side rails are often provided to accommodate workpieces having different widths.

Lift-and-Carry Devices. One lift-and-carry device, which employs a parallelogram motion, is illustrated in Fig. 12. Two rails move into slots milled in a die, rise vertically to lift a stamping from the die, retract and lower to deposit the stamping on a set of idle rails, and return to pick up the next stamping. Each time the presses cycle, the stampings are progressively moved from one press to the next. This type of transfer unit maintains full control of the stampings, from unloading them from one die to loading them into the next die.

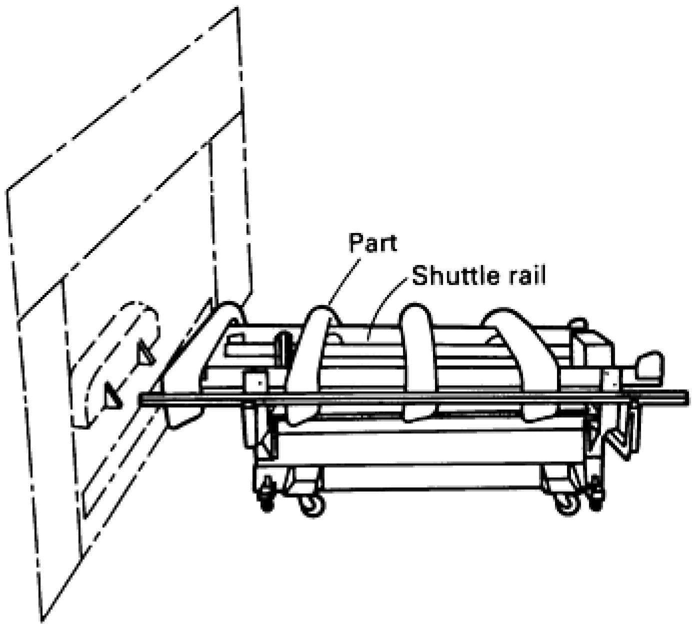

Fig. 12 Lift-and-carry transfer device for stampings.

Turnover or turnaround devices are sometimes added to transfer systems in order to change the positions of the stampings as they pass from one press to another. Turnaround devices generally consist of turntables that lift the stampings, rotate them the required amount, and lower them onto the transfer system. Turnover devices often have one arm and use one or more vacuum cups. In operation, the stamping is transferred to a position above the arm, the arm is raised, the cup or cups engage the stamping, vacuum pulls the stamping against the cups, and the arm rotates about 180°. At the end of the arm movement, the vacuum is released, and the arm returns to its horizontal position. Other devices are of the Ferris wheel type.

Industrial robots, electrically interlocked to two or more presses, are also being used for the automatic unloading, transferring, and loading of stampings. Advantages include increased flexibility, with programmability permitting different stampings to be produced over the same press line.

Computer Numerical Control (CNC). Transfer systems controlled by programmable CNC units are available for automating press lines. Such systems are independent of the presses, can be adapted to stampings of all sizes, and are easily reset. The transfer slides have integral drives, transfer level is programmable in three coordinates, and transfer rates can be varied along certain sections. Grippers or suction cups are used to handle the stampings. Modular construction of the CNC transfer units permits their use with conveyor belts, buffer storage devices, and turnover or turnaround units.

Stackers or conveyor loaders are often provided at the ends of the lines to stack or remove finished stampings that are unloaded from the last press. Low-profile under-the-die conveyors are used for some applications.

Coil-Handling Equipment

Coil cradles, reels, uncoilers, re-coilers, and other types of coil-handling equipment are important to the successful operation of a press.

Coil cradles may be either nonpowered or powered. In the nonpowered type, the stock is pulled from the coil by a powered feed, a straightener, or pinch rolls, or by the equipment being fed.

A powered cradle is preferable for coils that weigh more than 900 kg (2000 lb) or when stock is going directly from the reel to the press feed. In a powered cradle, the coil is supported by chain-driven or gear-driven rolls or by a driven conveyor belt. The drive should be automatically self-equalizing to prevent skidding of the coil.

Coil cradles should have motors that can stand frequent starting of inert loads. A slack loop is created between the coil and the straightener or feed devices by starting and stopping the motor intermittently on signal from a dancer roll, paddle, or other control device. This intermittent operation may cause a standard motor to fail prematurely. With a variable time delay (electronic or adjustable-cam), the motor can overrun to a controllable extent after the control has commanded it to stop.

A variable-speed drive reduces the number of starts and stops, prolongs the life of the motor and drive, and often makes it possible to match the speed of the cradle to that of the machine being fed. A clutch can be used so that the motor will run continuously and the slat conveyor or rolls are driven only when stock is required.

Stock Reels and Uncoilers. Commercial stock reels can accept coils weighing as much as 22,700 kg (50,000 lb). There are reels of the proper size and type for almost any pressworking application.

Selection of a reel should be based on the maximum coil weight and the widths of stock to be unwound. It is better to overestimate future requirements than to underestimate them and find out later that reel capacity limits improvement in equipment and production methods.

Plain or nonpowered reels are usually adequate when the press feed or stock straightener has pinch rolls with enough gripping power to pull the stock from the reel. When stock is going directly from reel to press feed, the reel should be powered so that the feed does not have the job of both feeding the press and unwinding the coil. If the stock becomes taut between the reel and the feed, the feed may start to advance and the stock may slip, resulting in a short feed length. If a straightener is used between the press feed and the reel, a plain reel can be used. However, materials with low tensile strength and lightweight materials should be unwound from a powered reel; otherwise, they might be stretched between the reel and the feeding device.

Powered reels with variable speed and a loop control are preferred for a smooth operation. Noncontact sensor units, such as photoelectric cells or proximity switches, on the loop control should be used for soft metals, polished surfaces, and prepainted stock. These prevent damage inherent with contact-type (rolling or sliding) sensor units. Without powered reels or loop control a sudden pull can cause the stock feed to slip and mark the work metal.

Other equipment useful for handling coil stock includes re-coilers, turnstiles, down-layers, coil cars, coil grabs, and coil ramps.

Re-coilers are used for winding coil stock after slitting and for winding the scrap skeleton after pressworking.

Turnstiles (or horns) are two-arm or three-arm devices used to store coils temporarily before processing. In function, a turnstile resembles a coil ramp. Turnstiles may be equipped with hydraulic push-off devices, which add to their speed and efficiency.

Downlayers, sometimes called up-enders, are turnover devices for rotating the coil from a horizontal to a vertical position.

Coil grabs, for use with cranes, are devices that can handle stock in the horizontal or vertical position. Some similar devices are available for use with forklift trucks. Other devices will pick up a coil and change the position from horizontal to vertical.

Coil ramps are inclined storage units for use with reels or cradles. Most coil ramps operate by gravity.

Other Auxiliary Equipment

Lubricant Applicators. In blanking or forming, a lubricant is usually applied to metal that is fed into the press from coils. The lubricant can be swabbed or brushed onto the metal as it leaves the reel, but this is inefficient and wasteful and produces inconsistent results. An automatic applicator improves efficiency and uniformity. The type of applicator used depends on whether the lubricant is a powder or a liquid and, if a liquid, on its viscosity and flow characteristics. Roller coating, drip feeding, and spraying are common. Information on these application methods, as well as on the types of lubricants used, is available in the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume.

Straighteners have upper and lower rolls alternately mounted in a staggered position. The minimum number of rolls that can be used is three; however, five-roll or seven-roll straighteners are most common for the usual range of stock thickness. Straightening of stock less than 0.51 mm (0.020 in.) thick requires additional rolls; as many as 17 have been used for some thin stock.

Some straighteners have a separate screw adjustment for each of the upper rolls; others have one adjustment for the entire series of upper rolls. A straightener should not be overloaded. When stiff, thick metal is passed through a straightener designed for thin metal, it may deflect the rolls permanently or break their shafts. Stiff, thick stock requires larger, stronger rolls spaced well apart. Thin metal requires more straightening rolls than does thick metal. These rolls are usually smaller in diameter and more closely spaced.

Stock straighteners are available in a wide range of capacities and speeds, with either powered or nonpowered straightening rolls. Either the upper or lower set of rolls, or sometimes both sets, is powered. Nonpowered rolls can be used when there is enough pulling or pushing force to get the stock through the rolls. Powered pinch rolls are used to push or pull the stock through the straightener.

Thin stock requires more working to straighten than does thick stock. For this reason, two sets of pinch rolls are used, and all straightening rolls are power driven. The speed of powered straighteners can be adjusted so that the material is delivered by the rolls at the rate it is fed into the press plus 10%. The ideal condition is to have the stock run through the rolls continuously, so that there are no breaks or bends in the stock when it is stopped on the rolls. When straighteners are operated intermittently, breaks or bends occur in the stock and are almost impossible to remove.

Roller levelers, like straighteners, have staggered pairs of meshing rolls, but the rolls are smaller and more closely spaced. All of the rolls are powered, and some of the upper and lower working rolls have backup rolls. Levelers with backup rolls can impose strains on the metal to remove stack edges or a crowned center. More information on the use of roller revelers is available in the article "Slitting and Shearing of Coiled Sheet and Strip" in this Volume.

Presses for High Production

Mass-produced parts are often formed in presses that are made especially for high-production operation. High speed, or the highest number of strokes per minute, is not the only factor in a high production rate. The capability of a press to run continuously for several hours without full operator attention and with a minimum of wear and vibration contributes more to high productivity than does running at high speed for a short period and then stopping for reconditioning of dies.

The more common types of high-production presses are discussed in this section.

Dieing machines, also known as die presses, are set up with conventional progressive dies for long-run operation. These machines are used extensively for the blanking of laminations; however, drawing and forming can be done. The height of the bed above the floor makes it easy to install stacking chutes for laminations and other parts.

Dieing machines are single-action underdrive presses. The drive mechanism for a dieing machine is located beneath the press bed. Four guide rods from a guided lower crosshead pass up through bronze bushings in the bed and are fastened to a platen to which the upper die half is attached. The lower crosshead is reciprocated by a crank-shaft through connecting rods. By this action, the die halves are pulled together, rather than pushed together, as in a conventional press.

The size of the guide rods and bushings results in excellent die alignment and long die life. The underdrive construction keeps the center of gravity of the press low. The progressive dies mounted in the machine are near eye level, and there are no columns or side members to obstruct the operator's view. Ejection chutes for finished parts and scrap are comparatively high above the floor so that containers are easy to position. Pneumatic cushions, fastened to the top of the platen for better accessibility for service and adjustment, are used as strippers and blankholders.

Stock is fed through the guide rods with either single- or double-roll feeders. A scrap cutter can be mounted on the end of the machine. Both devices are operated by the upper platen or by a power take-off on the end of the crankshaft.

Multiple-slide machines are fully automatic machines for mass production of small parts from metal strip or wire in coil form. Detailed information on these machines is given in the article "Forming of Steel Strip in Multiple-Slide Machines" in this Volume.

Transfer Presses. Performing multiple operations on a single press can increase productivity and decrease costs. Transfer presses eliminate the need for secondary operations; annealing requirements between operations; and in-process inspection, storage, and handling of workpieces.

Transfer presses should be considered whenever 4000 or more identical stampings requiring three or more operations are needed daily. A total production run of 30,000 to 50,000 identical parts is generally economical between tooling changes. Most transfer presses are designed to make more than one part, and they are often used for families of parts that are similar in size, shape, and thickness. One press is being used to produce 22 different parts.

Stampings are being produced in a wide range of sizes and shapes. Any configuration that can be grasped by mechanical fingers is suitable, and the parts do not have to be concentric. Practically any operation that can be done in any other press can be performed on transfer presses. Typical operations include blanking, piercing, forming, trimming, drawing, flanging, embossing, and coining.

Major users of transfer presses are the automotive and appliance industries. Automotive parts produced on these presses include wheel covers, taillight assemblies, control and suspension arms, transmission parts, catalytic converters, and timing-gear case covers. Appliance components include refrigerator, freezer, washer, and dryer parts.

Fine Blanking Presses. The fine blanking process, discussed in the article "Fine Edge Blanking and Piercing" in this Volume, is generally performed in special triple-action presses designed specifically for the purpose. The presses are available in a range of sizes varying in capacity from 220 to 22,000 kN (25 to 2500 tonf) or more.

Basic components of most fine blanking presses are the frame, upper and lower tables for supporting the tooling, a power system, a stock feeder and lubricator, a control system, and a tool safety device. The frames are generally of welded plate construction, with four-column or double-frame web design, but some smaller presses have single-casting frames. Most fine blanking presses are designed for vertical operation of the ram, but horizontal presses are available. On vertical presses, ram movement for shearing is usually upward, but some presses have a downward movement.

Flexible-Die Forming Presses. Forming, and sometimes blanking, with flexible dies (rubber pads or diaphragms backed by oil under high pressure) is an economical method because it requires only half a die, and materials of different thicknesses can be formed with the same tool. Also, one pad or diaphragm can be used to produce different workpieces, thereby reducing tooling costs. No scratch marks are produced on the side of the blank facing the flexible die.

Another advantage of flexible-die forming is that localized stress concentrations are avoided because of the uniformly distributed pressure achieved with a rubber pad or diaphragm and the gradual wrapping of the blank around the tool. A limitation is that the process is slower than forming with mating die halves, thus sometimes restricting applications to low-volume requirements. However, depending upon workpiece complexity and size, the method may be competitive for part production runs to 20,000.

Flexible-die forming is used extensively by the aircraft and aerospace industries, as well as by other manufacturers with low-volume requirements. The three major types of flexible-die forming are rubber pad, fluid cell, and fluid forming, all of which are performed on either standard or special hydraulic presses. These processes are discussed in the articles "Rubber-Pad Forming" and "Deep Drawing" in this Volume.

Press Safety

The safest press is one operating continuously with a stock feeder and part unloader. This type of machine does not require the full attention of an operator, and there is no need for him to reach into the danger area. Flywheels, gears, and other moving parts likely to catch an operator or passerby are usually covered.

For hand feeding, shields should be interlocked with press controls, so that the press will not run unless the shields are in place. The best practice is to make the guard or shield a part of the die, so that protection is automatically in place when the setup is made or installed. Shields also can be attached to the press frame and adjusted for various kinds of work. These guards should suit all the work done in the press, should be easy for the setup man to adjust, and should give the operator an unobstructed view.

Usually, it is more difficult to guard hand-fed secondary operations, because the workpiece requires special handling. However, if production rate and quantity warrant the expenditure, standard or special devices can replace hand feeding of presses.

Available safeguards include barriers or interlocking guards that keep the operator away from danger, sweep and pulling devices that push the operator's hands away, and devices that require both hands to trip the press. All safeguards should be inspected and adjusted before and after every press run.

Important considerations in choosing safety devices are: number of operators at the press, size and type of press, size and shape of workpieces, length of press stroke, and number of strokes per minute. Protective devices cannot do the job by themselves; they should be used with a well-planned and strictly enforced safety program. More information on press safety is available in the Selected References.

Introduction

PRESS FORMING is a process in which sheet metal is made to conform to the contours of a die and punch--largely by bending or moderate stretching, or both (see the Section "Forming Processes for Sheet, Strip, and Plate" in this Volume). The suitability of a tool material for a press forming die is determined by the number of parts that can be produced using that die. This number is in turn influenced by such process variables as size of the part, type and thickness of the metal being formed, lubrication practice, quantity of parts needed, and the allowable variation in dimensions.

Process Variables

Part Size. For small stampings, cast or plastic dies are uneconomical unless they are made from a model already available and with only minor finishing operations required on the dies. When the cost of patternmaking is included, cast or plastic dies are usually more expensive than are dies machined from other materials. The cost of the die material is usually a small fraction of the total cost of dies for a small part, and the availability of material in such a size that would minimize machining on the dies is usually a greater factor in cost than is any other.

As the size of the part increases, cost savings resulting from minimizing machining by the use of a casting close to final size more than offsets the cost of a pattern. However, tool steel or carbide inserts must be used on high-production dies subject to severe wear and galling. The selection of both the material and the locations of the inserts should be conservative when it is important that production not be interrupted to alter the tooling. If tools can be taken out of production, gray cast iron dies may be used, with the wear surface flame hardened and inserts added later if needed because of wear on the critical surfaces.

Work Metal. High-hardness sheet metals wear dies more rapidly than do softer materials, but other factors, such as the presence of scale on the surface of hot-rolled unpickled steels, cause two to five times more wear. However, scaled surfaces cause less galling, which, on tool materials, may be an even more serious condition than wear, because galling or "pickup" on a die causes frequent interruptions of production forming for reconditioning of the die.

Soft brass and aluminum cause less wear and galling than does carbon steel; stainless steels and heat-resistant alloys cause more wear and galling. When galling is anticipated, it is desirable to use materials such as D2 tool steel that can be treated subsequently, if necessary, to eliminate the difficulty. Possible treatments include chromium plating of any hardened steel, the hardening of alloy cast iron, and the nitriding of tool steels such as A2 and D2, which are preferred for nitriding because of the presence of nitride formers such as chromium and molybdenum.

Sheet Thickness. Thick sheets of any metal exert greater pressure on the dies than do thin sheets of the same metal. Both abrasive wear and adhesion (galling) increase with increasing sheet thickness.

Lubrication Practice. In making parts at low and medium production (up to 10,000 pieces), it is often economical to use lubricants. Lubrication is required when zinc alloy dies are used. However, the most effective lubricants are difficult to apply and remove, and they add significantly to cost. Efficient application of lubricants is particularly difficult in high-production operations in which presses are automatically fed. In such operations, it is often economical to use die metals that are more costly but more resistant to galling in combination with the usually less-effective lubricants that can be applied automatically. Examples of these materials are aluminum bronze, nitrided D2 tool steel, and carbide, which often can be used for forming low-carbon steel with only mill-oil lubrication.

More information on lubricants is available in the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume.

Quantity. The number of parts to be produced is an important factor in material selection for large dies in which the cost of material is equal to or greater than the cost of machining. In smaller dies, the difference between the cost of the most expensive and the cheapest steels is less important than the assurance of long life without the necessity for rebuilding tools if the quantity should be increased above original expectations, or if the die material should prove to be inadequate. However, for large dies, both the choice of tool material and the design of the dies depend on the number of parts to be produced, particularly if it is more than 1000.

Adjustable inserts are often impractical for small dies. Therefore, for high-production dies working under severe wear conditions and producing parts to close tolerances, it is often desirable to use a complete insert or to make the die of wear-resistant material such as carbide or nitrided D2 tool steel.

Dimensional requirements of a part may have an important effect on the choice of tool material when the part is to be finished without restriking. If the part is to be restruck, the material used in the restriking die is of less importance, because it will usually be subjected to less wear than will the die that performs the primary operation. A major factor in the choice between a wear-resistant material and a less costly and less wear-resistant material is the necessity for maintenance during the production run.

Materials, Die Wear, and Die Life

Table 1 lists the nominal compositions of the tool materials most often used for press forming dies. Tool materials are usually selected on the basis of providing adequate die life at minimum cost. However, the final choice often depends on availability rather than on a small difference in die life or cost.

Table 1 Tool materials commonly used for press forming dies

Material	Nominal composition
AISI tool steels	
W1	**Fe-1.0C**
S1	**Fe-0.50C-1.5Cr-2.5W**

O1	**Fe-0.9C-1Mn-0.5Cr-0.5Mo**
A2	**Fe-1C-5Cr-1Mo**
A4	**Fe-1C-2Mn-1Cr-1Mo**
D2	**Fe-1.5C-12Cr-1Mo-1V**
D3	**Fe-2.25C-12Cr**
D5	**Fe-1.5C-12Cr-1Mo-3Co**
D7	**Fe-2.35C-12Cr-1Mo-4V**
M2	**Fe-0.8C-4Cr-5Mo-6W-2V**
M4	**Fe-1.3C-4Cr-4.5Mo-5.5W-4V**
Other ferrous alloys	
Hot-rolled low-carbon steel	**Fe-0.10 to 0.20C**
Unalloyed cast iron, 185 to 225 HB	**Fe-3C-1.6Si-0.7Mn**
Alloy cast iron, 200 to 250 HB	**Fe-3C-1.6Si-0.4Cr-0.4Mo**
Cast high-carbon steel, 185 to 225 HB	**Fe-0.75C**
Cast alloy steel, 200 to 235 HB	**Fe-0.45C-1.1Cr-0.4Mo**
4140 alloy steel	**Fe-0.4C-0.6Mn-0.3Si-1Cr-0.2Mo**
4140 modified	**Fe-0.4C-1.2Cr-0.2Mo-1Al**
Nonferrous alloys	
Zinc alloy (UNS Z35543)	**Zn-4Al-3Cu-0.06Mg**
Aluminum bronze (UNS C62500), 270 to 300 HB	**Cu-13Al-4Fe**
Nonmetals	

Polyester-glass	**50% polyester, 50% glass in the form of cloth, strand, or chopped fibers**
Epoxy-glass	**50% epoxy, 50% glass as above**
Polyester-metal	**Polyester reinforced with metal powder**
Epoxy-metal	**Epoxy reinforced with metal powder**
Nylon-metal	**Polyamide reinforced with metal powder**
Polyester or epoxy-glass-metal	**Polyester or epoxy with both glass and metal as above**

Die Life. Wear determines the useful performance of a press forming die. Total wear is primarily affected by the length of the production run and the severity of the forming operation. This total wear may be produced by abrasion or adhesion (galling), or both.

The amount of wear on a given die during forming is proportional to the total accumulated distance over which the sheet metal slides against the die at a given pressure between the surfaces in contact. Thin, soft, or weak sheet metals exert the least pressure and thus cause the least wear; thick, moderately hard or strong metals cause the most rapid wear. The rate of wear for each combination of work metal and die metal may vary considerably depending on surface characteristics, speed of forming, and die lubrication. In situations in which wrinkles form in the parts, high localized pressures develop on the tools because of the ironing that takes place at these locations, and prohibitively high rates of abrasive wear and galling are almost always encountered.

Typical Tool Materials. Tooling for the part shown in Fig. 1 consists of a punch and a lower die. In operation, the punch pushes the blank through the lower die, which causes wear of the lower die. The metal closely envelops the punch, with little sliding. In this situation, a punch generally produces about ten times as many parts as a lower die made of the same material. However, at areas in which the part shrinks against the punch during forming, wear (and possibly galling) of the punch surface occurs, particularly when the forming is done in single-action dies. For a small die and punch, the cost of steel is of minor importance, and D2 tool steel may be used for production quantities as low as 10,000. If galling occurs during preproduction trials, the tool can be nitrided. Typical materials for lower dies used in press forming small parts similar to that shown in Fig. 1 are given in Table 2.

Table 2 Typical lower-die materials for forming a small part of mild severity from 1.3 mm (0.050 in.) thick sheet

For die cross section and part shape, see Fig. 1.

(a) Description of die materials is given in Table 1. When more than one material for the same conditions of tooling is given, the materials are listed in order of increasing cost; however, final choice often depends on availability rather than on small differences in cost or performance. When mild steel is recommended for forming fewer than 10,000 pieces, the dies are not heat treated. For forming 10,000 pieces or more, such dies should be carburized and hardened. When 4140 is recommended for fewer than 10,000 pieces, it should be pretreated to a hardness of 28 to 32 HRC. Flame hardening of high-wear areas is recommended for quantities greater than 10,000 pieces.

(c) Soft.

(d) With inserts.

(e) Heated sheet.

(f) Use lubrication to make 1 to 100 parts.

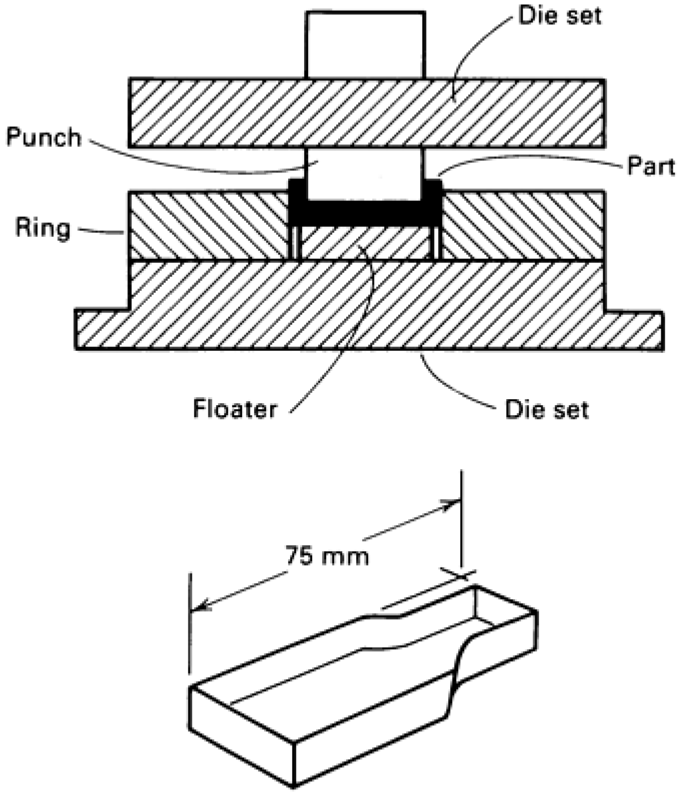

Fig. 1 Cross section of die used to form small part of mild severity. See Table 2 for typical die materials.

Tooling for the part in Fig. 2 consists of a punch, an upper die, and a lower die. Without the upper die, excessive wrinkling would occur at the shrink flanges. As for the part shown in Fig. 1, a less wear-resistant material is required for the punch and upper die than is needed for the lower die. Under conditions for which the tooling is typically made of tool steel (see Table 3), the tooling is in the form of inserts in a lower die made of cast iron, as shown in Fig. 2, and the punch is made of a cast tool steel such as D2. For example, a cast iron die with A2 or D2 inserts at points of greatest wear is typical for production quantities of 10,000 to 100,000 pieces. When this part must be held to close tolerances over lengthy production runs, type D2 tool steel inserts should be used at all surfaces subject to wear.

Table 3 Typical lower-die materials for forming a large part of mild severity from 1.3 mm (0.050 in.) thick sheet

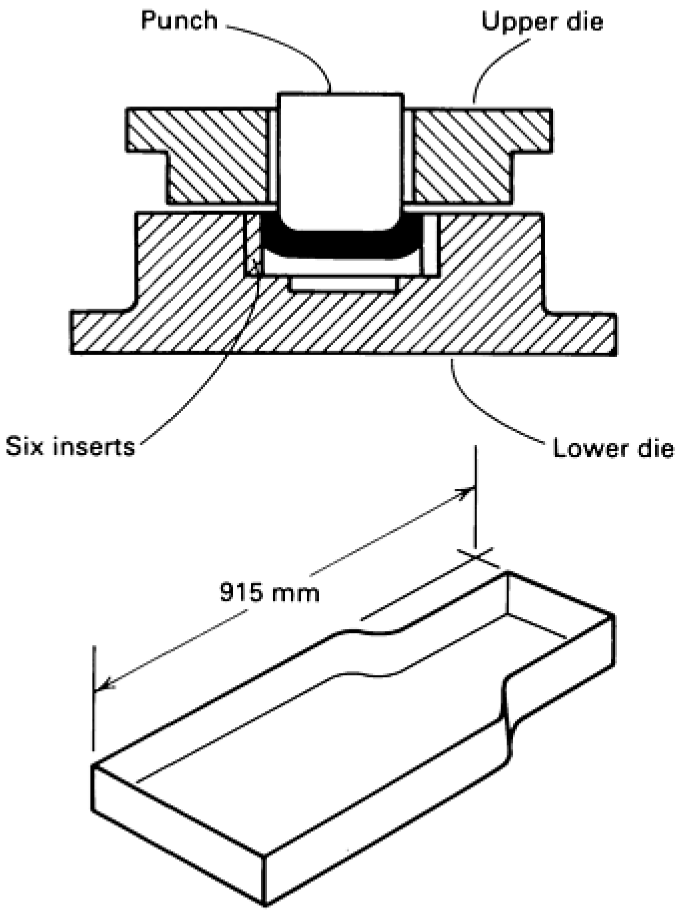

Fig. 2 Cross section of die used to form large part of mild severity. See Table 3 for typical die materials.

Typical lower-die materials for press forming large parts similar to that shown in Fig. 2 are given in Table 3. For quantities of less than 100,000 pieces, the entire lower die is typically made of the material indicated in the selection table, without inserts. The punch is made of a less wear-resistant material, which is usually the same as the lower-die material in the first column to the left of the quantity being considered.

Tables 2 and 3 may be used to select lower-die materials for parts made of sheet thicker or thinner than the 1.3 mm (0.050 in.) thick sheet used in the tables, or for parts of greater or lesser severity than those shown in Fig. 1 and 2. For parts of greater severity or sheet of greater thickness, use the die material recommended for the next greater production quantity than the quantity actually to be made (the column to the right of the actual production quantity in the table). Similarly, for parts of lesser severity or sheet of lesser thickness, use the die material recommended for the next lower production quantity (the next column to the left of the actual production quantity).

Selection for Galling Resistance. As indicated previously, galling, which is cold welding of the metal being formed to that of the dies, drastically reduces the number of parts that can be made using a particular set of dies. Galling is caused by attempts to stretch sheet metal beyond practical limits, by inadequate lubrication, by poor tool fitting, or by rough finishes on tool surfaces. Therefore, when galling is encountered, the tool fit and the thickness of the metal being formed should first be checked to determine whether clearance is adequate. If clearance is considered adequate, lubrication practice should be reviewed before considering a change in die materials. Galling is less likely to occur if the die materials and the metal being formed are dissimilar in hardness, chemical composition, and/or surface characteristics. For example, effective combinations are: aluminum bronze tools for forming carbon steel and stainless steel; tool steel tools for forming aluminum and copper alloys; and carbide tools for forming carbon steel, stainless steel, and aluminum.

Aluminum bronzes have excellent resistance to galling and are desirable for dies in applications in which the best finish is required on carbon steel or stainless steel parts. However, for medium-to-high production (10,000 to 100,000 parts), the use of inserts permits easy reconditioning of worn tools.

Nitriding minimizes or prevents galling of dies made of alloy steels or alloy tool steels (such as A2 or D2) that contain chromium and molybdenum. However, the nitrided surfaces may spall off at radii smaller than about 3.2 mm ($\frac{1}{8}$ in.), especially from dies having very complex contours.

Hard chromium plating usually eliminates galling of mild steel, alloy steel, and tool steel dies, and it is often used for severe duty. For operations involving high local pressures, hardened alloy steels or tool steels are less likely to yield plastically and cause cracking of the hard chromium plating. With dies for complex parts, hard chromium plating may spall off at radii smaller than about 6.4 mm ($\frac{1}{4}$ in.).

For some press forming operations, dies made from tool steels other than those discussed above may be desirable. For example, shock-resistant tool steels such as S1, S5, and S7 may be used for die components subjected to severe impact in service. H11 and H13, possibly nitrided for greater wear resistance, also may be used for such components. In press forming operations requiring significantly greater wear life than is routinely attained with D2 or nitrided D2, it may be necessary to specify a more wear-resistant cold work tool steel such as A7, D3, D4, or D7, or a high-speed steel such as M2, M4, or T15. Cost generally determines the desirability of changing to an alternative material, although toughness may also be a determining factor. Costs to be considered include not only material costs but also tool fabrication costs and the cost of periodic resharpening.

Other Tool Materials. Significant advances have been made in recent years in the area of tool steels made by powder metallurgy (P/M) techniques. For example, P/M high-speed steels, hot isostatically pressed to full density, offer greater ease of fabrication and significantly improved toughness compared to conventional ingot-cast steels of the same compositions. New grades that could not have been produced economically by conventional steelmaking practices have been introduced through the use of powder metallurgy. One such alloy is Crucible CPM 10V (Fe-2.45C-5.0Cr-9.75V-1.25Mo), which is an air-hardened cold-work tool steel designed specifically for tooling applications requiring long wear life and good toughness. This material can be a cost-effective alternative to carbide in applications in which breaking or chipping of carbide is a problem or in which the full potential of carbide is either not realized or not required. More information on these materials is available in the article "Particle Metallurgy Tool Steels" in *Powder Technologies and Applications*, Volume 7 of the *ASM Handbook.*

When maximum resistance to galling and wear is required, cemented carbides have traditionally been recognized as the ultimate tooling materials. However, because of the high cost of these materials and their tendency to be brittle in service, carbides are frequently used only for inserts in critical die areas. These inserts are usually made of a straight grade of tungsten carbide containing about 6% cobalt binder, but higher cobalt contents can be specified to provide greater shock resistance. The more recently developed steel-bonded carbides offer greater ease of fabrication and very often can be demonstrated to be cost-effective substitutes for the more costly cemented carbides with cobalt binder.

These materials use tool steel or stainless steel matrices filled with titanium carbide at volume fractions ranging from 15 to 45%. Several grades are available.

Selection of Material for Deep-Drawing Dies

Introduction

DEEP DRAWING is a process in which sheet metal is formed into round or square cup-shaped parts by making it conform to a punch as it is drawn through a die (see the article "Deep Drawing" in this Volume). In conventional deep drawing, successive draws are made in the same direction. The types of dies and other tooling used for conventional deep drawing are illustrated in Fig. 1.

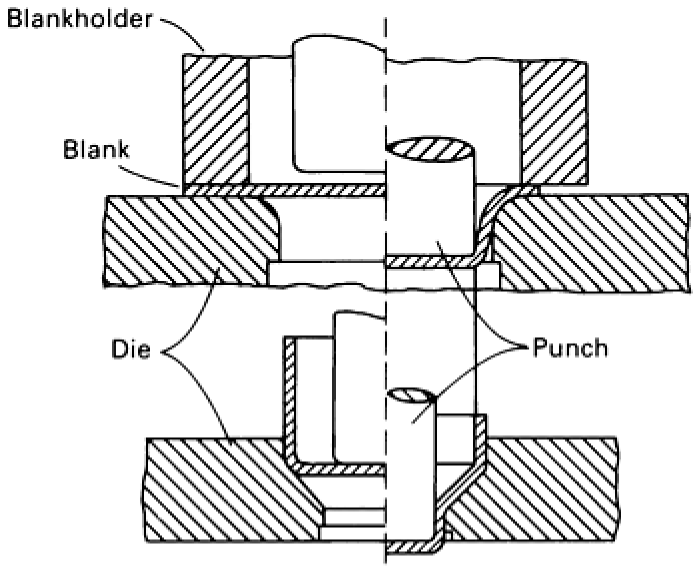

Fig. 1 Schematic showing tools used for the first draw (top) and the first redraw (bottom) in deep drawing.

It is sometimes necessary for redrawn shells to have a wrinkle-free sidewall of uniform thickness or a section in the bottom of the cup that is sharply raised, usually by forming in two operations. Such operations are difficult, impossible, or uneconomical to perform by conventional single-action drawing, but they are easily done by reverse redrawing. Figure 2 shows typical tooling for the reverse redrawing of thin-wall shells.

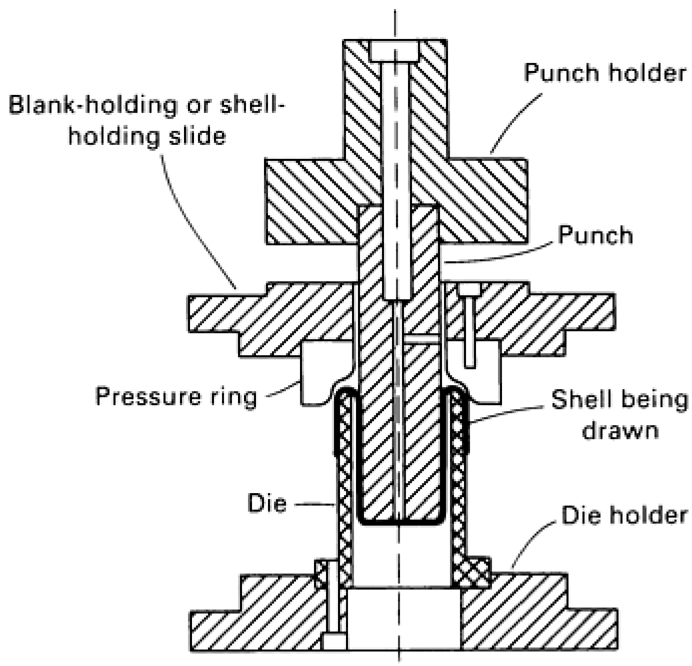

Fig. 2 Typical tooling used for the reverse redrawing of thin-wall shells.

For economical manufacture, a drawn part should always be produced in the fewest steps possible. Ironing (that is, thinning the walls of the part being drawn by using a reduced clearance between punch and die) is almost universally used in multiple-operation deep drawing. Ironing helps to produce deep draws and uniform wall thickness in the fewest operations. Each operation is designed for maximum practical reduction of the metal being drawn. Accordingly, the information given in this article is based on ironing reductions near the maximum of about 35%.

The selection of material for a drawing die is aimed at production of the desired quality and quantity of parts with the least possible tooling cost per part. In small dies (for example, those for making parts up to 75 mm, or 3 in., across), performance is the primary consideration. Material cost is a minor factor because the cost of even the more highly alloyed tool steels is probably less than 5% of the total die cost. In dies for parts larger than about 203 mm (8 in.), material cost is more important, and in a die for a 305 mm (12 in.) part, it may amount to nearly one-half the total die cost, even when the tool consists of a tool steel insert in a flame-hardened alloy cast iron die.

Selection of Material for Deep-Drawing Dies

Die Performance

The performance of a drawing die is determined by the total amount of wear (abrasive and adhesive) that occurs during a production run. The wear of a given die material is largely determined by its hardness, type and thickness of the sheet metal being drawn, sharpness of die radii, lubrication, and construction and surface finish of the die. The amount of wear on die radii can vary by a factor of 20 between the sharpest and most liberal radii. In drawing square cups, the formation of wrinkles at the corners, accompanied by high localized pressures, may produce prohibitively high rates of wear.

Lubrication. Correct lubrication of the sheet metal is essential if friction, wear, and galling are to be held to the lowest possible levels during deep drawing. In fact, deep drawing is impossible if the sheet metal is not lubricated. In actual practice, die materials are selected after trials using one or more candidate production lubricants. If excessive wear or galling occurs, a better lubricant is usually applied. For extremely difficult draws, the best lubricants are usually applied at the outset.

Table 1 lists typical lubricants used for different work metals and severities of drawing. Lubricants are marketed under proprietary names, but any supplier of lubricants can recommend commercial compounds fitting the descriptions given in Table 1. More information on lubrication in sheet forming is available in the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume.

Table 1 Typical lubricants for deep drawing

When more than one lubricant is given, they are listed in order of increasing effectiveness.

Metal being drawn	**10% or less**	**Severity of drawing 25% average**	50% or more
Aluminum and aluminum alloys	Straight mineral oil, 100 SUS viscosity(a); mineral oil with approximately 10% lard oil	Straight mineral oil, 200-250 SUS viscosity(a); mineral oil with approximately 15% lard oil	**Mineral oil with extreme-pressure additives--sulfur and others; coating of soap or wax dried on blanks (or shells) prior to drawing (or redrawing)**
Copper and copper alloys	5% soap solution; lard and soap emulsion	10% soap solution with stearic or oleic acid; lard oil and mineral oil with stearic acid	**Lard oil blended with 50% mineral oil, coating of soap or wax dried on blanks or draws prior to draw or redraw**
Carbon steel	Mineral oil, 250-350 SUS viscosity(a); 5% soap solution	Emulsions of lard oil, mineral oil, and sulfonated oils	**Phosphate coating impregnated with dried soap or wax**
Stainless steel	**Castor oil and soap emulsion**	**Castor oil with fillers, such as mica or zinc oxide**	**Boiled linseed oil with mica or lithopone; phosphoric acid etch with dried soap or wax film**

(a) Saybolt universal seconds at 40 °C (100 °F)

Materials for Specific Tools

Draw Rings. Table 2 lists typical materials for draw rings (both dies and backup rings) used in drawing and ironing cups of various diameters and lengths. The data in Table 2 are for round and square cups drawn from stock 1.6 mm (0.062 in.) thick in three typical production quantities. Similar data for a large square cup and a large pan are also provided. Design dimensions for all seven parts referred to in Table 2 are given in Fig. 3. The square parts have liberal corner radii consistent with favorable die life.

Table 2 Typical materials for draw rings used in the drawing and ironing of round and square parts

See Fig. 3 for part designs and overall dimensions.

Metal to be drawn	Total number of parts to be drawn		
	10,000	**100,000**	1,000,000
Cups up to 76 mm (3 in.) across, drawn from 1.6 mm (0.062 in.) sheet (parts 1, 2, and 3)			
Drawing-quality aluminum and copper alloys	W1; O1	O1; A2	**A2; D2**
Drawing-quality steels	W1; O1	O1; A2	**A2; D2**
300-series stainless steels	W1 chromium plated; aluminum bronze	Nitrided A2; aluminum bronze	**Nitrided D2 or D3; cemented carbide**
Cups 305 mm (12 in.) or more across, drawn from 1.6 mm (0.062 in.) sheet (parts 4 and 5)			
Drawing-quality aluminum and copper alloys	Alloy cast iron[(a)]	Alloy cast iron [(a)]; A2 inserts[(b)]	**A2 or D2 inserts[(b)]**
Drawing-quality steels	Alloy cast iron[(a)]	Alloy cast iron[(c)]; A2 inserts[(b)]	**A2 or D2 inserts[(b)]**
300-series stainless steels	Alloy cast iron[(d)]; aluminum bronze inserts[(b)]	A2 or aluminum bronze inserts[(b)]	**Nitrided A2 or D2 inserts[(b)]**
Square cups similar to part 6, drawn from 1.6 mm (0.062 in.) sheet			
Drawing-quality aluminum and copper alloys[(e)]	W1	O1; A2	**A2; D2**
Drawing-quality steels[(e)]	W1	O1; A2	**A2; D2; nitrided A2 or D2**
300-series stainless steels[(f)]	W1; aluminum bronze	Nitrided A2; aluminum bronze	**Nitrided A2 or D2**
Large pans similar to part 7, drawn from 0.8 mm (0.031 in.) sheet			
Drawing-quality aluminum and copper alloys	Alloy cast iron[(a)]	Alloy cast iron[(a)]; A2 corner inserts[(b)]	**Nitrided A2 or D2 inserts[(b)]**
Drawing-quality steels	Alloy cast iron[(a)]	Alloy cast iron[(a)]; A2 corner inserts[(b)]	**Nitrided A2 or D2 inserts[(b)]**
300-series stainless steels	**Alloy cast iron[(d)]; aluminum**	**Nitrided A2 or aluminum**	**Nitrided A2 or D2 inserts[(b)]**

	bronze	**bronze inserts**[(b)]	

(a) Wearing surfaces flame hardened.

(b) In flame-hardened alloy cast iron.

(c) Quenched and tempered for part 4; flame hardened for part 5.

(d) Flame hardened on wearing surface to not over 420 HB.

(e) For drawing aluminum, copper, and steel, the tool material would be used as corner inserts.

(f) For drawing stainless steel, inserts would be used for all wear surfaces.

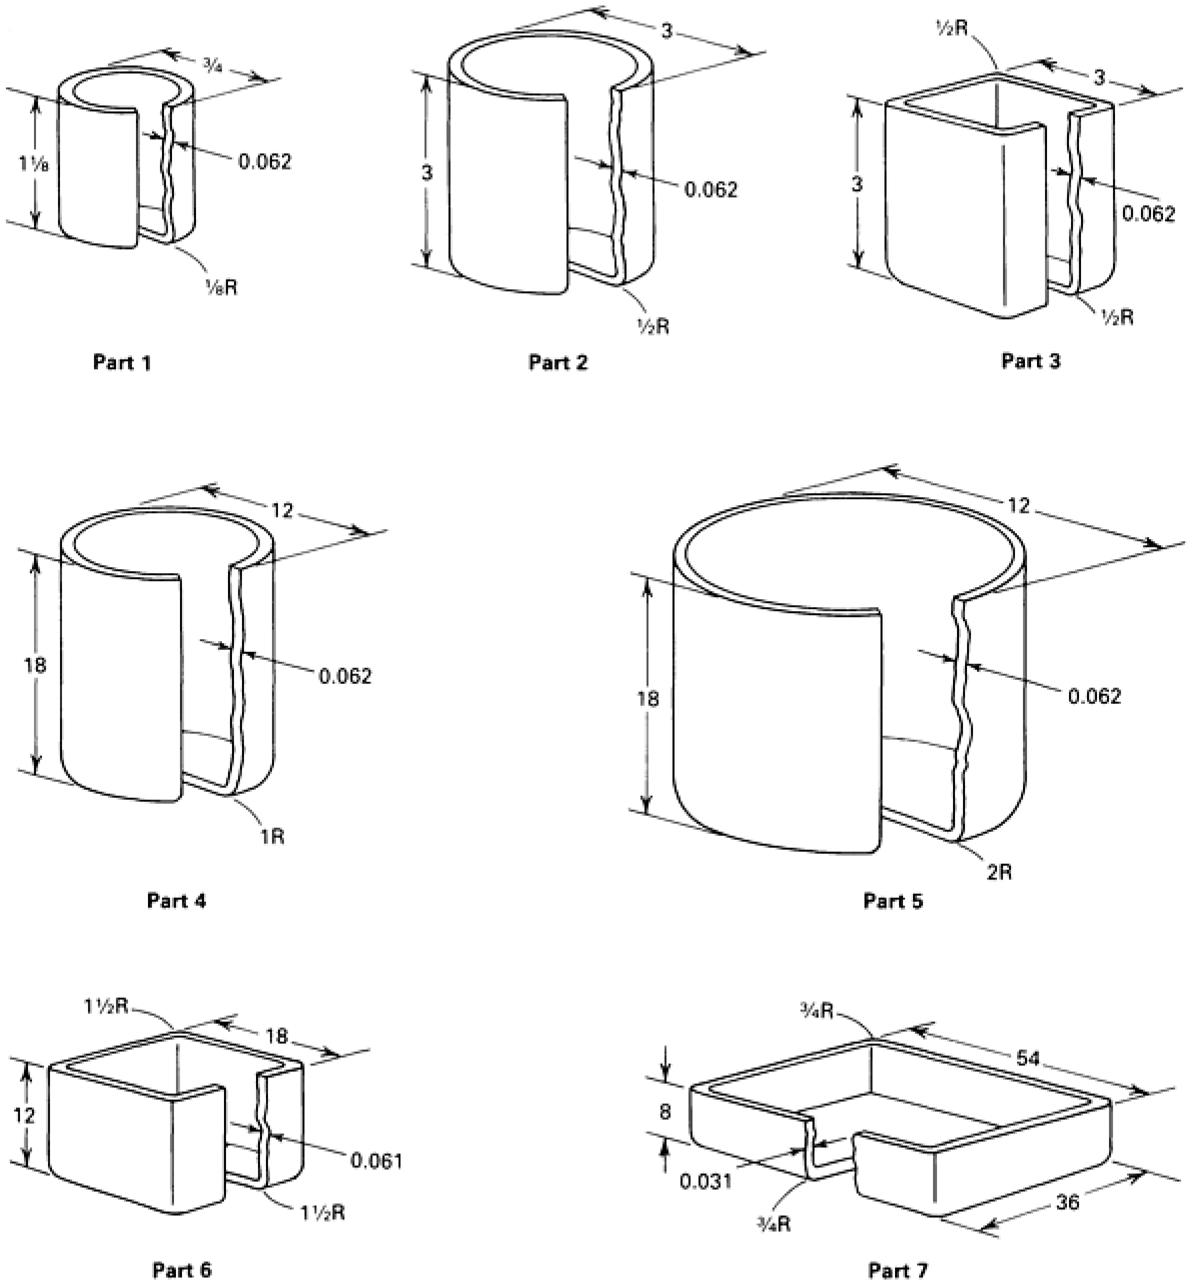

Fig. 3 Seven typical deep-drawn parts. Corner rodii comply with standard commercial practice. Table 2 lists typical die materials used for drawing parts of similar configuration. Dimensions given in inches.

Table 3 indicates the effect on material selection of changing the thickness of the sheet metal being drawn. Tool materials of increasingly greater wear resistance are required as the thickness of the work metal or the total quantity of parts is increased.

Table 3 Typical materials for draw rings used in making part 4 from flat-rolled steel of six thicknesses

See Fig. 3 for part design and overall dimensions.

Thickness of steel		Total number of parts to be drawn			
mm	**in.**	**1,000**	**10,000**	**100,000**	1,000,000

0.4	0.015	Alloy cast iron[a]	Alloy cast iron[a]	Alloy cast iron[a]	**Alloy cast iron[b], O1, A2**
0.8	0.031	Alloy cast iron[a]	Alloy cast iron[a]	Alloy cast iron[b]	**A2, D2**
1.6	0.062	Alloy cast iron[a]	Alloy cast iron[b]	Alloy cast iron[b], A2	**A2, D2**
3.2	0.125	Alloy cast iron[b]	Alloy cast iron[b]	A2, D2	**D2**
6.4	0.250	A2	A2	D2	**D2**
12.7	**0.500**	**A2[c]**	**A2[c]**	**D2[c]**	**D2[c]**

Note: Where tool steels are recommended, they are used as inserts in flame-hardened alloy cast iron.

(a) Flame hardening not necessary.

(b) Wearing surfaces flame hardened.

(c) In drawing 12.7 mm (0.500 in.) plate with A2 or D2 inserts, press speed is slower than for thinner stock, and the plate is phosphate coated.

Punches and Blankholders. Typical materials for punches and for blankholders or shellholders are listed in Table 4. These materials are for punches and blankholders used in drawing and ironing round and square steel cups similar to parts 2 through 7 in Fig. 3.

Table 4 Typical materials for punches and blankholders

See Fig. 3 for part designs and overall dimensions.

Die component	Total number of parts to be drawn		
	10,000	**100,000**	1,000,000
For round steel cups such as part 2			
Punch[a]	Carburized 4140; W1	W1; carburized S1	**A2; D2**
Blankholder[b]	W1; O1	W1; O1	**W1; O1**
For square steel cups such as part 3			
Punch[a]	Carburized 4140; W1	W1; carburized S1	**A2; D2**
Blankholder[b]	W1; O1	W1; O1	**W1; O1**

For round steel cups such as parts 4 and 5			
Punch[a]	Alloy cast iron[c]	O1[d]	**A2[c]; D2[c]**
Blankholder[b]	Alloy cast iron[c]	Alloy cast iron[e]	**O1; A2**
For square steel cups such as parts 6 and 7			
Punch[a]	Carburized 4140[f]	W1; O1[d]	**Nitrided A2; D2[d]**
Blankholder[b]	**Alloy cast iron[c]**	**W1; O1**	**O1; A2**

(a) Chromium plating is optional on punches to reduce friction between part and punch and therefore facilitate removal of the part. Cast iron, however, should not be plated.

(b) Also applies to shellholder and blankholder.

(c) Flame hardening not necessary.

(d) The punch holder is flame-hardened alloy cast iron with a nose insert of the indicated tool steel.

(e) For part 4, this blankholder is quenched and tempered; for part 5, it is flame hardened.

(f) The punch holder is alloy cast iron with a nose insert of the indicated steel.

More wear-resistant materials are required not only for the tools used in drawing and ironing harder or thicker stock or for those used for longer runs but also for tools used to achieve greater percentages of reduction during ironing. Table 5 lists typical tool steels used in punches and dies for short-, medium-, and long-run production at four levels of reduction in ironing. Typical materials for punches and dies used in the reverse redrawing of steel cups are listed in Table 6.

Table 5 Typical tool steels for punches and dies to iron soft steel sheet at various reductions

Ironing reduction, %	Total quantity of shells[a] to be ironed			
	1000	**10,000**	**100,000**	1,000,000
Ironing punches[b]				
Up to 25	W1	O1	A2	**A2; S1 carburized**
25-35	W1	A2	A2; S1 carburized	**D2**

35-50	A2	A2; S1 carburized	D2	**D2**
Over 50	D2	D2	D2	**D2**
Ironing dies				
Up to 25	W1[c]	O1	O1	**D2**
25-35[d]	W1[c]	O1	D2	**D2**
35-50[d]	O1	D2	D2	**D2**
Over 50[d]	**D2**	**D2**	**D2**	**D2**

(a) Steel sheet up to 75 HRB, or softer metals.

(b) All tool steel punches should be plated with chromium 5-10 μm (0.2-0.4 mils) thick for easier removal of the part from the punch.

(c) W1 is quenched on the inside and tempered to a minimum of 60 HRC for these applications.

(d) Draw rings must be inserted in shrink rings for ironing at reduction greater than 25% and for quantities of more than 10,000 parts.

Table 6 Typical punch and die material for the reverse redrawing of steels

Die component	Total quantity of parts[a] to be redrawn			
	1000	**10,000**	**100,000**	1,000,000
Small thick-wall cups				
Die and pressure ring	O1	O1[b]	A2[c]	**D2[c]**
Punch[d]	4140, 6150	O1, A2	D2	**D3**
Medium and large thin-wall cups				
Die and pressure ring	1018[e], 4140	4140[f], O1	A2[c]	**D2[c]**

(a) No specific finish or tolerance requirements.

(b) Dies are polished and chromium plated.

(c) A2 and D2 should be nitrided.

(d) All punches used for making more than 1000 pieces should be heat treated to 60-62 HRC, polished, and chromium plated.

(e) Carburized, hardened, and polished to a fine finish.

(f) 4140 or 6150 can be used if carburized and highly polished.

Combatting Specific Service Problems

Wear (most notably galling) is the most common sign of deterioration in deep-drawing tools. Wear can be reduced by selecting a harder and more wear-resistant material, by applying a surface coating such as chromium plating to the finished tools, or by using a surface treatment such as carburizing or carbonitriding. The following sections in this article are intended to supplement the basic information given in Tables 2, 3, 4, 5, and 6.

Galling. The typical causes of galling of deep-drawing tooling are:

- Attempts to stretch sheet metal beyond practical limits
- Poor tool fit-up, with poor alignment or insufficient die clearance for the sheet thickness
- Excessive wrinkling
- Insufficient or otherwise inadequate lubrication
- Use of tool steels that are susceptible to galling without applying a surface coating to the tools or using a lubricant of superior lubricating qualities
- Rough finishes on tool surfaces

For short runs, dies made of carburized hot-rolled steel or hardened alloy steel will often produce parts equal in quality to those drawn over most tool steel dies. Exceptions may be encountered in ironing to severe reductions or in drawing metals that tend to gall, such as austenitic stainless steels. These exceptions may be of little consequence, however, because tool steel dies may also become galled under the same circumstances. The longest die life can be expected when die surfaces have a very fine finish, with final surface scratches parallel to the direction of drawing. Die materials can be selected for resistance to galling on the basis of the following two criteria.

First, for parts drawn from carbon steel or nonferrous alloy sheet, the die material can be selected without regard to galling, and then, as a finishing operation, the punch and die should be either nitrided or chromium plated. If a tool steel such as A2, D2, D3, or D4, which contain chromium and molybdenum, has been selected, the smoothly ground tools should be nitrided and then polished or buffed.

Second, for parts drawn from stainless steel or from high-nickel alloy steel, the draw ring material with the best resistance to galling is aluminum bronze. The second choice is D2, D3, or D4, smoothly ground, nitrided, and polished. The third choice is alloy cast iron, quenched and tempered to 400 to 420 HB.

Chromium plating is used to extend the service lives of tool steel draw rings. On punches, the primary function of chromium plating is to reduce frictional forces and to facilitate the removal of parts from the punch after the sidewalls have been ironed tight to the punch. The improvement in punch life that results from chromium plating is usually somewhat less than that attained by changing the punch material to the next best tool steel.

For successful tool performance, chromium plating must always be deposited on a surface harder than 50 HRC; preferably, plating thickness should be 5 to 10 μm (0.2 to 0.4 mils) and never less than 2.5 μm (0.1 mil). This provides the required hardness and reduction of friction without excessive spalling or chipping at corners. Chromium-plated dies should be heated to 150 to 205 °C (300 to 400 °F) for a minimum of 3 h immediately after plating to minimize the possibility of hydrogen embrittlement.

Combined operations have found increasing use over the past 30 years. The more popular combined operations include one that combines drawing and coining and another that combines successive or tandem drawing (or ironing) operations. This latter combination is called double drawing or double ironing. Advancements in combined operations have paralleled advancements in die materials--for example, better selection of drawing steels as well as improvements in the engineering and construction of tools and especially in surface treatments such as those using zinc phosphate with emulsified soap.

These operations have increased production by doubling reductions and decreasing the number of operations, but at the same time have required capital investment in larger presses. In addition, tool steels of greater resistance to compression and heat have become necessary for drawing and ironing tools.

Double-drawing and double-ironing operations are successive operations in one tooling setup, with two dies placed in tandem so that a punch forces the cup through one die and then directly through the second die while the cup is still warm from deformation heating. The punches are longer than those used in conventional deep drawing and, because of their slenderness, are preferably made of S1 tool steel. Die materials are much the same as in single operations, except that selection is confined to tool steels such as A2 and D2 when temperatures are high in the second operation. These more temper-resistant steels can better withstand the effects of the higher temperatures developed by increased plastic deformation of the workpiece.

Cemented carbides. For long runs, cemented carbide inserts are widely used in deep-drawing dies. In dies up to 203 mm (8 in.) across for continuous production of over 1 million drawn parts, carbide has often proved to be the most economical die material. Such dies have maintained size in drawing 500,000 parts with 60% reductions and have made as many as 1 million parts with reductions greater than 40% when the steel to be drawn was surface treated with zinc phosphate and soap. However, cemented carbide dies do not provide satisfactory service with inferior lubricants. In addition, carbide dies are not superior to dies made of a tool steel such as D2 in complex deep-drawing operations (for example, those that combine drawing with coining or forming and in which the reduction in drawing is greater than 40%).

The cemented carbides that are most often used for deep-drawing inserts are straight tungsten carbide grades, of normal particle size, that contain about 9 to 10% cobalt or nickel binder. Steel-bonded carbides are also used for deep-drawing tools.

Plastics are the most economical tooling materials for short runs especially when a prototype part is available as a pattern for the lay-up of plastic-impregnated glass cloth facing, which is backed with chopped glass fibers impregnated with 50% resin. Among resins, polyester, epoxy, phenolic resin, and nylon have been used. The plastic dies that exhibit the longest life are those constructed so that the wearing surface is faced with glass cloth that has had most of the plastic material forced out under pressure before and during curing. Except for very short runs, plastics should not be selected as blankholder materials where burred edges of the blank slide over the plastic surface and produce severe wear or gouging.

Zinc Alloy Tools. Because they are relatively soft, zinc alloy tools should be used only in drawing (without ironing) small quantities of large-diameter thin-wall parts. Zinc alloy tools work best for drawing well-lubricated stock into parts 305 mm (12 in.) or more in diameter under circumstances in which wrinkling is not likely to occur.

Selection and Use of Lubricants in Forming of Sheet Metal

Elliot S. Nachtman, Tower Oil & Technology Company

Introduction

LUBRICANTS AND LUBRICATION are relatively low-cost components of a metal-forming system, yet lubricants are important and often indispensable for efficient forming of quality parts.

An overview of the interfacial interactions between a die and metal to be formed with the interposed lubricant film is presented in this article. Lubricant mechanisms, chemistry, qualification testing, application methods, property test methods, and some aspects of microbiology and toxicity are discussed, as are the increasingly important health and economic implications of some recent laws and regulations dealing with metal-working lubrication. Much of the discussion is relevant to metal-forming operations in general, although targeted at sheet metal forming operations. The final sections deal with lubricant selection as influenced by the metal to be formed and particular sheet metal forming operations.

Selection and Use of Lubricants in Forming of Sheet Metal

Elliot S. Nachtman, Tower Oil & Technology Company

Surfaces

In general, the specific characteristics of the surfaces of both the sheet and the dies make up the environment in which sheet metal lubrication is considered. As such they provide the boundaries between which the lubricant must operate. These surfaces are complex. The chemistry of the surface is not the same as the bulk chemistry of the sheet or tools. The lubricant interacts with an oxide layer of varying complexity; various contaminants may infiltrate the oxide layer (oil, gases, acids, rust preventives, and so forth); and the surface may be carburized or decarburized, nitrided or subjected to some other surface treatment, or coated with a polymer or phosphate. Many other surface chemistry variations are possible. Furthermore, the surface may have residual compressive or tensile stresses from prior processing. The fine structure of the metal surface may also vary with prior history and be quite different from that of the bulk material. The surface roughness also varies in many geometrically significant ways. Interposed between these non-homogeneous surfaces is a lubricating film that may be quite complex in structure, activity, and wetting ability.

The complexity of the lubricant/metal interface fundamentally affects the lubricant performance by preventing galling or wear of the tooling, as well as tearing, scratching, or imperfect forming to desired dimensions of the sheet metal.

Selection and Use of Lubricants in Forming of Sheet Metal

Elliot S. Nachtman, Tower Oil & Technology Company

Lubrication Mechanisms

In sheet metal forming, several different lubrication regimes have been identified. One or more of these regimes may be operational depending upon the sheet metal forming process. Figure 1 illustrates three of the lubrication regimes that are discussed below.

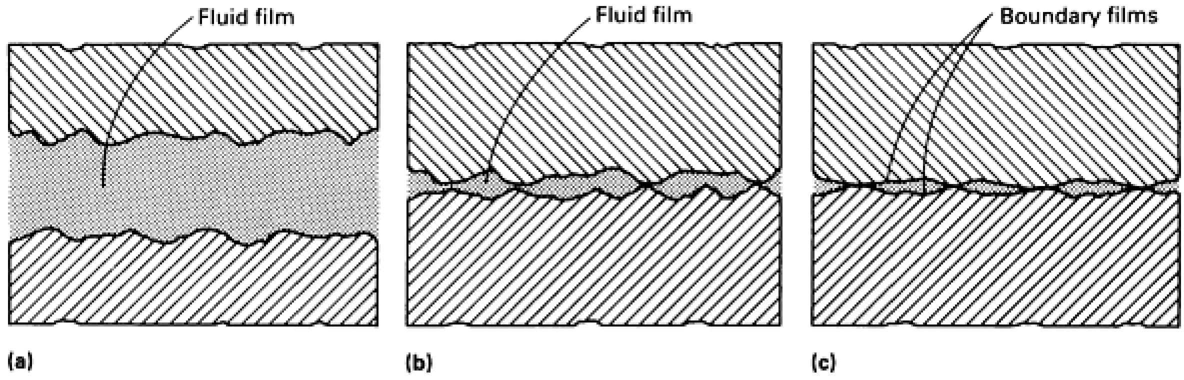

Fig. 1 Three lubrication regimes experienced in sheet metal forming. (a) Thick-film lubrication. (b) Thin-film lubrication. (c) Boundary lubrication.

Thick-film (hydrodynamic) lubrication (Fig. 1a) is the occurrence of a thick film of lubricant between tool and workpiece that completely prevents metal-to-metal contact. In this regime, the bulk properties of the lubricant (viscosity) and the mechanical system operating during deformation create the necessary conditions.

Thin-Film (Quasi-Hydrodynamic) Lubrication. The film between tool and workpiece is thinner, and some metal-to-metal contact takes place (Fig. 1b). This regime, also called mixed lubrication, occurs in bar and wire drawing and less frequently in sheet metal forming.

Boundary Lubrication (Fig. 1c). Physical adherence of the lubricant to the surface occurs, and relatively thin lubricant films may be effective. Dependence on viscosity is lower, and chemisorption (chemical adherence of the lubricant to the metal surface) becomes more important. The adherence and strength of the adsorbed film governs lubrication effectiveness.

Extreme-Pressure Lubrication. The metal surfaces are chemically altered because of reaction between the lubricant and the metal surface. These reactions often involve sulfur, chlorine, or phosphorus present in the lubricant reacting with the metal surface to form sulfides, chlorides, or phosphides. These compounds may be very complex in composition. Lubrication is provided because the films formed are low in strength and shear readily under deformation.

In solid-film lubrication, separation of tool and workpiece occurs by interposing a film consisting of molybdenum disulfide, graphite, sodium carbonate, Teflon, nylon, and other solids in a carrier. These solids act to provide a hydrodynamic film as long as they maintain surface integrity. The mechanism of solid-film lubrication is essentially the same as that of thick-film lubrication (Fig. 1a), except that the lubricant is a solid substance.

More than one of these regimes may occur during sheet metal forming. Indeed, a single regime often cannot be effective in providing the necessary film integrity between tool and workpiece. The specific regimes that are operational depend upon the severity, temperature, and geometry of the deformation mode. Detailed information on lubricating mechanisms is available in Ref 1 and 2.

Lubricant Forms

The three principal fluids (water, oil, and synthetic) that comprise the primary ingredients of sheet metal forming lubricants are combined with additives to achieve the desired operating characteristics. Table 1 lists the relative effectiveness of four types of lubricants for various functions. Some of the more important additives used to achieve particular lubricant characteristics are described in the section "Additives" in this article. However, it is first desirable to discuss the various possible forms of the lubricant (solutions, emulsions, and pastes).

Table 1 Relative effectiveness of different types of lubricants for various functions

Function	Relative effectiveness[(a)]			
	Compounded oil	**Oil-in-water emulsion**	**Semisynthetic solution**	Synthetic solution
Provide lubrication at high pressure (boundary lubrication)	1	2	3	**4**
Reduce heat from plastic deformation (heat transfer)	5	2	2	**1**
Provide cushion between workpiece and die to reduce adhesion and pickup (film thickness)	1	2	3	**4**
Reduce friction between die and workpiece and, thus, heat	1	2	2	**1**
Reduce wear and galling between tool and workpiece (chemical surface activity)	4	3	2	**1**
Flushing action to prevent buildup of scale and dirt (fluid flow)	5	4	3	**2**
Protect surface characteristics; nonstaining	5	2	2	**1**
Minimize processing costs, welding, cleaning, and painting	5	2	2	**1**
Minimize environmental effect, air contamination, and water recovery	**5**	**2**	**2**	**1**

(a) 1, most effective; 5, least effective.

Solutions. A fluid in which all components are mutually soluble is a solution. All of the fluids mentioned may form solutions, with soluble additives selected for their mutual solubility with the fluid and for their effect on properties. It is common practice in the field to call water-base solutions synthetic fluids or lubricants; oil-base solutions are called compounded oils; synthetic fluids that are compounded are also called synthetic lubricants. This shop language can be misleading if not understood.

Aqueous solutions have the highest cooling capacity and tend to promote operational cleanliness. Resistance to biological contamination is superior except for the possible formation of mold. Corrosion protection and operator skin inflammation (dermatitis) are potential problems.

Compounded oils tend to have superior thick-film lubrication properties and resistance to biological attack. They also provide good corrosion protection. On the other hand, workpiece cleanliness, cleaning of parts, welding, and higher end-use cost may be problems.

Synthetic compounded lubricants have superior high-temperature properties, but much higher costs restrict their use in forming operations.

Emulsions. A mixture in which one immiscible fluid is suspended in another in the form of droplets is called an emulsion. The continuous phase in most sheet metal forming operations is water. The suspended phase is oil or a synthetic fluid and may contain solid lubricants such as graphite, mica, or sodium carbonate. The continuous phase also may contain additives. In all cases, however, stabilization of an emulsion requires one or more surface-active agents (surfactants), finely divided solids, or special mixing techniques.

Surfactants such as fatty acids exist in an emulsion with the acid radical of the molecule preferentially soluble in the water, and the organic, fatty portion of the molecule dissolved in the oil phase. In this way the surfactant acts as a glue across the water/oil interface, thereby improving stability. This phenomenon is illustrated in Fig. 2, which shows the emulsifier action of three different emulsion systems as droplets of oil are suspended in water. In Fig. 2(a), the surface-active ingredients sodium cetyl sulfate and cholesterol are close-packed at the oil/water interface, thus producing an excellent tight emulsion. In Fig. 2(b), the sodium cetyl sulfate and oleyl alcohol interact at the interface to form a poor, or loose, emulsion. The effect of the surfactants is minimal in reducing the surface free energy of the oil droplets; therefore emulsion stability is poor. Figure 2(c) illustrates an intermediate case, which may be desirable in some cases because relatively large oil droplets occur, rather than the small droplets that are present in a tight emulsion. The presence of larger oil droplets may benefit the performance of the lubricating film.

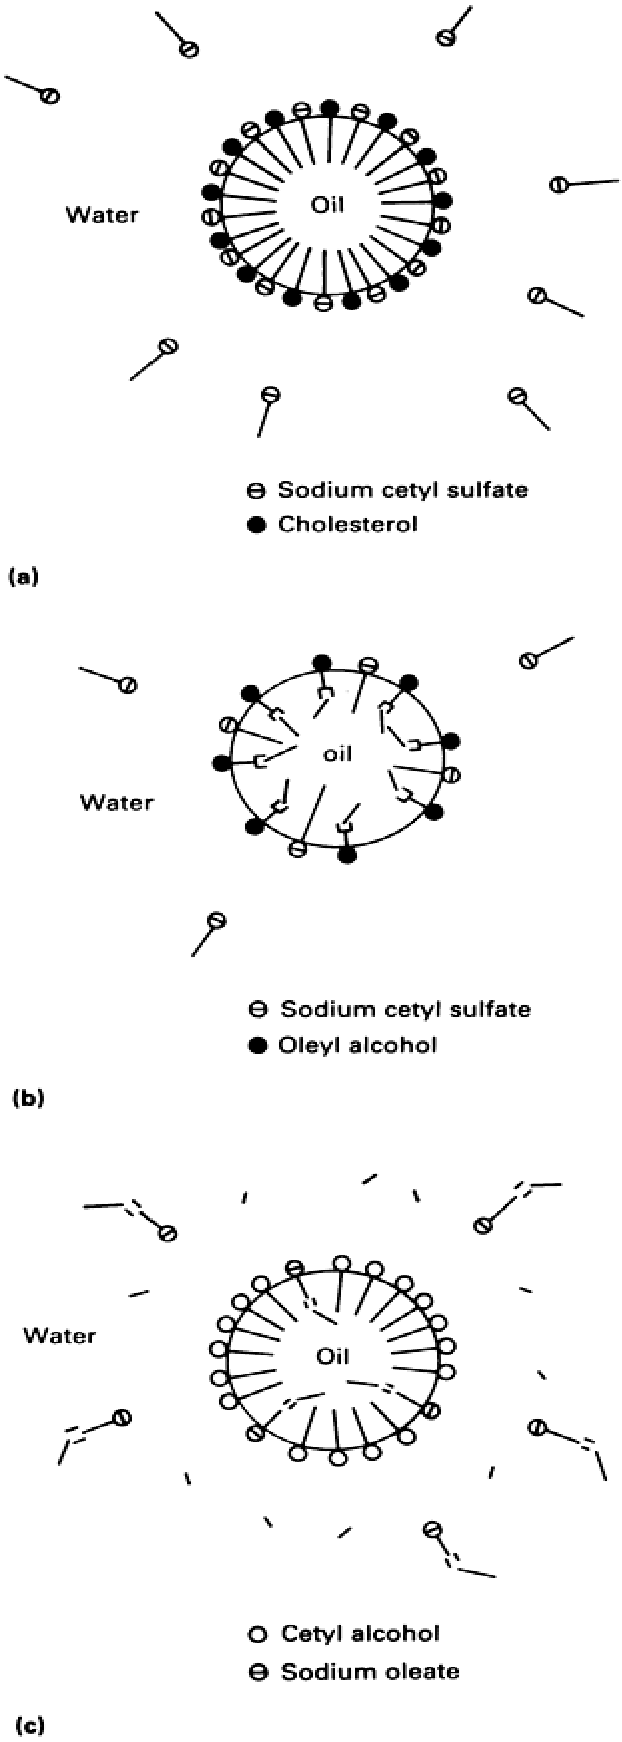

Fig. 2 Three types of emulsions seen in sheet metal forming lubricants. (a) Excellent (tight) emulsion. (b) Poor (loose) emulsion. (c) Intermediate case with poor emulsion stability.

A special case of emulsion is frequently used in sheet metal forming to take advantage of the cooling properties of water and the lubricity of suspended oil. The particle size of the suspended oil is small enough that the lubricant concentrate, even when water is added, remains clear rather than turning white or off-white, as is typically the case with an emulsion.

Emulsions generally are relatively easy to remove from parts and equipment. They provide superior cooling, but may be more susceptible to biological contamination and have less effective lubricating and corrosion-preventive properties than other lubricants.

Pastes, Suspensions, and Coatings. When difficult press work operations require film strength in excess of that which is possible with solutions and emulsions, a paste, suspension, or coating may prove to be the best lubricant choice.

Pastes may be oil- or water-base, pigmented or nonpigmented. Pigments include talc, mica, or similar inactive but effective high-strength barrier film formers. Sodium or potassium soaps are widely used in the production of all types of pastes. Buildup of lubricant in the tooling and the necessary cleaning of workpieces are the main drawbacks of pastes.

Suspensions are frequently used to provide a desired barrier film. Fine particles of a solid, such as graphite, Teflon, or clay, are suspended in a fluid carrier. Surfactants of an appropriate chemistry are generally required in order to provide suspension stability. Stability and lubricant buildup on dies are potential problems during use.

Coatings applied to sheet metal surfaces--most often at the sheet or strip finish mill--have been used alone or as undercoatings to lubricants applied at the press. Water-soluble polymers, phosphate conversion coatings, soap solutions, and organic resins (either with or without other additives), are used to form the coating. Generally, coatings are applied by dipping or spraying and then are heated to promote film formation and adhesion. Control of deposit thickness and chemistry, as well as removal, may be operating problems during production.

Selection and Use of Lubricants in Forming of Sheet Metal

Elliot S. Nachtman, Tower Oil & Technology Company

Lubricant Chemistry

Tool life and part integrity are directly affected by lubricant choice. The mechanical and chemical properties of the lubricant are influenced by operating conditions (temperature, pressure, geometry), as well as by the surface characteristics of the tool and workpiece. Further, the lubricant chemistry has important implications with respect to cleaning costs, welding integrity, corrosion of equipment and parts, recycling and disposal costs, and operator health and safety.

Carriers (Bases)

The chemical components of the lubricant consist of a combination of a carrier (base) with various additives. Different lubricants have different viscosities: fluids, solids, pastes, or gels may be used. Fluids are currently the most widely used lubricants for sheet metal forming. Lubricating fluids are based on mineral oils or solvents, synthetic fluids, water, or some combination of these.

Oils. Mineral oils or solvents used as a base for lubricants result from fractional distillation of crude oil. The oils are generally immune to biological attack, are readily recycled, have inherent lubricity and good metal-wetting characteristics, and afford some metal corrosion protection. The viscosity of selected oil or solvents varies over a wide range, as does the molecular structure (Fig. 3). The oils selected for use are complex organic compounds, as illustrated in

Fig. 1. The naphthenic oils (Fig. 1b) tend to be more reactive, while the paraffinic oils (Fig. 1a) are more oxidation resistant.

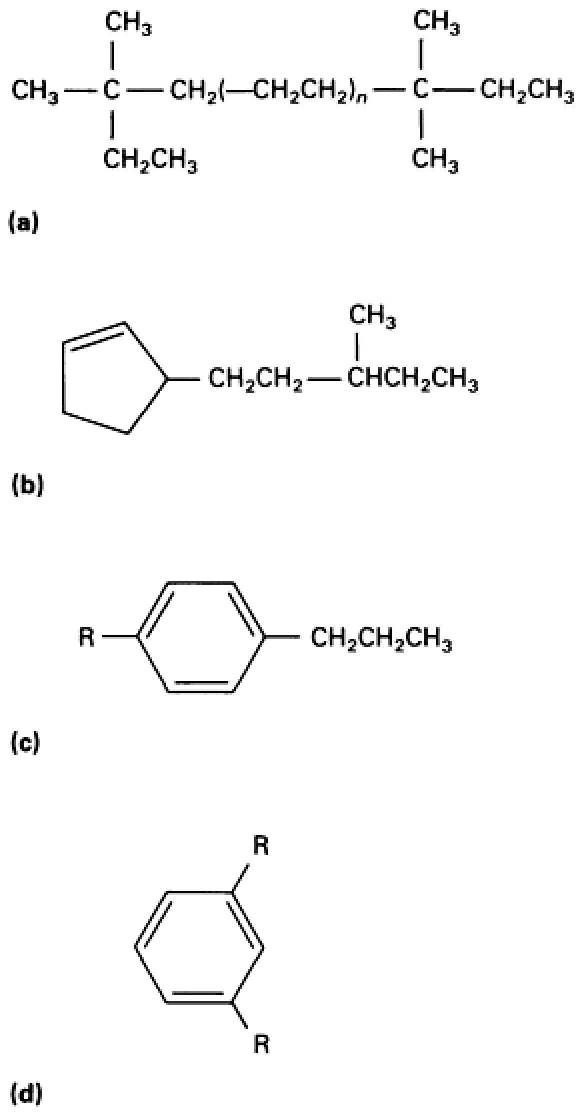

Fig. 3 Molecular structures of four mineral oil carriers used in sheet forming lubricants. (a) Paraffinic. (b) Napthenic. (c) Aromatic. (d) Alkylated aromatic. R, alkyl group.

Synthetic fluids with a specific molecular structure are becoming more widely used as lubricants. These fluids are based on synthesized hydrocarbons (polyalphaolefins) and polybutane derivatives (Fig. 4). The polyalphaolefins are similar to refined base oils in characteristics, but have superior resistance to oxidation. The polyglycols, polyolesters, and dibasic acid esters have superior high-temperature stability; however, they are not as readily combined with desired additives for corrosion protection or metalworking ability. Synthetic fluids are higher in cost than refined mineral oils.

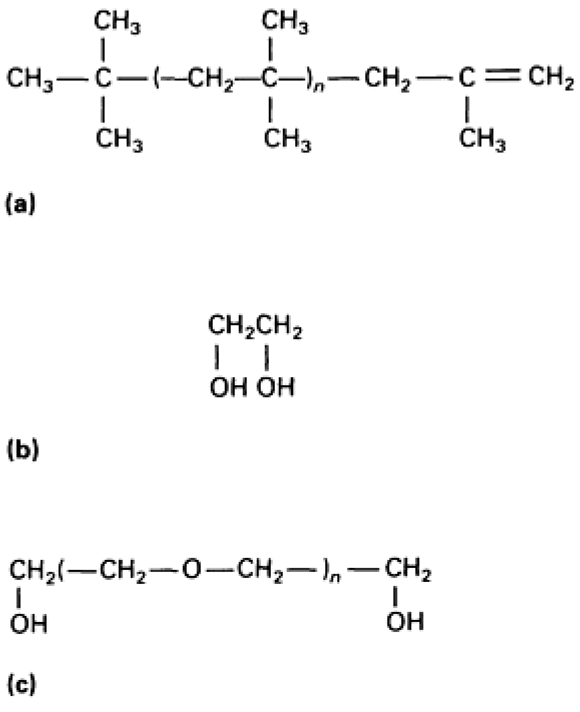

Fig. 4 Molecular structures of three types of synthetic fluids used as carriers for sheet forming lubricants. (a) Polybutene. (b) Ethylene glycol. (c) Polyethylene glycol ether.

Water. Because of the rising cost of refined mineral oil as well as the intrinsically high cost of synthetic fluids, water as the base fluid for sheet metal lubrication has become more widely used. A whole new technology is developing using various forms of water-base fluids (solutions, emulsions, gels, and pastes).

Of particular importance in the performance of water-base lubricants is the superior heat transfer capability of water. The sheet metal forming operation generates heat due to friction and metal deformation; water is the most efficient fluid for dissipating this heat.

Additives (Ref 4, 5)

Although uncompounded fluids may successfully serve as lubricants in light sheet metal forming, other processing requirements such as cleaning and corrosion protection may only be satisfied by the addition of chemical additives. Further, in difficult forming operations, additives must be used to provide necessary film characteristics to prevent die-part welding. Some common additives and their functions are discussed in this section.

Emulsifiers are used to promote stable emulsions and in some cases the cleanability of oils. Anionic and nonionic surfactants are the preferred emulsifiers. Typical nonionic emulsifiers are complex esters, fatty acids plus alcohols, monoglycerides, and ethoxylated alcohols. Some anionic surfactants used are soaps of long-chain fatty acids, alkyl aromatic sulfonates, and phosphate esters. Soaps are the most widely used anionic emulsifiers, but they may react with hard water to form compounds that can be difficult to remove from die or part surfaces.

Extreme-pressure (EP) additives are used when the fluid alone does not prevent excessive tool-part friction and wear. The film formed by interaction of the EP additive and the metal surface is created through chemical reaction. Sulfur-, chlorine-, or phosphorus-containing compounds react with the metal to form sulfides, chlorides, or phosphides. These chemical compounds are relatively weakly bonded and fracture and slide easily under the conditions of forming, providing a separating layer between tool and workpiece. Instability of the lubricant, as well as staining and corrosion, may be encountered during use. Cleaning and welding may also be adversely affected.

Thickeners are used to alter the flow characteristics (viscosity) of the fluid lubricant. Flow characteristics are influenced by temperature and pressure and affect lubricant performance. Organo-clays, polymers, natural gums, and metal hydroxides are used to vary flow properties. Stability of the lubricant system and buildup on tooling may cause operating problems.

Antimisting agents are used to reduce the incidence of airborne particles of the metalworking lubricant. Particularly in the case of solvents or low-viscosity oils, air mists may form that are detrimental to health and may also cause equipment-operating problems. To reduce mist formation, small quantities of polymers such as acrylates or polybutanes are added. When contacted with polymer, the lubricant base builds larger particles so that they do not readily form a mist.

Passivators are added to reduce the activity of the metal surface in order to prevent staining, particularly of nonferrous metals. Organic amines, sulfur, and nitrogen-containing compounds are used as passivators. Frequently, a so-called passivator is used in conjunction with corrosion prevention additives such as complex borates to improve the performance of each.

Antifoaming agents may be required to prevent foam formation if the lubricant is recirculated. Foaming is undesirable because it may interfere with reservoir cleanup and fluid flow or complicate fluid application. In order to prevent foam formation, the surface free energy of the film must be reduced. This may be achieved with a wide variety of additives, including silicones, amides, glycols, and fine particles of selected solids such as silica. The concentration of these agents needed for effective foam control is low; however, monitoring concentration to maintain control may be a problem.

Solid lubricants are often suspended in oil- or water-base fluids for extremely heavy-duty forming of sheet metal. These solids are graphite, carbonates, mica, Teflon, nylon, metal powders, and molybdenum disulfide. Buildup on tooling and cleaning of workpieces are potential problems during operations with these suspended-solid lubricants.

Corrosion inhibitors are frequently added to both water- and oil-base lubricants to provide part protection during processing and storage. Part corrosion may be a particularly difficult problem when water-base lubricants are used; however, sulfonates, carboxylates, borates, and phosphonates have been successful in alleviating corrosion. In oil-base lubricants, organic amines and sulfonates, as well as phosphates and unsaturated fatty acids, have been used successfully. Toluyltriazole has been used successfully to protect copper sheet from staining and corrosion.

Antimicrobial agents may be required in order to prevent the growth of anaerobic or aerobic bacteria. Bacteria frequently cause various operating problems (corrosion, odor, buildup of lubricant on workpieces, or emulsion instability) in emulsions or solutions that contain oil and water. In solutions formulated with various chemical components, bacteria will generally not be the problem; rather, formation of mold can cause malfunction of pumps and filters, and buildup on tooling and workpiece surfaces. It may also alter the solution chemistry. Biocides are not required when lubricant application does not involve repeated use or recirculation of the fluid. Care in handling as well as monitoring are important if biocides are to be used safely and effectively.

Selection and Use of Lubricants in Forming of Sheet Metal

Elliot S. Nachtman, Tower Oil & Technology Company

Lubricant Effectiveness

Selection of an appropriate lubricant for a specific sheet metal forming operation or for a series of different operations is often a costly hit-or-miss proposition. There are, however, laboratory test procedures that can often reduce the possibility of error.

Because of the difficulty of translating laboratory test results to an operating condition, several simulation tests have been developed to screen lubricants for sheet metal forming. Small-capacity presses have been installed as test machines with the ability to control speed of forming, metallurgy of tools and work metal, and lubricant application method.

Strip drawing through a wedge-shaped die on a tensile machine has been developed to measure lubricant effectiveness. One end of the strip is gripped and pulled through the die. The die may also be modified in order to simulate drawing over draw beads. In these tests, resistance to sliding is measured for different lubricants applied to the strip.

Standard deep-drawing tests, such as the Swift cup test, can also be used to measure lubricant effectiveness. Poor surface finish, score marks, or splits are indications of unsatisfactory lubrication. More information on tests for measuring the drawability of metals is available in the article "Formability Testing of Sheet Metals" in this Volume; Ref 6 and 7 include more details on evaluation of lubricant effectiveness. The larger the blanks formed and the deeper the cup, the more effective the lubricant film. A wide variety of punch and sheet metal geometry, size, and tool material can be used along with the lubricant coating. The limiting draw ratio (LDR) depends on the draw ratio (DR), which is equal to the ratio of the blank diameter to the punch diameter. For a given punch diameter, the greater the blank diameter, the more severe the operation. The LDR is the maximum DR that results in a satisfactory cup.

Selection and Use of Lubricants in Forming of Sheet Metal

Elliot S. Nachtman, Tower Oil & Technology Company

Lubricant Application (Ref 8)

The method used to apply the forming lubricant directly influences handling, part quality, and direct costs, as well as indirect costs (cleaning) and the metal forming operation itself. It is very important to deliver the appropriate volume of lubricant to the right location with the correct velocity at the right temperature in order to achieve optimum lubrication. Some of the more widely used application methods are discussed in this section.

Roller coating (Fig. 5a) is frequently used to coat strip before the strip enters the press. The strip passes through rollers, either top and bottom rollers or one or the other, and is coated with lubricant. The lubricant is fed to the roller either by dripping or by having the roller revolve, in a lubricant reservoir. The roller may be the same width as the strip and may be made of various materials. Pressure on the rollers can be varied to control lubricant thickness.

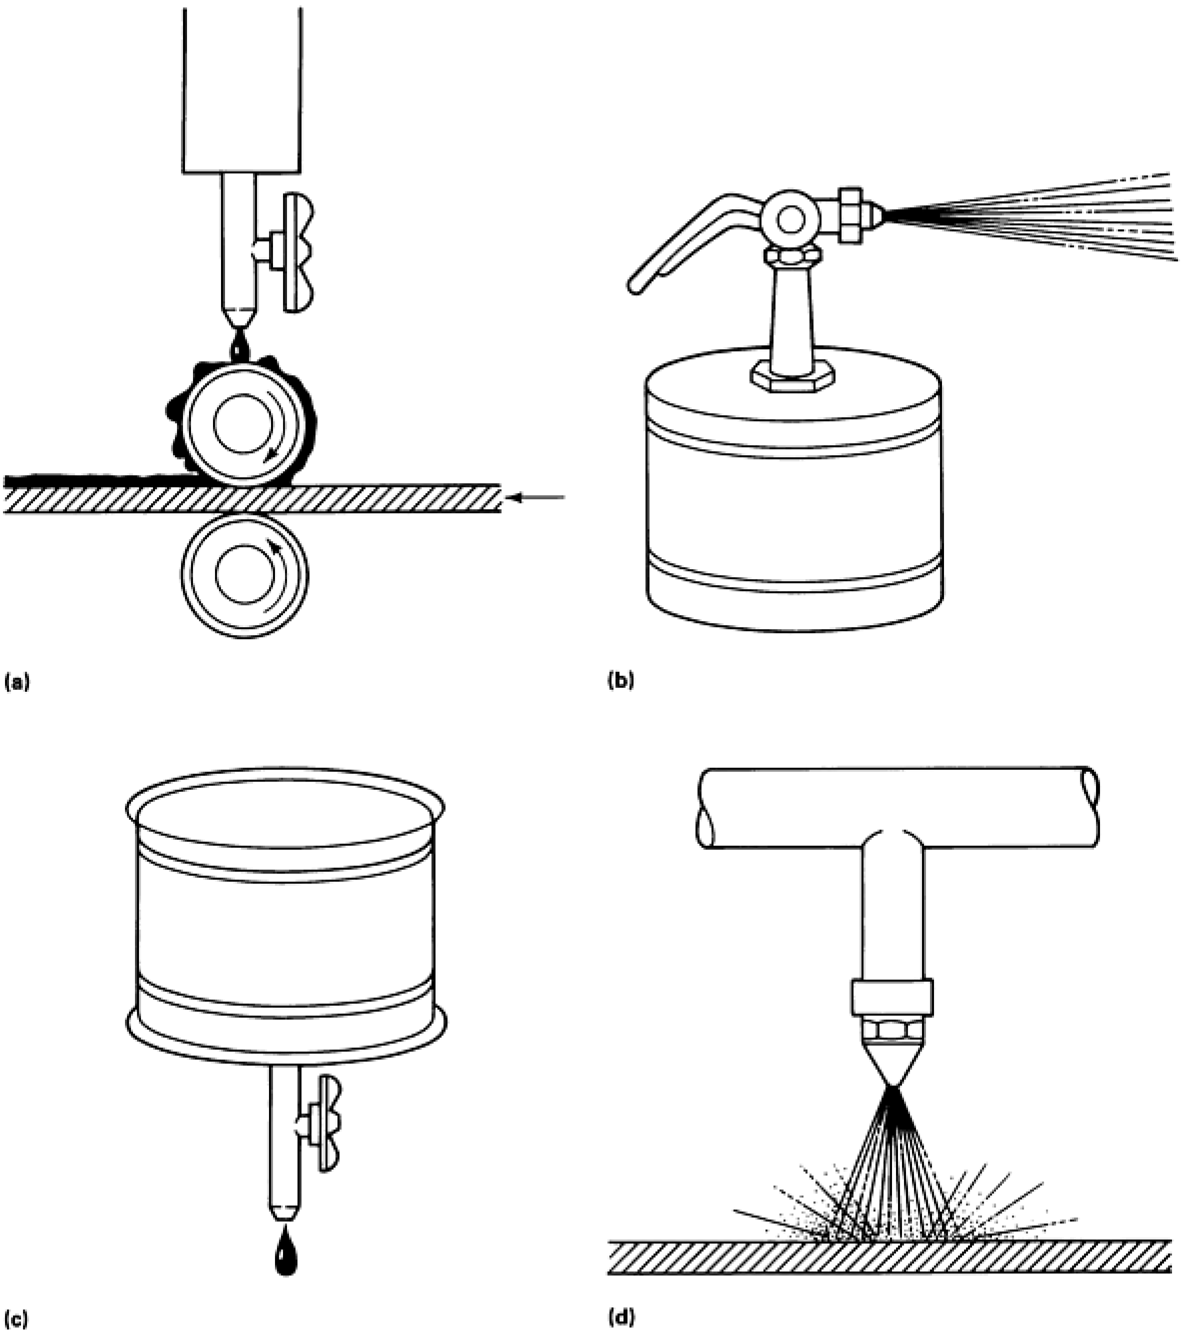

Fig. 5 Four common methods of applying lubricants. (a) Roller coating. (b) Spraying (simple spray apparatus shown here). (c) Drip application. (d) Recirculating flood.

Air or airless spray devices (Fig. 5b) are used to apply lubricant to preselected areas of the workpiece and/or tooling at the required frequency. Generally, higher-viscosity lubricants are applied by airless spray rather than by air spray units.

Drip application to the workpiece (Fig. 5c) can be used effectively when parts are relatively small and the cost of alternative application devices is not justified by the production demand. Heavy lubricants cannot be applied readily by this method, nor can the geometry of application be tailored selectively.

Flood application methods (Fig. 5d) require suitable press modifications to provide for recirculation of the fluid. Water-proofing to protect sensing elements must be provided for if a water-base fluid is used, and lubricant flooding must be controlled to confine it to the press work area. Flooding can be very useful when cooling is desirable and debris must be removed continually from the work area.

Control of Lubricant Characteristics

Maintaining the physical and chemical properties of lubricants is central to control of the sheet metal forming process itself. Table 2 lists some important characteristics of metal-forming lubricants for which tests have been developed, and the applicability of testing to various types of lubricants. Control methods developed under the aegis of the American Society for Testing and Materials (ASTM) are widely used. Some of the ASTM test methods for important characteristics are discussed below.

Table 2 Lubricant characteristics and their applicability to various types of lubricants

Characteristic	Lubricant system						
	Oil-base	**Solvent-base**	**Solids**	**Water-base emulsions**	**Solutions (water)**	**Coatings**	Pastes
Particulate concentration	X			X	X		**X**
Emulsifier level				X			
Viscosity	X			X	X		
Sulfur concentration	X	X	X	X	X

Viscosity (ASTM D 445, D 446, and D 88) is as important as any physical property of fluids used in sheet metal forming. Viscosity control is based on the measurement of the time required for a lubricant to flow through a fixed orifice at a controlled temperature.

Sulfur and chlorine (ASTM D 129 and D 808) are measured by carrying out a controlled combustion of a lubricant sample in a so-called bomb. ASTM D 129 describes a technique used for sulfur, and ASTM D 808 describes the appropriate technique for chlorine.

Corrosion potential can be very important in both evaluating the appropriateness of a specific lubricant, and for purposes of corrosion control during continued use. The methods most commonly used, for example, ASTM D 130 for copper-base metals and ASTM D 1748 for steel corrosion test strips, are based on the potential of water-lubricant interaction with the metal surface in a controlled way. Immersion in the fluid at elevated temperatures or exposure of a lubricant-coated strip in a humidity cabinet are techniques frequently used; they may be varied in many ways to attempt to duplicate as closely as possible particular operating conditions.

Emulsion stability is often of importance in maintaining a reproducible and reliable parts production line. A common method used to evaluate stability is ASTM D 1479, in which water available at the work site is used to make an emulsion. The emulsion is then stored for a specified period of time and evaluated. The concentration of oil in the bottom portion of the sample is a measure of the emulsion stability.

Fatty compounds are frequent components of a metal-forming lubricant. The test method ASTM D 94, using saponification number as a basis for fat determination, may be used as long as the basic fat component is known.

Hydrogen ion concentration (pH) is important in water-base lubricants. Variation of pH can be an important indication of fluid contamination or degradation due to biological or chemical reaction. Monitoring of pH on a regular basis can serve as an important control of fluid properties in a manufacturing environment. The pH can be measured with specially prepared pH paper or a pH meter.

Selection and Use of Lubricants in Forming of Sheet Metal

Elliot S. Nachtman, Tower Oil & Technology Company

In-Plant Control

Very important test procedures that do not require sophisticated laboratory facilities or highly skilled personnel are used for in-plant control. Some of the test procedures useful for lubricant control in plants are discussed below.

Emulsion concentration is one of the most important characteristics of a lubricant in metalworking. Variation in concentration occurs during use because of water evaporation, selective drag-out, and, frequently, lack of emulsion makeup control. A number of control techniques can be used successfully in the plant. These include the use of titration, a refractometer, and acid split.

Titration can be used to measure either emulsifier concentration or, in turn, emulsion concentration. Anionic emulsifiers can be titrated by using a cationic material with an appropriate indicator. Water hardness effects on the titration must be accounted for to improve the reliability of the titration.

A refractometer may be used to measure concentration. The refractive index of the emulsion or water-base solution varies with concentration. Fluid compositions also vary; therefore, the refractive index must be calibrated for each fluid. Fluid contamination can cause a false index reading and may prevent use of this measurement method.

Acid split is used to determine water concentration in an emulsion. The emulsion is split by using a strong salt solution or acid. If oil (tramp or machine oil) enters the emulsion, then the acid split will reflect all the oil present, and thus incorrect concentration values will be obtained.

Corrosion tests have been developed for measuring the possibility of change in this characteristic of a lubricant. A plant procedure is based on taking pieces of sheet metal to be formed, coating them with the lubricant to be used, and placing the specimen in a plant location most likely to encourage corrosion. Experience with a procedure standardized as much as possible with respect to lubricant, metal, and environment can be useful for plant testing. Various tests using metal coupons coated with lubricant and subjected to a high-humidity environment (humidity cabinet) can also be used. Cast iron blocks and chips can be used for accelerated testing, using any of a number of procedures involving contact with lubricant and subsequent aging in a selected room or plant environment.

Biological testing in the plant can be carried out to advantage if reasonable control of test conditions can be maintained. Dip sticks have been developed that consist of a plastic substrate coated with a nutritive gel selected for growth of either bacteria or mold, as desired. The method, though qualitative, is useful as a fluid control procedure in the plant. References 9 and 10 contain more information on control of lubricant characteristics.

Lubricant Toxicity (Ref 11)

Because the environment, as well as the biochemical characteristics of the human body, are extremely complex, effects on health in the workplace are difficult to isolate and measure. In general, exposure to sheet metal working lubricants may result in dermatitis, acne, tumors, and pigment changes in the skin. All of these may occur also from exposure to other by-products in the workplace, in the home, or in the environment in general.

Skin patch tests of a suspect material may reveal the potential for dermatitis. A small patch is coated with the material in question and taped to the skin.

The Ames test, which measures the effect of a test material on bacteria, has been used as a screen for possible causes of mutagenic effects in humans. Most materials which may cause mutagenic effects are not necessarily carcinogenic. Evaluation of a metal-working fluid for its possible adverse biochemical effects should be a part of the lubricant selection process. The recent requirement of a completed material safety data sheet (MSDS) on all chemicals and their mixtures can serve as an important source of information for the screening procedure. Appropriate work practices and personal hygiene can significantly reduce adverse biochemical effects.

Microbiology of Lubricants

Microbiological contamination of lubricants can be a serious problem. When water is part of the composition of a metalworking fluid, microbes can grow in the fluid, either deliberately or accidentally as a result of contamination. Bacteria are the main problem in mineral-oil emulsions; in water solutions, molds and yeasts are the principal microbiological contaminants. These microbes feed and grow on one or more of the lubricant constituents or contaminants. If they grow by attacking a single constituent, the constituent can be so altered chemically in short order, frequently as rapidly as in one day, that the lubricant no longer operates effectively as intended. An emulsifier may no longer promote stable emulsification, a rust-preventive additive may no longer prevent rust formation, or a lubricity additive may no longer provide an effective lubricant film.

Anaerobic bacteria, often present in fluids, operate in the absence of oxygen and cause the breakdown of sulfur compounds in the fluid, creating the strong rotten-egg odor that may occur in the fluid reservoir. Aerobic bacteria grow in the presence of oxygen and are the most aggressive in promoting overall chemical breakdown of the lubricant. Molds and yeasts, when present, do not drastically degrade lubricant chemistry; they do, however, block filters, and may build up on tools and generally have a disagreeable feet and appearance.

Bacteria and mold or yeast infestation of the lubricant may be controlled by appropriate formulation of the lubricant, use of an effective biocide, pasteurization, and sometimes effective filtration. Good practices involving clean work habits and avoidance of contamination of the fluids by plant dirt, food, and so forth, will contribute to longer life of fluids. References 12, 13, and 14 contain more detailed information on the effects of microbiological contamination.

Selection and Use of Lubricants in Forming of Sheet Metal

Elliot S. Nachtman, Tower Oil & Technology Company

Environmental and Occupational Health Concerns

In recent years, concerns about the environment, health, and safety have led to the enactment and enforcement of a number of laws and regulations. Some of the most important of these as they affect the use and disposal of sheet metal forming lubricants are discussed below.

The Environmental Protection Agency (EPA) was established by the U.S. Congress to ensure protection of the environment in which we live and work. Over the years, clean air and water have become a subject of increasing concern. Several acts addressing these concerns have been passed, requiring enforcement by EPA. Some of the more important are:

- The Toxic Substance Control Act, designed to regulate the manufacture, processing, distribution, use, and disposal of chemicals. Material Safety Data Sheets (MSDS) are required for all lubricants, with information about the toxicity, handling, and safe disposal of such materials
- The Clean Air Act, as amended in 1977, which specifically regulates the concentration of volatile lubricant components in air. It established permissible concentrations that must not be exceeded in the workplace
- The Water Pollution Control Act regulates the passage of waste into the water supply. The condition, type, and concentration of waste that may be permitted to enter the water supply is established and regulated. Disposal of lubricants, if it involves entry into a water system, must satisfy the appropriate criteria for disposal
- The Resource Conservation and Recovery Act (RCRA) regulates hazardous waste management and disposal. Lubricants, if they contain hazardous components, are categorized as hazardous materials and must be stored, transported, and disposed of as prescribed by regulation. Appropriate records must accompany each step, as regulated.

The Occupational Safety and Health Administration (OSHA) is concerned with safe working conditions in the workplace. The impact of occupational safety and health legislation on lubrication as practiced in the workplace concerns prevention of occupational illnesses due to hazardous or toxic chemicals. Companies are required to record all injuries or illnesses as they occur. The relative toxicities of approximately 1500 chemicals found in the workplace are being systematically established by OSHA. Regulation of these chemicals is occurring as appropriate information is developed.

Product liability is of increasing concern because of the exploding cost of defending a product liability case as well as the bringing of nonmeritorious claims to court. At the same time, increasing attention has been paid to safer, better products as well as a safer, better work and living environment. Lubricant manufacturers and users are faced with claims for improper formulation, usage, and performance. Appropriate steps to anticipate and eliminate possible product liability claims occupy increasing time and attention on the part of both the supplier and user of lubricants.

The laws and regulations described in this article illustrate only a few of the more important ones that govern and regulate the use, disposal, and manufacture of sheet metal forming lubricants. New developments in lubrication technology will surely be conditioned by this regulatory and liability environment.

Selection and Use of Lubricants in Forming of Sheet Metal

Elliot S. Nachtman, Tower Oil & Technology Company

Lubricant Selection

Selection of an appropriate lubricant for a specific sheet metal forming operation depends on a number of diverse criteria that must be successfully satisfied:

- Effect of lubricant on the forming operation (effect on both tool wear and part tolerance and finish)
- Application method and efficiency thereof
- Maintenance of lubricant performance, taking into account problems of recirculation, testing, and disposal
- Corrosion of tooling, machine, and finished parts
- Cleaning
- Welding, painting, or coating of the work material
- Worker response
- Supplier support
- Toxicity and health
- Cost, including cost of lubricant and its effect on overall product cost

A wide variety of operations are commonly used to form parts from sheet metal. Blanking, piercing, ironing, forming, drawing, fine blanking, and spinning are some of the operations that are used separately or in sequence to form parts, and are discussed in other articles in this Volume. Unlike bulk deformation processes, the temperature increase in sheet metal forming is generally low unless the complexity of deformation and/or the strength of the material is very high. Generally, except in the case of ironing, sheet metal forming involves little or no thickness change. Deformation is generally biaxial in the plane of the sheet. However, there can be considerable relative motion between tool and workpiece. Further, the area of tool contact is often large. Surface finish and part tolerance depend on tool geometry and finish, speed and temperature of deformation, the combination of forming steps required, and the choice and application of lubricant. Table 3 illustrates some of the types of lubricants used successfully in sheet forming of various metals at room temperature and at elevated temperatures. The type of metal, complexity of part shape, part tolerance, and surface finish specifications all influence the choice of lubricant. The more critical the operation, the more important the need for film strength and adhesion of the lubricant film to the metal substrate. Further, there may be a need for increased film thickness.

Table 3 Lubricants for forming of specific sheet materials

Metal or alloy	Recommended lubricants for:

	Cold forming	Hot forming
Aluminum alloys	Synthetic solutions, emulsions, lanolin suspensions, water suspensions, soap solutions, mineral oil plus fatty oils	**Graphite suspension**
Copper alloys	Emulsions plus fatty oils, mineral oils plus fatty oils, soap suspensions, water suspensions, tallow suspensions, synthetic solutions	**Pigmented pastes, graphite suspensions**
Magnesium alloys	Solvent plus fatty compounds, mineral oils plus fatty compounds	**Graphite plus molybdenum disulfide, soap plus water, tallow plus graphite**
Nickel, nickel-base alloys	Emulsions, mineral oils plus EP additives, water plus chlorine additives, conversion coatings plus soap	**Graphite suspension, molybdenum disulfide suspension, resin coating plus salts**
Refractory metals and alloys	Copper plating	**Molybdenum disulfide, graphite suspension**
Carbon and low-alloy steels	Emulsions, soap pastes, water, fatty oils plus mineral oils, polymers, conversion coating plus soap, molybdenum disulfide or graphite in grease, synthetic solutions	**Graphite suspension**
Stainless steels	Fatty oils plus mineral oil, water, polymers, conversion coating plus soap, mineral oil plus EP additives, pigmented soaps	**Graphite suspension**
Titanium, titanium alloys	**Water, pigmented soaps, polymers, conversion coating plus soap**	**Graphite and molybdenum disulfide suspension**

The relationship of many process variables, including speed of operation; tool geometry; number and severity of discrete forming operations; worker exposure to lubricant; fluid makeup; circulation, recycling, and disposal; and the effect of the lubricant film on subsequent operations such as welding, cleaning, and plating influence the choice of lubricant. A simple recommendation based on material, tooling, and process may prove to be far from optimum; many other factors can and should influence lubricant choice.

Nevertheless, in order to give some background information that may provide guidelines in the selection of a lubricant, a number of processes applied to various sheet materials relative to the choice of an appropriate lubricant will be discussed below.

Forming of Carbon and Low-Alloy Steels

A wide range of lubricants are successfully used to form steel sheet. The speed of operation and resulting temperature, as well as thickness of stock and complexity of shape, influence lubricant choice. Oil-, solvent-, and water-base fluids, as well as pastes and gels, may be effective, depending on operating conditions.

Blanking and Piercing. Straight oil, compound oil, or emulsions with sulfur, chlorine, and/or fatty esters are used for most operations. Solutions may be used when the operation is less severe.

Coining. Because die buildup must be prevented, light oils straight or compounded with fatty additives or chlorine-containing additives are used. Water-base solutions may be effective when formulated with alkanolamides, fatty esters, and/or long-chain derived fatty acid soaps.

Other Operations. Compression, tension, binding, or shearing forces may occur during forming on a particular part; therefore an appropriate choice of lubricant viscosity and chemistry varies widely from part to part, depending on part configuration. Essentially all classes of lubricants have been successful. Generally, however, the present emphasis is on formulating solutions or emulsions that prevent galling or tearing of the sheet metal.

Multislide Forming. Light compounded oils and water-base emulsions and solutions with chlorine and fatty additives are used successfully. Care must be taken to prevent buildup on the dies and corrosion of machine or formed parts when water-base lubricants are used.

Deep Drawing. Progressive- and multiple-die sets are being used more and more frequently, and thus carry-through of the lubricant becomes more and more important. Multiple-die lubrication sites to provide die lubrication at succeeding stations may be an alternative method for ensuring adequate lubrication. Compounded oils and emulsions or pastes are being used successfully. Chlorinated compounds and fatty esters are commonly chosen additives. Soap-base lubricants are also applied frequently and successfully.

Spinning. Both lubrication and cooling are important effects provided by appropriate lubricant choices. Water-base emulsions and solutions containing chlorinated or sulfochlorinated additives and/or fatty esters are used. Nonpigmented water-base pastes are also effective.

Roll Forming. Water-base emulsions and solutions have been used to form both bare and coated steel. In the case of galvanized steel, white rust can be a problem if water-base lubricants are used and not properly applied and removed. Solvent-base fluids are often the preferred lubricant, particularly when minimal residue is important. Light oils may also be used, both compounded and uncompounded with chlorinated compounds, soaps, or fatty esters.

Forming of Stainless Steels

In general, stainless steels are more difficult to form than carbon or low-alloy steels because of their higher strength. Care must be taken in the choice of chemically reactive lubricants containing sulfur or chlorine. Furnace treatments should be carried out on formed parts after removal of the lubricant film. Sometimes this step may be avoided if high molecular weight polymers or complex fats are used in lubricant formulation.

Blanking and Piercing. Solutions and emulsions containing sulfur and/or chlorine are particularly effective for lighter-gage material. Oils compounded with sulfur and/or chlorine are effective in heavier-gage material.

Multiple-Slide Forming. Oil- and water-base fluids are successfully used. Recently, solutions with complex esters and fatty compounds have been used, successfully eliminating cleaning of parts before use.

Deep Drawing. Because of the high work-hardening characteristics of some stainless steels and attendant high die pressure and temperatures, oils with extreme-pressure additives such as sulfur, chlorine, and phosphorus are most often the lubricants selected. Pigmented and nonpigmented pastes are often used with or without extreme-pressure additives.

Roll Forming. Thin-gage sheet may be formed by application of solvent-base as well as water-base fluids at the roller. Thicker material and/or more complex shapes, on the other hand, require oils or emulsions compounded with fatty oils, extreme-pressure additives, and soaps.

More information on forming of stainless steel sheet is available in the article "Forming of Stainless Steel" in this Volume.

Forming of Heat-Resistant Alloys

In general, heat-resistant alloys (complex iron-, nickel-, and cobalt-base materials) as a class use lubricants that are suitable for stainless steel. Cobalt-base alloys are particularly difficult to form into sheet because of their high strength and relative inertness. Care must be taken to avoid embrittlement by sulfur diffusion in nickel-base alloys. Pigmented lubricants are difficult to remove after forming, and this may discourage their use. More information on forming of heat-resistant alloy sheet is available in the article "Forming of Heat-Resistant Alloys" in this Volume.

Blanking and Piercing. Soap-base oils and emulsions are used with and without chlorinated additives. Wax and polymer additives may be used if the blanking step is complex.

Spinning. Chlorinated additives in an oil base as well as in emulsions containing fatty esters are effective. Soap-base pastes are also often chosen for application.

Forming of Refractory Metals and Alloys

Although warm or hot forming of materials such as molybdenum, tungsten, tantalum, niobium, and their alloys is often required, room-temperature deformation is successfully carried out using metal coatings with auxiliary lubricant application.

Drawing. Fluorinated complex polymers are used to form tantalum; graphite in fat has been used for forming niobium. Both metals may be formed at room temperature.

Spinning. Room-temperature spinning of niobium has been carried out using molybdenum disulfide in oil or graphite in a soap-base paste.

Forming of Aluminum and Aluminum Alloys

Aluminum and aluminum alloy sheet may be stained or corrosion may occur through the improper choice of lubricant. Aluminum oxides build up during forming and may necessitate cleaning of both parts and equipment. The lubricant may contribute to undesirable buildup. Lubricant chemistry differs from the chemistry used in formulating lubricants for steel and refractory metals or high-temperature alloys.

Blanking and Piercing. Oils or compounded oils of light viscosity are used. Fatty esters and chlorinated compounds are the compounding additions frequently chosen. Fatty compounded emulsions as well as soap-base solutions are also effective. Oxide deposits may be a problem with some compounded oils and emulsions.

Roll Forming. Solvent-base lubricants containing fatty esters as well as emulsions and solutions are frequently used lubricants. Light viscosity oils also may be used; however, oxide buildup on the rolls can be a problem. Soap-base lubricants are used if care is taken to prevent soap deposits.

Deep Drawing. Viscosity and lubricity are critical attributes of lubricants. Water-base fluids may be used if appropriate fatty additives and/or soap additives are used to provide the required barrier and lubricity. Oils of varying viscosity or dry soap films may be used for more difficult draws. Pastes that are soap- and fat-base have been applied successfully. Progressive draws involving multiple steps frequently should provide lubrication at more than one station.

Spinning. Waxes and soaps are effective lubricants. Colloidal graphite suspended in an oil carrier is also used successfully. Cleaning can be difficult depending on the severity of the spinning operation.

Forming of Copper and Copper Alloys

Staining and/or corrosion of these metals in their forming is of particular concern. Lubricants chosen must be formulated to prevent both from taking place.

Multislide Forming. Soap- and fat-containing oil and/or water-base lubricants are effective. Solvent-base lubricants containing a fatty ester or an inhibited chlorine-containing compound may be used.

Roll Forming. All classes of lubricants using fatty compounds and/or soap-base additives are used successfully in water, oil, or solvent fluids.

Deep Drawing. Depending on severity of draw, oil- or water-base lubricants in fluid or paste form may be effective. Soap and fatty compounds, as well as inhibited chlorine-containing compounds, are commonly used additives.

Forming of Magnesium Alloys

Magnesium alloys are most often formed warm or hot. Forming at these elevated temperatures is not normally required for other metals of industrial importance.

Drawing. At temperatures to approximately 120 °C (250 °F), soap-base lubricants, fatty esters, polymer additives in oil and water, and pastes formulated with chlorinated additives are successful lubricant systems. At temperatures in excess of 120 °C (250 °F), the choice of lubricant is restricted to synthetic fluids formulated with soap, fatty esters, and/or chlorinated compounds. Above 230 °C (450 °F), graphite and/or molybdenum disulfide in various carriers are preferred.

Spinning. At elevated temperatures, the synthetic fluids compounded with graphite and/or molybdenum disulfide are applied. Water carriers for the solid lubricants may be preferred to reduce the occurrence of smoke and the possibility of fire.

Forming of Nickel and Nickel-Base Alloys

These metals are difficult to wet with lubricants; thus heavy-duty lubricants with exceptional film-priming characteristics are necessary for effective lubrication. On the other hand, lubricants containing sulfur, chlorine, or solid additives such as zinc oxide or lead carbonate can, if not removed from the nickel surface, can cause embrittlement of the metal.

Shearing, Blanking and Piercing. Oils incorporating sulfur- or chlorine-containing additives may be used. Water-base lubricants of similar composition may be applied if they are removed as soon as possible after forming to prevent embrittlement. Fatty esters and polymers have grown in application as components of formulated lubricants.

Deep Drawing. Soap-base pastes as well as oils with fatty esters, amides, and/or sulfur and chlorine additives have been used. Emulsions fortified with amides and polymers also have been formulated and applied.

Spinning. Pigmented pastes and chlorinated wax in oils are successful lubricants. Plain waxes and soaps are frequently important components of these lubricants.

Forming of Titanium Alloys

Galling of titanium alloys is a particular problem because of the affinity of the metal for die materials. Notch sensitivity and embrittlement may also lead to splitting or cracking of formed parts. Cold and warm forming may be carried out with suitable films designed to prevent metal-to-metal contact. Frequently, overlays of steel sheet or plastic sheet are used with an auxiliary lubricant.

Deep Drawing. Overlays are often used with oil-base lubricants formulated with chlorinated waxes. Oxidized or phosphated coatings are successful in relatively severe drawing operations at elevated temperatures. Graphite and/or molybdenum disulfide in oil may be used.

Roll Forming. Oils compounded with sulfurized or chlorinated fats are used. Oil- or water-soluble polymers may also be added. Chlorinated waxes, high molecular weight waxes, or polymers soluble in oil may be effective for relatively moderate deformation.

Spinning. Colloidal graphite and/or molybdenum disulfide blended in oil may be used at temperatures up to approximately 205 °C (400 °F). Chlorinated wax and/or sulfurized fat in oil also may serve as lubricants. At higher temperatures, fillers such as bentonite or mica with graphite and/or molybdenum disulfide formulated into a grease are used successfully.

Forming of Platinum-Group Metals

Surface contamination due to metal contact at surfaces with iron or other metals may adversely affect surface integrity and electrical resistivity. Separation of tool and workpiece by an appropriate lubricant film is critical. Platinum and palladium can be formed by most standard sheet metal forming operations (blanking, piercing, and deep drawing). Cold welding of the workpiece to the tooling must be avoided, and therefore continuous lubricant films are important in operation. Many of the lubricants used for forming copper alloys may also be used for forming platinum and palladium. Rhodium and iridium are more difficult to form, and ruthenium and iridium are extremely difficult to form.

Introduction

PUNCH PRESSES are used for bending, flanging, and hemming low-carbon steel when production quantities are large, when close tolerances must be met, or when the parts are relatively small. Press brakes are ordinarily used for small lots, uncritical work, and long parts.

To estimate the press capacity needed for bending in V-dies, the bending load in tons can be computed from:

$$L = \frac{lt^2kS}{s}$$

where L is press load (in tons of force), l is length of bend (parallel to bend axis) (in inches), t is work metal thickness (in inches), k is a die-opening factor (varying from 1.2 for a die opening of $16t$ to 1.33 for a die opening of $8t$, S is tensile strength of the work metal (in tons of force per square inch), and s is width of die opening (in inches).

For U-dies, the constant k should be twice the values given above. Bending of flanges with wiping dies is discussed in the section "Straight Flanging" in this article. The characteristics of the various presses commonly used for forming sheet metal are summarized in the article "Presses and Auxiliary Equipment for Forming of Sheet Metal" in this Volume.

Bendability and Selection of Steels

Figure 1 shows the types of bends for which the standard AISI tempers of cold-rolled carbon steel strip are suited. Stock of No. 1 temper is not recommended for bending, except to large radii. Stock of No. 2 temper can be bent 90° over a radius equal to strip thickness, perpendicular to the rolling direction. Stock of No. 3 temper can be bent 90° over a radius equal to strip thickness, parallel to the rolling direction; it can also be bent 180° around a strip of the same thickness when the bend is perpendicular to the rolling direction. Stock of No. 4 or No. 5 temper can be bent 180° flat on itself in any direction. The No. 5 temper stock may develop stretcher strains and should not be used if these markings are objectionable.

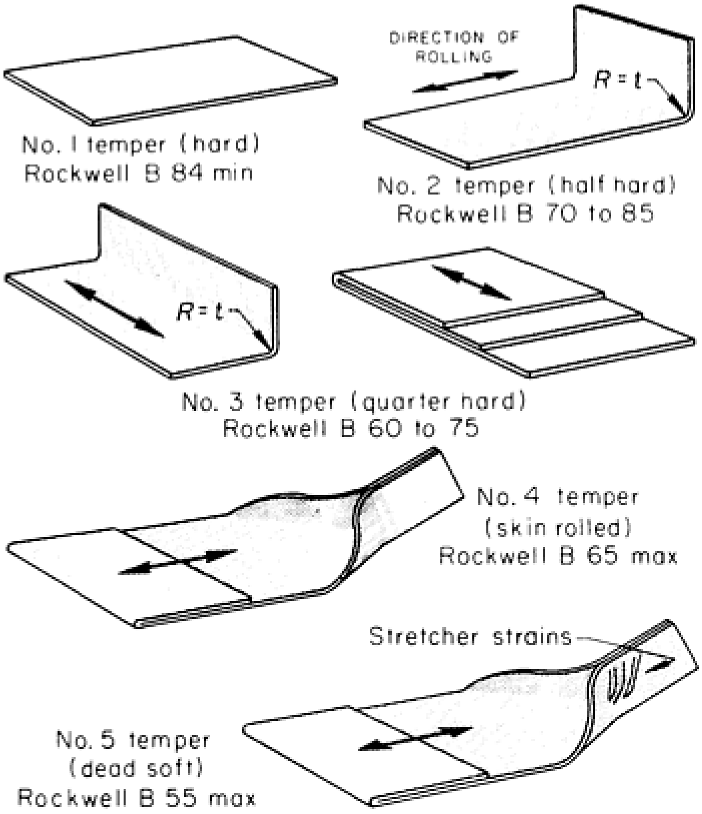

Fig. 1 The most severe bend that can be tolerated by each of the standard tempers of cold-rolled carbon steel strip. Stock of No. 1 (hard) temper is sometimes used for bending to large radii; each lot should be checked for suitability, unless furnished for specified end use by prior agreement. Hardnesses shown are for steel containing 0.25% C (max) in the three hardest tempers and 0.15% C (max) in the No. 4 and 5 tempers. Hardness for No. 1 temper applies to thicknesses of 1.8 mm (0.070 in.) and greater; for thinner sheet, hardness would be a minimum of 90 HRB.

Table 1 shows the effect of carbon content of some grades of carbon steel strip and sheet on bend radius in standard bend tests. Table 2 shows the effect of quality or temper on minimum bend radius of 1008 or 1010 steel sheet. Table 1 in the article "Press Forming of High-Carbon Steel" in this Volume shows the effect of composition on minimum bend radius by comparing the minimum radii for common grades of carbon and low-alloy steels.

Table 1 Bending limits for hot-rolled commercial-quality carbon steel strip and cold- or hot-rolled carbon steel sheet

If greater ductility is needed, drawing quality or physical quality steel can be used.

Carbon, %	**Bending limit**
0.15 or less	180° bend flat on itself, in any direction
0.15-0.25	180° bend around one thickness of the material, in any direction

Table 2 Minimum bend radii for 1008 or 1010 steel sheet

Quality or temper	Minimum bend radius, mm (in.)

	Parallel to rolling direction	Across rolling direction
Cold rolled		
Commercial	0.25 (0.01)	**0.25 (0.01)**
Drawing, rimmed	0.25 (0.01)	**0.25 (0.01)**
Drawing, killed	0.25 (0.01)	**0.25 (0.01)**
Enameling	0.25 (0.01)	**0.25 (0.01)**

Press Bending of Low-Carbon Steel

Minimum Bend Radius

Minimum bend radii are limited by angle of bend, length of bend, material properties, condition of the cut edge perpendicular to the bend line, and orientation of bend with respect to direction of rolling. Minimum bend radii are larger for a larger angle of bend.

Parts in which the length of the bend (direction parallel with the bend axis) exceeds eight times metal thickness have a fairly constant minimum bend radius. When the bend length is less than eight times metal thickness, the bend radius generally must be greater.

The temper of the metal affects the minimum bend radius (Fig. 1). Steel in the higher tempers (low hardness and high ductility) can be bent 180° to a sharp radius without cracks or tears. Bend radii can usually be smaller for bends made across the rolling direction than for bends made parallel to it. However, examples in this article demonstrate that sharp bends are often made parallel to the rolling direction.

Effect of Edge Condition. When bending low-carbon steel, the condition of the edge perpendicular to the bend axis has little effect on the minimum bend radius. Steels that are susceptible to work hardening or hardening by heating during gas or electric-arc cutting may crack during bending because of edge condition. For these steels, it is often necessary to remove burrs and hardened edge metal in the bend area to prevent fracture. Edges can be prepared for bending by grinding parallel with the surface of the sheet and removing sharp corners in the bend area by radiusing or chamfering.

If the burr side is on the inside of the bend, cracking is less likely to occur during bending. This is important on parts with small bend radii in comparison with the metal thickness and on parts with metal thickness greater than 1.6 mm ($\frac{1}{16}$ in.), because fractures are likely to start from stress-raising irregularities in the burr edge if it is on the outside of the bend.

Effect of Metal Thickness. Minimum bend radii are generally expressed in multiples or fractions of the thickness of the work metal. On parts that require a minimum flange width or a minimum width of flat on the flange, stock thickness will limit both of these dimensions. If thickness is not critical in the design, the use of thinner stock can make the bending of small radii and narrow flanges feasible.

Carbon Steels. Table 2 lists minimum bend radii for 1008 or 1010 hot- and cold-rolled steel sheet in each of the available qualities. Bend radii for higher-carbon steels and two low-alloy steels are given in Table 1 in the article "Press Forming of High-Carbon Steel" in this Volume.

As suggested by Table 2 in this article, the quality of steel has a major influence on the minimum bend radius that can be made in it. This is especially true of hot-rolled steel, for which, according to Table 2, a change from commercial quality to drawing quality reduces minimum bend radius by 33 to 50%. Low-carbon steels of commercial quality differ in bendability, as indicated in Table 3, which is for typical commercial-quality steels suitable for 90 and 180° bends.

Table 3 Suitability of commercial-quality low-carbon steel sheet for bending

Class and hardness of steel, and bending conditions	90° bends	180° bends

Cold-rolled steel up to 1.6 mm (0.062 in.) thick				
Suitable commercial-quality steels	1008 or 1010, rimmed, temper passed		**1008 or 1010, rimmed, annealed**	
Maximum HRB hardness	80[(a)]		**65**	
Minimum bend radius	1*t*		**0.25 mm (0.01 in.)**	
Hot-rolled steel up to 6.4 mm (0.250 in.) thick				
Suitable commercial-quality steels[(b)]	1008, 1010	Up to 1030	1008, 1010	**Up to 1015**
Maximum HRB hardness[(c)]	68	80	68	**72**
Minimum bend radius				
Sheet up to 2.3 mm (0.090 in.) thick	$\frac{3}{4}t$	$1\frac{1}{2}t$	1*t*	$\mathbf{1\frac{1}{2}}\boldsymbol{t}$
Sheet 2.3-6.4 mm (0.090-0.250 in.) thick	**1*t***	**2*t***	$\mathbf{1\frac{1}{2}}\boldsymbol{t}$	**2*t***

(a) For 90° bends made across the direction of rolling. The acceptable maximum hardness for 90° bends parallel with the direction of rolling is 70 HRB.

(b) Rimmed or capped.

(c) Can be met on hot-rolled unpickled steel or steel pickled in sheet form. Hardness values will be higher on mill-pickled hot-rolled coil. With higher hardness values, somewhat larger bend radii will sometimes be required.

High-strength low-alloy steels, because of their higher yield strength and lower ductility, are more difficult to bend than plain carbon steels--requiring more power, greater bend radii, more die clearance, and greater allowance for springback. It may be necessary to remove shear burrs and to smooth corners in the area of the bend. Whenever possible, the axis of the bend should be across the direction of rolling. If the bend axis must be parallel with the rolling direction, it may be necessary to use cross-rolled material, depending on the severity of the bend.

All high-strength low-alloy steels are not equal in formability; however, for the more readily formable grades and the quenched-and-tempered grades, the minimum bend radii in the following table are recommended:

Steel thickness (*t*), mm (in.)	Minimum bend radius for steel with minimum yield strength, MPa (ksi), of:

	310 (45)	345 (50)
Up to 1.6 ($\frac{1}{16}$)	$\frac{1}{2}t$	**1*t***
1.6-6.4 ($\frac{1}{16}$-$\frac{1}{4}$)	1*t*	**2*t***
6.4-13 ($\frac{1}{4}$-$\frac{1}{2}$)	**2*t***	**3*t***

These minimum bend radii are for bending with the bend axis across the rolling direction. The use of smaller bend radii increases the probability of cracking. Hot bending is recommended for thicknesses greater than 13 mm ($\frac{1}{2}$ in.).

Hot bending is necessary when the product shapes are too complex or when bend radii are too small for cold forming. The high-strength low-alloy steels can be successfully hot bent at temperatures as low as 650 °C (1200 °F); however, when maximum bendability is needed, temperatures of 845 to 900 °C (1550 to 1650 °F) are recommended. Cooling in still air from these temperatures returns the material nearly to the as-rolled mechanical properties.

Orientation of Bend

Ordinarily, it is better to orient a part on the stock so that bends are made across the rolling direction. Sharper bends can be made across than can be made parallel with the rolling direction, without increasing the probability of cracking the work metal (Fig. 1 and Table 2).

When bends are to be made in two or more directions, the piece can sometimes be oriented in the layout such that none of the bends is parallel with the rolling direction. In some applications, however, as in that described in the following example, there is no practical way to avoid making bends parallel with the rolling direction. This example demonstrates approximate limits for bending parallel with the rolling direction. A choice must be made in orientation to favor one or another consideration. For example, a blank can be oriented in a strip for economy and the least possible scrap. It can be oriented so that the grain direction will reinforce the metal that receives maximum stress in service. Alternatively, it can be oriented so there is no end-grain runout on a wear surface. In any of these cases, orientation may not be optimal for bending.

Example 1: Bending Parallel with Rolling Direction.

Conflicting demands called for a choice in the orientation of the blank for the can-opener blade shown in Fig. 2. Because an orientation that would favor the bends would have meant a cross-grain surface on the cutting edge, with consequent poor wearing quality, the blank was oriented so that the grain favored the cutting edge, and the bends were made nearly parallel with the direction of the rolling.

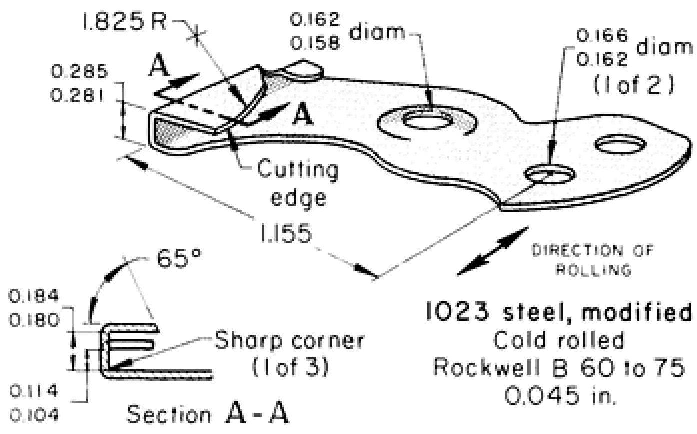

Fig. 2 Can-opener blade that was bent parallel with the direction of rolling in order to promote long service life of the cutting edge. Dimensions given in inches.

To ensure that the stock would withstand the three sharp-radius 90° bends, the steel specification called for stock that would withstand a 180° bend both parallel with and across the direction of the rolling. Steel that could be oil hardened was specified in order to limit distortion during subsequent heat treatment. A modified 1023 steel (with 0.85 to 1.15% Mn) met all of the requirements. The stock was 50 mm (2 in.) wide cold-rolled strip 1.1 mm (0.045 in.) thick. A No. 2 finish was specified to minimize the amount of polishing or burnishing before plating.

The blade was made in a 12-station progressive die, run in a 670 kN (75 tonf) mechanical press. Operations performed in the die included:

- Pierce four holes (one in the scrap area served as a pilot hole)
- Notch outline of part
- Coin cutting edge
- Emboss center hole
- Form bends
- Cut off

The die was made of D2 tool steel, except at station 12 (bending and cutoff), for which the die material was C-5 carbide at 71 HRC. The die life per grind was 300,000 pieces. Mineral oil was the lubricant.

The production rate was 4500 pieces per hour. Annual production was 8 million pieces, in 700,000-piece lots. After forming, the part was oil hardened, barrel finished in oil and sawdust, and bright nickel plated.

Orientation of bends with respect to the grain affects not only the severity of bend that can be made but also the service life of that bend. This is demonstrated in the following example.

Example 2: Bending Across the Rolling Direction.

Vibration of an internal combustion engine frequently caused failure of the fuel tank bracket shown in Fig. 3. The bracket broke at the upper bend, where a comparatively narrow tab attached the tank to the engine head. To eliminate premature failure at this bend, a reinforcing strip 2.8 mm (0.109 in.) thick was welded to the back of the upper bend at the narrowest section of stock, where the bracket overhung the engine head (Section A-A, Fig. 3). To reinforce the bracket and reduce vibration, the front leg, which was flattened back (bent 180°) was spot welded to the tank cradle in two spots (Section B-B, Fig. 3). The bend at the 19 mm ($\frac{3}{4}$ in.) wide tab, the 180° bend at the front, and the bend on the reinforcing strip were all made perpendicular to the rolling direction.

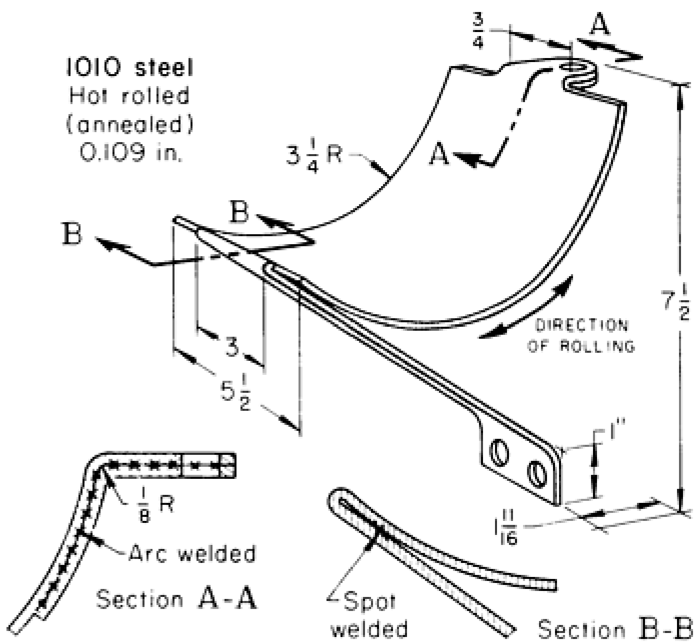

Fig. 3 Severely bent fuel tank bracket that was protected against fatigue failure by bending across the grain and by local reinforcement. Dimensions given in inches.

Because of offsets in the developed blanks, they could be nested slightly by reversing every other one in stock layout. The production procedure was as follows:

- Shear blank 267 × 451 mm ($10\frac{1}{2}$ × $17\frac{3}{4}$ in.)
- Blank and pierce two parts from sheared blank
- Form 83 mm ($3\frac{1}{4}$ in.) radius and 25 mm (1 in.) flange
- Bend 75 mm (3 in.) leg down 90°
- Flatten 75 mm (3 in.) leg
- Spot weld 75 mm (3 in.) leg
- Arc weld reinforcing strip

An 890 kN (100 tonf) single-action mechanical press was used for the second, third, and fourth operations listed above; the fifth operation was done in a press brake. Single-operation dies were used for all operations. Blanking tools were of D2 tool steel; bending tools were of O1 tool steel with a ground finish. Life of the tools before regrind was 50,000 pieces. Mineral oil was the lubricant. The production lots were about 2500 pieces, and annual production was approximately 10,000 pieces.

Die Construction

The same types of bending dies as those used in press brakes can generally be used in presses. However, there are major differences, as follows.

First, because presses ordinarily are not long and narrow like press brakes, more consideration must be given to clearance for removing the finished workpiece when the press is open, as well as clearance for the legs of the bend when the piece is being formed. The bed dimensions of a press also limit the size of workpiece that can be bent.

Second, presses cycle rapidly, and shut height is not as easy to change; therefore, fewer pieces are bent in air, as described in the article "Press-Brake Forming" in this Volume. More frequently, pieces are formed by bottoming the dies. This has the advantage of decreasing springback.

Lastly, presses are usually used for workpieces less than 610 mm (2 ft) long, and press brakes for pieces longer than 610 mm (2 ft). However, the automotive industry bends very large sheet metal structural members on large presses by mass-production methods.

V-dies are composed of a V-block for a die and a wedge-shaped punch (Fig. 4a). The width of the opening in the V is ordinarily at least eight times the stock thickness. In bending, the workpiece is laid over the V in the die, and the punch descends to press the workpiece into the V to form the bend.

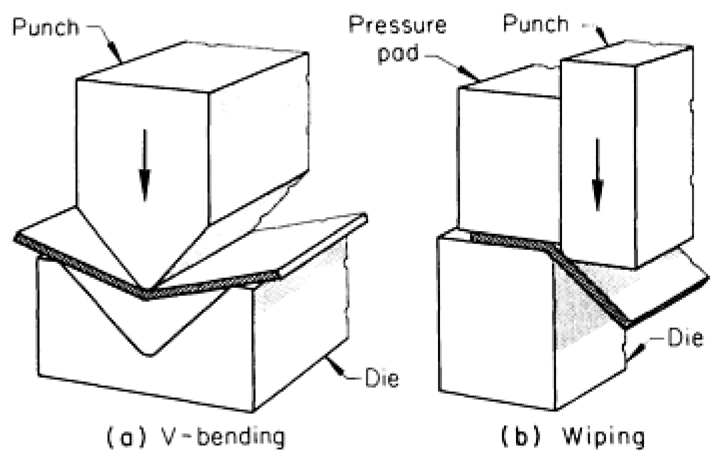

Fig. 4 Bending in a V-die (a) and a wiping die (b). The wiping die can be of inverted design. The workpiece would move downward by the action of the punch against the pressure pad, and the flange would bend upward.

The included angle of a V-bend can be changed by adjusting the distance that the punch forces the sheet metal into the V-die. When the piece must be overbent (to allow for springback), the angle of the punch is smaller than the included angle on the part. Bottoming the punch and striking the metal severely at the bend is a means of reducing springback.

In V-die bending of a flange along the edge of a wide sheet, distortion is likely to occur. Most of the sheet overhangs the die and lifts up as bending takes place. If the punch strikes too fast, the workpiece will distort and will have irregular break lines. However, if the press ram is slowed down just before the punch hits the work, distortion is minimized.

For this type of V-die work, presses are available in which the ram advances rapidly, slows down just above the work, proceeds slowly through the bottom of the stroke, and returns rapidly. In addition, there are presses in which the rate of ram advance can be controlled somewhat by the operator.

Wiping Dies. Another type of bending die is the wiping die (Fig. 4b). A pressure pad that is either spring loaded or attached to a fluid cylinder clamps the workpiece to the die before the punch makes contact. The punch descends and wipes one side of the workpiece over the edge of the die. The bend radius is on the edge of the die. To prevent the wiping action from being too severe, there may be a radius or chamfer on the mating face of the punch. When springback must be compensated for, the die is undercut to permit overbending. The flange metal can be put in slight tension by ironing it between the punch and the die. Sharp bends generally cannot be made in one operation in a wiping die without cracking the metal, because a punch or die with a sharp edge will cut the metal rather than bend it.

Interchangeable V-Dies. Figure 5 shows equipment for making various sizes of V-bends in a punch press. Four different sizes of punches can be mounted into the punch holder, which is attached to the press slide. In operation, the groove in the die that gives the needed bend is aligned with the punch, and the die is then fastened to the bolster plate on the press bed. Adjustable side and end stops can be used to position the blanks for bending.

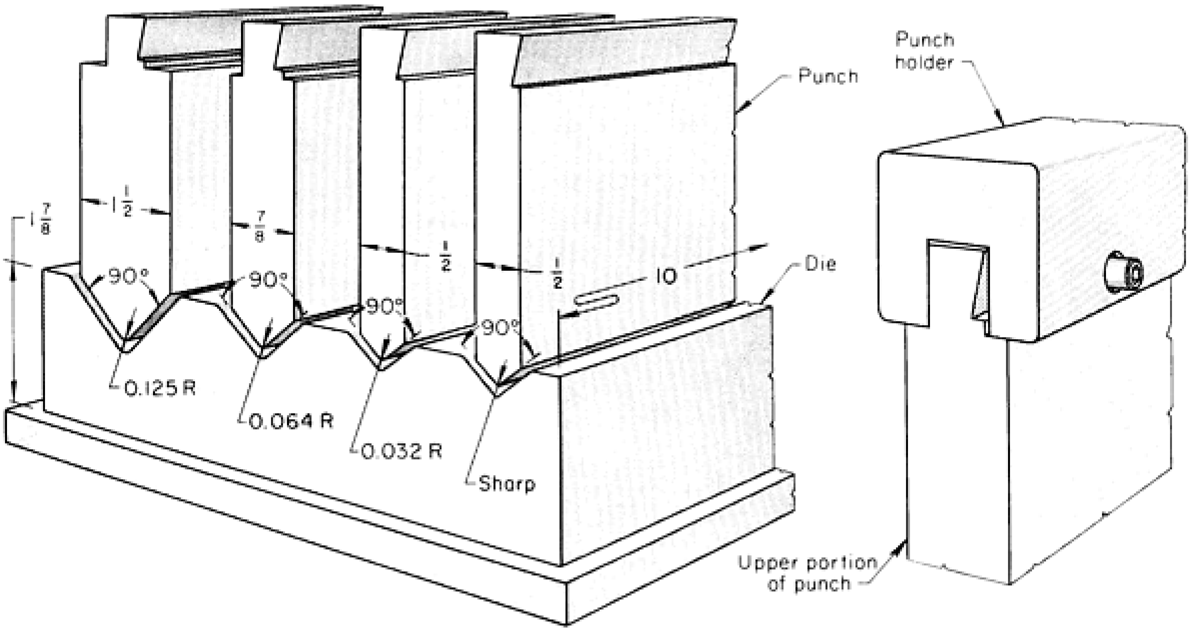

Fig. 5 V-bending punch and die for making a variety of bends in a punch press. Dimensions given in inches.

With equipment such as that illustrated in Fig. 5, rectangular boxes in a range of shapes and sizes are often produced more economically by bending flat blanks into folded-end shapes than by deep drawing. Making folded-end pans by bending in adjustable wing dies and cam dies with interchangeable punches is described in the article "Press Forming of Coated Steel" in this Volume.

U-Bending Dies. U-shaped pieces can be bent in a die such as the one shown in Fig. 6. The width of the U is adjustable by means of spacers and by changing the width of the knockout. Punches can be mounted in the press with a holder similar to that shown in Fig. 5 and can be provided to the proper width and shape to make either a U or a channel shape. Side clearance should be 10% more than stock thickness.

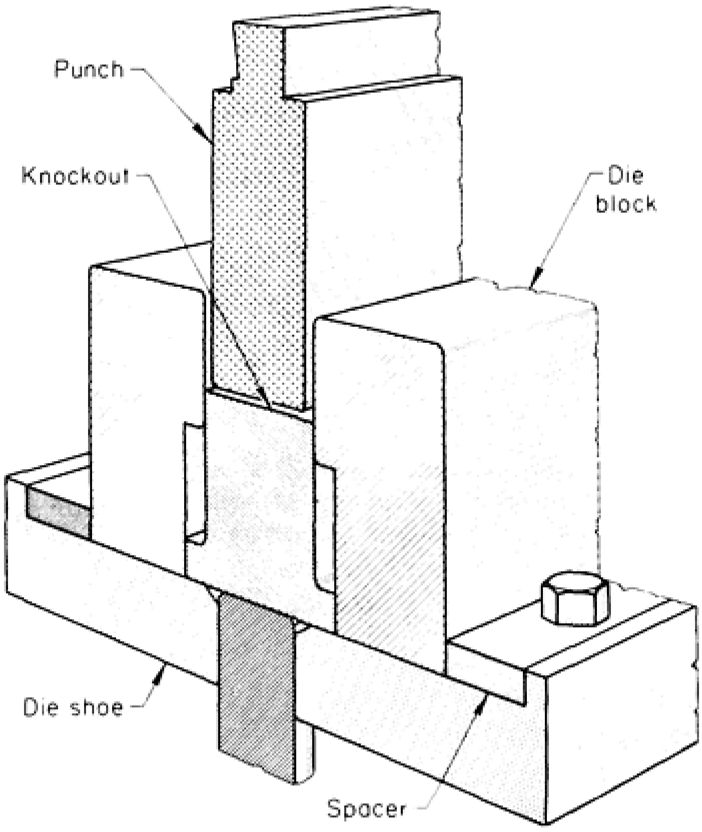

Fig. 6 Adjustable U-bending die for use in a punch press.

Rotary-bending dies (Fig. 7) are used to make bends or twists in bars or strip. These dies use cam action to rotate the workpiece.

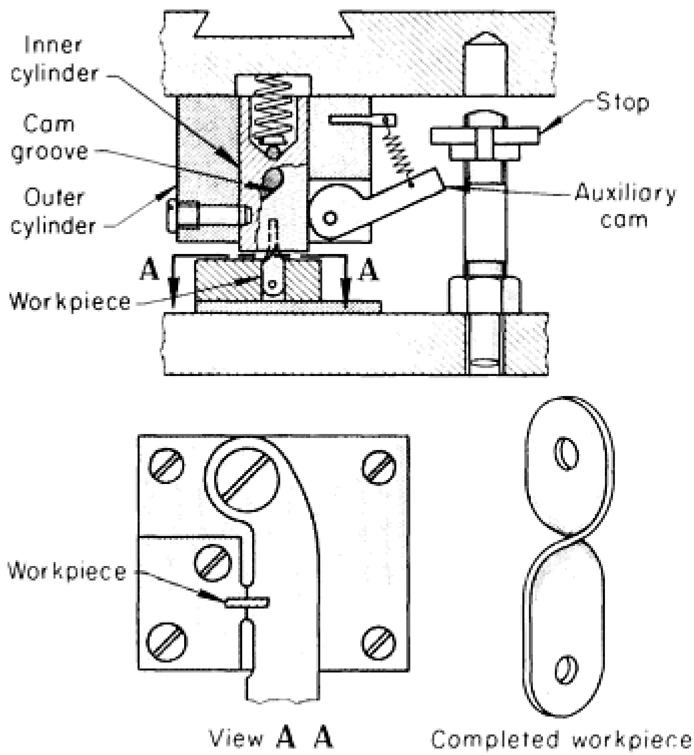

Fig. 7 Rotary-bending die used for 90° twisting of strip metal. Die is shown in closed position; inner cylinder has rotated to give workpiece a 90° twist. The auxiliary cam prevents rotation of the inner cylinder until it is free of workpiece.

As shown in Fig. 7, a 90° twist is given to strip metal to make a connecting link. The punch is made in two major parts: a hollow cylinder that is solidly mounted to the ram, and inside it a solid cylinder that is free to rotate. The inner cylinder has a 90° helical cam groove in its cylindrical surface that engages a hardened pin in the outer cylinder.

When the ram descends, a slot in the face of the inner cylinder engages the end of the workpiece. After the inner cylinder bottoms, as the ram continues to move down, the spring compresses, letting the outer cylinder move down over the inner cylinder. The action of the pin in the groove makes the inner cylinder rotate, giving the workpiece a 90° twist.

An auxiliary cam keeps the inner cylinder from rotating back in the return stroke, until it has cleared the workpiece. Near the top of the stroke, the auxiliary cam is released by a stop, allowing the inner cylinder to return to its starting position.

Cam-Actuated Flanging Dies. Horizontal motion is often needed to form, or partially form, a flange on a workpiece. One of the most commonly used methods of producing this motion at right angles to the motion of the main press ram is with an inclined surface, or cam, in the die mechanism.

As shown in Fig. 8, a blankholder contacts the work first and holds it in position. Resiliency, either in the form of pressure pins leading to a die cushion or in the form of a spring, allows the ram to continue to descend. A cam actuates the sliding punch, which either forms or completes the forming of the flange and is then retracted. The blank is placed on the pressure pad, where it is held by punch A and wiped past the cam-actuated sliding punch to form the flange. Near the bottom of the stroke, punch B contacts the cam head, which moves the sliding punch to set the flange to the 10.3 mm (0.406 in.) dimension and a 90° angle. Cam-actuated sliding punches on each side of the forming punch can be used for setting flanges on channel and U-shape parts.

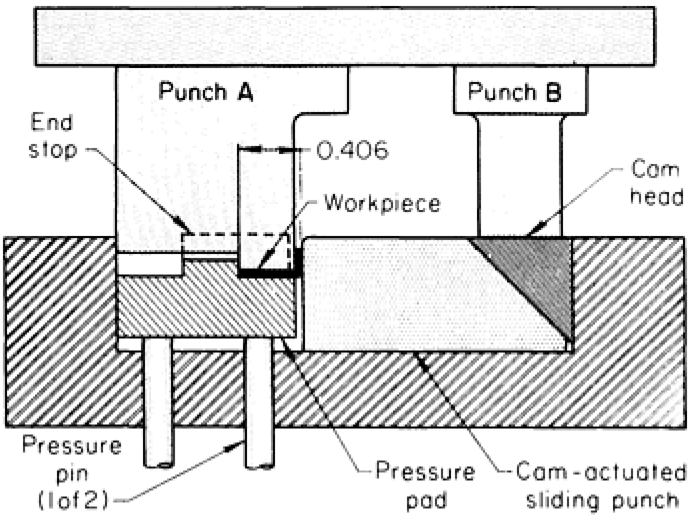

Fig. 8 Cam-actuated single flanging die used for producing a multiflanged part. See text for description of operation. Dimensions given in inches.

Cam-actuated dies are often used in combination with other tooling to produce complicated parts. When used in tandem with a progressive die, a cam-actuated die can significantly reduce the number of operations needed to produce a part. A drawer front that originally required nine separate operations (two shearing, two notching, one piercing, one box-forming, and three flanging) when using a press brake was produced in only four separate operations (slitting coil to width; notching, piercing, and cutting off in a progressive die; box-forming in a second die; and flanging the sides, top, and bottom in a cam-actuated flanging die) with the incorporation of a cam-actuated die.

Compound Flanging and Hemming Die. The compound flanging and hemming die shown in Fig. 9 is unusual in having no horizontal motion of punches or dies. There are two cushions: a spring-loaded hold-down plate and an air cushion for the die plate. As the ram descends, the hold-down makes first contact, clamping the piece securely to the die. As the ram continues to descend, the springs compress, and the angled flange is formed between the angled face of the bending punch and the die plate.

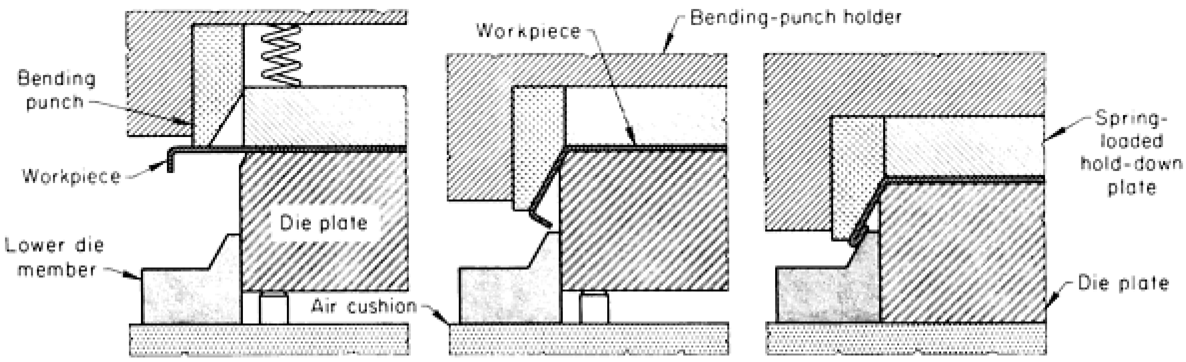

Fig. 9 Compound flanging and hemming die without horizontal motion.

The angle of the bend is set and slightly coined between the chamfer on the edge of the die plate and the angled face of the punch. At this point, the hold-down plate bottoms against the bending-punch holder, then the air cushion begins to yield, lowering the die plate. The edge of the workpiece bumps the corner of the lower die member and folds up into a hem that is completed between the angled face of the bending punch and the mating face of the lower die member.

Wing Dies. Special dies for making U-shape bends have wings that turn up on each side as the punch descends. These dies are described in the article "Bending and Forming of Tubing" in this Volume.

Die Materials. Simple bending dies are ordinarily subjected to less shock than other press-working tools; therefore, they can often be made of low-carbon steel, heat-treated low-alloy steel such as 4140, or cast iron for low production of low-carbon steel pieces. For moderately high production, they should be made of flame-hardening grades of carbon steel, such as 1045, or flame-hardening cast iron, such as class 40 gray iron. Cam-operated dies, wiping dies, and dies used to make curved flanges (shrink or stretch) must be made of a higher grade of material. Tool steels such as O1 or A2 are used for moderately long production runs. For a total tool life of 1 million or more pieces, D2 tool steel is used.

Single-Operation Dies

Single-operation dies are used for low production or on pieces that are so difficult to bend that only one operation at a time is feasible. Some single-operation dies are general-purpose dies that can make bends in simple workpieces of many different designs. Others are single-purpose dies for a particular piece.

Use of Compound Dies

In a compound die, two or more operations are combined at a single work station without relocating the workpiece in the die, so that a finished piece is produced with each stroke of the press. One or more of the operations done in the die can be bending. The press speed (strokes per minute) for compound dies is generally only slightly lower than for single-operation dies; therefore, production time and labor cost per piece are decreased almost in proportion to the number of operations done in the compound die.

In most applications, the cost of a compound die does not differ greatly from the combined cost for equivalent separate dies, and is sometimes less. Operations must be judiciously combined in making a compound die in order not to have die sections that are too thin to be heat treated without distortion, or that will break down under the cyclic loading of ordinary die operation. If these precautions are observed, die life and die maintenance costs should be nearly the same as the costs for equivalent simple dies. Compound dies can be fed individual blanks, or they can be fed strip stock, as in the following example.

Example 3: Use of a Compound Die for Production of Blower Blades from Strip Stock.

Blower blades, shaped as shown in Fig. 10, were cut off from strip stock and bent in a compound die in a 530 kN (60 tonf) mechanical press. The blades were made of 0.76 mm (0.030 in.) thick cold-rolled commercial-quality 1008 or 1010 steel, either plain or galvanized. Some aluminum blades were also made in the same die.

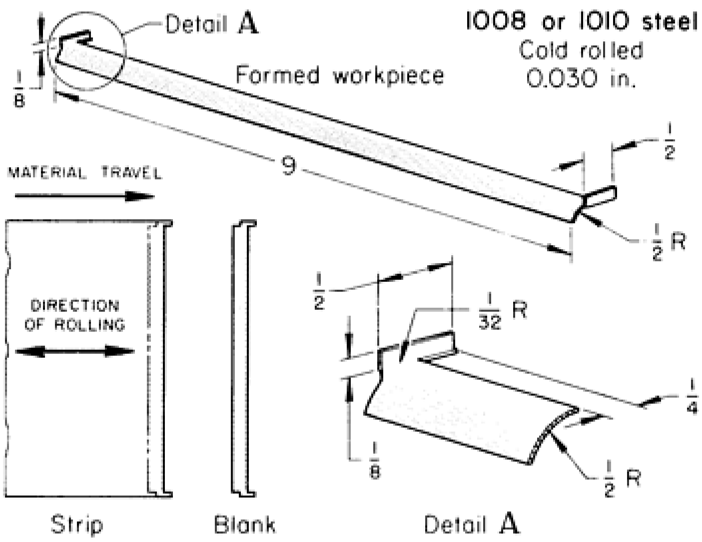

Fig. 10 Blower blade that was blanked and formed from strip stock in a compound die. Dimensions given in inches.

As shown in Fig. 10, the leading edge of one blade was made with the same cut as the trailing edge of the next. The bend axis of the flanges was parallel with the rolling direction of the metal, and the curvature on the surface of the blade behind the flanges was formed across the rolling direction.

The die material was W2 or A5 tool steel. For both materials, die life between regrinds was 1 million pieces. A 1:5 mixture of soluble oil and water was used as a lubricant because a wiping action was used in bending the flanges. The production rate was 1600 pieces per hour, and the annual production was 150,000 pieces. The flanges at the ends of each blade were used for attaching the blades at assembly.

Use of Progressive Dies

Progressive dies are similar in function to compound dies in that they combine in one die set several operations that are performed with one stroke of the press. In a progressive die, however, the operations are separated and distributed among a number of stations. The stock progresses through these stations in the strip form until the finished workpiece is cut from the strip at the last station. Consequently, at the start of a strip, there are several press strokes before a piece is produced. Thereafter, a finished workpiece is produced with each stroke of the press, up to the end of the strip.

If the strips are short, sheared from sheets, they can be fed into the die so that each strip is butted against the end of the preceding strip for continuous production. Otherwise, starting stops are used for each new strip.

Coil stock is fed into the die at one end. A hole or notch is usually made in the strip at the first station, and subsequent stations use this as a pilot to keep the strip properly aligned and positioned while the operations are performed. When the workpiece is complete, it is cut from the strip, which has acted as a holder to carry the piece from station to station. Intricate pieces, often needing no further work, can be made in one press.

In planning the strip layout for progressive-die operations, consideration must be given to development of the part outline, to provision for piloting, to distribution of press load and strength of die elements, and to ensuring minimum metal waste. Some compromise among these factors is usually necessary in developing a sequence of operations and designing a progressive die to accomplish these operations. The strip layout in the following example used the metal efficiently by having the developed flanges surround the body of the preceding part.

Example 4: Nesting of Workpieces to Minimize Stock Waste.

The bracket shown in the lower part of Fig. 11 was formed from hot-rolled 1010 steel strip in a progressive die with three working and two idle stations. As shown in the upper part of Fig. 11, pieces were nested on the strip to minimize scrap. The operations in the three working stations were as follows: pierce one pilot hole and two flange holes and notch the contour, bend two tabs upward, and flange and cut off from the center connecting tab.

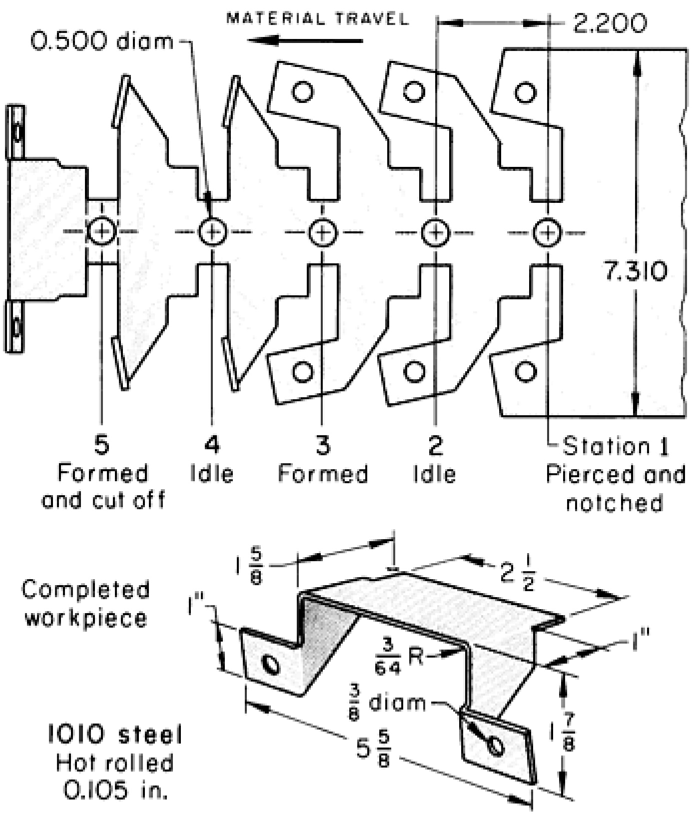

Fig. 11 Layout for progressive-die production of a bracket, with blanks nested to save stock. Dimensions given in inches.

The die was used in a 1330 kN (150 tonf) mechanical press that could make 50 strokes per minute. Allowing for setup and downtime, production was 2800 pieces per hour. A light mineral oil was the lubricant.

The die was made of W1 tool steel hardened to 58 and 60 HRC. The punch-to-die clearance for cutting elements was 6% of stock thickness per side. Annual production was 100,000 brackets.

Press Bending of Low-Carbon Steel

Use of Progressive Dies Versus Separate Dies

The choice between a progressive die and two or more separate dies (single-operation or compound) is not always clear-cut. Various considerations can influence the decision; perhaps the most important is the size of the production order. Other considerations are the rate of obsolescence of the product and the rate at which tool cost must be amortized.

The following example shows how these considerations can affect choice of type of die. In this example, increased annual production requirements justified the use of a progressive die.

Example 5: Change from Three Separate Dies to a Progressive Die.

The part shown in Fig. 12(b) was produced from 1.6 mm (0.062 in.) thick cold-rolled 1010 steel that had a hardness of 58 HRB maximum. A progressive die, which made a finished part at each press stroke, replaced three dies in which 12 press strokes were required for producing one piece. The separate dies were a standard piercing and notching die, an embossing die, and a conventional V-die. Setup time for each die was 30 min.

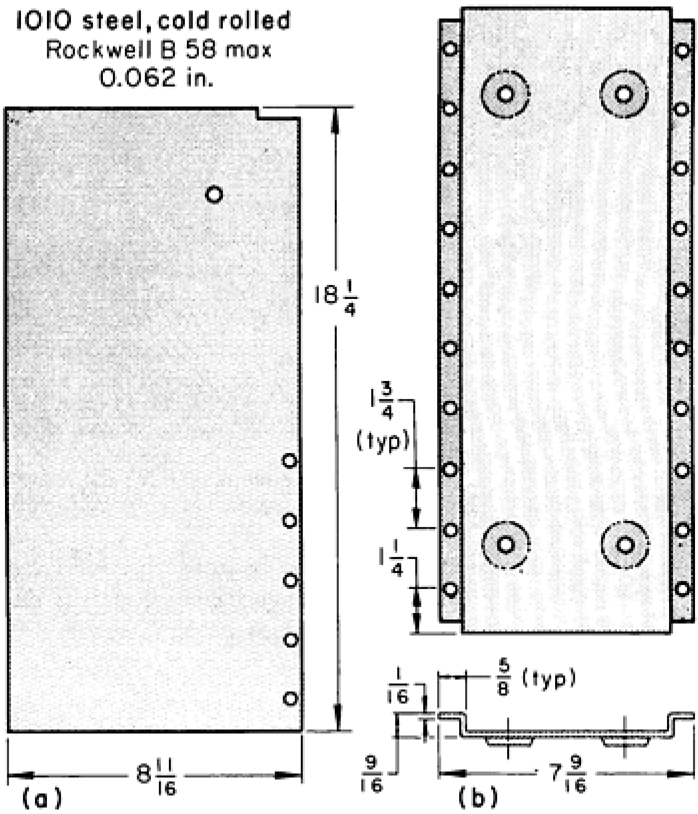

Fig. 12 Strut that was produced in fewer press strokes with a progressive die than with standard press-brake tooling. (a) Blank after first stroke with standard tooling. (b) Finished part. Dimensions given in inches.

The cost of the progressive die was justified for the annual production of 60,000 parts (break-even point was 34,000 parts). Both methods made parts that were within the maximum dimensional tolerance of ±0.4 mm (± $\frac{1}{64}$ in.), and to the maximum bend radius of 0.8 mm ($\frac{1}{32}$ in.).

The original dies had been used in an 890 kN (100 tonf) press brake that operated at 600 strokes per hour on sheared blanks 220 mm ($8\frac{11}{16}$ in.) wide by 464 mm ($18\frac{1}{4}$ in.) long. The press-brake operation consisted of piercing five holes in the flange and one in the center and notching one corner (Fig. 12a). The other holes and the three other corner notches were produced with three more strokes, with the workpiece being turned after each stroke. Four more strokes were needed for embossing four holes (Fig. 12b). Bending required four strokes, bringing the total to 12 strokes.

The progressive die, made of O1 tool steel, pierced, embossed, notched, and cut off the strut from 220 mm ($8\frac{11}{16}$ in.) wide coil stock at a rate of 225 per hour. The die was set up in a 2700 kN (300 tonf) mechanical press. Mineral oil was used as the lubricant for both methods.

Transfer Dies

Transfer dies are similar in operation to progressive dies. The important difference is in the method of transferring workpieces from station to station. The workpieces remain fastened to the stock strip in a progressive die, but they are separate in a transfer die and are transferred from station to station within the die between press strokes by mechanical fingers, levers, or cams. Transfer dies are particularly suited to the fabrication of parts that would be difficult to connect to the stock skeleton with carrier tabs. Bends that cannot be made in a single step are often made in several stages in transfer dies, and bending is often combined with cutting or other forming operations in transfer dies.

The advantages of transfer dies for bending include high production rate, greater versatility than progressive dies, and more efficient use of stock. The last advantage is ordinarily achieved by blanking in a separate press, which permits close nesting of parts. The disadvantages include high equipment cost (for dies, press attachments, and feeding devices), high setup and tool maintenance cost, difficulty in handling thin work metal, and poor applicability to large or oddly shaped parts that need variations in blankholder pressure and contour.

Transfer dies are well suited to the bending of small rings, cups, and cylinders. Transfer dies are used to make rings with one joint.

Lubrication

Lubrication is less important for most bending operations than for other types of forming. In many bending operations, no lubricant is used; in others, the mill oil remaining on the stock or a light mineral oil applied before forming is sufficient to prevent galling.

Exceptions to this practice are hole flanging, compression and stretch flanging, an severe bending in which wiping, ironing, or drawing of the work metal may call for more effective lubrication. More information on lubrication, including recommendations, is available in the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume.

Three examples in this article describe applications in which lubricants were used because of the nature of the bending operations performed. In Example 1, in which accuracy was important and sharp-radius bends were made parallel with the direction of rolling, the workpiece was lubricated with mineral oil before bending. In Example 2, mineral oil was applied to the workpiece before flattening a bend to 180°. In Example 3, a soluble oil-water mixture was used with a compound die that had a wiping component.

Bending Cylindrical Parts

Generally, as the bend radius becomes larger, the allowance for springback must be more generous because less of the bent metal has been stressed beyond its yield strength. Very large radii cannot be easily formed by ordinary bending, but must be stretch formed (see the article "Stretch Forming" in this Volume). For large-radius bends, in which the workpiece is formed to half a circle or more, the bend is often made in several stages, as in the following example.

Example 6: Bending a Cylindrical Part in a Progressive Die.

The part shown in Fig. 13 was made in a six-station progressive die from 1.2 mm (0.048 in.) thick cold-rolled 1010 or 1020 steel having a hardness of 65 to 75 HRB. The part was a valve used to adjust the size of the air intake in a gas burner.

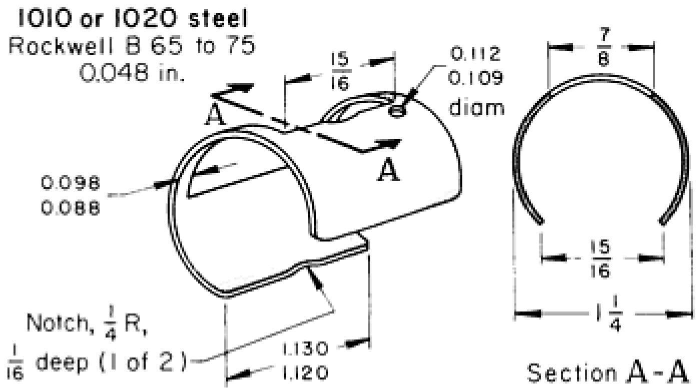

Fig. 13 Air-intake valve that was bent to circular form in three stages in a six-station progressive die. Dimensions given in inches.

The operations for making the part included piercing the 2.84/2.77 mm (0.112/0.109 in.) diam hole, blanking the rectangular cutout, notching the outside of the blank (leaving a 13 mm, or $\frac{1}{2}$ in., wide center carrier tab), bending the circle in three steps starting at the outside edge, and cutoff. The 2.84/2.77 mm (0.112/0.109 in.) diam hole was tapped with 6-32 UNC threads in an automatic tapper at 12 pieces per minute. The two 1.6 mm ($\frac{1}{16}$ in.) deep circular notches were to ensure that the air intake could not be closed completely.

The cutting and forming elements of the die were made of O1 tool steel hardened to 58 to 60 HRC. Die life was 80,000 pieces per regrind. The die was run in a 400 kN (45 tonf) press at the rate of 40 pieces per minute to produce lots averaging 10,000 pieces. The part later was zinc plated and bright dipped.

Edge Bending

Edge bending is the bending of parts with the bend radius perpendicular to the width rather than to the thickness, as is usually done. It is sometimes possible to save material by producing fairly large blanks in simple rectangular form (square-sheared) and then edge bending them into shape. Finish blanking (trimming) is frequently done after edge bending.

Before edge bending can be selected in preference to blanking from sheet, it is necessary to consider the effect of cold work from the bending operation on subsequent forming. High breakage during edge bending can eliminate the cost advantage of the savings in material. Another consideration is the higher cost of labor and tooling for edge bending, which can also offset the savings in material. The following example describes edge bending that was done to save material and to strengthen the part.

Example 7: Edge Bending.

Figure 14 shows a curved-end automotive foot-pedal lever that was produced by edge bending a blank sheared from a bar of hot-rolled 1010 steel. The bar, 6.4 mm ($\frac{1}{4}$ in.) thick, 60 mm ($2\frac{3}{8}$ in.) wide, and 368 mm ($14\frac{1}{2}$ in.) long, was sheared lengthwise to produce two blanks 41 mm ($1\frac{5}{8}$ in.) wide at one end and 19 mm ($\frac{3}{4}$ in.) wide at the other. Edge bending resulted in substantial material savings over blanking and also a stronger part.

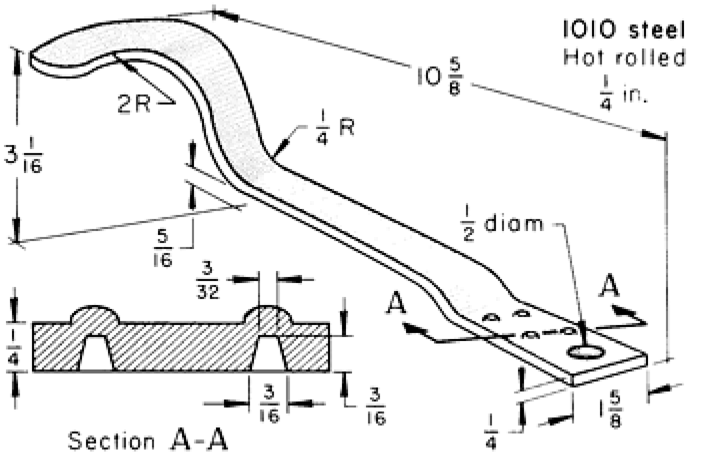

Fig. 14 Pedal lever that was edge bent to save metal and to increase the strength of the part. Dimensions given in inches.

Each blank was edge bent to a 50 mm (2 in.) radius at the narrow end. Other operations included bending the offset and making the two other bends, piercing the 13 mm ($\frac{1}{2}$ in.) diam hole, extruding four weld projections (section A-A, Fig. 14), and trimming the radius on the small end. The cutting and forming sections of the dies were made of air-hardened tool steel.

The stock was cut to length in an 1100 kN (120 tonf) end-wheel press (mainshaft extending front-to-back) operating at 60 strokes per minute. Edge bending, forming, trimming, and piercing were done by separate dies in a 1700 kN (190 tonf) open-back inclinable press at 30 pieces per minute.

Limitations. The size of the offset radii, the length and depth of the offset, and the location of the offset with respect to the flanges may preclude the edge bending of a rectangular blank. The potential cracking and thinning of the outer edge and the wrinkling of the inner edge make the use of a blanked shape more practical.

Press Bending of Low-Carbon Steel

Straight Flanging

Flange bending (flanging) in a wiping die is similar to the cantilever loading of a beam. To prevent movement during bending, the workpiece is clamped to the die by a pressure pad before the punch contacts the workpiece. The bend axis is parallel with the edge of the die.

Flanging dies are often cam actuated, with an accompanying loss of efficiency. Hold-down pads must be used, adding further to the press capacity requirement. Considering all factors, the press capacity for flanging in a wiping die may be up to ten times that for forming a similar length of bend in a V-die with a spacing of at least eight times the thickness of the work metal.

In some operations, only single flanges are bent. More often, more than one flange is bent at a time, as in Examples 3, 9, 12, and 13. Dies can be simple V-dies, U-dies, wiping dies, or complex flanging dies such as shown in Fig. 8.

Even when fairly close tolerances must be held, simple V-dies can be used to make a complex part if production is low. Flanging dies are more expensive than ordinary press-brake dies, but considering the time and labor saved in making simple flanged pieces in flanging dies, they often pay for themselves quickly.

Hemming is an operation in which flanges are flattened against the workpiece in 180° bends to make a finished or reinforced edge. If the flange to be hemmed has been bent somewhat more than 90°, the hemming die can be a simple flat bed or anvil and a simple flat punch. Flanging and hemming can both be done in one press in a compound die, as shown in Fig. 9.

Press Bending of Low-Carbon Steel

Bending of Curved Flanges

When a flange has concave curvature, the metal in the flange is in tension, and the flange is called a stretch flange (Fig. 15a). When the curvature is convex, the metal in the flange is in compression, and the flange is called a shrink flange (Fig. 15b). The amount of tension or compression in either type of flange increases from the bend radius to the edge of the flange. Excessive tension in a concave (stretch) flange causes cracks and tears; excessive compression in the convex (shrink) flange causes wrinkles.

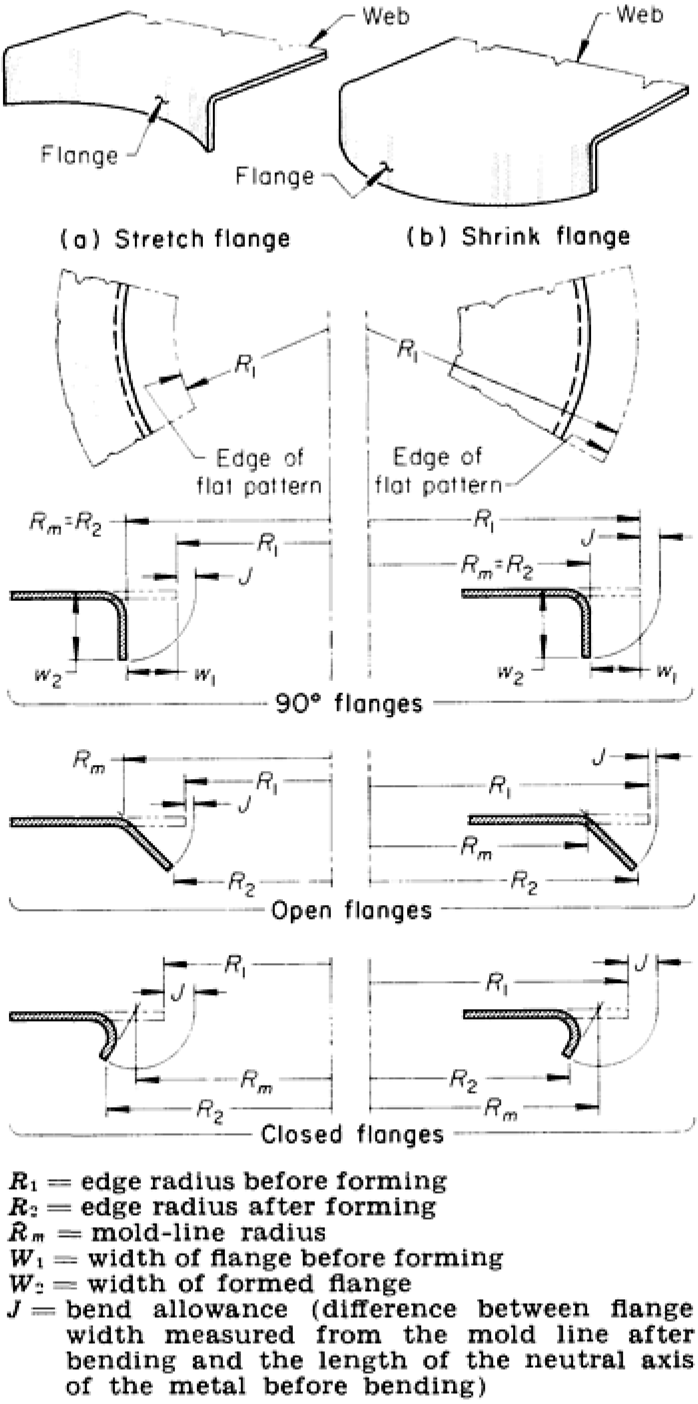

Fig. 15 Dimensional relationships for three types of stretch and shrink flanges.

Stretch and shrink flanges are commonly formed adjacent to each other, producing a reverse flange (as shown in Fig. 17, Example 9). Bend allowances for use in developing a flat blank are given in the article "Press-Brake Forming" in this Volume.

Flanging Limits. Flange radii, flange width, and angle of bend for curved flanges are primarily limited by the amount of deformation that can be tolerated by the flange edges--which depends on the type, thickness, and hardness of the metal and the method of forming. Greater fineness of detail can be achieved in conventional dies than by rubber-pad forming, because of the limited pressures in rubber-pad forming. However, rubber pads provide a uniform pressure over the entire surface of the workpiece, and they can be used to advantage where conventional dies would shear or tear the material.

The approximate percentage of deformation of the free edge is equal to 100 [(R_2/R_1) - 1], where R_1 is the edge radius before forming (flat-pattern radius) and R_2 is the edge radius after forming, as shown in Fig. 15. For 90° flanges, R_2 is the same as R_m. Positive values of percentage of deformation indicate elongation (stretch); negative values indicate compression (shrink).

The permissible limits for the conventional die forming of curved flanges in three common steels 1.0 mm (0.040 in.) thick or more, are as follows:

Steel	**Stretch, %**	Shrink, %
1010	38	**10**
1020	22	**10**
8630	**17**	**8**

These limits should be reduced slightly for thin stock, particularly for shrink flanges. The limits for stretch flanges can be increased if there is an adjoining shrink flange. The compression in the shrink flange helps to relieve the stress in the stretch flange (and vice versa). In addition, the limits of permissible stretch may be increased by filing or grinding the edges of the blank lengthwise; flanges having a calculated stretch of about 100% can be formed by this procedure, as in Example 9. Shrink flanges are more easily formed if the motion of the die causes some ironing of the metal in the direction of the edge of the flange.

Severe Contour Flanging. In small pieces, when enough press force is available, shrink flanges can be formed with sufficient metal flow that the flanges resemble drawn shapes, without using bend reliefs. Such severe flanging is shown in the following example.

Example 8: Severe Contour Flanging of Thick Stock.

The hinge half shown in Fig. 16 was formed in one stroke of an 8000 kN (900 tonf) press. By close control of clearances, it was possible to produce the contour, the sharp inside corner on the bend of the flange, and close matching of the outside planes of the flanges and the edges of the part. The metal was drawing-quality hot-rolled 1010 steel 6.07 mm (0.239 in.) thick.

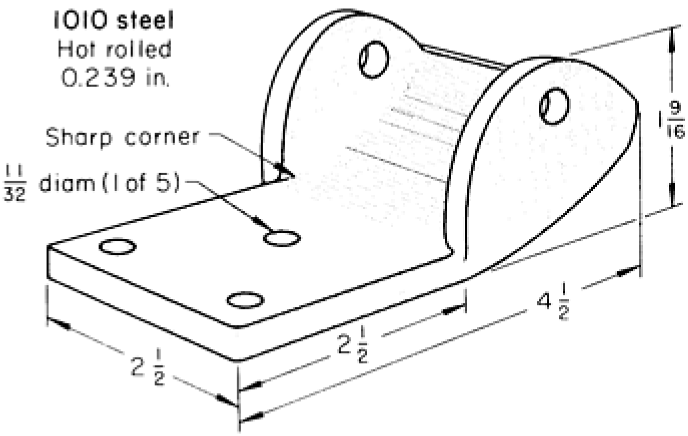

Fig. 16 Hinge half on which flanges were formed flush with adjacent surfaces. Dimensions given in inches.

A slight puckering of the metal at the corners between the flanges and the back indicated the severity of the forming. Relief cutouts were not used in this piece, but because of the severity of the forming, the five holes were pierced after forming to hold the location of the two in-line holes in the flanges within ±0.25 mm (±0.010 in.) of the three other holes. This practice is quite different from that described in Example 12, in which holes were pierced before the part was flanged and yet hole locations were held within ±0.25 mm (±0.010 in.).

The forming die was made of W1 tool steel and was hardened to 58 to 60 HRC. The die was reconditioned after each production lot of 20,000 to 25,000 pieces. The production rate was 600 hinge halves per hour.

Edge Grinding. If they are rough, the edges of stretch flanges may crack or tear at critical points. In the following example, a severe bend was made in a difficult-to-form flange, without cracking, after the rough edges had been ground to smooth the surface.

Example 9: Use of an Edge-Ground Blank to Minimize Cracking of a Severe Stretch Flange.

The crossmember of a truck chassis was made from hot-rolled low-carbon steel that had been pickled and oiled. It was bent from a developed blank into the channel shape shown in Fig. 17. In bending the blank, the edges of the stretch flanges cracked and tore. This problem was solved by filing the edges smooth in the portion of the blank where the stretch and shrink flanges would be formed. Bends were made parallel to the rolling direction.

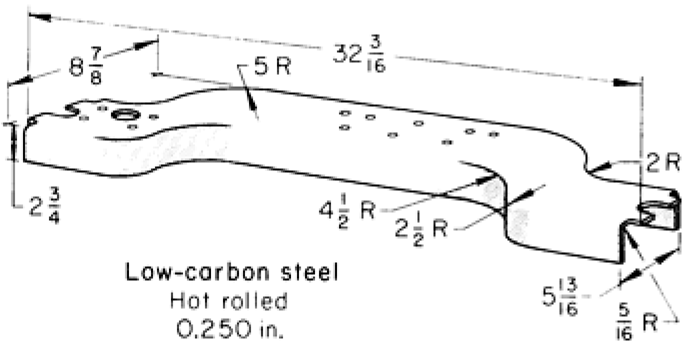

Fig. 17 Truck-frame cross member that was bent from edge-ground blanks to prevent cracking and tearing of the stretch flanges. Over the length of the two stretch flanges, the 7.9 mm ($\frac{5}{16}$ in.) inside bend radius was increased, varying to a maximum of 25 mm (1 in.). Dimensions given in inches.

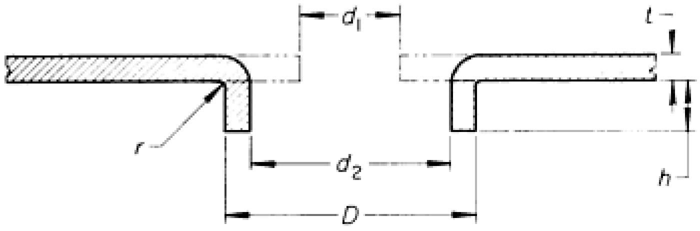
Because hand filing of the rough edges was costly, grinding was tried, with good results so long as the direction of grinding was along the edge rather than across it. Cross grinding left grooves that increased stress to the same degree as did the original roughness.

Forming was done in a 3800 kN (425 tonf) hydraulic press. The die was a single-action pressure-pad type made of tool steel and had an estimated life of 300,000 pieces. The production rate was two or three channels per minute, in 800-piece production lots.

Hole Flanging. A flange formed around a pierced hole is a continuous stretch flange. One manufacturer has standardized flange dimensions for holes to be tapped in low-carbon steel. These dimensions, as related to workmetal thickness, are shown in Fig. 18.



$D = d_2 + 5t/4$ when t is 0.045 in. or less
$D = d_2 + t$ when t is greater than 0.045 in.
$h = t$ when t is less than 0.035 in.
$h = 4t/5$ when t is 0.035 to 0.050 in.
$h = 3t/5$ when t is greater than 0.050 in.
$r = t/4$ when t is 0.045 in. or less
$r = t/3$ when t is greater than 0.045 in.

$$d_1 = \sqrt{\frac{tD^2 + 4td_2^2 + 4hd_2^2 - 4hD^2}{9t}}$$

Fig. 18 Dimensions of flanged holes to be tapped, as a function of thickness, for low-carbon steel.

In thick stock, the length of the flange around a hole can be greater than that shown in Fig. 18, but the flange thickness will taper rather than be relatively uniform.

Control of Springback

Springback has little effect in the bending of low-carbon steel. It is considered only when close dimensional control is needed. Springback ordinarily ranges from $\frac{1}{2}$ to $1\frac{1}{2}$° and can be controlled by overbending or by restriking the bend area. Factors that affect springback include ratio of bend radius to stock thickness, angle of bend (degrees of bend from flat), method of bending (V-bending or wiping), and amount of compression in the bend zone.

When the bend radius is several times the stock thickness, the metal will need more overbending to stress it beyond the yield point than when the radius is 2*t* or less. A greater amount of overbending is needed to correct for springback on small bend angles than on large bend angles.

In curved flanges, the radius of curvature and the flange length have an effect on the tension or compression in the flange metal, which in turn affects springback. Springback can vary in a production run of a given part because of variation in stock thickness, variation in stock hardness or temper, tool wear, variation in tool adjustment, and variation in power input (line surges).

Multiple Bends. When more than one bend is made in a part, the effect of springback is ordinarily cumulative and may necessitate closer control of the operation than would be needed for just one bend. The following example demonstrates the variation in springback in a part with more than one bend.

Example 10: Variation in Springback in a Part with Eight Bends.

The part shown in Fig. 19 was produced from 1008 steel in three operations: blank, bend, and trim. In three of the eight bends, springback reduced the 54.74 mm (2.155 in.) dimension, and in five, it increased that dimension.

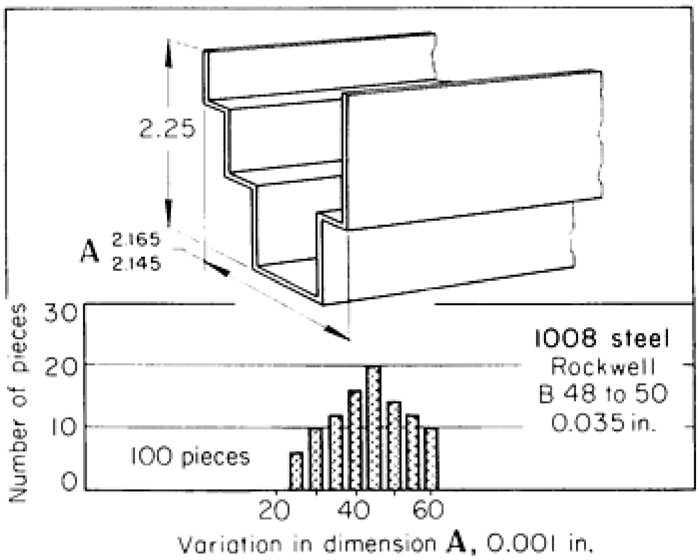


Fig. 19 Variation in flange spacing caused by springback in a part with eight bends. Dimensions given in inches.

To find the net magnitude of the springback and how much variation could be expected, 100 random samples were measured from a production lot of 10,000 pieces. As expected, the net effect of the springback was to enlarge the 54.74 mm (2.155 in.) dimension by amounts ranging from 0.64 to 1.52 mm (0.025 to 0.060 in.), as shown in Fig. 19.

The variation in stock thickness was ±0.05 mm (±0.002 in.). The inside radius on all bends was equal to stock thickness.

Restriking and overbending can be used to set flanges and to offset the effects of springback, as in the following example.

Example 11: Use of Restriking and Close-Fitting Tools to Control Springback in a Flanged Part.

The column-support bracket shown in Fig. 20 was made of 3.35 mm (0.132 in.) thick drawing-quality cold-rolled 1008 or 1010 steel having a hardness of 48 to 51 HRB. The use of close-fitting punches and dies for certain areas and restriking other areas made it possible to obtain the dimensional accuracy necessary for hole positions, cutouts, and flanges.

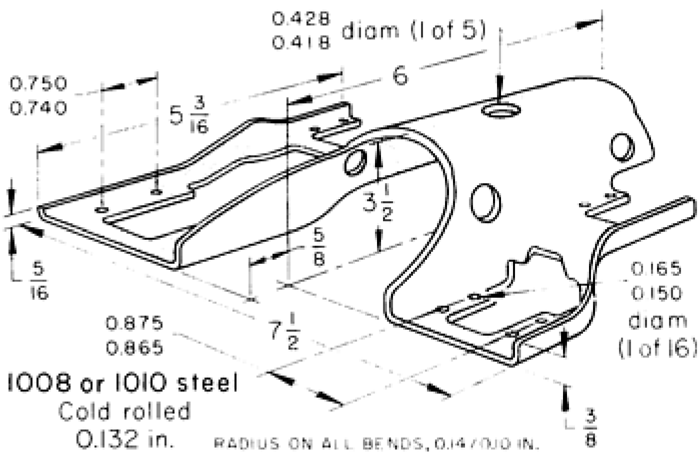

Fig. 20 Bracket with unbalanced shape that was held within bending tolerances by restriking and by extra-close

tolerances on some parts of bending dies. Dimensions given in inches.

All of the round holes were pierced in the flat strip before notching, trimming, punching, and forming. The positions of the small holes with respect to the center were important. The spacing of each set of four small holes was also critical. The flanges along the outer edges had to be uniform in height and set square with the adjacent surface. The open center design and the unbalanced form made it difficult to hold the hole distances and the uniform flange heights.

The forming was done in a progressive die, which was made of O2 tool steel. The cutting punch-to-die clearance was 10% of stock thickness per side. To hold the burr to a minimum height, the die was resharpened after each 50,000 strokes.

The die operated at 400 to 500 strokes per hour. The die was expected to produce parts at this rate for 2 years, and it would then be used for making replacement parts, for which the tolerances were less critical.

Press Bending of Low-Carbon Steel

Accurate Location and Form of Holes

Hole position sometimes cannot be held to tolerance when a workpiece is pierced before bending. When this is so, holes must be pierced after bending--which may require the use of cam-actuated punches, specially shaped dies to support overhanging formed flanges, or punches and dies that are shaped to pierce at an angle.

Holes made before bending are likely to be displaced during bending. Whether or not this displacement can be tolerated must be carefully considered in planning the sequence of operations.

The following example typifies the kind of variation in hole location that can be expected in formed pieces. In this example, if the tolerance on the spacing of the holes had been ±0.025 mm (±0.001 in.) instead of ±0.25 mm (±0.010 in.), the holes would have been pierced after forming, as they were in Example 8.

Example 12: Variation in Distance between Prepierced Holes in a Formed Part.

The bracket shown in Fig. 21 was formed in three operations: blanking and piercing, bending the two small flanges, and bending the two large flanges. The 130.0 mm (5.120 in.) spacing between hole centerlines in opposite flanges had to be held within ±0.25 mm (±0.010 in.).

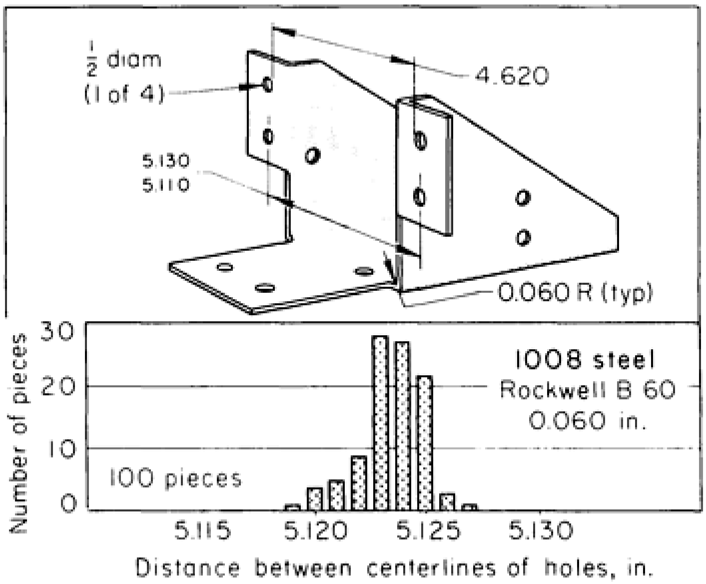

Fig. 21 Variation in distance between centerlines of holes prepieced in opposite flanges of press-bent workpieces. The plotted distances from centerline to centerline were determined by adding 13 mm (0.500 in.)

to the gage readings of distances between the inner edges of the holes. Dimensions given in inches.

A reference dimension of 117 mm (4.620 in.) between the inner edges of the holes was computed for the purpose of checking hole spacing with vernier calipers. Caliper measurements of that dimension on 100 randomly selected pieces (from a run of 10,000 pieces) showed variations of -0.025 to +0.18 mm (-0.001 to +0.007 in.) (Fig. 21).

Free bending of a workpiece is likely to displace holes from true position and to distort and elongate them. In many press-bent workpieces, this deformation is slight enough to be negligible, but it sometimes causes serious difficulties in assembly or fitting. The likelihood of distortion is minimized when holes are located at least one stock thickness away from the beginning curve of a bend. Other precautions include trapping the hole with a hold-down pad that is heavily loaded or relieving the area around the hole with a crescent-shaped cut-out. Additional information on the design and protection of pierced holes during subsequent bending is available in the section "Effect of Forming Requirements" in the article "Piercing of Low-Carbon Steel" in this Volume. Examples in that article describe applications in which holes were pierced after bending to avoid hole distortion and displacement during the bending operation.

An instance of acceptable distortion of pierced holes by subsequent bending is described in the section "Piercing Holes at an Angle to the Surface" in the article "Piercing of Low-Carbon Steel" in this Volume. That article also contains other examples on piercing holes before and after bending.

Accurate Spacing of Flanges

The distance between flanges is another dimension that depends on accuracy of bending. For assembly purposes, this distance may need to be held very closely. Ordinarily, the dimensions at the bases of the flanges are fairly uniform, and variation in the distance between flanges is greater near the free edges. If a flanged part is to fit over a mating piece, oversize dimensions may be preferable to undersize dimensions, as in the following example.

Example 13: Flange Spacing That Was Obtained by Maintaining Tight Gibs and a True Ram.

The bracket shown in Fig. 22 was produced from 5.54 mm (0.218 in.) thick commercial-quality 1010 steel by shearing, blanking, forming, and piercing. The flanges and other bends in the bracket were produced in a five-station transfer die mounted in a 3600 kN (400 tonf) mechanical press. The opposing holes in the flanges were either 16.0/15.9 or 12.8/12.7 mm (0.630/0.626 or 0.505/0.501 in.) in diameter and were pierced after forming. Bend radii were 5.6 mm (0.22 in.). Workmetal hardness was 55 HRB maximum.

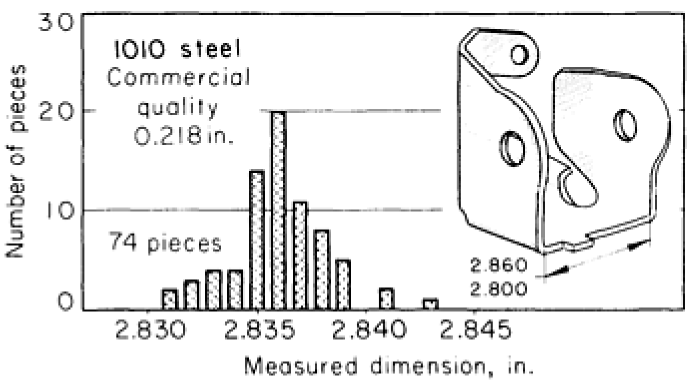

Fig. 22 Accuracy of flange spacing obtained by maintenance of small gib clearance and close ram-to-bolster parallelism in press bending of control-arm brackets for passenger-car frames. Dimensions given in inches.

For proper fit of the bracket with its mating part, the dimension between the two opposing flanges had to be held between 71.12 and 72.64 mm (2.800 and 2.860 in.); the basic dimension was 71.12 mm (2.800 in.). Figure 22 plots the distance between flanges as measured on 74 pieces during a total production run of 6345 brackets. As these data show, all samples were well within tolerance.

To obtain this degree of accuracy on the heavy-gage bracket, gib clearance in the press was kept between 0.15 and 0.20 mm (0.006 and 0.008 in.), and parallelism of the face of the ram with the top of the bolster was maintained within 0.51 mm (0.020 in.). In addition, before forming, the blanks were checked for thickness, and the forming tool was adjusted to compensate for variations. The dies were made of A2 tool steel and were hardened to 60 to 62 HRC.

Safety

Press bending, like all other press operations, involves potential hazards to operators, maintenance men, and other personnel in the vicinity. The articles "Presses and Auxiliary Equipment for Forming of Sheet Metal" and "Blanking of Low-Carbon Steel" in this Volume contain information and literature references on safe operation.

Introduction

PRESS-BRAKE FORMING is a process in which the workpiece is placed over an open die and pressed down into the die by a punch that is actuated by the ram portion of a machine called a press brake. The process is most widely used for the forming of relatively long, narrow parts that are not adaptable to press forming and for applications in which production quantities are too small to warrant the tooling cost for contour roll forming.

Simple V-bends or more intricate shapes can be formed in a press brake. Operations such as blanking, piercing, lancing, shearing, straightening, embossing, beading, wiring, flattening, corrugating, and flanging can also be carried out in a press brake. Information on press-brake forming can also be found in the articles "Press Bending of Low-Carbon Steel," "Press Forming of Coated Steel," "Contour Roll Forming," "Forming of Stainless Steel," and "Forming of Aluminum Alloys" in this Volume.

Principles

In press-brake forming, as in other forming processes, when a bend is made, the metal on the inside of the bend is compressed or shrunk, and that on the outside of the bend is stretched. The applied forces create a strain gradient across the thickness of the work metal in the area of die contact. Tensile strain occurs in the outer fiber, and compressive strain in the inner fiber; both decrease in magnitude toward the neutral axis.

The setup and tooling for press-brake forming are relatively simple (Fig. 1). The distance the punch enters the die determines the bend angle and is controlled by the shut height of the machine. The span width of the die, or the width of the die opening, affects the force needed to bend the workpiece. The minimum width is determined by the thickness of the work and sometimes by the punch-nose radius. After the tools have been set up and the shut height has been adjusted, the press brake is cycled, and the work metal is bent to the desired angle around the nose radius of the punch.

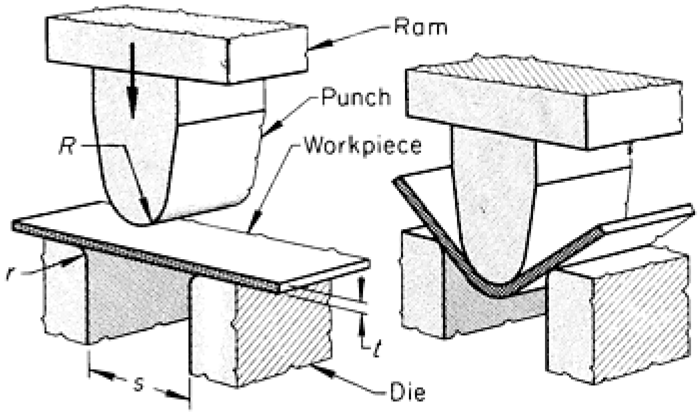

Fig. 1 Typical setup for press-brake forming in a die with a vertical opening. *R*, punch radius; *r*, die radius; *s*, span width; *t*, metal thickness.

Applicability

Press-brake forming is most widely used for producing shapes from ferrous and non-ferrous metal sheet and plate. Although sheet or plate 6.4 mm (0.250 in.) thick or less is most commonly formed in a press brake, metals up to 25 mm (1 in.) thick have often been used, as in the following example.

Example 1: Bending 25 mm (1 in.) Thick Steel Plate.

A 280 mm (11 in.) long bend was made in a 25 mm (1 in.) thick low-carbon steel plate in a 2700 kN (300 tonf) press brake to make the part shown in Fig. 2. The bend radius was 51 mm (2 in.); the included angle was 130°. The plate was air bent in a V-die with a punch that was made from a steel tube 102 mm (4 in.) in diameter.

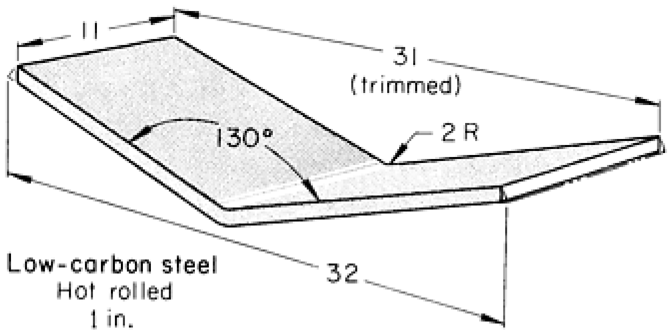

Fig. 2 Frame brace that was air bent from thick plate in a V-die in a 2700-kN (300-tonf) press brake. Dimensions given in inches.

After bending, the edges of the part were machined parallel, as shown in Fig. 2. The workpiece became part of a welded assembly--a frame brace on an industrial lift truck.

Workpiece Dimensions. The length of plate or sheet that can be bent is limited only by the size of the press brake. For example, a 5350 kN (600 tonf) press brake can bend a 3 m (10 ft) length of 19 mm ($\frac{3}{4}$ in.) thick low-carbon steel plate to a 90° angle, with an inside radius of the bend equal to stock thickness. If the included angle of the bend is greater than

90°, if the bend radius is larger than stock thickness, or if the length of bend is less than the bed length, a press of correspondingly lower capacity can be used.

Forming can be done at room or elevated temperature. For elevated-temperature forming in which the punch bottoms, the punch and die should be heated as well as the blank. In air bending, the blank is heated, and the punch is sometimes heated, depending on the area of contact between punch and blank and the metal thickness.

Work Metals. Press-brake forming is applicable to any metal that can be formed by other methods, such as press forming and roll forming. Low-carbon steels, high-strength low-alloy steels, stainless steels, aluminum alloys, and copper alloys are commonly formed in press brakes. High-carbon steels and titanium alloys are less frequently formed in a press brake, because they are more difficult to form.

The formability of all metals decreases as the yield strength increases. Therefore, in press-brake forming, power requirements and springback problems increase and the degree of bending that is practical decreases as the yield strength of the work metal increases.

Press Brakes

The primary advantages of press brakes are versatility, the ease and speed with which they can be changed over to a new setup, and low tooling costs. A press brake is basically a slow-speed punch press that has a long, relatively narrow bed and a ram mounted between end housings (Fig. 3). Rams are actuated mechanically or hydraulically.

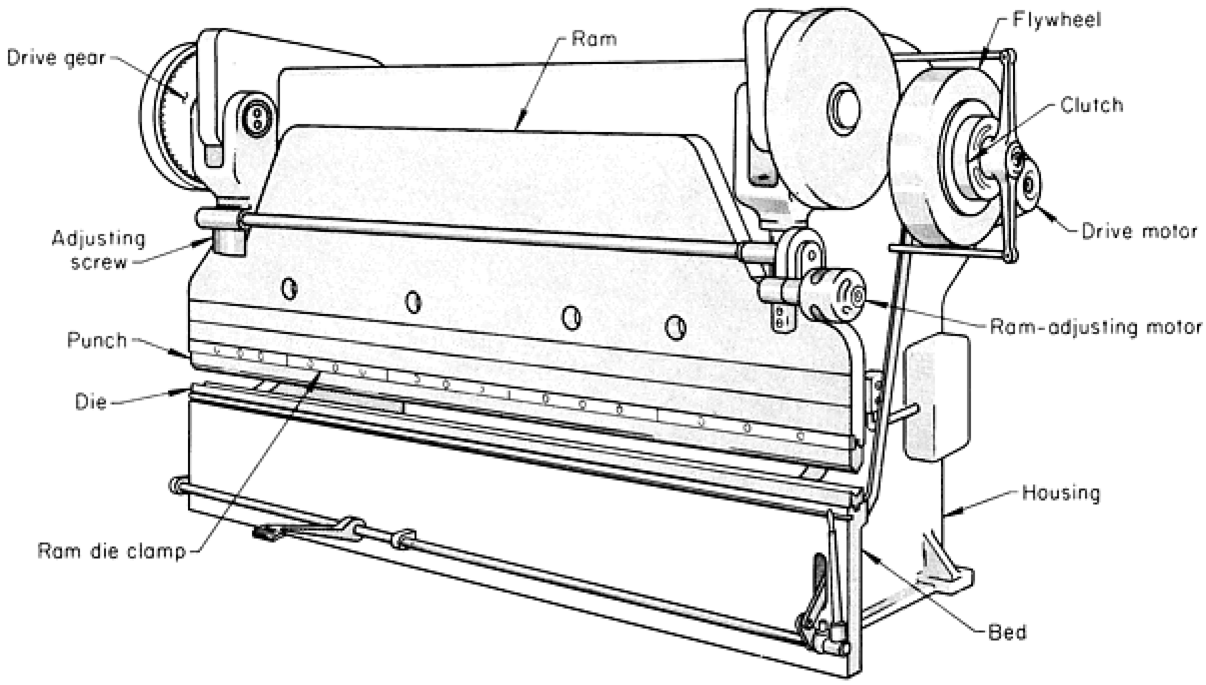

Fig. 3 Principal components of a mechanical press brake.

Mechanical Press Brakes. The ram of a mechanical press brake is actuated by a crank or an eccentric through a gear train in which there is a clutch and a flywheel. The gear train is usually designed to provide fast movement of the ram. Shut height (the distance between ram and bed at the bottom of the stroke) is adjustable by means of a screw (usually powered) in the pitman, or link, at each end of the ram. The length of the ram stroke, however, is constant.

One advantage of a mechanical press brake over a hydraulic press brake is that the mechanical type can develop greater-than-rated tonnage, because of the inertia of the flywheel moving the ram and the mechanical advantage of the crank near the bottom of the stroke. As a result, most mechanical press brakes have extra-strong frames to allow for occasional overloading. However, overloading should not be encouraged, because serious damage to the press brake may occur from improper setup. Another advantage is that operating speeds are greater in mechanical press brakes than in hydraulic press brakes. The greater speed is especially useful for long-run production of workpieces that are easily handled. Greater speed also permits instantaneous, high impact forces when the punch contacts the work metal. This impact force is useful in some operations, although it can damage the machine if the setup lacks rigidity.

A disadvantage of a mechanical press brake is that the stroke cannot be adjusted or controlled to the same degree as is possible with the hydraulic type. However, mechanical press brakes are available at additional cost with devices that permit a rapid advance to work and then a slower speed during forming.

Hydraulic Press Brakes. The ram of a hydraulic press brake is actuated by two double-acting cylinders, one at each end of the ram. Force supplied by the hydraulic mechanism will not exceed the press rating; therefore, it is almost impossible to overload a hydraulic press brake. (When thicker metal is inadvertently used, the ram stalls.) Therefore, frames can be lighter and less costly than those for mechanical press brakes, which are subject to overloading.

In hydraulic press brakes, length of stroke and location of the top and bottom of the stroke (within limits of the cylinder length) are adjustable. The point of rapid advance and return of the ram and its speed during contact with the workpiece are also adjustable; this adjustment makes possible a dwell period, which is often helpful in controlling springback. Cycles established by means of the various adjustments are reproduced by switches in the control circuit.

Even though devices are available that permit some control of the stroke of a mechanical press brake, the degree of control that is possible for a hydraulic press brake is considerably greater. For example, the ram on a hydraulic press brake can be reversed or its speed can be changed at any point on the stroke. Because of these features, a hydraulic press brake is often preferred for the segmental forming of stock longer than the dies, for the forming of large sheets that would be likely to whip in a mechanical press brake, and for the forming of difficult-to-form metals.

Hybrid press brakes incorporate both mechanical and hydraulic elements in the ram drive. The hydraulic-mechanical hybrid consists of a mechanical press brake driven by a rotary hydraulic motor. Containing a vane that rotates 270° between stops, the rotary hydraulic motor has replaced the piston used in a hydraulic cylinder. As it moves between the two stops, the motor propels the eccentric shaft through one complete cycle, driving the ram to the stroke bottom and back to the top.

The hybrid press brake combines the best features of both mechanical and hydraulic press brakes. It offers the same accuracy and operating speeds obtainable with the mechanical press brake while providing the adjustable length and controllability of the hydraulic press brake.

Selection of Machine

A mechanical press brake is usually preferred for quantity production because its speed is greater than that of a hydraulic press brake. Conversely, a hydraulic press brake is generally preferred for varied short-run production because it is more versatile.

Apart from the method of actuating the ram, major factors that must be considered in the selection of a press brake for a given application are the size, length of stroke, and tonnage capacity of the press brake. Table 1 lists capacities and other details for mechanical and hydraulic press brakes.

Table 1 Capacities, sizes, speeds, and ratings for mechanical and hydraulic press brakes

(a) Normal press speed gives rated capacity. High press speeds, m/min (in./min), together with press tonnage ratings, are as follows:

(b) 1.4 and 1.7 m/min (57 and 65 in./min) at 620 kN (70 tonf);

(c) 1.1 and 1.6 m/min (44 and 62 in./min) at 1070 kN (120 tonf);

(d) 1.3 and 1.6 m/min (51 and 62 in./min) at 1420 kN (160 tonf);

(e) 1.4 and 1.5 m/min (54 and 58 in./min) at 1780 kN (200 tonf);

(f) 1.4 and 1.3 m/min (56 and 51 in./min) at 2140 kN (240 tonf);

(g) 1.2 and 1.2 m/min (48 and 47 in./min) at 2670 kN (300 tonf);

(h) 1.5 and 1.1 m/min (58 and 44 in./min) at 3560 kN (400 tonf)

Size is determined by length of bed and length of stroke (maximum stroke, in a hydraulic press brake). The bed length must be able to accommodate the longest bend required. Bed length can also be dictated by the need to mount more than one die in the press to permit a sequence of related operations in the machine at the same time. Under these conditions, it may be necessary to shim the dies so that the punches will bottom simultaneously. For example, if the parts are 305 mm (12 in.) long and six dies are required, the parts could be mounted on a press brake with a bed length of 1.8 m (72 in.) plus allowance for space between dies.

Standard press brakes are available with a maximum bed length of 7.3 m (24 ft). Still larger press brakes are available on special order. The longer the bed, however, the more massive it must be to provide enough rigidity for holding product dimensions, until a length is finally reached at which cost is prohibitive. Similarly, for a given capacity, the maximum stock thickness that can be accommodated decreases as bed length increases.

Length of stroke is an important consideration in any operation in which the height of the sides of the member after bending (such as a deep channel or box) causes interference between the top edge of the formed section and the ram. In addition, the greater the leg height after forming, the longer the stroke must be to allow the finished part to be withdrawn (unless it can be withdrawn from the end, under which conditions length of stroke is not important). Press brakes having a stroke length as great as 152 mm (6 in.) (mechanical) and 457 mm (18 in.) (hydraulic) are available as standard equipment. Modifications for providing increased stroke length are available at extra cost.

Capacity is stated in tons of force developed by the ram at the midpoint of the stroke. Capacities of commercial press brakes range from 70 kN to 22 MN (8 to 2500 tonf). Required capacity is governed by the size and bending characteristics of the work metal and by the type of bend to be made. A formula for determining the capacity required for 90° bends using V-dies without bottoming is:

$$L = \frac{lt^2kS}{s} \quad \textbf{(Eq 1)}$$

where L is press load (in tonf), l is length of bend (parallel to bend axis) (in inches), t is work metal thickness (in inches), k is a die-opening factor (varying from 1.2 for a die opening of 16t to 1.33 for a die opening of 8t), S is tensile strength of the work metal (in tons per square inch), and s is width of die opening (in inches) (Fig. 1).

Sample Calculation. Assume a constant of 1.33, a V-die opening of 8*t*, and a bend 305 mm (12 in.) long made in 6.35 mm (0.250 in.) thick plate having a tensile strength of 30 tsi. Substituting these numerical values in Eq 1 yields:

$$L = \frac{12 \cdot 0.250^2 \cdot 1.33 \cdot 30}{2} \quad \textbf{(Eq 2)}$$

or approximately a 130 kN (15 tonf) capacity requirement for this 90° bend.

For simple bending, the force required increases proportionately with the length of the workpiece or with the square of the work metal thickness. For example, in Eq 2, if the workpiece were 1220 mm (48 in.) long, a 530 kN (60 tonf) capacity would be needed. For producing offset bends (Fig. 4b), about four times as much pressure is required as for simple V-bends.

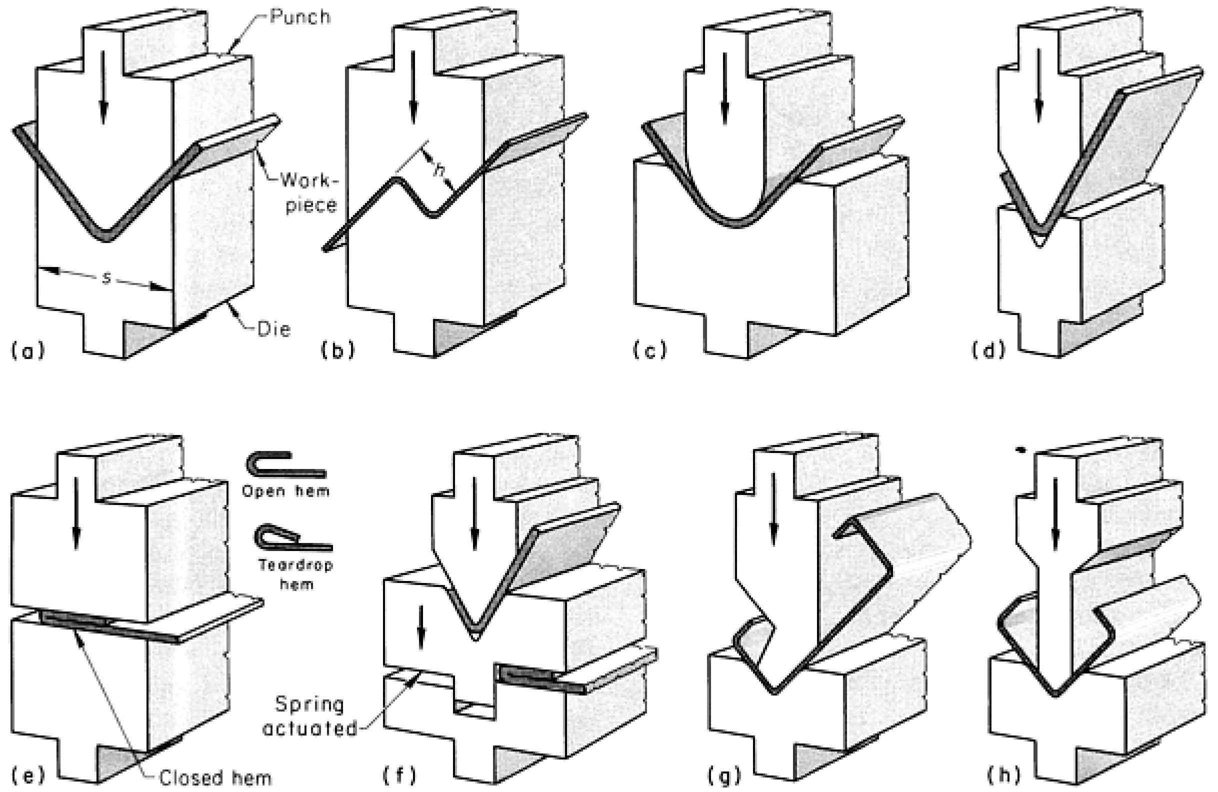

Fig. 4 Dies and punches most commonly used in press-brake forming. (a) 90° V-bending. (b) Offset bending. (c) Radiused 90° bending. (d) Acute-angle bending. (e) Flattening for three types of hems. (f) Combination bending and flattening. (g) Gooseneck punch for multiple bends. (h) Special clearance punch for multiple bends.

Dies and Punches

V-bending dies and their corresponding punches (Fig. 4a and d) are the tools most commonly used in press-brake forming. The width of the die opening (*s,* Fig. 4a) is usually a minimum of 8*t* (eight times the thickness of the work metal).

The nose radius of the punch should not be less than 1*t* for bending low-carbon steel, and it must be increased as the formability of the work metal decreases. The radius of the V-bending die must be greater than the nose radius of the punch by an amount equal to or somewhat greater than the stock thickness in order to allow the punch to bottom. Optimal dimensional control is obtained by bottoming the punch to set the bend.

When producing 90° bends in a bottoming die, the V-die is ordinarily provided with an included angle of 85 to 87°. Several trials are often necessary, and various adjustments must be made on the punch setting before the required 90° bend can be obtained.

Offset Dies. Punch and die combinations such as the one shown in Fig. 4(b) are often used to produce offset bends. Because an offset bend requires about four times as much force as a 90° V-bend, offset bending is usually restricted to relatively light-gage metal (3.2 mm, or 0.125 in., or less). The depth of offset (*h,* Fig. 4b) should be a minimum of six times the work metal thickness to provide stability at the bends.

Radius forming is done with a 90° die and a punch, each having a large radius (Fig. 4c). When the punch is at the bottom position, the inside radius of bend in the workpiece conforms to the radius of the punch over a part of the curve. The harder the punch bottoms, the more closely the work metal wraps around the punch nose, resulting in a smaller radius of bend and less springback. Uniformity of bend angle depends greatly on the uniformity of the work metal thickness.

Acute angles are formed by the die and punch shown in Fig. 4(d). The air-bending technique (see the section on "Air Bending" in this article) is often used to produce acute angles. Acute angles are formed as the first step in making a hem. For this purpose, the die is often bottomed to make the bend angle as acute as possible. A disadvantage of bottoming is that the metal becomes work hardened, so that the hem is likely to crack when formed.

Flattening dies, shown in Fig. 4(e), are used to produce three types of hems (also shown in Fig. 4e) after the metal has been formed into an acute angle. The combination die shown in Fig. 4(f) produces an acute angle on one workpiece and a hem on another, so that a piece is started and a piece completed with each stroke of the press brake.

Gooseneck punches (Fig. 4g) and narrow-body, or special clearance, punches (Fig. 4h) are used to form workpieces to shapes that prevent the use of punches having conventional width (two such workpiece shapes are also shown in Fig. 4g and h).

Tongue Design. The punches shown in Fig. 4 as well as in several other illustrations in this article are provided with a simple, straight tongue for securing the punch to the ram. Although this design of tongue is generally accepted, in some shops punches with a hook type of tongue (see Fig. 8, and the punch for operation 4 in Fig. 20) are used exclusively as a safety precaution. A punch mounted with a hooked tongue cannot fall out. In one shop, it was estimated that hooked tongues increased punch cost by about 10% over the cost of straight-tongue punches.

Special Dies and Punches

Dies that combine two or more operations to increase productivity in press-brake forming are generally more complicated and costly than those illustrated in Fig. 4. Before special dies are designed for a specific application, the increased tooling cost must be balanced against decreased time on the press brake. Generally, the quantity of identical parts to be produced is the major factor in selecting special dies.

Channel Dies. A channel die (Fig. 5a) can form a channel in one stroke of the press brake, while two strokes would be required using a conventional V-die. Because it is necessary to have an ejector in the die to extract the workpiece, channel dies cost more than conventional dies. This higher cost can be justified only on the basis of large-quantity production. It is ordinarily not necessary to have a stripper on the punch, because springback usually causes the part to release. The ejector in the die may be of the spring, hydraulic, or air-return type. The stripper for the punch (if needed) is a release-wedge device or a knockout piece. The use of a channel die, regardless of production quantities, is limited by work metal thickness, corner radii, and required flatness of the web.

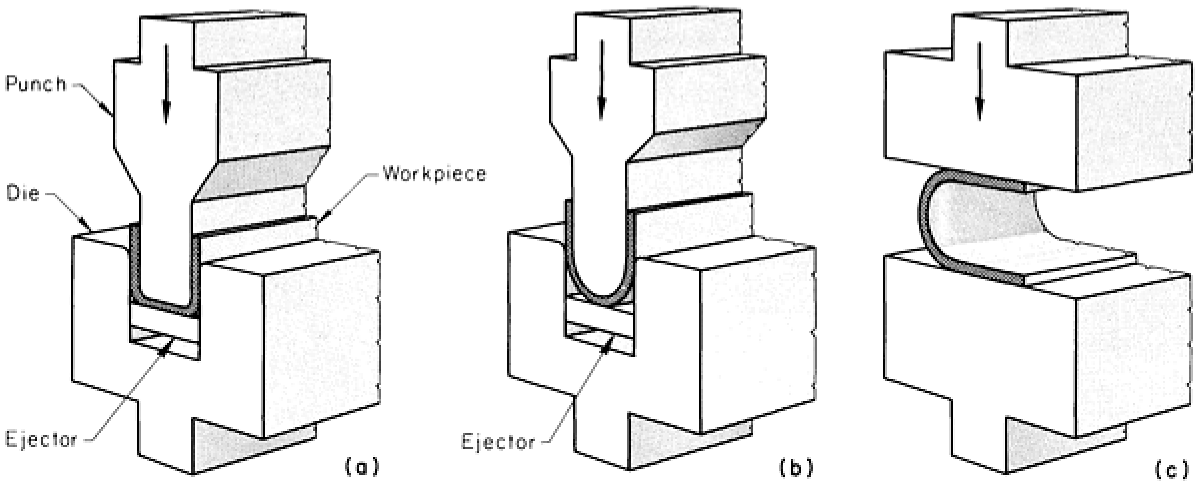

Fig. 5 Three types of special punches and dies for press-brake forming. (a) Forming a channel in one stroke. (b) Forming a U-bend in one stroke. (c) Flattening to remove springback after U-bending.

A modification of the channel die is the U-bend die (Fig. 5b). Springback is a common problem with this type of die; one means of overcoming it is to perform a secondary operation on flat dies, as shown in Fig. 5(c).

Air Bending. In air bending, the die is deep enough that setting does not take place at the bottom of the stroke. The die can have a V shape (Fig. 6), or the sides can be vertical (Fig. 1). The shape and nose radius of the punch are varied to suit the workpiece. The required angle is produced on the workpiece by adjusting the depth to which the punch enters the die opening. This permits the operator to overbend the metal sufficiently to produce the required angle after springback.

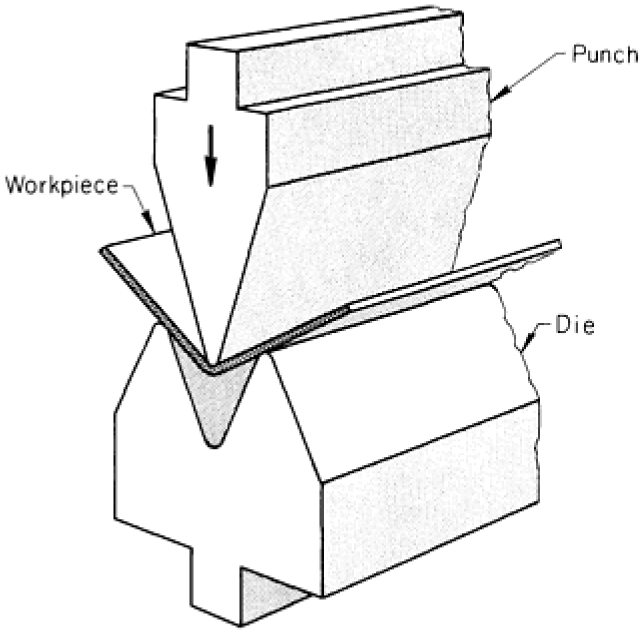

Fig. 6 Setup for air bending with an acute-angle punch and die in a press brake.

When metal is bent beyond its yield strength, the radius formed bears a definite relationship to the opening in the die. A small die opening produces a small radius; the use of a large die opening increases the radius, but also increases the amount of springback. Springback must be compensated for by overbending. Changing the size of the die opening also changes the amount of force needed to make the bend. As the die opening is increased, less force is required; as the die opening decreases, the bending leverage is less, and more force is therefore required.

For the air bending of metal up to 13 mm ($\frac{1}{2}$ in.) thick, the die opening is usually equal to eight times the work metal thickness. This keeps the bend radius approximately equal to the metal thickness. For metal thicker than 13 mm ($\frac{1}{2}$ in.) and for some high tensile strength metals, the die opening should be at least ten times the work metal thickness to increase the bend radius and therefore reduce the possibility of fracture at the bend.

The principal advantage of the air-bend method is the variety of forming that can be done with a minimum number of punches and dies. Air bending also requires less force for a given bend, thus preventing excessive strain on the press brake.

The primary disadvantage of air bending is the possible inconsistency in the bends. Because of variations in dimensions and temper of the work metal as it is received from the mill, springback can vary throughout a production run. However, the operator can adjust the ram to compensate for these irregularities. When air bending in a hydraulic press brake, the operator can use a preset pressure, check each part with a gage, and restrike if necessary. With a mechanical press brake, the shut height can be easily adjusted for a restrike and then reset for the next part.

Box-forming dies are similar to standard V-dies, except that the punch is sometimes specially made to clear the sides of the box being formed. For square boxes, the punch length can be the inside length, and the sides of the box can be formed in any sequence. However, for the forming of rectangular boxes, different tools or techniques are required. One approach is the use of a punch that is split vertically (Fig. 7) so that the punch can clear the sides on the long dimension while forming the sides of the short dimension. In most cases, however, a punch long enough for forming the long sides can be used without splitting; this is accomplished by forming the short sides first.

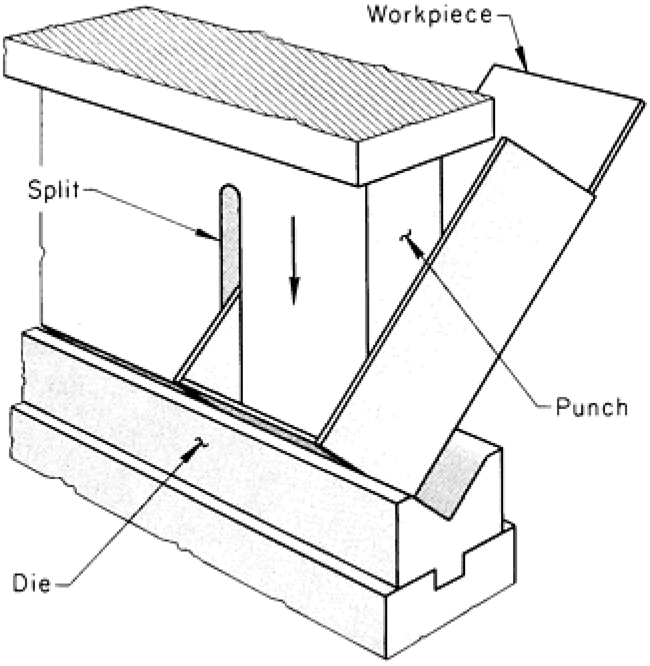

Fig. 7 Setup for forming a rectangular box using a punch split vertically to clear the long sides during forming of the short sides.

When bottoming dies are used in box forming (to overform and coin the metal to reduce springback), the metal can be work hardened excessively if the force used to form the short sides is the same as that used for the long sides. In some shops, when the short sides are less than two-thirds as long as the long sides, force is reduced for forming the short sides.

Arbor-type punches can be used when the sides of a boxlike workpiece must be folded over (Detail A, Fig. 8). The head of the punch extends beyond the punch body so that the formed-over sides can fit over the punch extensions while the remaining folds are made (Fig. 8). The extensions on the punch are approximately triangular in cross section so that the punch can be withdrawn after opposite sides of the workpiece are closed.

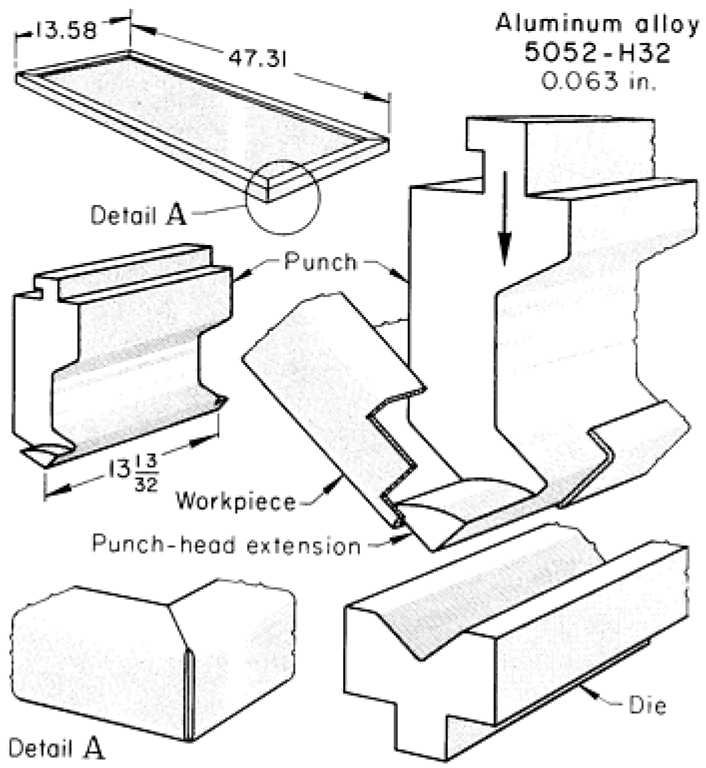

Fig. 8 Folding-over sides of a boxlike workpiece using an arbor-type punch for forming beneath reverse flanges. Dimensions given in inches.

Lock-Seam Dies. Lock seams are made in a press brake when quantities are too small to warrant more elaborate equipment. The usual procedure is to form one component with a special punch and die as shown in Fig. 9(a). The second component of the assembly is formed in a simple V-die. The two components are then locked together in a single stroke of the press brake using another special die (Fig. 9b).

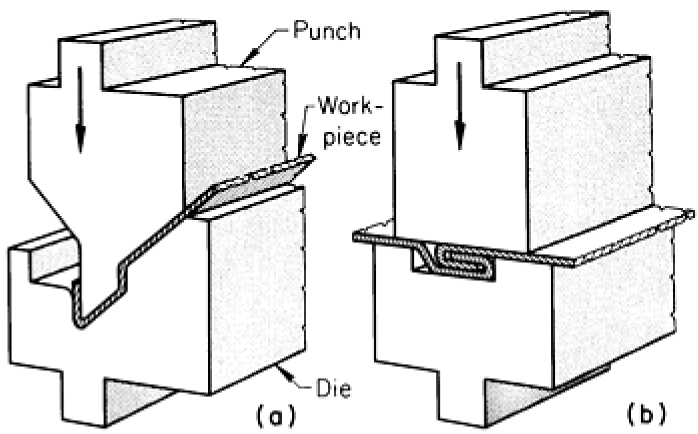

Fig. 9 Special punches and dies for producing lock seams in a press brake.

Curling Dies. Curling in a press brake is usually done in two steps using special dies such as those shown in Fig. 10(a).

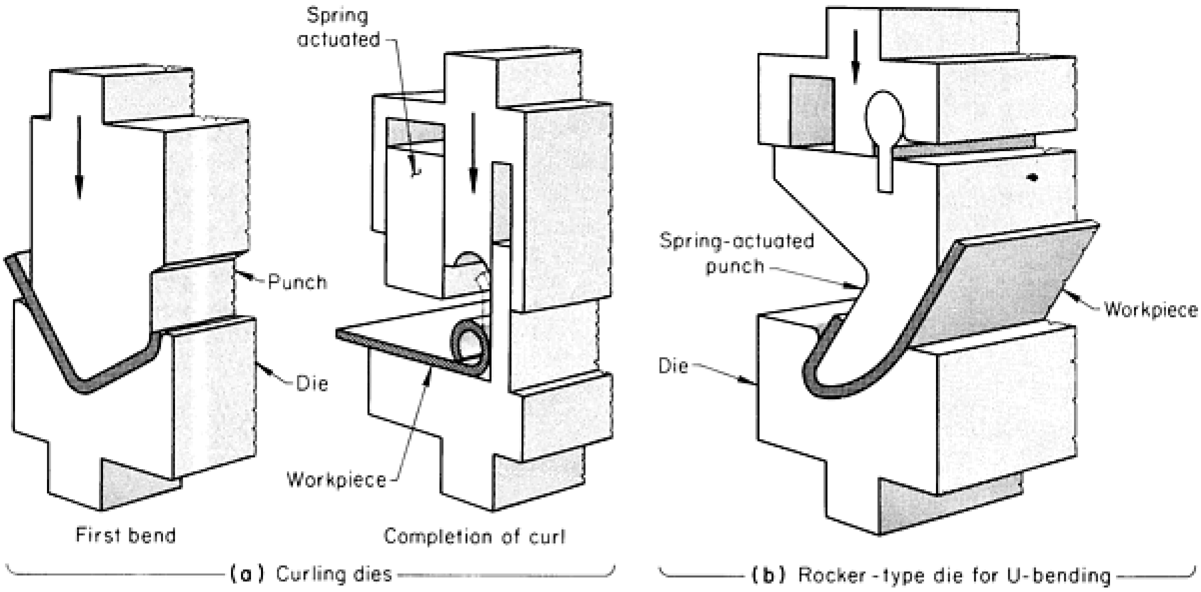

Fig. 10 Special punches and dies for curling and U-bending in a press brake.

Tube- and pipe-forming dies resemble curling dies. To ensure that the workpiece rolls up properly, the edges of the metal must initially be bent. Small tubes can be formed by using a two-operation die (Fig. 11a), while larger tubes require the use of a bumping die such as that shown in Fig. 11(b). Where accuracy is required, tubes formed in a bumping die should be sized over a sizing mandrel. If seams are required, they can be formed on the tube edges prior to the rolling operation.

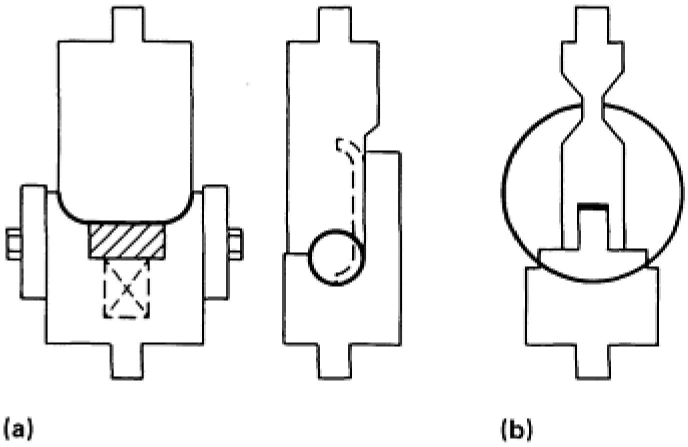

Fig. 11 Tube- and pipe-forming dies. (a) Two-operation die for the forming of small tubes. (b) Bumping die used to form large tubes.

Rocker-Type Dies. Dies that operate with spring-actuated rocker punches can produce bends that would be impossible with the punch operating in a vertical direction only. A typical rocker-type die for U-bending is illustrated in Fig. 10(b).

One-Stroke Hemming Dies. With specially designed spring-actuated dies, it is possible to hem a length of metal sheet in a single stroke. A typical die used for this operation and the movement of die components required for completing the hem are illustrated in Fig. 12. When provided with an adjustable stop, the die shown in Fig. 12 can produce hems of different widths (over a narrow range).

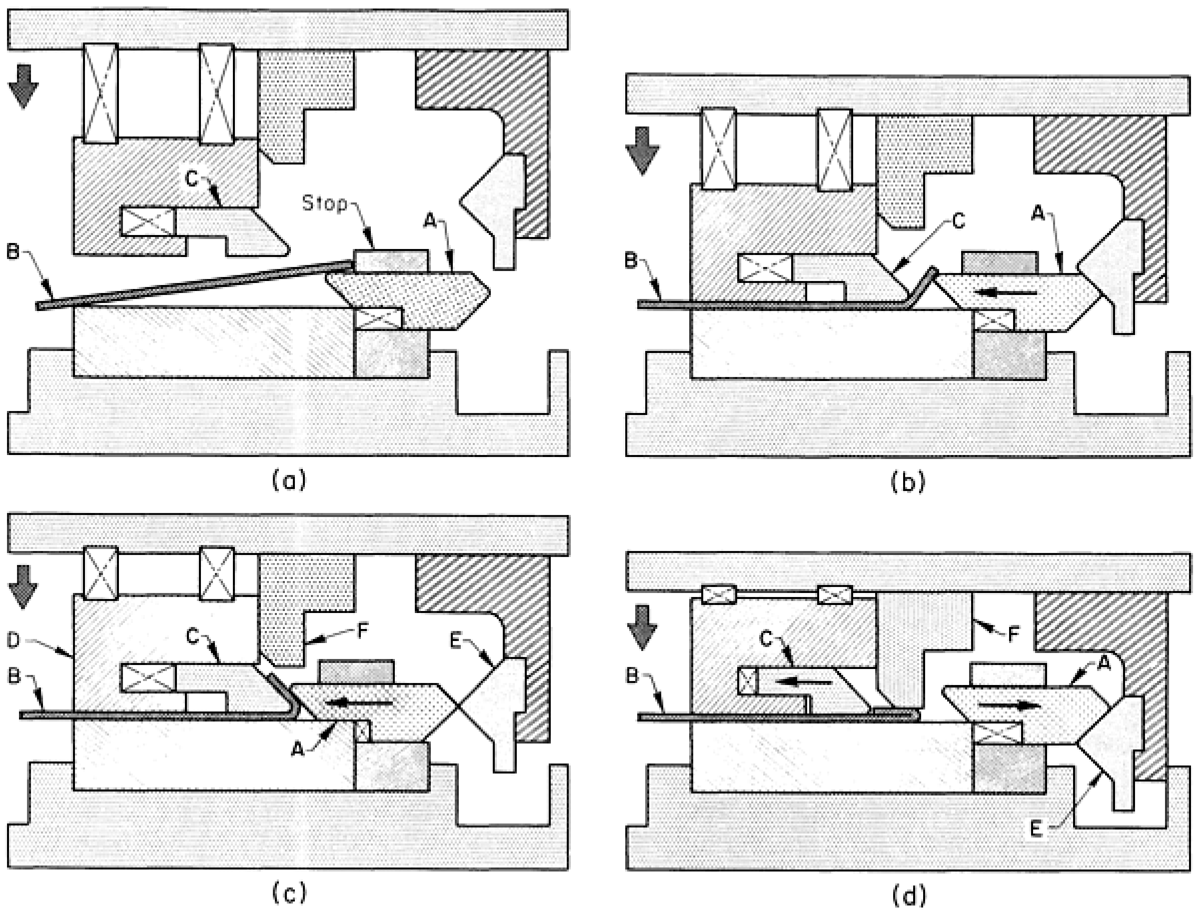

Fig. 12 One-stroke hemming die and movement of die components during hemming. (a) Workpiece, B, is placed over slide A using a component of the die as a stop, and the entire upper die section begins to move down. (b) Slide C contacts the workpiece and makes the first bend for the hem. (c) With slide D holding the workpiece rigidly in place, die component E forces slide A to the left, forming the bent section of the workpiece into an acute angle. (d) As the die continues to move down, die component E permits slide A to retract, providing clearance for F to contact and flatten the workpiece as it forces slide C to the left, thus completing the hem. On the upstroke of the press brake, die components return to original positions.

Beading dies form beads (stopped ribs) to add rigidity to flat sheets. The dies form either open beads that extend from edge to edge of the sheet or closed beads that fade out in the sheet. The hemispherical depressions that constitute the open bead are formed by the die shown in Fig. 13. Closed beads, on the other hand, necessitate the use of spring-pressure pads at the ends, which fade out to minimize wrinkling of the metal.

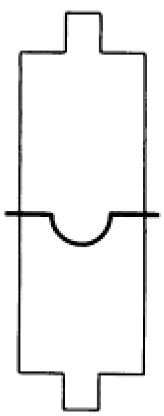

Fig. 13 Die used to form open bead in flat sheet to add stiffness to material.

Corrugating dies can be used to produce numerous corrugations, as shown in Fig. 14.

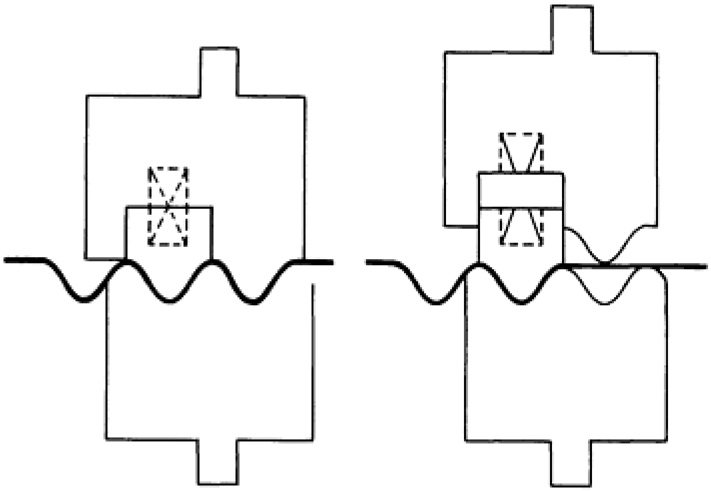

Fig. 14 Corrugating die used to form corrugations in a continuous sheet of material.

Cam-driven dies, also known as wedge-driven dies, can be used to increase production rates as well as workpiece quality. When using an acute-angle die at normal press speeds, the sheet travels in a large arc, causing a bend at the outside die edge. This problem can be solved by decreasing the speed of the operation, but a better solution is to use a cam-driven die to ensure that the sheet will lay flat while maintaining the press speed at the desired rate.

Dies for Shearing, Lancing, Blanking, Piercing, and Notching

Shearing can be done in a press brake, but hold-downs and knife supports must be used to obtain reasonable accuracy. For optimal results, a shearing machine should be used (see the article "Shearing of Plate and Flat Sheet" in this Volume). There are, however, applications in which shearing in a press brake is convenient because it can be combined with another operation.

Lancing is often done in a press brake. An example is the production of louvers, which are used in cabinet or locker doors. The punch, die, and die pad used for the simultaneous lancing and forming of sheet metal into louvers are shown in Fig. 15.

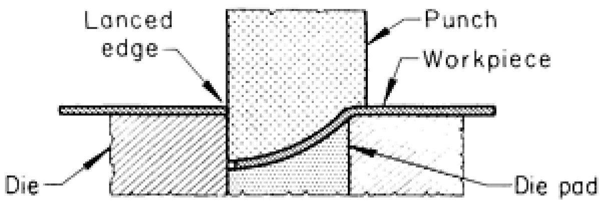

Fig. 15 Punch, die, and die pad used for the simultaneous lancing and forming of louvers in a press brake.

Blanking. When long, narrow dies are required for a given application, metal can be blanked in a press brake if adequate support can be provided by the dies or the press brake. The removal of long, narrow workpieces is sometimes a problem. Spring-type or rubber strippers can be added if excessive adherence to the punches is encountered.

Piercing and Notching. Press brakes are extensively used for piercing (punching) and notching. A press brake is more practical than a punch press for the piercing or notching of long, narrow workpieces, such as flats, channels, or other cross-sectional shapes. Press brakes are especially well adapted to piercing holes close to the edge of long panels or to notching the edges. Quick-change punching units help to extend the versatility of a press brake for piercing and notching. These punching units can be quickly changed to accommodate different workpieces by using setup templates.

Rotary Bending

Wiping dies, V-dies, and U-dies have traditionally been used in press-brake forming. Rotary bending is gaining wide acceptance in industry because it significantly reduces the time required to bend materials. Rotary bending is accomplished by using a tool that simultaneously holds and bends the material.

Key components of a rotary bender are the saddle (punch), the adjustable rocker, and the die anvil. The cylindrical rocker features an 88° V-notch cut out along its full length. To minimize marking, the edges of the rocker jaws are flatted and radiused. Figure 16 illustrates the three stages of a rotary-bending operation. Initially (Fig. 16a), the material is clamped, and the rocker rotation begins. Figure 16(b) shows how humping is controlled and confined to the space between the rocker edges. The final step (Fig. 16c) shows how the rocker clamps the workpiece in place and overbends it sufficiently to compensate for springback.

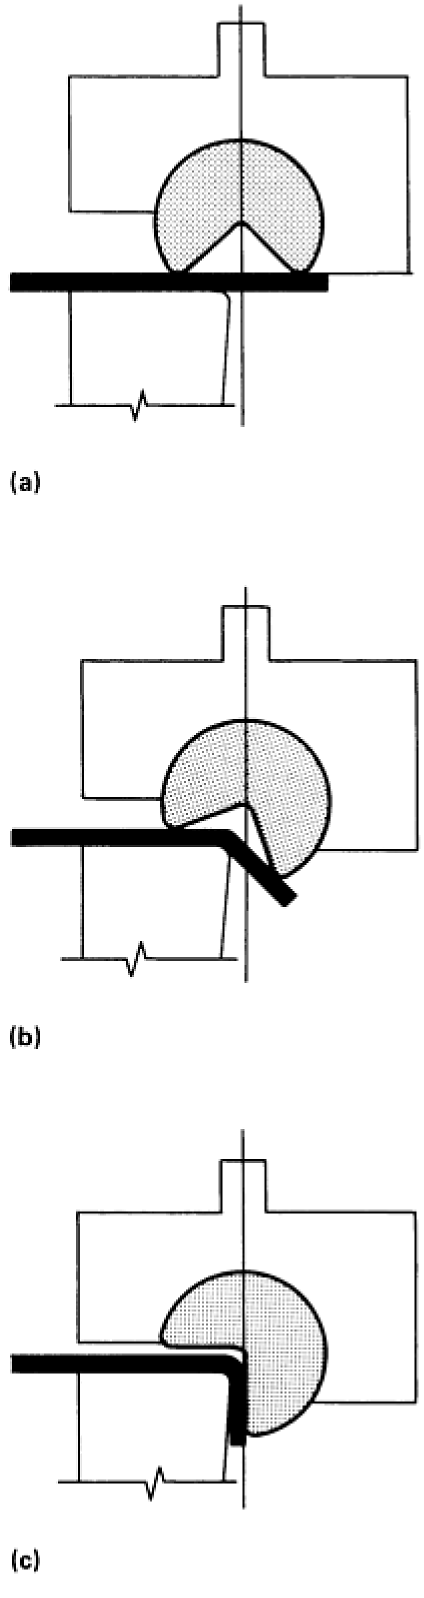

Fig. 16 Sequence of operations illustrating rotary bending in a press brake. (a) Material is clamped, and rocker rotation begins. (b) Humping is controlled and limited to space between edges of rocker. (c) Workpiece is clamped in position by rocker and overbent to allow for springback.

Rotary benders have been primarily used in conjunction with progressive dies to form Z-bends and short-leg bends in a single operation. Also, dart stiffeners can be rolled into the workpiece simultaneously as it is being bent.

Selection of Tool Material

Selection of tool material for punches and dies used in press brakes depends on the composition of the work metal, the shape of the workpiece (severity of forming), and the quantity to be produced. The tool material used for press-brake bending and forming ranges from hardwood to carbide, although the use of carbide has usually been confined to inserts at high-wear areas. Hardwood and carbide represent the rare extremes; hardwood is suitable only for making a few simple bends in the most formable work metal, and carbide would be considered only for making severe bends in a less-formable work metal (such as high-strength low-alloy steel) in high production.

Simple Bending. Most dies and punches used for simple V-bending operations are made from low-carbon steel (such as 1020) or gray iron. Both of these materials are inexpensive and give acceptable tool life in mild service.

If production runs are long or if the work metal is less formable, some upgrading of the tool material may be desired to retain accuracy over a longer period. Gray iron can be upgraded without adding greatly to tool cost by making both punch and die from a hardenable grade (such as ASTM class 40) and then flame hardening the nose of the punch and the upper edges (high-wear areas) of the V-die to 450 to 550 HB. Low-carbon steel tools can be upgraded by changing to a hardenable grade of steel (such as 1045). High-wear portions of the tools can be flame hardened (usually to 50 to 55 HRC) in the same manner as the gray iron tools.

Severe Bending. As the severity of bending and forming increases, such as in producing channels in a single stroke (Fig. 5a), tool materials should be upgraded when more than low-production quantities are needed. For operations that require severe bending, tool material requirements for press-brake operations parallel those for punch-press operations (see the article "Selection of Material for Press-Forming Dies" in this Volume).

Blanking and piercing are done in a press brake with tools of the same materials as those used in punch presses (see the article "Selection of Material for Blanking and Piercing Dies" in this Volume).

Rubber Pads. The use of rubber pads in press-brake dies (Fig. 17) enables the forming of shapes that are difficult or impossible to form without the pads. The pads also minimize damage to work metal surfaces and decrease die cost. Additional information is available in the article "Rubber-Pad Forming" in this Volume.

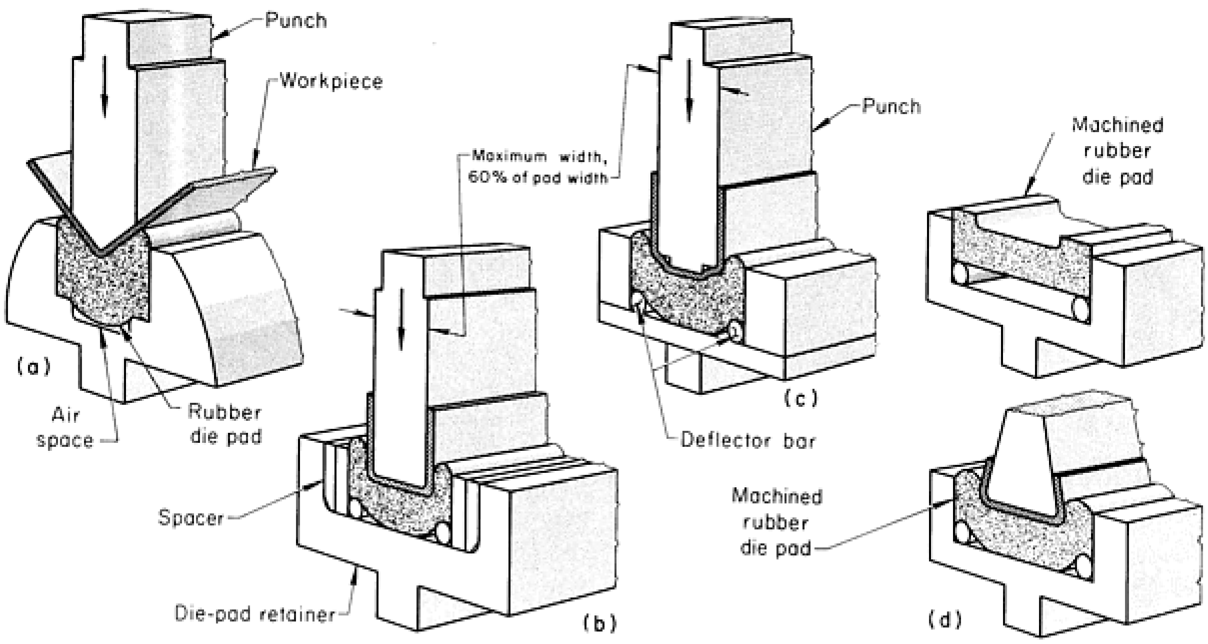

Fig. 17 Setups for rubber pad forming of various shapes in a press brake. (a) Simple 90° V-bend. Air space below die pad permits deep penetration. (b) Simple U-bend or channel. Spacers enable channels of varying widths to be formed in the same die-pad retainer. Deflector bars help to provide uniform distribution of forming

pressure. (c) Modified channel, with partial air bending. (d) Acute-angle channel. High side pressures are obtained by using a conforming rubber die pad and deflector bars.

Urethane rubber is the type most widely used. Pads inserted into the bottom of the die can be used for forming V and channel sections in various metals ranging from soft aluminum to low-carbon steel up to 12 gage (2.657 mm, or 0.1046 in.) in thickness. When using the urethane-pad technique, the urethane is, in effect, the die. It is almost impossible to compress urethane; its shape changes but not its volume. With minimum penetration of the punch, the pad begins to deflect, exerting continuous forming pressure around the punch. At the bottom of the stroke, the urethane has assumed the shape of the punch. When the pressure is released, the pad returns to its original shape.

Urethane pads are generally used for short-run production. However, in one plant, 14,000 boiler-casing channels were formed from 16 gage (1.52 mm, or 0.0598 in.) low-carbon steel in 4.9 m (16 ft) lengths on the same urethane pad before replacement.

Urethane rubber is made in several different grades ranging in tensile strength from 18 to 76 MPa (2600 to 11,000 psi) and in hardness from Durometer 80A to 79D. (Additional information is available in the article "Miscellaneous Hardness Tests" in *Mechanical Testing*, Volume 8 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.) Selection of grade depends on work metal hardness and thickness and on severity of forming. Experimentation is often needed to determine the optimal grade of urethane for the application.

Work Metal Finish. When preservation of work metal finish is a primary objective, the dies or punches or both are sometimes chromium plated. Other means of preserving the work metal finish include the use of oil-impregnated paper between the tools and the work metal, or spraying the tools with a plastic of the type used to coat metal sheets for deep drawing.

Procedures for Specific Shapes

Procedures and tooling for press-brake operations vary widely and are mainly influenced by workpiece shape. The following examples describe the procedures used for producing several different shapes, including simple boxlike parts, panels, flanged parts, architectural columns, fully closed parts, and semicircular parts.

Example 2: Four-Stroke Forming of Closed-Bottom Boxes From Notched Blanks.

Closed-bottom boxes were produced from 1010 steel blanks sheared to 508 × 610 mm (20 × 24 in.) in a press brake. The four corners were notched to a depth of 102 mm (4 in.) in a standard notching die in the same press brake as that used to make the blanks. The box was then formed in four strokes of the press brake, using a standard 90° V-die but with a deeper-than-normal punch (Fig. 18). By bending the 305 mm (12 in.) sides first, all four bends could be made with a die 406 mm (16 in.) long. Hourly production rates for the three operations were:

Operation	Pieces
Shear blanks	**55**
Notch corners (four strokes)	**57**
Bend from sides (four strokes)	**44**

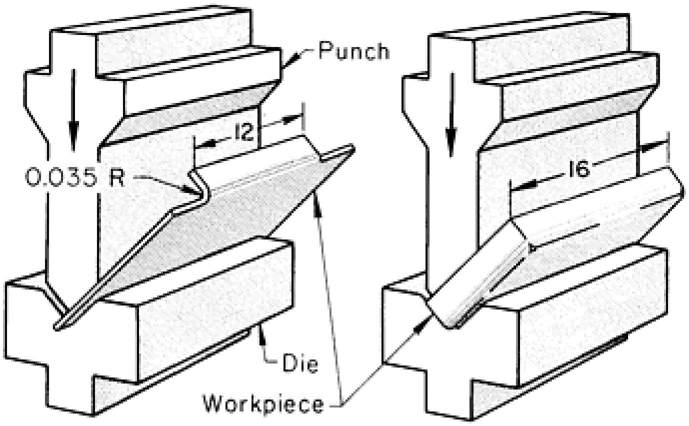

Fig. 18 Die and punch setup for bending sides in the production of a closed-bottom box. 1010 steel, 55-65 HRB. Dimensions given in inches.

Example 3: Six-Operation Forming of an Architectural Column.

An architectural column 3 m (10 ft) long was produced in six operations in a press brake. Figure 19 shows the sequence of shapes produced. Channel dies were used for operations 1 and 2. Operation 3 required a special punch and die for producing the large-radius bends. A simple channel die was used for operation 4, and a V-die for operation 5. Operation 6 was performed with a gooseneck punch that was necked-in sufficiently to clear the edge flanges as the part closed in.

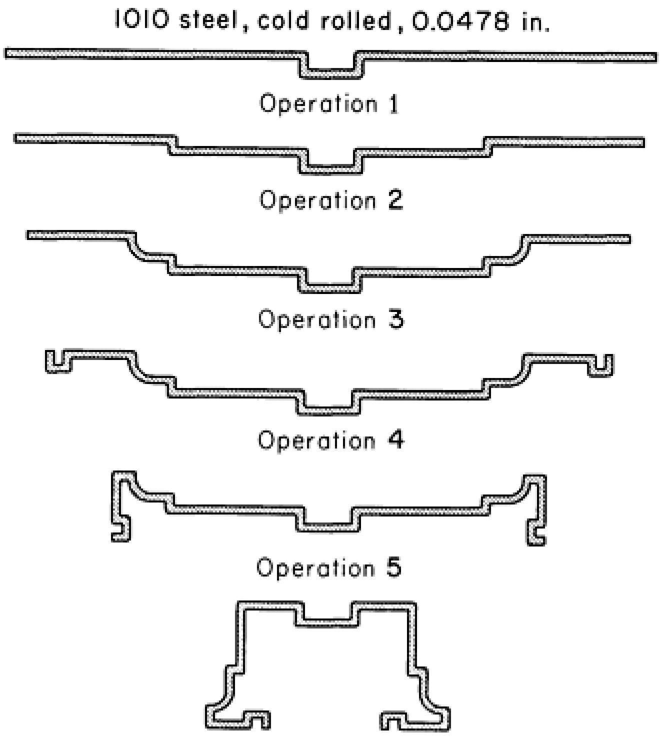

Fig. 19 Shapes progressively produced in six-operation forming of an architectural column in a press brake using 1.21 mm (0.0478 in.) thick steel sheet.

The major problem in forming this shape was to obtain sharp 90° bends at all corners and to keep the flanges in the same plane. Because the part was 3 m (10 ft) long, considerable shimming of the tools was required to produce satisfactory parts.

Correct shimming is a major factor in maintaining accuracy when producing shapes in a press brake such as that shown in Fig. 19. Shims are required to adjust for the discrepancies between bed plate and bolster. Also, deflections produced by the punch bottoming on all hits will be greater in the center of the die than at the edges, and shimming is required to equalize the pressure along the entire length of the bend. Optimal shimming is accomplished mainly by trial and error, because of the variations among machines, tools, and workpieces.

Example 4: Producing a Completely Closed Triangular Shape.

Figure 20 shows the four separate setups that were used to produce an 864 mm (34 in.) long completely closed triangular part in a press brake. The 541 × 864 mm ($21\frac{9}{32}$ × 34 in.) blanks were prepared by shearing on separate equipment. As shown in Fig. 20, the first pressbrake operation produced a 90° bend, and the second operation produced a 68° bend; simple straight-sided punches were used for both bends. In the third operation, a special punch 29 mm ($1\frac{1}{8}$ in.) thick and having an offset nose was used to produce a 32° bend. By bending only to 32°, sufficient space was allowed for withdrawal of the punch. The punch had an offset nose because of the off-center seam location (a design requirement); if the seam had been centered, the punch would have been symmetrical. In the fourth operation, the part was closed. The part just before the fourth operation is shown at the upper right-hand corner in Fig. 20. Time to complete the four operations was 0.9916 min. Total time per part was 1.0412 min (production rate: 57.7 parts per hour).

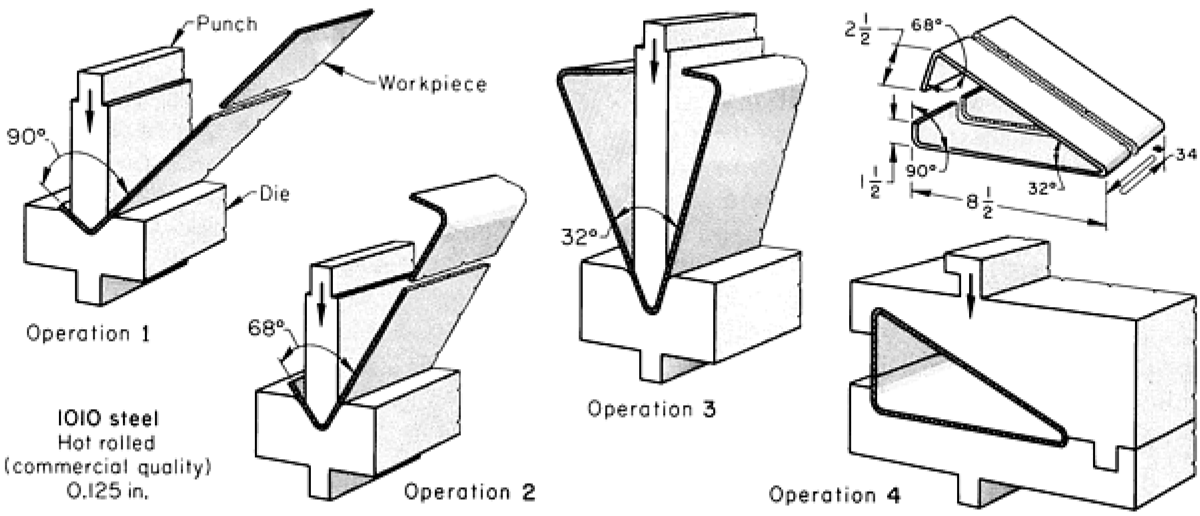

Fig. 20 Sequence of operations for forming a closed triangle in a press brake. Dimensions given in inches.

Semicircular Shapes and U-Bends. Flat stock can be formed into semicircular shapes and U-bends in a press brake. If the press capacity is adequate for the work metal thickness and the dimensions required, forming can be done in one operation, as in 90° V-bending. As shown in Fig. 5(b), the radius of the punch nose forms the inside radius of the workpiece.

Air bending is used to form semicircular shapes and U-bends when the work metal thickness and the dimensions exceed press capacity. A typical setup is shown in Fig. 21. Starting from the end of the workpiece at the right, and a distance of half the span of the die opening, pairs of equally spaced center-punch marks are made near each side of the workpiece, progressing to the left in two straight lines at 90° to the bend axis. These two rows of punch marks guide the operator in maintaining the alignment of the bend.

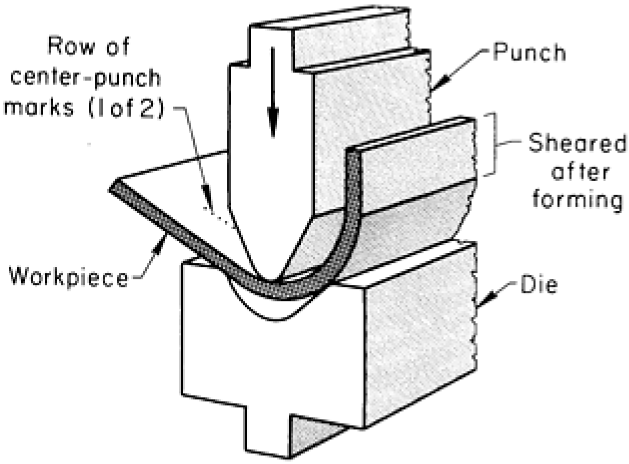

Fig. 21 Air bending to form a semicircular part by progressive strokes of the punch.

To form the part, the blank is placed across the die opening with the center-punch marks facing up, so that the punch will contact the blank at the first pair of punch marks. A bend is made at each pair of punch marks progressively toward the center of the blank (Fig. 21). When the center is reached, a quarter circle will have been formed. The blank is rotated 180°, and the procedure is repeated until a semicircle is formed. The radius of the semicircle will depend on the amount of bending done with each blow of the press and on the distance between the punch marks.

Bending should always proceed from the end of the blank toward the center in order to avoid interference between the ram and the formed workpiece. After forming, the straight section at each end of the workpiece is sheared off. The following example describes an application of this procedure for producing semicircular parts by air bending.

Example 5: Forming Semicircular Parts by Air Bending.

Two semicircular parts were formed from 19 mm ($\frac{3}{4}$ in.) thick low-carbon steel plate, and the parts were welded together to produce a 254 mm (10 in.) OD hollow cylinder 254 mm (10 in.) long. Blank size for each semicircular part was 254 × 470 mm (10 × 18$\frac{1}{2}$ in.). The bend length required for each part was 368 mm (14$\frac{1}{2}$ in.), but the blanks were cut to 470 mm (18$\frac{1}{2}$ in.) to allow for trimming after forming (Fig. 21).

Before forming, two rows of center-punch marks were made on the blanks (Fig. 21). The first mark was 50 mm (2 in.) from the blank edge, with subsequent marks every 13 mm ($\frac{1}{2}$ in.) of the 368 mm (14$\frac{1}{2}$ in.) bend length.

The parts were formed in an 1800 kN (200 tonf) mechanical press brake using a standard V-die and round-nose punch. Thirty bends were required to form each semicircular part. After several bends, the curve was checked with a template to determine the accuracy of the bend. After forming a quarter of the circle, the workpiece was rotated 180°, and the operation was repeated to complete the half circle. The final bend was made at the center of the workpiece. The 50 mm (2 in.) allowance at each end of the workpiece was then sheared off.

Corrugated Sheet. Special procedures allow bends to be fabricated in corrugated metal that are perpendicular to the corrugations, without flattening the corrugations. This can be achieved by using cast-on plastic blankets.

Effect of Work Metal Variables on Results

Thickness variations, yield strength, and rolling direction are the work metal variables that have the greatest effect on results in press-brake operations. Whenever possible, any metal to be formed should be purchased only to commercial tolerances; special tolerances increase cost. However, when workpiece tolerances are close, it is sometimes necessary to purchase metal with special thickness tolerances, because normal variations can use up a substantial amount of the assigned final tolerance (see the section "Dimensional Accuracy" in this article).

Yield Strength. As the yield strength of the work metal increases, so does the difficulty in bending. This difficulty occurs as cracking at the bends, increased power requirements, or an increase in springback.

For example, bending of stainless steel requires about 50 to 60% more power than bending a comparable thickness of low-carbon steel. Because of its resistance to bending, stainless steel often causes difficulty in obtaining acceptable results. Additional information is available in the article "Forming of Stainless Steel" in this Volume.

Springback. In a wiping type of bending operation, in which the metal is bent to position but the corner is not coined to set the bend, the metal attempts to return to its original position. This movement, known as springback, is evident to some extent in all metals, and it increases with the yield strength of the metal. The amount of springback is usually negligible for a soft metal such as 1100 aluminum alloy. However, for aluminum alloys such as 2024, the amount of springback can be significant. In general low-carbon steels exhibit more springback than aluminum or copper alloys do, and still more springback can be expected for stainless steel.

A common technique for overcoming springback is to overbend by approximately the number of degrees of springback. Several trials in tool development may be needed to obtain the proper angle, because of variations in mechanical properties, work-hardening rate, metal thickness, and die clearances. Springback from one bend can sometimes be used to offset that from another. Tables and graphs for springback have been developed for specific metals. Detailed information on the subject of springback is provided in the Section "Forming of Nonferrous Sheet Materials" in this Volume.

Another technique for overcoming springback is the use of specially designed bottoming dies that strike the workpiece severely at the radius of the bend. This action stresses the metal in the bend area beyond the yield point through almost the entire thickness and thus eliminates springback. Bottoming must be carefully controlled, particularly if it is done in a mechanical press brake, because the force developed by this machine can be very high.

Restriking in the original dies or special fixtures will reduce springback to a low level. It requires an additional operation, but may entail little or no additional equipment. In the following example, a second stroke was used.

Example 6: Correcting Springback in the Forming of a Complex Shape.

The shape shown at the lower right-hand corner in Fig. 22 was produced from 0.91 mm (0.036 in.) thick 1010 steel in lengths ranging from 0.9 to 2.4 m (3 to 8 ft). The five operations used in producing the part are shown in Fig. 22(a) to (e). The box section was formed by a wiping action (Fig. 22d) with no force on the outermost portion of the box. Consequently, springback occurred and required another step to correct by overforming (Fig. 22e). The shut height of the die was adjusted to provide the correction.

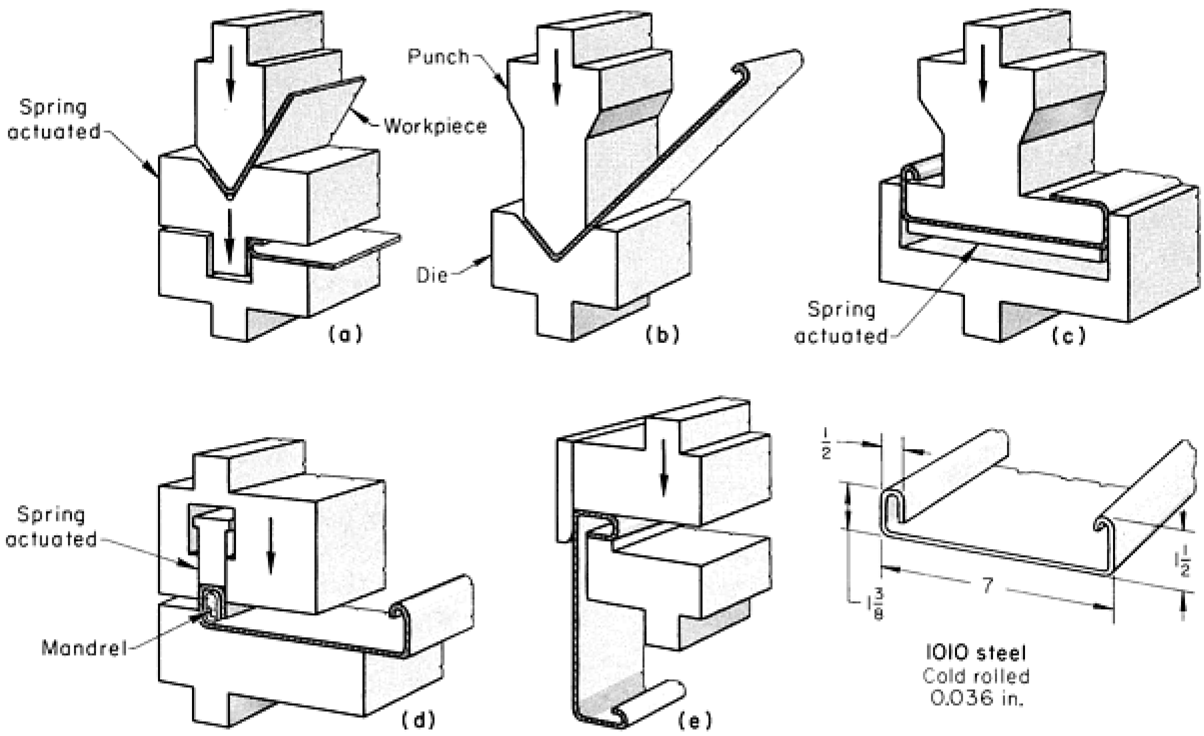

Fig. 22 Setups and sequence of operations for forming a complex shape in a press brake showing use of a restriking operation to eliminate springback. (a) Forming hem in two strokes. (b) Forming of first 90° angle for box section. (c) Forming channel. (d) Closing of box section over a mandrel. Part was moved by sliding it off mandrel. (e) Restriking of box section to eliminate springback. Dimensions given in inches.

Rolling Direction. In the press-brake forming of steel, the effect of rolling direction is often a greater problem than in other methods, because long members are usually bent in a press brake and bends are made with axes parallel to the rolling direction, which is the least favorable orientation. However, it is sometimes possible to take advantage of directionality. The most severe bends can be made perpendicular to the direction of rolling, or if several bends are required along axes that are not parallel with each other, the layout can be planned so that all bends run diagonally to the direction of rolling. The difference in behavior of the same steel bent in both directions in a press brake is demonstrated in the following example.

Example 7: Effect of Rolling Direction on Bending.

An axle bearing support was produced in four bends (Fig. 23) in a press brake using standard 90° V-dies. Cracks could not be tolerated. No cracks appeared on the flanges formed on the short dimensions, which were bent 90° to the direction of rolling to a 6.4 mm ($\frac{1}{4}$ in.) radius. However, in bending the flanges on the long dimensions, parallel with the direction of rolling, open breaks appeared along the length of the bend. To prevent this cracking, it was necessary to increase the bend radius on the long dimensions to 13 mm ($\frac{1}{2}$ in.) and to prepare the blanks so that the long flanges were formed at a slight angle to the direction of rolling.

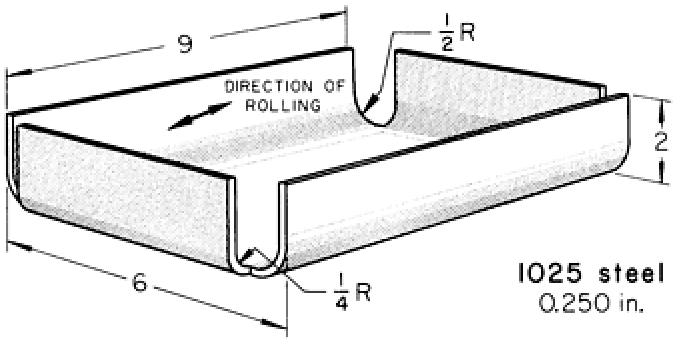

Fig. 23 Axle bearing support for which blank was prepared so that long flanges were formed at a slight angle to direction of rolling to prevent cracking. Dimensions given in inches.

Relation Between Bend Angle and Rolling Direction. As the thickness and yield strength of the work metal increase, the relationship between bend angle and grain direction becomes more important. For example, when stock thickness reaches about 25 mm (1 in.) and the yield strength is relatively high, as in high-strength low-alloy steels, the bend radius should be at least twice (and preferably three times) the stock thickness, even for bends of no more than 45°, when the bend axis is parallel with the direction of rolling.

In the press-brake forming of long, narrow workpieces, bending at an angle to the direction of rolling is seldom practical. For such work, the use of steel sheet that has been cross rolled or subjected to a pinch pass is a simple but relatively expensive means of minimizing the adverse effects from grain direction.

Press-Brake Forming

Dimensional Accuracy

The generally accepted tolerance for dimensions resulting from bending is ±0.41 mm (±0.016 in.) for metals up to and including 3.2 mm (0.125 in.) thick. For thicker metals, the tolerance is increased proportionately. As in many other mechanical operations, obtainable tolerances are influenced by design, stock tolerances, blank preparation, and condition of the machine and tooling. In some cases, close control of variables can provide closer dimensions at no additional cost; in others, cost will be increased.

Design. Bends or holes too close to the workpiece edges make it difficult to maintain an accurate bend line. Notches and cutouts on the bend line make it difficult to hold accurate bend location. Offset bends will shift unless the distance between bends in the offset is at least six times the thickness of the work metal.

Stock tolerances affect the dimensional accuracy of the finished part because they use up a portion of the assigned final tolerance. Commercial tolerances, particularly on thickness to which the specified metal is furnished, should be ascertained. For aluminum, there are minor differences in thickness limits between clad and unclad alloys. For steels, there are significant differences both in thickness tolerances and in cost among hot-rolled sheet, hot-rolled strip, cold-rolled sheet, and cold-rolled strip.

Cold-rolled steel sheet is produced to closer tolerances than hot-rolled sheet, but its cost is higher. Tolerances on steel strip, either hot rolled or cold rolled, are closer than those for corresponding sheet. Established tolerances are closer as the product becomes narrower or thinner.

Thickness tolerances for steel plate are considerably wider than those for hot-rolled steel sheet and strip. When ordered to thickness, the allowable minimum is 0.25 mm (0.010 in.) less than that specified, regardless of thickness, and the allowable maximum for an individual plate is $1\frac{1}{3}$ times the values that are published by the mills and expressed as a percentage of the nominal weight. Therefore, when tolerance requirements are stringent, it should be determined whether the metal can be obtained as strip or sheet rather than as plate.

Blank preparation can have an important effect on the tolerances and the cost of the finished part. If a blank is prepared by merely cutting to length from purchased stock, it will be low in cost, but the width tolerance will be that of the mill product. This may be greater than the tolerance obtainable by shearing. If it is necessary to shear all sides of a blank, the cost will increase, but good shearing can result in greater accuracy.

The stock from which blanks are cut must be flat enough for the blanks to be properly inserted into tooling and to remain in position during forming. Stretcher-leveled and resquared sheet costs a little more, but it is usually necessary when tolerances are close.

Blank Size. To determine the size of the blank needed to produce a specified bent part, the blank dimension (usually, the blank width) at 90° to the bend axis can be developed on the basis of the dimension along the neutral axis.

For 90° bends, as shown in Table 2, the developed blank width can be obtained by deducting bend allowances from the theoretical distance along the outside mold line. These allowances take into account the type and thickness of the work metal and the bend radius--each of which can affect the location of the neutral axis and therefore the developed width. The application of these allowances, which are based on shop practice with low-carbon steel and aluminum alloy 5052, is shown in the illustration in Table 2, for parts having one, two, three, or four bends.

Table 2 Bond allowances for 90° bends in low-carbon steel and aluminum alloy 5052

Metal thickness (*t*)		Bend allowance mm (in.), for bends with inside radius (*r*) of:									
		0.8 mm ($\frac{1}{32}$ in.)		**1.6 mm ($\frac{1}{16}$ in.)**		**2.4 mm ($\frac{3}{32}$ in.)**		**3.2 mm ($\frac{1}{8}$ in.)**		**6.4 mm ($\frac{1}{4}$ in.) steel**	13 mm ($\frac{1}{2}$ in.) steel

Note: w, developed width of blank; t, metal thickness; r, inside radius of bend

For setting the stock stops from the centerline of the punch and die, the distance from the edge of the workpiece to the bend line at the neutral axis (Table 2) must be determined. To establish this value for 90° bends, subtract one-half the bend allowance from the outside flange width.

For bend angles other than 90° or radii other than those listed in Table 2, the width of a strip needed to produce a given shape can be calculated by dividing the shape into its component straight and curved segments and totaling the developed width along the neutral axis. Equation 3 can be used to determine the developed width, *w*, of a curved segment:

$$w = 0.01745\,\alpha(r + kt) \qquad \textbf{(Eq 3)}$$

where 0.01745 is a factor to convert degrees to radians; α is the included angle to which the metal is bent (in degrees); *r* is the inside radius of the bend (in inches); and *k* is the distance of neutral plane or axis from the inside surface at the bend expressed as the fraction of the metal thickness, *t,* at the bend. Empirically determined values of *k* are: $\frac{1}{3}$, for bends of radius less than 2*t;* and $\frac{1}{2}$, for bends of greater radius. Sample calculations showing the use of Eq 3 are presented in the article "Contour Roll Forming" in this Volume.

Permissible bend radii depend mainly on the properties of the work metal and on tool design. For most metals, the ratio of minimum bend radius to thickness is approximately constant, because ductility is the primary limitation on minimum bend radius. Another complicating factor is the effect of work hardening during bending, which will vary with metal and heat treatment.

Condition of Machines and Tools. Machines and tools must be kept in the best possible condition for maintaining close dimensions in the finished product. General-purpose tooling is seldom built for precision work and is frequently given hard use, which contributes further to inaccuracy through wear. Uneven wear aggravates the condition. If the press brake has been allowed to become loose and out-of-square and if ram guides and pitman bearings are worn, accurate work cannot be produced. Good maintenance is as essential in successful press-brake operation as in any other mechanical process.

Press-Brake Forming Versus Alternative Processes

For many applications, press-brake forming is the only practical method of producing a given shape. In one case, for example, press-brake forming was used for a massive workpiece 3 to 3.7 m (10 to 12 ft) long that required several bends spaced at least 152 mm (6 in.) apart.

Under certain conditions, either a punch press or a contour roll former will compete with a press brake in performance and economy. When a workpiece can be produced by two or all of these methods, the choice will depend mainly on the quantity to be produced and the availability of the equipment.

Press Brake Versus Punch Press. When a given workpiece can be made to an equal degree of acceptability in either a press brake or a punch press, the punch press is usually more economical, and it is more efficient than the press brake in terms of power requirements for a given force on the ram and number of strokes per unit of time. In addition, air ejection is more readily adapted to a punch press than to a press brake; this is a factor when air is required for ejecting either the workpiece or scrap.

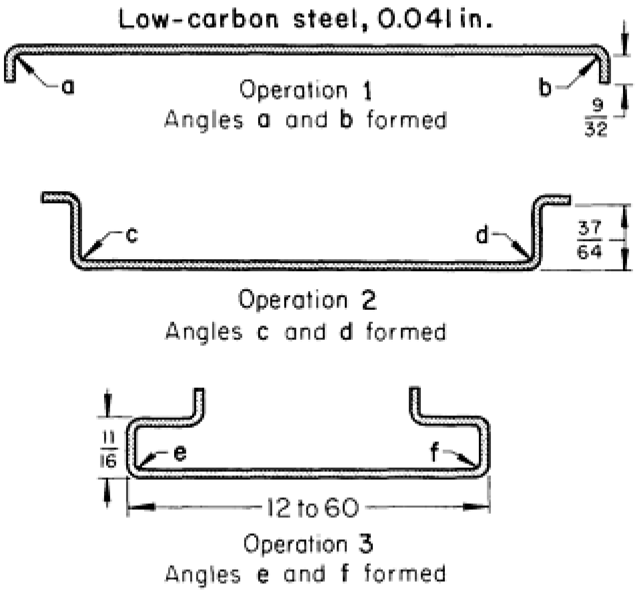
The advantages of a punch press over a press brake are generally greater when production quantities are large and workpieces are relatively small. As workpiece size increases, the advantages of a punch press diminish.

Tooling for a press brake is usually simpler and less costly than counterpart tooling for a punch press--an important consideration for small production quantities. One disadvantage of punch presses is that they are more sensitive to thickness variations of the work metal because they operate at a faster rate.

Press-Brake Versus Contour Roll Forming. For many parts usually formed in a press brake, contour roll forming is an acceptable alternative method of production, and the choice between the two processes depends mainly on the quantity to be formed. Press-brake forming is adaptable for quantities ranging from a single piece to a medium-size production run, while contour roll forming is usually restricted to large-quantity production because of higher tooling costs. An advantage of contour roll forming is that coil stock can be used, while cut-to-length stock must be used in a press brake (see the article "Contour Roll Forming" in this Volume). The following example compares the efficiency of press-brake forming and contour roll forming.

Example 8: Press-Brake Forming Versus Contour Roll Forming.

Parts were produced to the shape shown in Fig. 24 in lengths up to 3.7 m (12 ft) and widths varying from 0.30 to 1.5m (12 to 60 in.). The six bends were originally made in a press brake in three operations. When quantity requirements increased, production was changed to contour roll forming in a tenstation machine, from sheared-to-size sheets. Contour roll forming not only decreased the production time (Table , Fig. 24) but also resulted in improved surface finish, because less handling of the work metal was required.



Item	Time, h	
	Press brake	Roll former
Setup	2.1[(a)]	**9.2**[(b)]

(a) Total for all operations, including dies and gages.

(b) Includes dismantling.

(c) Pieces are 2.5 m (100 in.) long and 1.2 m (48 in.) wide.

Fig. 24 Workpiece formed in six bends in either a press brake or a ten-station contour roll former. Dimensions given in inches.

Safety

Press-brake operations involve the hazards of other press operations. Proper feeding devices are vital in order to ensure the safety of the press operator. Because more than one operator is often needed, added precautions are necessary to prevent the operation of a press brake without the direct consent of each man.

The article "Presses and Auxiliary Equipment for Forming of Sheet Metal" in this Volume contains information and literature references on safe operation. Some of the precautions noted are discussed below.

Barrier guards should be used wherever possible. Hand feeding devices such as vacuum lifters, special pliers, or magnetic pick-ups should always be used to keep operators' hands clear of dies.

When a large workpiece extends in front of the die, the operator often must use his hands to support the workpiece during forming. If a barrier guard cannot be used, because of the arc of travel of the front leg during forming or because the workpiece is of such shape that a guard would prevent loading or unloading of the workpiece, the sheet should be inserted against back gages. These gages, or stops, are adjusted so that the workpiece cannot slide over them.

The workpiece is supported by hand only if there is no other way to support it, and even then only if the operator's hands are not within reach of the die or any pinch point. A die apron or table should be provided to aid in loading large sheets into the die and to act as a support for sheets that do not require hand support. The formed sheet should be removed from the front of the press; parts that cannot be unloaded from the front of the press are moved to the end for removal. End supports may be required to prevent the workpieces from falling.

For versatility, a press brake is provided with a foot pedal to operate the machine. The foot pedal must have a cover guard so the press cannot be tripped accidentally. A foot-operated press brake should incorporate a single-stroke mechanism and be used as a single-operator machine.

When a press brake is used as a power press for stamping, shearing, and notching operations, the foot pedal should not be used. Instead, the press brake should be equipped with electropneumatic clutch and brake controls and should be provided with a single-stroke device. The foot pedal is replaced with two-hand palm switches, which are spaced so that the operator must use both hands to hold the switches until the die is closed. If a press brake is used exclusively for press work, the foot pedal should be permanently removed.

Press Forming of Low-Carbon Steel

Revised by John Siekirk, General Motors Technical Center

Introduction

PRESS FORMING is a metalworking process in which the workpiece takes the shape imposed by the punch and die. The applied forces may be tensile, compressive, bending, shearing, or various combinations of these. In some applications, the metal requires appreciable stretching in order to retain the shape of the formed part.

Although some of the applications described in this article include cutting operations, such as blanking, trimming, and piercing, these operations are discussed in more detail in the articles "Blanking of Low-Carbon Steel" and "Piercing of Low-Carbon Steel" in this Volume. The production of hollow shells from flat blanks is covered in the article "Deep Drawing" in this Volume. Forming that involves only bending is treated in the article "Press Bending of Low-Carbon Steel" in this Volume. The selection of low-carbon steel sheet for formability is discussed in the article "Formability Testing of Sheet Metals" in this Volume and in the article "Sheet Formability of Steels" in *Properties and Selection: Irons, Steels, and High-Performance Alloys*, Volume 1 of the *ASM Handbook.*

Presses

The characteristics of the various types of presses used in forming sheet metal parts are discussed in the article "Presses and Auxiliary Equipment for Forming of Sheet Metal" in this Volume. Restriking, coining, and embossing are usually done in presses with more available force capacity than that needed for the simple forming of similarly sized areas, because in these operations the metal is confined while being forced into plastic flow. Progressive dies are used in presses with enough force capacity to meet the total demands of the various stations and with enough dimensional capacity for the long multiple-station dies. Although some progressive dies are hand fed, most have auxiliary equipment, such as stock feeders, scrap choppers, coil reels, and chutes, to carry the finished parts to containers.

Whether or not a press has a die cushion has some effect on die design and construction costs. Single- and double-action presses are available in about the same ranges of bed size and force capacity. Shallow forming can be done in single-action presses using die cushions or springs to provide the blankholder pressure. Deeper forming and the forming of large irregular shapes generally must be done in double-action presses with die cushions.

Springs, cams, fluid pressure, or press knockouts are used for piece ejection. The use of blank feeders and piece ejectors or extractors depends on the production rate and safety requirements.

Transfer Presses. In transfer machines (eyelet machines), the mechanism for moving the workpiece from station to station is a part of the machine to which suitable transfer fingers are attached. Transfer presses are generally long-bed straight-side presses. The transfer mechanism as a part of the press is actuated by the main press drive or is powered separately. A dial feed is a type of transfer mechanism that moves the workpiece from die to die in a circular path rather than in a straight line. Transfer press technology has progressed to the point at which large automotive outer body panels can be formed in transfer presses.

Multiple-slide machines are designed for automatic, complete production of a variety of small formed parts. Flat stock is fed into a straightener, into a feed mechanism, and then through one or more presses incorporated in the multiple-slide machine for operations such as piercing, notching, and bending--often in a progressive die. The feed mechanism then moves the metal into the multiple-slide forming area, where it is first severed by a cutoff mechanism to predetermined lengths. The piece is usually formed around a center post by four sets of tools mounted 90° apart around the forming post. Finally, the part is stripped off the center post and dropped through a hole in the bed. More information on the forming of steel in these machines is available in the article "Forming of Steel Strip in Multiple-Slide Machines" in this Volume.

Press Forming of Low-Carbon Steel

Revised by John Siekirk, General Motors Technical Center

Speed of Forming

Speed of forming has little effect on the formability of steels used for simple bending or flanging or for moderate stretching. The maximum velocity of the punch when it contacts the blank in such conventional press forming is usually not greater than about 1 m/s (200 ft/min). However, the steels used for most parts that involve local stretching of more than 20% in forming move considerably over the face of the punch or flow appreciably over the blank-holder. The flow of the metal in such operations is controlled by frictional forces so sensitive to speed that the steel often stretches to failure before moving against the frictional forces, provided the punch velocity exceeds a critical value, which differs for each steel and die combination. A maximum punch velocity of 0.2 m/s (40 ft/min) is recommended; high punch speeds also shorten tool life.

Lubrication

The type of lubricant used usually has little effect on the grade of steel selected to form a given part. The main purposes of a lubricant are to prevent die galling and die wear and to reduce the friction over critical areas, thus allowing proper flow of metal and possibly a reduction in severity class. The selection of the optimal lubricant for a given part is a complex problem that depends on part geometry and the forming process used.

In progressive dies, a light oil sprayed on the strip as it enters the die is often enough to keep the stock lubricated through all stages. The oil is generally applied to the stock between the feeding device and the die. Applying oil to the stock ahead of the feeder may cause variation in the feed length, depending on the type of feeder.

For some applications, residual mill oil or the residue from emulsion cleaning provides enough lubrication for forming. When this is not adequate, a spray or mist lubricant can be applied to the work metal as it enters the die. More information on lubricants is available in the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume.

Press Forming of Low-Carbon Steel

Revised by John Siekirk, General Motors Technical Center

Dies

Dies for the press forming of low-carbon steel are made from a wide range of materials, including plastics, cast irons, tool steels, and cemented carbides. Severity of forming, number of parts to be produced, workpiece shape, work metal hardness, specified surface condition, and tolerances affect selection of the die material. These factors are discussed in the article "Selection of Materials for Press-Forming Dies" in this Volume.

Low-carbon steel can be formed by any of the several types of dies described in the following paragraphs. Workpiece size and shape, production volume, tolerances, and available presses are the major factors that determine the most suitable type of die for a specific application.

Single-operation dies perform one operation at a time and are individually loaded and unloaded. They are usually set up in a press, and the operation is performed on a specific lot size. The die is then removed from the press, and the next die in the sequence is set up. For continuous production, a line of presses, each operating a single die, can produce finished pieces from raw stock without interruption for change in setup. Occasionally, more than one die is set up in a press at a time, and the parts are moved manually from one die to the next. With this type of tooling, more than one operation is done in each stroke of the press. Single-operation dies are used when:

- The operations are so interrelated that they cannot be done in a compound die
- The amount of work done on a part is approaching press capacity, and more work would overload the press
- Production quantity is low, and two or more single-operation dies would be less costly than a die combining operations

Single-operation dies do not necessarily have a low production rate. Coil stock can be fed automatically into blanking dies at a high rate. Blanks can be fed into, and workpieces ejected from, forming dies either manually or mechanically. Presses with inclined beds permit high-speed loading and unloading.

Single-operation dies can often be run at high speed. When a higher rate of production is needed, it is sometimes more practical to increase the speed of the press than to use an additional die, provided the flywheel, bearings, gibs, and gears can withstand the additional speed.

Compound dies are one-station dies in which more than one operation is done on a workpiece in one press stroke without relocating the workpiece in the die. The operations must be such that their inclusion does not weaken the die elements or restrict other operations. The operations are generally done in succession in the course of the press stroke, rather than simultaneously.

Typical combinations of operations include:

- Cutting a blank from a strip and then forming
- Lancing and forming a tab or louver
- Forming a flange and embossing stiffening bead

When a die is used for blanking and forming a part, holes can often be pierced in the bottom with the same die. When pierced holes are required in a flange, piercing should be done after the flange has been formed; otherwise, the hole (and perhaps the edge of the flange) can be distorted. The combination of lancing and forming is common. Continued travel of the lancing punch does the forming. Flanging can be combined with forming or embossing if no metal flow is necessary after the flange has been formed.

A compound die may or may not cost more than a set of single-operation dies. Loading and unloading can be automated or manual. Compound dies are generally operated at slower speed than single-operation dies. In the automotive industry, single-operation and compound dies are both set up in a press line. Coil stock or blanks are automatically fed into the first press, and the workpiece is automatically removed and transferred to the next press, where the cycle is repeated until the workpiece is completed. Typical parts are front grills, hoods, roof panels, and deck lids.

Several operations can be performed successively on a workpiece in a press, using two or more compound or single-operation dies. The parts can be manually transferred from die to die, eliminating storage and transfer between presses. The capacity of a large-bed press may be more fully utilized by performing several operations during each press stroke.

Progressive dies perform a series of operations at two or more die stations during each press stroke as the stock is moved through the die. One or more operations are done on the workpiece at each die station. As the outline of the workpiece is developed in the trimming or forming stations, connecting tabs link the workpiece to the strip until the workpiece reaches the last station, where it is cut off and ejected from the die. Pilot holes that are engaged by pilot pins in the die keep the workpieces aligned and properly spaced as they progress through the die.

The initial cost of a progressive die is generally greater than that of a series of individual dies for the same workpiece. However, unless the production quantity is low, the lower setup, maintenance, and direct-labor costs for the progressive die will often outweigh its higher initial cost.

A set of individual dies is sometimes used for making a complex part prior to the designing and building of a progressive die. This is done for two reasons. First, a set of individual dies can usually be made in less time than a progressive die, thus permitting earlier production startup, and second, the experience gained in producing the parts in individual dies can be used in designing the progressive die. From this experience, it can be determined:

- How the metal flows and reacts in the die
- How much work can be done in each operation
- What is the best sequence of operations
- What the size and shape of the developed blank should be

Although a progressive die runs more slowly than a single-operation or a compound die for similar work, overall production is usually higher because the die is operated more continuously. Progressive dies are used to perform an almost endless variety of operations on one piece. Operations that can be combined in a progressive die include notching, piercing, coining, embossing, lancing, forming, cupping, drawing, and trimming.

Transfer dies are similar to progressive dies except that the workpieces being processed are not attached to a strip but are mechanically moved from station to station. A blank is automatically fed into the first station and moved to the next at each press stroke. The first station can be a blanking die, which cuts a blank from manually or automatically fed stock during each press stroke.

Selection of Steel for Forming

Hot-rolled commercial-quality rimmed steel is suitable for many forming applications and has the advantage of minimum cost. Cold-rolled, drawing-quality, special-killed, and temper-passed steel has maximum formability and yields parts with the best appearance and finishing characteristics, but it is more expensive.

In selecting steel for forming, attention must be paid to deoxidation practice. Killed steel is preferred where sheets must be free of significant changes in mechanical properties (strain aging) for a long time, where neither stretcher strains (Lüders lines) nor roller leveling is permitted, or where better mechanical properties are desired for severe forming applications.

Generally, killed steel has mechanical properties that are superior to those of drawing-quality rimmed steel (particularly, it has low yield point); killed steel also has better formability and performance, less tendency to form buckles, and is usually free from aging. However, inferior surface properties and more surface defects can be expected from killed steel than from rimmed steel, with consequent higher scrap or repair loss because of these defects. In addition, panels produced from killed steel are usually less resistant to handling damage and oil canning because of the lower yield strength of this steel.

Most major producers of stampings restrict the use of killed steel to the most severe draws, to low-volume parts when the steel inventory cannot be used before aging begins in rimmed steel, and to small or irregularly shaped parts for which sheet cannot be roller leveled successfully. To ensure optimal performance, killed steel should have a fine, flat, elongated grain; ASTM grain size 7 to 8 is preferred. Stretcher strains may often be removed by roller leveling if the size and shape of the blank permit. However, this is the responsibility of the supplier because killed steel is expected to be usable without roller leveling.

Adding a die operation may reduce the severity of forming enough so that a rimmed steel can be used instead of a killed steel. The overall cost of producing a part is usually the criterion for determining whether to use a more expensive grade of steel or a more expensive die system. Depending on blank size, die complexity, and number of pieces to be produced, the savings in material may offset the additional die costs.

Press Forming of Low-Carbon Steel

Revised by John Siekirk, General Motors Technical Center

Stretcher Strains

Stretcher strains, or Lüders lines, and the Piobert effect, also known as worms, are characteristic markings that appear on the surface of low-carbon steel that has been annealed as a final mill operation. These lines appear during the early stages of stretching and almost disappear as the stretch exceeds 5 to 10%. In tension, the lines are depressions in the surface; in compression, they are raised; and in bending, the same phenomenon causes flutes or kinks. Stretcher strains have no harmful effect on strength. In stampings that are visible in service, stretcher strains are generally unacceptable, because they show clearly through paint.

Stretcher strains can be avoided by a temper pass of about 1% cold reduction after final annealing. The correction is normally permanent in killed steel, but stretcher strains frequently recur in rimmed steel unless it is formed in 1 week or less, depending on the amount of temper pass, the temperature, steelmaking practice, and the amount of forming in the stamping.

The probability of stretcher straining can be eliminated from temper-passed rimmed steel and from insufficiently temper-passed killed steel by roller leveling through a machine that flexes the sheet sufficiently in bending to remove the sharp yield point and the yield point elongation that cause stretcher strains. This amount of cold work does not reduce drawing quality (in some steels, the quality may be improved by reducing the yield point), but additional strain aging is induced, which reduces formability if the steel is stored after roller leveling. Roller-leveled steel should be used within 24 to 72 h after leveling. The sheet should be passed through the roller leveler once in each direction because about 455 mm (18 in.) of the entering end of the sheet is not flexed.

Occasionally, a lift, or even a shipment, of steel does not respond to roller leveling. If such material is unsatisfactory after two passes through the roller leveler, it should not be used for parts that will be exposed in service. However, the performance of annealed steel used for a very difficult unexposed part can be improved by a single pass through the roller leveler.

Annealed sheet cannot be roller leveled for an exposed part, because the flex roll kinks the sheet so severely that, after forming, the deformation will not disappear. In addition, small stretcher strains will occur between the kinks.

Coil breaks and stickers have the appearance of stretcher strains, but both are distinctly different. Coil breaks are regularly spaced, and stickers are spotty. Roller leveling has no effect on these defects.

Strain Aging

The effect of aging of rimmed steel on formability is variable and may be impossible to predict on the basis of tests. One rimmed steel may not age at all, while another may make the most difficult draws when received and, after aging 30 days, may not make minimum draws.

After an operation such as blanking, forming, or finishing, strain aging is more pronounced than for unworked steel. It is therefore advisable to complete the sequence of operations on a part without intervening storage unless artificial aging tests positively indicate the absence of aging.

Artificial aging tests give an approximate measure of the strain-aging characteristics of the steel, but do not predict the time at which definite changes in mechanical properties will occur. Artificial aging does not change the tensile strength appreciably; however, yield strength and hardness will always increase, while elongation and uniform elongation will always decrease.

Press Forming of Low-Carbon Steel

Revised by John Siekirk, General Motors Technical Center

Surface Finish

The surface roughness of sheet steel has an effect on the finishing cost and the appearance of the formed product as well as on processing in dies and on other operations. Dull or slightly roughened surfaces are used especially in parts with the deepest draws in order to retain lubricant through the operations for minimum scoring of the dies and for better flow of metal over pressure pads. Sheet with a surface roughness of about 0.75 to 1.3 μm (30 to 50 μin.) draws well and is smooth enough for most painted parts, such as hood tops and fenders, that require average paint finish.

Single-dip or painted parts intended for trim and interior moldings require a smoother surface of about 0.25 to 0.5 μm (10 to 20 μin.). Sheet for average decorative chromium-plated parts should have surface roughness no greater than 0.25 μm (10 μin.) where the surface is to have no preparation except a light polishing to remove die marks. Parts with surface roughness as high as 0.4 μm (15 μin.) require additional surface preparation--for example, buffed copper plate applied before another plating.

The selection of fine-grain steel (ASTM grain size of 9) with minimum surface roughness for forming usually sacrifices some ductility and latitude in die design. With fine grain, the steel will be somewhat harder, higher in yield point and elastic ratio (yield point/tensile strength), lower in elongation and uniform elongation, and more likely to strain age.

Surface defects in unexposed parts may be acceptable if the function or the strength of the part is not affected. The following example describes the use of two different grades of steel for forming a concealed panel on which surface defects were acceptable and for forming a panel that required a smooth surface for painting.

Example 1: Effect of Grade of Steel on Surface Finish of Severely Formed Parts.

Figure 1 shows an inner panel for a glove-compartment door that was made of 0.81 mm (0.032 in.) thick cold-rolled drawing-quality rimmed 1008 steel. On some parts, stretcher strains appeared in the severely stretched flat surface, as shown in Fig. 1. When the stock strained, the parts were used for a part number where the surface was covered by another detail. Parts that had severe stretcher strains also cracked in the areas shown in Fig. 1 and were not acceptable.

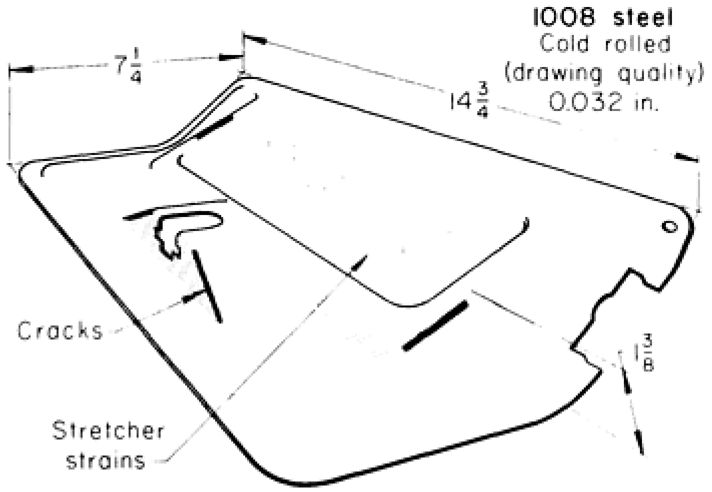


Fig. 1 Formed panel on which stretcher strains and cracks sometimes occurred. Some of the strained parts could be used in applications in which they were concealed in service; cracked parts were unacceptable. Dimensions given in inches.

The outer panel for the same door, however, was visible and had to have a maximum surface roughness of 1.15 μm (45 μin.) before it was painted. Killed or flex-rolled steel strip was used for the outer panel to minimize the stretcher strains.

The transfer die for the door panel was set up in a 7 MN (800 tonf) straight-side mechanical press operating at 500 strokes per hour. The die was cleaned after each shift, and it was resharpened after making 40,000 pieces. Lubrication was a chlorinated oil applied to the stock by rollers.

Revised by John Siekirk, General Motors Technical Center

Process Development

Users should control the type of tryout steel furnished for process and tool development and tryout runs. Steels that are below the average quality expected in regular production shipments should be selected. For tentative severity classification of a part, a steel near maximum in hardness and near minimum in formability should be used.

Tools developed with steel of below-average quality are seldom troublesome and run with minimum tool breakage and steel rejection when the production run begins. They are also less sensitive to pressure adjustments, variations in sheet thickness, or normal variations in steel properties, and maintenance costs are usually less. Conversely, tools developed with steel of above-average quality are often unsatisfactory when forming regular production shipments of steel. In the following example, rimmed steel was replaced by killed steel after initial forming experience.

Example 2: Use of Killed Steel to Avoid Annealing.

The steel originally used to form the cross-suspension member shown in Fig. 2 was 2.44 mm (0.096 in.) thick hot-rolled, drawing-quality rimmed 1010 steel. The blank edges strain-age hardened sufficiently during the time (up to several days) between blanking and forming to cause the edge in the hump area (Fig. 2) to fracture during forming.

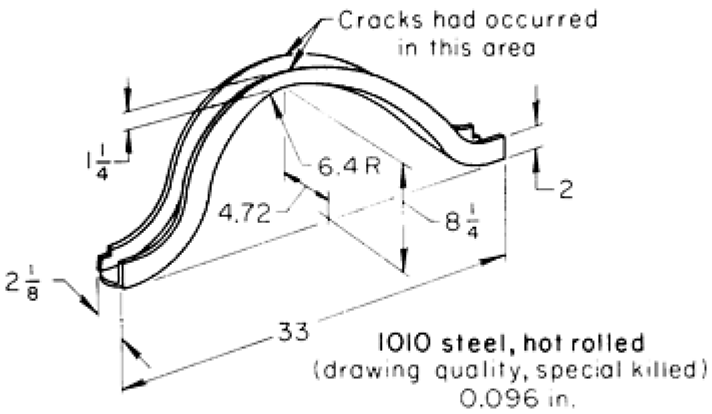

Fig. 2 Cross-suspension member that was made of killed steel rather than rimmed steel to avoid strain-age hardening that caused cracking during forming. Dimensions given in inches.

The part was produced in the following sequence of operations:

- Blank
- Coat with dry soap film lubricant
- Preform to start the center hump
- Form
- Pierce holes in the side of the channel section (not shown in Fig. 2)

In the hump area, the stretch along the edge was 25 to 33%. The blanking operation was separate from the forming operation, and 1 day or more usually elapsed between blanking and forming. Strain aging occurred during this period. The time between blanking and forming included application of the lubricant, which involved heating the blanks to 100 °C (212 °F) to dry the film. The strain aging occurred as a combined result of the baking temperature and time lapse.

In the first effort to correct this condition, the rimmed steel blanks were annealed before forming. The use of special-killed 1010 steel (also hot rolled and drawing quality) was then considered. The killed steel cost more than the rimmed steel, but the elimination of annealing and handling costs yielded a cost savings.

The parts were run in a 4.5 MN (500 tonf) double-action toggle press at 12 strokes per minute. Annual production was 300,000 pieces.

Annealing

Descriptions of procedures for full annealing, in-process annealing, spheroidizing, and normalizing are given in *Heat Treating*, Volume 4 of the *ASM Handbook.* Pieces formed from fully annealed sheet have a tendency toward stretcher straining and fluting; therefore, fully annealed sheet is used most often for unexposed parts, for which these conditions are not objectionable. Workpieces that must have a specified hardness after forming are made of annealed, spheroidize-annealed, or pretempered stock, depending on the severity of the forming operation.

Where only a spot or local anneal is needed for further forming, the area can be heated with torches to 870 to 925 °C (1600 to 1700 °F). The disadvantages of torch annealing are the lack of close control and the formation of scale. Areas that have been heated must be cleaned by pickling, abrasive blasting, or polishing.

In-process annealing is done after some press-forming operations to remove the effects of cold work and to increase formability for subsequent operations. To prevent the formation of scale, a protective atmosphere is used during the heating and cooling of the workpiece. An inexpensive exothermic atmosphere is sufficient for low-carbon steel. If a protective atmosphere is not available, the annealed work usually must be pickled or abrasive blasted to remove scale.

Process annealing often causes excessive grain growth. If the pieces have been subjected to a considerable amount of cold work before annealing, they may crack during subsequent forming and may have a rough surface appearance in the formed area.

Press Forming of Low-Carbon Steel

Revised by John Siekirk, General Motors Technical Center

Cleaning

The procedure for cleaning steel sheet before forming depends on the type and amount of soil present and on the finish specified for the formed surface. Removing soil before forming improves the surface finish, prevents marking of the formed piece, and prolongs die life. Large particles can be removed by wiping, which allows oil to remain and act as a lubricant. Coil stock can be cleaned by feeding it between wiping pads at the press. Another method is to feed the coil through a vat of emulsion cleaner or a light-duty drawing lubricant before it passes between the wiper pads. This procedure is an economical means of simultaneously removing foreign material and providing lubrication.

Cleaning the steel in this manner normally does not completely remove the smudge from the surface. This condition is generally desirable because the smudge acts as a filler in the lubricant. Many parts are formed using only mill oil with its smudge for lubrication. If the smudge must be removed, a rotating brush can be used between the emulsion cleaner and the press to scrub the work metal surfaces.

Scale is often removed by abrasive blasting or pickling before the hot-rolled sheet is formed. Both methods remove the residual lubricant. Workpieces that have been in-process annealed without a protective atmosphere are usually cleaned by abrasive blasting before final forming. The need to clean parts after forming is determined by the subsequent operations and by the necessary finish. The necessity for cleaning immediately after forming can be minimized by choosing lubricants that are compatible with welding, painting, plating cycles, and handling. More information on the cleaning of parts is available in *Surface Engineering*, Volume 5 of the *ASM Handbook.*

Deburring of Blanks

The deburring of blanks prior to forming depends on the operations performed on a blank and on the end use of the formed part. Burrs on blanks that will be severely formed can reduce formability and increase breakage. Burrs are unsafe and unsightly on the exposed portions of consumer products. Burrs on blanked or pierced parts cannot be avoided, but their formation can be minimized by the use of proper clearance between punch and die and by keeping tools sharp (see the articles "Blanking of Low-Carbon Steel" and "Piercing of Low-Carbon Steel" in this Volume).

Revised by John Siekirk, General Motors Technical Center

Work Metal Thickness

Thickness variations in sheet steel can cause parts made on the same tooling to be of different shapes. This is because of springback or because the pressure applied is either insufficient or excessive at sharp corners or at sides that are to be held at a predetermined angle.

If the sheet is too thick, a die or roll adjusted to a certain thickness may pinch the steel and localize the stretching, thus causing fracturing; or it may work harden the steel and cause excessive springback in a subsequent operation. Thickness greater than the die clearance may cause undesirable marring of the surface of the part or galling and scoring on the surface of the tools, and in some cases, it may be the reason for tool breakage.

Revised by John Siekirk, General Motors Technical Center

Workpiece Shape

The size and shape of the workpiece and the number of operations needed to make it must be considered in determining press capacity (both force capacity and bed size) and the type of tooling used. Open-end parts, or parts with one or more open edges, can be formed two or more at a time from a single blank. Sheet metal elbows that cannot be made from tubing are formed four halves at a time, then separated and assembled into two elbows. Small flanged parts with a low ratio of flange width to stock thickness are often difficult to form because of slippage and unbalanced forces. Forming two parts at a time can balance the forces and reduce scrap. More information on the factors that affect press selection is available in the article "Presses and Auxiliary Equipment for Forming of Sheet Metal" in this Volume.

Recessed parts require special precautions in forming to avoid wrinkling in the flat area surrounding the recesses and to prevent cracking the corners of the recess. In the forming of a deep recess in a large panel, for example, adjustment of the blank-holder pressure may be necessary to prevent such failures. In this application, the deep recess is formed first, with the material being drawn into the recess from the end and two sides of the blank; stretching done in the final forming removes wrinkles.

When the cross section of the recess is a circular arc, acceptable percentages of stretch for recesses with various height-to-diameter, h/d, ratios are:

h/*d* ratio	0.10	0.15	0.20	0.25	**0.30**
Stretch, %	**3**	**6**	**10**	**15**	**22**

Dish-shaped parts having only one recess, of regular or irregular shape, are commonly formed by stretching the metal over a punch. The punch nose should be smoothly contoured so as not to trap the metal and should have as large a radius as possible. Parts with a straight sloping surface can be free formed by stretching between a clamp ring and a small-diameter punch. On large parts, stretch is most severe near the punch, and the work metal elongates and drapes from its own weight, forming an undesirable concavity in the wall. Both of these defects, uneven stretch and concavity, can be minimized by using a stepped punch.

Cone-shaped parts that are formed by a combined stretch-and-draw operation can be made in a progressive die without first cutting the contour. This reduces the number of die stations that are required, and more than one part can often be formed at a time.

Shapes With Locked-In Metal. In the forming of some shapes, metal may become locked-in (formed so that metal flow is stopped) before enough of it has been drawn into the cavity to form the part completely, and the metal sometimes fractures before the punch has reached the bottom of the stroke. In some cases, the strain that causes fracturing can be relieved by piercing a hole or lancing the metal in a noncritical area.

Severely Formed Shapes. Developed blanks are sometimes used to provide sufficient metal in critical areas of severely formed parts. Preforming helps to distribute the metal before final forming and restriking operations, thus reducing the severity of these operations. Edge condition and ductility greatly influence the success of severe forming.

Offset Parts (Edge Bending). Scrap loss can sometimes be reduced when blanks can be produced in simple rectangular form and subsequently edge bent in the final shape (see the article "Press Bending of Low-Carbon Steel" in this Volume). Whether or not the severity of the edge-bending operation will adversely affect subsequent forming operations must be considered. A potential savings of work metal can be quickly lost if edge bending work hardens the pieces to the extent that many are broken in forming. In some applications, the tensile and compressive stresses set up in edge-bent blanks can be counteracted by forming stretch flanges around the inner contours of the bends and compression flanges on the outer contours. The same flanges made on a cut blank instead of an edge-bent blank could fracture during flanging. On the other hand, reverse flanges made on an edge-bent blank may cause more severe stress than they would on a cut blank and may possibly lead to a high scrap rate.

The edge-bending operation and its tooling are an added expense in the fabrication of a part. This expense must be compared to the savings of work metal when one method is to be selected over the other.

Revised by John Siekirk, General Motors Technical Center

Large Irregular Shapes

Large parts are usually formed in single-operation or compound dies mounted in large-bed presses. If the part is irregular in shape, care must be taken in shaping the blankholder surfaces, in planning the orientation of the workpiece in the die, and in planning the die operation to obtain approximately even stressing of all areas of the workpiece and to form the piece in the fewest possible operations.

To make shallow draws, sometimes the metal must be locked in place by the blankholder in order to stretch the sheet metal over the punch enough to set the contours. Draw beads or selective local applications of drawing compound are used to restrict and control metal flow.

Large, irregularly shaped parts are often made by preshaping blanks before forming. This method reduces scrap when making the blank and neutralizes the tensile and compressive stresses in the flanges. The blanks for automobile fenders and other parts are preshaped by bending and tack welding them into a cone shape.

Use of Shaped Blankholders. Some parts that are made from preformed blanks are formed with the aid of shaped blankholders to avoid distortion of the previously formed contours. In addition, parts that are not completely formed in one operation may have to be clamped in a shaped blankholder in a second-operation die. The part in the following example had a peripheral offset that served as a locating surface in the second-operation die, but the part had to be clamped to prevent distortion during final forming.

Example 3: Holding a Previously Formed Workpiece in a Shaped Blankholder to Prevent Distortion During Subsequent Forming.

After the first forming operation, the blank for the fan shown in Fig. 3 had a 4.78 mm (0.188 in.) offset outer rim and a 22 mm ($\frac{7}{8}$ in.) deep recessed inner web. The surfaces were used as locators in a shaped blankholder for the subsequent trimming and forming operations.

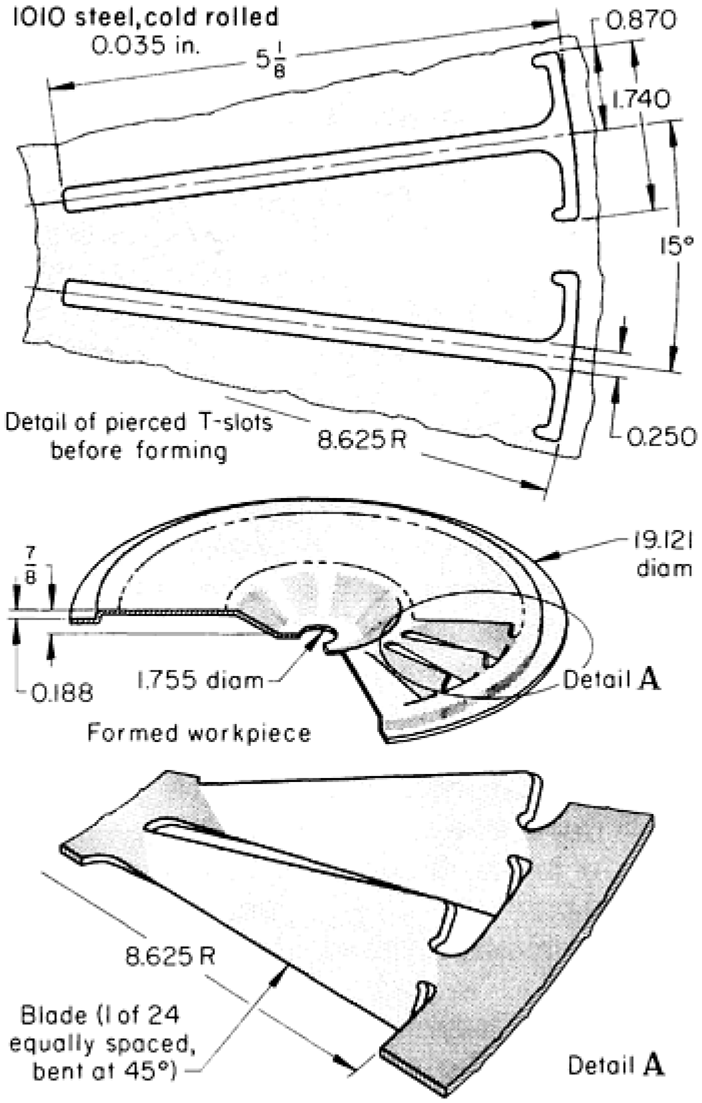

Fig. 3 Large sheet metal fan that was clamped in a shaped blankholder during the second forming operation. Dimensions given in inches.

Spring-loaded pressure pads were used to hold the rim and the web while the blades were twisted. The pressure pads bottomed at the end of the stroke so that any deformation in the rim or the web could be flattened. The 4.78 mm (0.188 in.) offset was placed over a close-fitting plug to prevent radial distortion of the rim.

Three operations were needed to produce the part. In the first operation, the 4.78 mm (0.188 in.) offset was formed to 471 mm (18.550 in.) in diameter, and the 22 mm ($\frac{7}{8}$ in.) deep recess was formed at the same time. In the second operation, the 485.7 mm (19.121 in.) outside diameter was trimmed, and the 44.6 mm (1.755 in.) diam hole and 24 T-shape cutouts at 15° spacing were pierced. The T-slots gave shape to the fan blades and necked the ends of the blades prior to twisting at 45°, which was done in the third operation.

The cutting elements in the dies were made of A2 tool steel. The forming dies for the offset rim and recessed web were of low-carbon high-strength alloy cast iron. The blade formers were made of prehardened low-alloy tool steel. The workpiece was made of a 0.89 mm (0.035 in.) thick cold-rolled 1010 steel blank 510 mm (20$\frac{1}{16}$ in.) square.

Recesses in Large Panels. The forming of recesses in large panels at some distance from the edge can be difficult. Because the sheet is large, the recesses appear to be shallow, but forming may actually be severe in terms of localized deformation.

If the recess is fairly small and far enough from the edges of the blank so that there is a large resistance to metal flow, the metal can be overstressed at the punch nose and can fracture or tear. To prevent tearing, blankholder pressure is kept as low as possible to allow almost unrestricted metal flow, but this may produce wrinkles radiating from the lip of the recess. These wrinkles can be removed by stretching the sidewalls of the recess in a second forming operation.

Large cup-shaped parts that must be stronger in the bottom surface than in the wall are often designed with tapered wall sections. A tapered section can be made by machining the part before or after drawing.

High-strength low-carbon steels of thinner gage than conventional low-carbon steels can be used without tapering, but they are more difficult to draw and are more expensive. The use of a tapered blank for a cup-shaped part is described in the following example.

Example 4: Forming a Large Disk From a Tapered Circular Blank.

The truck-wheel disk illustrated in Fig. 4 was formed from a blank 610 mm (24 in.) in diameter that had been roller tapered from a 500 mm ($19\frac{11}{16}$ in.) diam blank with a 90.5 mm ($3\frac{9}{16}$ in.) diam center hole. Taper was about 0.04 mm/mm (0.04 in./in.) of radius. The material was annealed hot-rolled 1012 or 1015 steel, 9.52 mm (0.375 in.) thick, abrasive blasted to removed scale and oxide.

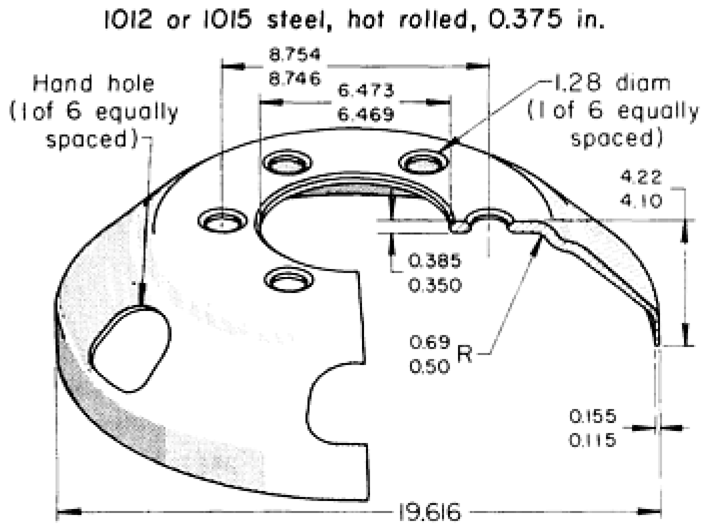

Fig. 4 Truck-wheel disk that was formed from a tapered blank. Dimensions given in inches.

The blanks were tapered back to back, two at a time, giving each disk only one rolled surface. The tapering rolls were stopped before reaching the edge of the blank in order to maintain an even taper. Otherwise, lack of resisting stock at the edge would have caused a torn edge. Tapering started at a diameter of 260 mm ($10\frac{1}{4}$ in.), just beyond the circle describing the outer edges of the six round holes; this gave a stock thickness of 8.38 mm (0.330 in.) at the 17.5/12.7 mm (0.69/0.50 in.) radius.

The combined forming and trimming operation was done in a 13.3 MN (1500 tonf) hydraulic press with the rolled surface of the work face down in the die. The blank was trimmed to 584 mm (23 in.) in diameter in a compound blank-and-draw die at a rate of 375 per hour. The die was made of O1 tool steel and was reworked after making 40,000 pieces.

A second operation sized the 498.2 mm (19.616 in.) outside diameter, enlarged the center hole to 164.4 ± 0.05 mm (6.471 ± 0.002 in.) in diameter, and pierced six 32.5 mm (1.28 in.) diam holes, using a 7.1 MN (800 tonf) mechanical press. In the third operation, six hand holes were punched, one at a time. To attach a rim to a disk, 16 rivet holes evenly spaced around the circumference of the flange were pierced in both the disk and the rim at the same time.

The optional 1015 steel had the highest carbon content that could be used in this part. Work hardening increased its strength and hardness. If the hardness of the workpieces exceeded 91 HRB, hairline cracks radiated from the rivet holes, causing rejection, as observed when 1020 steel was used.

Localized severe forming is encountered in making many large irregular shapes by press forming. This imposes stringent demands on process planning; quality of work metal; lubrication; and the design, material, and maintenance of dies--as demonstrated in the following example.

Example 5: Severe Embossing and Hole Flanging in Press Forming a Control Arm.

The severe embossing and hole flanging demanded on the automobile control arm shown in Fig. 5 required the use of drawing-quality steel for the workpiece and high-quality tool steel for the dies, close attention to tool maintenance, and the use of a heavy-duty lubricant. The stock was hot-rolled drawing-quality rimmed 1008 or 1010 steel, pickled and oiled, with a hardness of 55 HRB. Commercial-quality steel had been tried, but was unsatisfactory for the severe forming. Stock thickness was 3.96 or 4.17 mm (0.156 or 0.164 in.). Wall thickness of the hole flanges had to be at least 2.67 mm (0.105 in.), and flange width was 7.62 mm (0.30 in.). The parts were formed with dies of hardened W2 tool steel. A developed blank was used, making a final trimming operation unnecessary. The operations were as follows:

- Blank to developed outline, pierce two locating holes, form center boss--done in a 1.8 MN (200 tonf) mechanical press with W2 tool steel die inserts hardened to 57 to 60 HRC
- Form in a 5.3 MN (600 tonf) mechanical press using W2 tool steel dies hardened to 61 to 64 HRC
- Pierce two holes in flanges, enlarge one locating hole, pierce oval hole in center boss--done in a 620 kN (70 tonf) inclined-bed mechanical press
- Restrike to size and sharpen radii, form dimple, flange round hole and oval hole in a 5.3 MN (600 tonf) mechanical press
- Pierce remaining holes in a 620 kN (70 tonf) inclined-bed mechanical press
- Outward flange two side holes to 35.5/35.4 mm (1.398/1.394 in.) in diameter, 2.67 mm (0.105 in.) minimum wall thickness, and 7.62 mm (0.30 in.) minimum flange height, using hydraulic equipment designed for this part

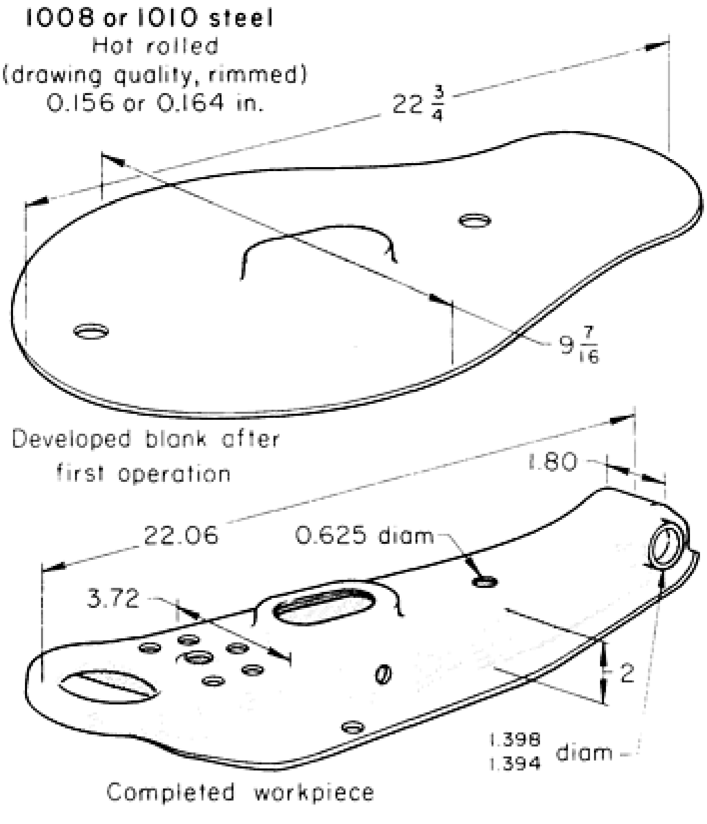

Fig. 5 Press-formed control arm on which embossing and hole flanging were of near-maximum severity. Dimensions given in inches.

A dry-film lubricant consisting of soap and borax was applied to the blank. Where further lubrication was needed, an oil-base compound was added. Production rate ranged from 200 to 325 pieces per hour, production-lot size was 10,000 pieces, and annual demand was more than 200,000 pieces. Except for minor repairs, the dies were good for one year of production.

Blanks That Cannot Be Nested. Irregularly shaped parts frequently must be made from developed blanks with a contour that makes close nesting of the blanks impossible. Channel-shaped parts with flanges or web of varying width use blanks that are cut with more scrap than parts with flanges or web of unvarying width, and an excessive amount of scrap may be generated in producing them.

In some applications, material that would otherwise be wasted can be moved into a useful location after notching or lancing. This was done in the following example, in which the web was notched at the end and then spread into a V-shape to increase flange height at the ends and to reduce blanking scrap.

Example 6: Use of a Notched Blank to Increase Flange Width and Reduce Scrap in Forming an Irregular Channel-Shaped Part.

A flange of varying width was needed on the channel-shaped truck-frame member shown in Fig. 6. Instead of using a contoured blank, which would have meant considerable waste in blanking, the additional flange width was gained by notching each end of a nearly rectangular blank and spreading the notch into a V-shape during the forming operation. The end of each notch was radiused to minimize cracking during forming. The stock saved by notching the blank was 1.4 kg (3 lb) per piece.

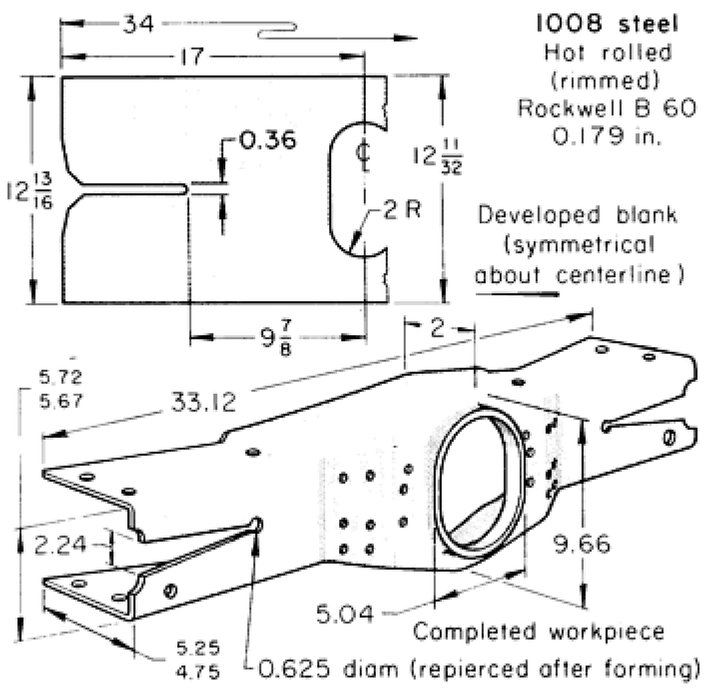

Fig. 6 Press-formed truck-frame member that was notched and spread to increase flange width locally and therefore save material in blanking. Dimensions given in inches.

The workpiece was made of 4.54 mm (0.179 in.) thick hot-rolled, rimmed 1008 steel, pickled and oiled. Each of the two notches in the blank was 9.1 mm (0.36 in.) wide by 181 mm ($7\frac{1}{8}$ in.) long. The notches were spread to make V-shape openings 56.9 mm (2.24 in.) wide at the ends. Flange widths varied from 50 mm (2 in.) at the center of the part to 127 mm (5 in.) at each end of the channel. The operations were:

- Cut blank to developed outline, and pierce large center hole (Fig. 6). A 3.1 MN (350 tonf) mechanical press with a mechanical unloader produced 300 to 400 blanks per hour
- Form completely, including flange around center hole, in a 16 MN (1800 tonf) hydraulic press
- Pierce all holes in the web, and trim 18.8 mm (0.74 in.) radius at two places on each end in a 2.9 MN (325 tonf) mechanical press
- Pierce holes in top and bottom flanges, and restrike flange ends in a 2.9 MN (325 tonf) mechanical press

Presses for the second, third, and fourth operations listed above, operating at 250 to 310 strokes per hour, were set up in a line with transfer equipment between them. In the second operation, a spreader was incorporated into the die to assist in opening the notch to a V-shape. The 181 mm ($7\frac{1}{8}$ in.) length of the notch had been carefully developed so that the notch would spread to the required maximum width without causing the work metal to split. After forming, a 15.87 mm (0.625 in.) diam hole was pierced at the end of each notch to remove any fractured material or other stress raisers aggravated by the severe edge forming.

The forming punches were made of 1045 steel. The wear surfaces on the punch and die were W2 tool steel hardened to 61 to 64 HRC. As a lubricant, a soap solution was dried on the stock. Some heats of steel were difficult to form; for these, an oil-base compound was used as additional lubricant.

The truck-frame member was made in lots of 27,000 pieces for an annual production of 270,000 pieces. Except for minor repairs, such as replacing small punches, the dies were good for 1 year of production.

Use of Draw Beads. A draw bead in a blankholder controls the movement of metal into the cavity by providing additional resistance to metal flow. The location of the beads is usually determined in die tryout; dies for producing similar parts can be used as a guide.

A single bead is generally placed around the cavity, and additional beads are placed in areas where more control is needed. Conditions may indicate that the bead size should be reduced or that the whole bead omitted in some places. Short beads can be placed at an angle to deflect metal into or away from local areas.

Whether the bead is placed in the draw ring or in the blankholder is determined by the die construction. Placing the groove in the upper member has the advantage that it will not catch dirt. However, the groove should be put in the member that is to be altered during spotting for mating of opposing surfaces. For convenience in making alterations, this is usually the lower member.

Unless they are part of the product design, draw beads are placed outside the trim line, as shown in Fig. 7(a). The trim line can be on the punch or the blankholder. A locking draw bead, such as that shown in Fig. 7(b), is used to provide maximum restriction to metal flow. Locking beads are used when forming to shape is done primarily by stretching the metal under the punch, rather than by moving metal into the cavity.

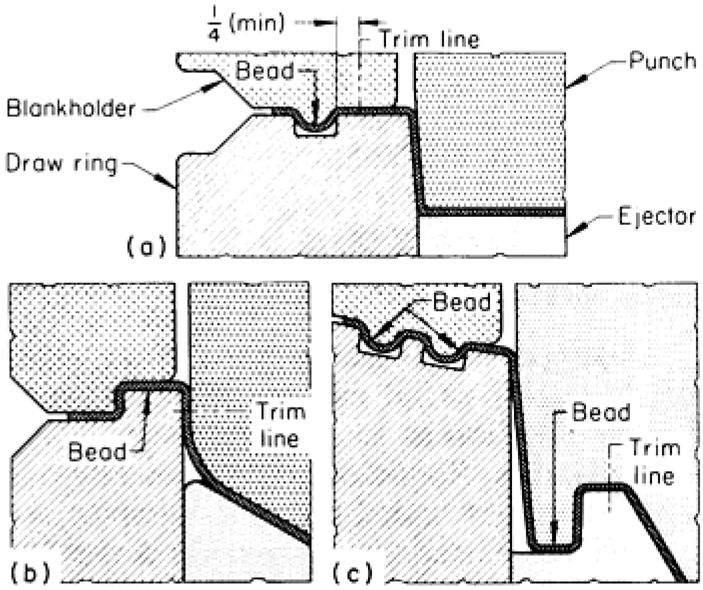

Fig. 7 Use of draw beads. (a) Conventional. (b) Locking. (c) Combined conventional and locking. Dimensions given in inches.

Figure 7(c) shows the use of conventional and locking beads. Here, conventional beads control metal flow into the die cavity until the last portion of the punch movement, when the locking bead gradually engages the metal to restrict its flow. The last fraction of a millimeter of punch travel causes stretch in the metal under the punch.

Beads in the concave surfaces of a blankholder are usually 3 mm (0.12 in.) deeper than beads on the top or straight surfaces. This eliminates locking on the top surfaces during preforming of the blank to the shape of the concave blankholder surface.

Sometimes, draw beads need not be used for the full depth of draw, or need to be used only in certain locations, such as the corners of regular or irregular polygon-shaped parts. In such cases, some of the material may be allowed to slip through the draw bead to be retained at the end of the stroke only by blankholder pressure. More information on the design and construction of draw beads is available in the article "Deep Drawing" in this Volume.

Press Forming of Low-Carbon Steel

Revised by John Siekirk, General Motors Technical Center

Forming of Ribs, Beads, and Bosses

Unsupported sheet metal surfaces that might buckle or oil can are often stiffened by the addition of long, thin bosses called beads or ribs. Round or nearly round bosses are sometimes called buttons. Dimples are occasionally used as a recess for a rivet or screw head. The forming of ribs, beads, and bosses is a combination of bending, stretching, and drawing and involves high shear forces.

Design of Bosses. Bosses are usually about one stock thickness in depth. The radius of curvature on the inside of bends is about one stock thickness. A typical bend appears to be about four stock thicknesses wide on the convex side and about three stock thicknesses wide on the concave side. Some recesses for screw heads have sloping sides with very little curvature.

Bosses are typically produced at the same time that other forming operations are done and in the same dies, although they can be formed at separate stations in a progressive die. Die clearances can be critical in the forming of decorative bosses and embossed lettering, especially when definition must be sharp and detail must be accurate. On the other hand, reinforcing beads usually do not require great accuracy and can be produced in dies with the clearances typical of ordinary forming.

Use of Bosses. Bosses are often used to provide flatness, stiffness, and reinforcement to formed parts. They can also serve as locators for subsequent operations. In Example 5 in this article, an oval boss was used as a hole-locating surface and as the hole flange. The most frequent use of embossed beads is to lighten the weight of products by making it possible to use thinner metal than would be feasible without bosses, as described in the following example.

Example 7: Use of a Bead for Stiffening a Corner Bracket.

The corner bracket shown in Fig. 8 had a bead on the flat surface to produce stiffness. The work material was 1.09 mm (0.043 in.) thick cold-rolled 1008 or 1010 steel. The bead made the use of heavier stock unnecessary. A short flange around the periphery of the bracket also added to the stiffness.

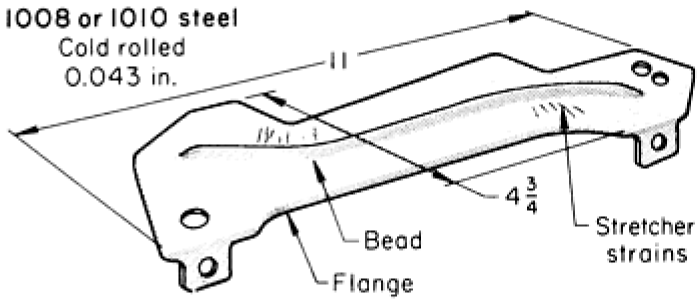

Fig. 8 Corner bracket that was stiffened by beading and flanging. Dimensions given in inches.

The bracket was produced in a progressive die in the following operations: trim to shape, pierce, form bead, form flange, and pinch trim from the carrier strip. The die was run in a 4.45 MN (500 tonf) press operating at 600 strokes per hour. Forming of the bead caused some distortion of the pilot holes and resulted in stretcher strains that extended from the inside radius of the bead to the edge.

The progressive die was made of D2 tool steel hardened to 62 to 64 HRC. One hour per week was needed to clean the die and to make minor repairs. Die lubricant was chlorinated oil.

Press Forming of Low-Carbon Steel

Revised by John Siekirk, General Motors Technical Center

Accuracy

Tolerances that can be maintained in the press forming of steel depend on press condition, accuracy of the tools, workpiece shape, and hardness and variation in the thickness of the work metal.

Flange Width. In forming 90° flanges, if the break lines in the plan view and side elevation are straight or nearly straight, there should be no difficulty in holding a tolerance of ±0.76 mm (±0.030 in.) on flange width. When flange break lines are curved significantly, tolerance usually must be increased to ±1.52 mm (±0.060 in.).

The overall length and width of large formed parts such as automobile hoods and deck lids can usually be held to a tolerance of ±0.76 mm (±0.030 in.). For small formed parts, closer tolerances can be met in production.

Bend Angle. Tolerances that can be held on bend angles depend greatly on the thickness and hardness of the work metal and on the flange height, because these factors affect springback. A 90° bend in low-carbon steel will spring back about 3°; therefore, either the dies are built to overform by this amount or the bend region is compressed to set the corner. To provide enough metal for gripping in the die, the minimum inside flange height should be $2\frac{1}{2}$ times the stock thickness, plus the bend radius.

Distance Between Holes. Distances between the centerlines of pierced holes that lie in a common surface of a formed part are commonly held within a total tolerance of 0.25 mm (0.010 in.) or less (see the article "Piercing of Low-Carbon Steel" in this Volume). The relation of hole positions in parallel or in-line surfaces of formed parts can be held to ±0.38 mm (±0.015 in.); holes with a smaller tolerance on the centerline distance should be pierced after forming (Fig. 9).

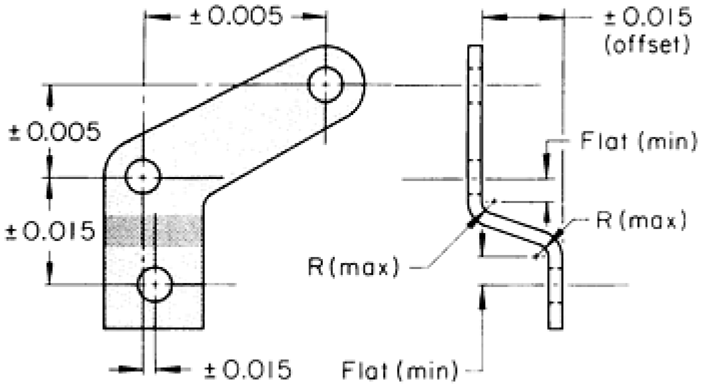

Fig. 9 Tolerances on hole position and distance between offset parallel surfaces on formed parts, and recommended dimensions to be specified for formed offsets. The tolerances shown apply to holes pierced before forming; holes in offset parallel surfaces with position tolerances less than ±0.38 mm (±0.015 in.) should be pierced after forming. Dimensions given in inches.

Distance Between Offset Surfaces. In ordinary commercial practice, the distance between two offset flat surfaces in parallel planes can be maintained within ±0.38 mm (±0.015 in.). For closer tolerances, extreme accuracy must be built into the tools, and the stock thickness must be held closer than normal mill tolerances. The following example describes the techniques used to maintain a tolerance of ±0.25 mm (±0.010 in.) on the distance between surfaces.

Example 8: Variation of a Critical Distance Between Offset Parallel Planes.

On the brake-assembly backing plate shown in Fig. 10, the distance between the tops of the six pads (A to F, Fig. 10) and the bottom of the center mounting face had to be within ±0.25 mm (±0.010 in.). The ranges of dimensions for all six pads as measured on 22 pieces are plotted in the graph in Fig. 10. Of the 132 individual measurements, only 7 exceeded the limits. The spread in dimensions was the result of a combination of variables, including stock thickness (±0.18 mm, or ±0.007 in.), springback after forming and coining, and condition of the press.

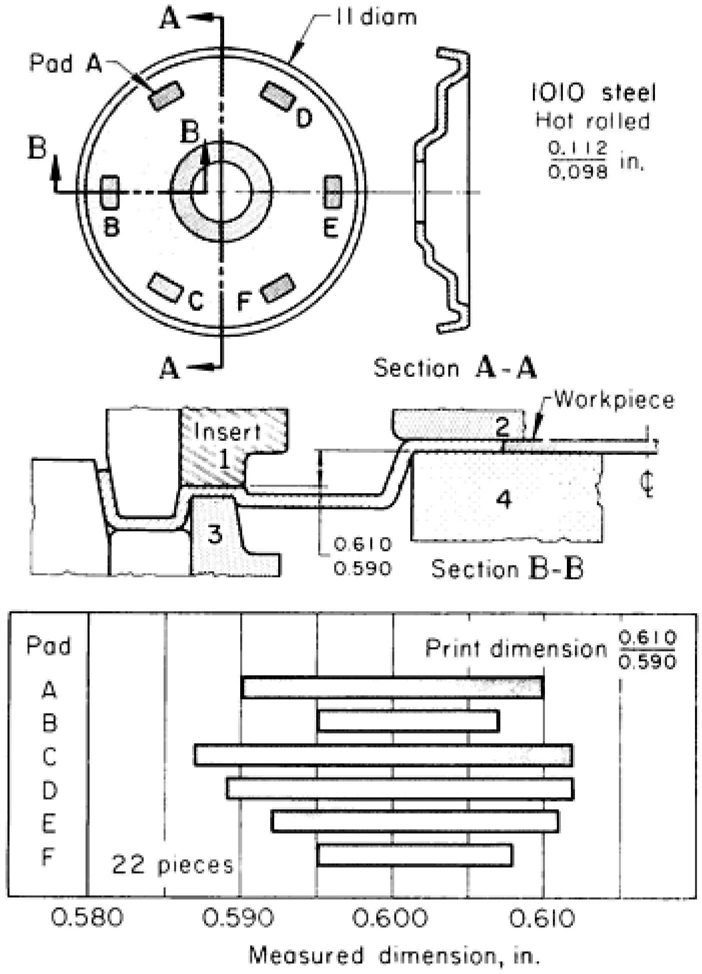

Fig. 10 Variation of offset distance in a formed and coined backing plate for a broke assembly. Dimensions given in inches.

Springback was unpredictable and varied among different lots of steel. Therefore, the die was made extra rigid, and the inserts for coining the pads (inserts 1 and 3, section B-B, Fig. 10) were made adjustable to compensate for variations in stock thickness. Coining reduced stock thickness at the 1600 mm^2 (2.5 in.^{2}) pads to 2 to 2.3 mm (0.080 to 0.090 in.)--a 15% reduction.

The backing plate was made in two operations, both in a 7.1 MN (800-tonf) mechanical knuckle press with a 127 mm (5 in.) stroke, which was operated at 20 strokes per minute. In the first operation, coil stock was fed into a progressive die, where the inner portions of the part were formed, the six pads were partly completed, the center hole was pierced, and the outside diameter was blanked. The outside flange was formed, and the six pads were coined to height and parallelism in a second die (section B-B, Fig. 10).

The press slide was parallel to the bolster within 0.25 mm/m (0.003 in./ft). The slide and the press bed were large enough to keep the die set centered, thus minimizing the possibility of error. The die set had four heavy guideposts in long bushings. The main parts of the punch and die were made of 6145 steel hardened to 45 to 50 HRC and ground after hardening, and the inserts for coining (inserts 1 through 4, section B-B, Fig. 10) were made of O1 tool steel hardened to 60 to 61 HRC and ground.

Holes Close to a Bend. Whether a hole that is close to a bend is pierced before or after forming depends on the function of the hole, its closeness to the bend, the bend radius, and the stock thickness. When the distance from the edge of the hole to the inside surface of the other leg of the bend is less than $1\frac{1}{2}$ times the stock thickness, plus the bend radius, the outer portion of the hole is likely to deform as a result of stretching of the metal. If the deformation is acceptable, the hole can be pierced before forming; otherwise, it must be pierced after forming. When the offset angle on formed parts is unimportant, stating the minimum flat and maximum radius dimensions as in Fig. 9 allows the maximum practical tolerance in producing acceptable parts.

Trimmed edges can be held to close tolerances when they are trimmed by one punch and when trimming is done after any forming that would cause distortion, as in the following example.

Example 9: Forming and Accurate Trimming in a Progressive Die.

Figure 11 shows an eggbeater side frame that was produced in a four-station progressive die from 1 mm (0.040 in.) thick cold-rolled 1008 to 1010 steel strip 19 mm ($\frac{3}{4}$ in.) wide. For accurate fit in assembly, the end of the part was trimmed to the close tolerances indicated in Fig. 11 after the U-shaped bead flanked by the vertical tabs had been formed. The bead was formed by drawing metal from the surrounding area and by stretching.

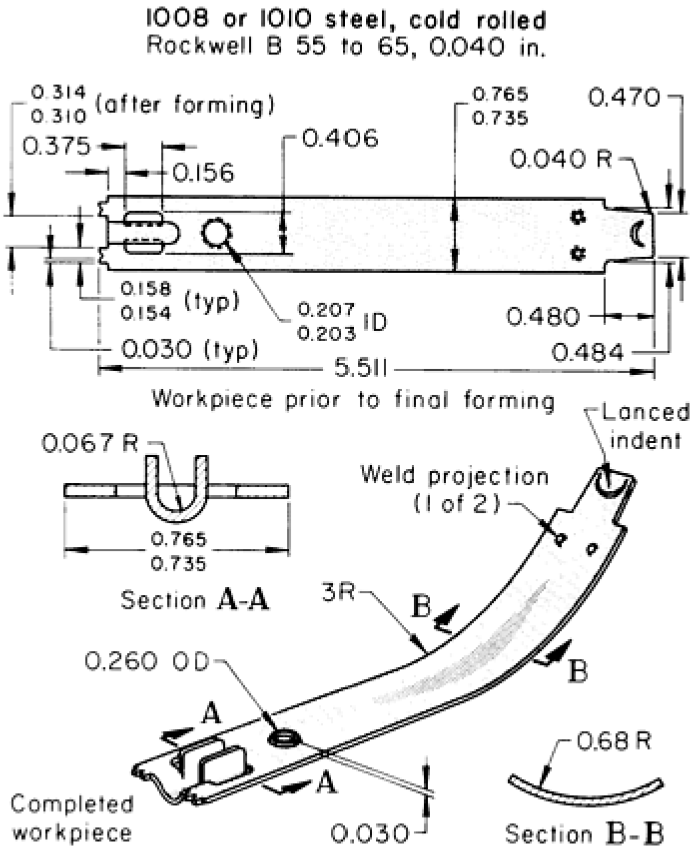

Fig. 11 Eggbeater side frame that was formed and accurately trimmed in a progressive die. Dimensions given in inches.

The stock had a No. 6 edge, a No. 3 finish, and a hardness of 55 to 65 HRB. The No. 6 edge (a square edge produced by edge rolling the natural edge of hot-rolled strip or slit-edge strip) was relatively burr free. Because the edges of the strip were also the edges of the completed part, the use of a No. 6 edge eliminated a deburring operation. The No. 3 finish was particularly suited to bright nickel plating without prior polishing or buffing. Stock was purchased to average in the lower part of the standard thickness range of ±0.05 mm (±0.002 in.) and within the standard width tolerance of ±0.38 mm (±0.015 in.). The sequence of operations in the four die stations was as follows:

- Lance and form semicircular indent, and notch-trim
- Pierce rectangular slot at one end, pierce round hole, and emboss weld projections
- Lance tabs, form bead and form flange around round hole

- Cut off (trim) and form contour

The die, made of D2 tool steel, was used in a 665 kN (75 tonf) press; die life between regrinds was 65,000 pieces. Mineral oil was used as the lubricant. The production rate was 360 pieces per hour; annual production quantity was 600,000 pieces.

Close Tolerances. Closer-than-conventional accuracy can be attained in sheet metal parts with accurate dies, precise location of the parts in the dies, and handling equipment designed to avoid damage to semifinished or finished workpieces. Press condition is also an important factor. The following example describes the techniques used for close-tolerance forming in progressive dies.

Example 10: Use of Progressive Die to Meet Close Tolerances on a Lamp Bracket.

The lamp bracket shown in Fig. 12 had several tolerances that were closer than normal. Three holes had to be pierced to a tolerance of +0.13, -0 mm (+0.005, -0 in.) on diameter, and two of the holes had to be in line within 0.25 mm (0.010 in.) after forming. In addition, when the 104° bend was made with the preformed flanges out, the radius of bend on the flanges had to be held within 0.38 mm (0.015 in.) total indicator reading, and the 10° angle of the flanges had to be held within ±5°. The bracket was produced in a seven-station progressive die with two piloting stations that could have been used for auxiliary operations such as shaving or restriking, if necessary. The operations were as follows:

- Notch for stop, pierce one 10 mm (0.395 in.) hole, pierce two 6.7 mm (0.265 in.) holes
- Blank the contour of the ears
- Pilot
- Blank the partial contour
- Form the two long flanges
- Pilot
- Form the 104° angle and cut off

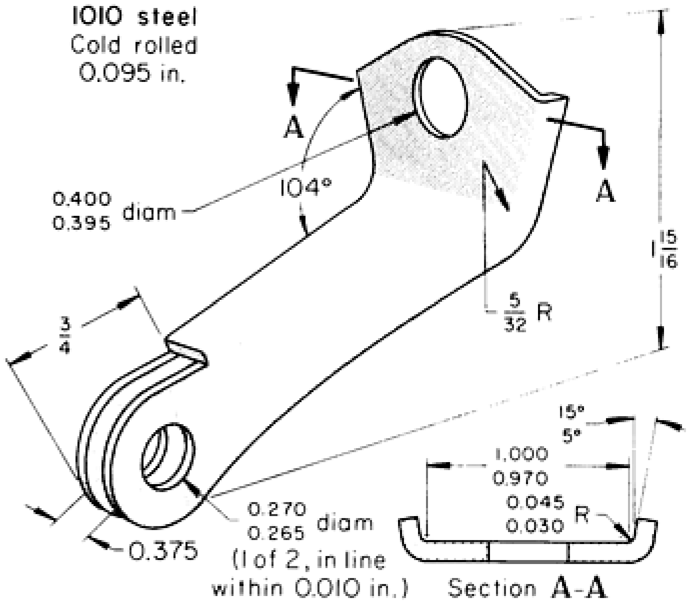

Fig. 12 Lamp bracket that was press formed to close tolerances in a progressive die. Dimensions given in inches.

The material was cold-rolled 1010 steel strip in No. 4 temper. The strip was 2.4 mm (0.095 in.) thick by 86 mm ($3\frac{3}{8}$ in.) wide. The progressive die was mounted in a 665 kN (75 tonf) straight-side mechanical press with a flywheel drive, a 152 mm (6 in.) stroke, and a maximum rate of 60 strokes per minute. The press was equipped with an air clutch. Ball-lock punches, die bushings, and easily reproducible die sections were used throughout.

The die was made of D2 tool steel hardened to 58 to 60 HRC and had a life of 55,000 pieces per regrind. Production was discontinued after 2.5 million lamp brackets had been made.

Flatness. The longitudinal and transverse stresses set up during the forming of a part can cause it to warp--particularly if the part is made of steel that is not uniform. Depending on the size and shape of the part, either smooth flattening or embossing can be used to maintain flatness.

Press Condition. The accuracy and condition of presses must be maintained within close limits when tolerances on formed parts are critical, regardless of the type of operation. Press slides that are not parallel with the bed at the bottom of the stroke can cause uneven stock thicknesses when the punch bottoms against the die surface. Unbalanced forming forces can shift the punch, producing out-of-tolerance workpieces. In some forming applications, shifting of the punch can be minimized by tipping the workpiece to balance the forces. Heel blocks and other means of positively maintaining the punch-to-die relationship are used to overcome unbalanced forming forces and shifting of the punch slide.

Press Forming of Low-Carbon Steel

Revised by John Siekirk, General Motors Technical Center

Hot Forming

In hot forming, the work metal is heated above its transformation temperature. Less press capacity is needed to hot form a given shape than to cold form it. However, the press, dies, and related equipment must be designed to withstand high temperature. Meeting this requirement is sometimes more difficult than obtaining a higher-capacity press for cold forming.

In some applications, a steel workpiece can be quenched directly from the forming temperature. In the following example, 25 mm (1 in.) thick high-strength low-alloy steel blanks heated to 815 °C (1500 °F) were press formed and then allowed to cool in air.

Example 11: Hot Forming of High-Strength Low-Alloy Steel.

A 25 mm (1 in.) thick blank of high-strength low-alloy steel was hot formed into a bucket blade for earthmoving equipment (Fig. 13). The blank was cut by oxy-fuel gas to 305 × 1700 mm (12 × 67 in.) from a flat plate, then furnace heated to 815 °C (1500 °F). The hot workpiece was formed with one stroke of a 1.8 MN (200 tonf) hydraulic press. No lubricant was used, because production quantities were small and the surface condition of the part was not critical. After being formed, the part was quickly removed from the die and allowed to cool on the floor. Time from furnace to press to floor was 4 min per piece.

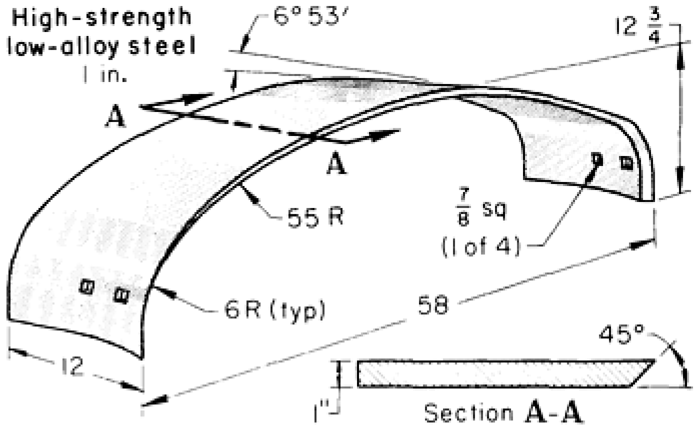

Fig. 13 Digger-bucket blade that was hot formed in a hydraulic press. Dimensions given in inches.

Heating the blank to 815 °C (1500 °F) permitted forming in a much smaller press and with greater accuracy than could have been done if the blank had been formed at room temperature. Tolerances of ±1.6 mm (± $\frac{1}{16}$ in.) were maintained on the overall dimensions of the formed part.

The forming die was a weldment made of hot-rolled 1045 steel, flame hardened at the critical wear points. Production was 400 buckets per year in lots of 60. Die life was 2400 pieces before reworking.

Press Forming of Low-Carbon Steel

Auxiliary Operations in Presses

Presses are used to fasten parts together by rivets or by plastically deforming mating areas in either or both of the parts. In operations such as staking, folding, crimping, curling, or press assembly, projections of various sizes and shapes are deformed so that the assembly is reasonably strong. In the following example, a press was used to curl the lip of a hub over a disk for a tight torque-resistant joint.

Example 12: Assembly of Hub to Center Disk by Curling in a Hydraulic Press.

Center disks of large blower wheels were assembled to hubs by curling, as shown in Fig. 14. The hub was an automatic bar machine product made of cold-drawn 1018 steel tubing. The length of the hub was 28.6 mm (1 $\frac{1}{8}$ in.) before curling, and the curled lip was 3.2 mm ($\frac{1}{8}$ in.) high.

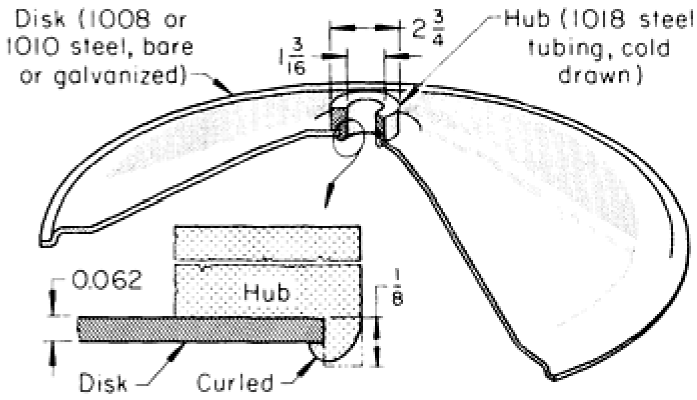

Fig. 14 Hub and disk that were assembled by curling in a press. Dimensions given in inches.

The work was done in a 490 kN (55 tonf) hydraulic press with no lubricant. Because the disks and hubs were assembled and positioned manually, the production rate was only 30 pieces per hour. The joint could have been made much faster by spinning, but spinning equipment that could accommodate the large disks was not readily available.

The curling tool was made of A5 tool steel and had a life of several years. The blower-disk assemblies were made in quantities of 20,000 per year.

Press Forming of Low-Carbon Steel

Revised by John Siekirk, General Motors Technical Center

Press Forming Versus Alternative Methods

If a part can be made by forming sheet metal in a press, this is ordinarily the least expensive method of manufacture, except when only a few pieces are needed. The low cost per piece results from the high production rates and the efficient use of metal usually obtainable in the press forming of sheet metal.

The accuracy inherent in press forming is satisfactory for most requirements. Greater accuracy can be achieved by the use of precision tooling and by maintaining close control over press conditions.

The disadvantages of relatively high tool cost and long tooling time can often be offset, except for the production of very small quantities, by the use of short-run tooling. The design of a part can sometimes be modified to permit the use of press forming instead of alternative methods. An application in which cost was reduced when forming replaced forging is described in the following example.

Example 13: Press Forming Versus Forging.

The bicycle handlebar stem shown in Fig. 15 was formed from hot-rolled commercial-quality 1008 or 1010 steel sheet 4.17 mm (0.164 in.) thick, pickled and oiled. The formed part cost much less than the machined forging it replaced. More than 1 year was required to perfect the forming process.

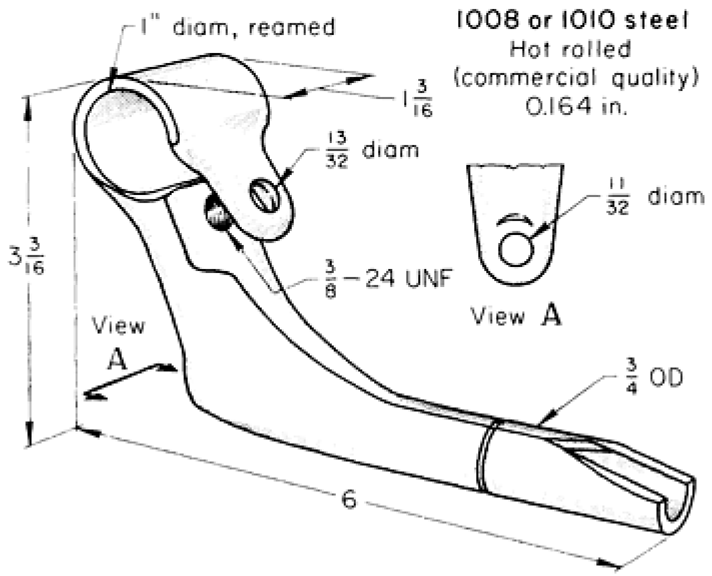

Fig. 15 Bicycle handlebar stem that cost less when formed from sheet steel than when produced as a machined forging. Dimensions given in inches.

The pieces were blanked two at a time in a 2.2 MN (250 tonf) press operating at 40 strokes per minute. They were formed in a nine-station transfer die that ran at 20 to 26 strokes per minute in a 2.67 MN (300 tonf) press loaded at 50% of its force-capacity rating, as shown by a meter. The blanks were fed into the first station from a magazine feeder by a slide. After forming, one hole was reamed and another was drilled and tapped in a rotary indexing machine.

The severity of forming require the use of a drawing compound. The production rate of 1 million pieces per year caused no unusual problems except those that resulted from aging of the stock. If the stock was not used shortly after receipt from the mill, there was some splitting at the most severely formed areas, such as the shoulders of the handlebar stem, and some surfaces showed an orange-peel effect. After forming, the part was plated for appearance and corrosion resistance.

The blanking die was of D2 tool steel hardened to 56 to 58 HRC. After runs of 50,000 parts, the die was resharpened by removing 0.3 mm (0.012 in.) from the punch and die. The forming punches were of O1 and A2 tool steels, hardened to 52 to 54 HRC. The forming-die sections were of D2 tool steel hardened to 54 to 56 HRC. The high-wear areas were coated with a deposit of cemented carbide. The dies made over 300,000 acceptable parts.

Workpieces that are very similar can sometimes be made equally well, and at about the same cost, by two or more different methods. Under these conditions, the choice of method may depend on the availability of equipment, as in the following example.

Example 14: Press Forming in V-Dies Versus Rotary Draw Bending.

The two types of rectangular frames shown in Fig. 16 were made by two different forming methods. Each type of frame could have been made by either method; but because of the type of equipment that was available, the corners of the frame shown in Fig. 16(a) were press formed in a V-die, and those shown in Fig. 16(b) were made by rotary draw bending. Each type of frame was made in a number of sizes by making individual bends in succession on precut lengths of contour-rolled or press-brake-formed steel strip and welding the ends together.

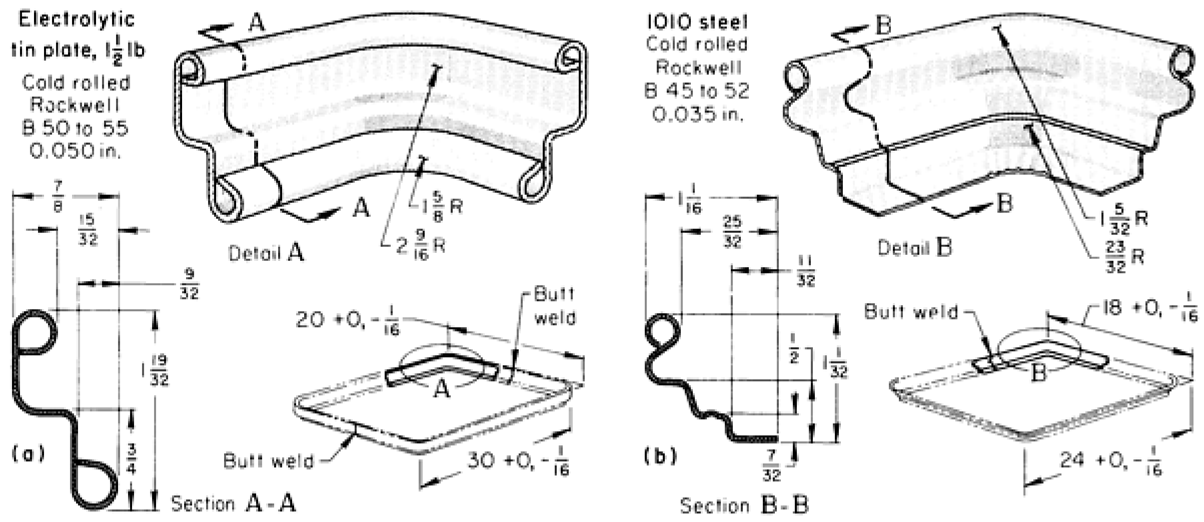

Fig. 16 Rectangular frames that were made by two different forming methods. (a) Press forming in a V-die. (b) Bending in a rotary draw bender. Dimensions given in inches.

The corners for frames made from 1.27 mm (0.050 in.) thick electrolytic tin plate (Fig. 16a) were formed one at a time in a 152 mm (6 in.) stroke, 500 kN (56 tonf) mechanical press, using a developed V-die made of D2 tool steel. Each corner was restruck twice for accuracy of bend angle and contour. Because of the tin coating, no lubricant was needed. The production rate was 420 corners per hour. Die life was indefinite. Lot size averaged about 1000 frames, for a yearly production of about 25,000 frames of various sizes.

The corners for a second line of frames (Fig. 16b) were bent from contour-roll-formed 54.8 × 0.89 mm ($2\frac{5}{32}$ × 0.035 in.) 1010 steel strip in a rotary draw bending machine equipped with conforming die and clamp blocks. The die and clamp blocks were made of D2 tool steel; residual mineral oil from the preceding contour roll forming operation provided sufficient lubrication for the draw bending. The production rate was 600 bends per hour for a total yearly production of about 1 million frames in lots of 1000 to 10,000 frames. These frames were phosphate coated and electrostatically spray painted after welding.

Press Forming of Low-Carbon Steel

Revised by John Siekirk, General Motors Technical Center

Safety

Press forming, like other press operations, involves potential hazards to operators, maintenance personnel, and other persons in the work area. No press, die, or auxiliary equipment can be considered ready for operation until hazards are eliminated by the installation of necessary safety devices. Operators and all persons working around the operation should be properly instructed in safe operation of the equipment. The article "Presses and Auxiliary Equipment for Forming of Sheet Metal" in this Volume contains additional information on safe operation.

Press Forming of High-Carbon Steel

Introduction

HIGH-CARBON STEEL strip (including spring steel and tool steel) is blanked, pierced, and formed to make a variety of parts. The practices, precautions, presses, and tools used in making high-carbon steel parts are comparable to those used for producing similar parts of low-carbon steel (see the preceding articles concerning the blanking, piercing, press bending, and press forming of low-carbon steel in this Volume). Differences that must be considered in blanking, piercing, and forming high-carbon rather than low-carbon steel include the following:

- More force is required for high-carbon steel because of its higher strength
- Greater clearance between the punch and die is necessary in blanking and piercing
- A more wear-resistant tool material may be required before acceptable tool life can be obtained

Blanking and Piercing

The most important difference between the blanking and piercing of high-carbon and of low-carbon steel is that greater clearance between punch and die is required for high-carbon steels. The clearances needed for producing each of the five edge types in blanking and piercing high-carbon and low-carbon steels are compared in Table 1 in the article "Piercing of Low-Carbon Steel" in this Volume. As shown in that table and in the accompanying Fig. 2, at equal clearance, rollover depth will be smaller and burnish depth greater for high-carbon than for low-carbon steel. For example, 12% clearance per side will produce a type 4 edge on high-carbon steel, and a type 2 edge on low-carbon steel.

This relationship of cut-edge characteristics to carbon content is different from the relationship of cut-edge characteristics to temper or hardness of low-carbon steel. Figure 4 in the article "Piercing of Low-Carbon Steel" shows that rollover depth and burnish depth are both smaller for harder tempers of low-carbon steel than for softer tempers.

Tool materials recommended for blanking and piercing high-carbon steel are listed in the article "Selection of Material for Blanking and Piercing Dies" in this Volume. Selection tables in that article show that although the complexity of the workpiece and the total quantity to be blanked are more significant factors than work metal composition in the selection of tool material, the hardness of the work metal is nevertheless significant. Carbide dies are often used for large quantities (see Example 1).

Die life in the blanking and piercing of high-carbon steel varies with different applications, depending greatly on the dimensional accuracy that must be maintained and the burr height that can be tolerated on the blanked parts. The following example describes an application in which a change in tool material increased die life by a factor of about 28.

Example 1: Change From Tool Steel to Carbide Punches and Dies.

The part shown in Fig. 1 was blanked and pierced from 48 mm ($1\frac{7}{8}$ in.) wide coils of bright-finish 1045 steel having a hardness of 70 to 75 HR15N (equivalent to 20 to 30 HRC). Thickness ranged from 0.48 to 0.986 mm (0.019 to 0.0388 in.); tolerance for all thicknesses was +0.000, -0.003 mm (+0.000, -0.001 in.).

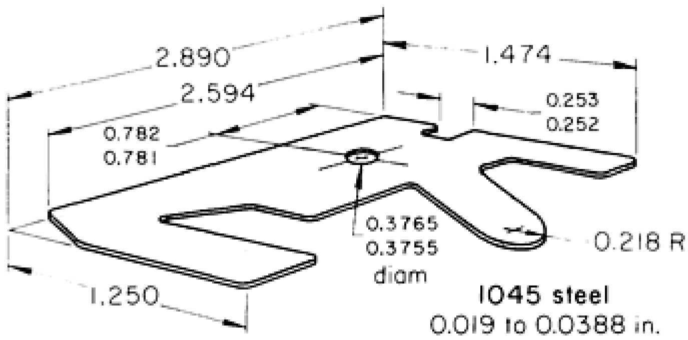

Fig. 1 Blanked and pierced textile machine part for which carbide compound dies had 28 times the total life of those made of D2 tool steel. Dimensions given in inches.

The punch and the die were both originally made of D2 tool steel at 62 to 63 HRC. To keep burr height on the parts at or below the maximum of 0.08 mm (0.003 in.), it was necessary to grind the die after each 25,000 pieces. The steel die had a usable depth of 16 mm ($\frac{5}{8}$ in.) and 0.20 mm (0.008 in.) was removed with each grinding. Therefore, with 78 grindings, the total die life was 1,950,000 pieces.

To improve die life, the tool material for both the punch and the die was changed to carbide. The carbide tools cost three times as much as the steel punch and die, but production between grinds increased to 350,000 pieces and only 0.10 mm (0.004 in.) of stock was removed per grind. Therefore, with the same amount of usable die, the total die life would be 54,600,000 pieces.

The die was a compound-type unit. It was operated in a 445 kN (50 tonf) open-back inclinable mechanical press having a 75 mm (3 in.) stroke and mechanical feed.

Tooling for Greatest Efficiency. Along with the increase in punch-to-die clearance, other tool changes are required for efficiency in the blanking and piercing of high-carbon steel. For example, with high-carbon steel more so than with low-carbon steel, the scrap skeleton from blanking and piercing operations is likely, in springing back, to adhere to the punch, sometimes causing spalling of the punch edges. To strip this scrap from the punch, it is common practice to include in the punch mechanism a second, chisel-pointed punch placed as close as possible to the blanking edge. This second punch serves to spread the scrap skeleton, minimizing its adherence to the blanking punch (see Example 2).

The following example deals with changes in tooling that reduced cost. In the example, blanking replaced machining.

Example 2: Cost Reduction When Blanking Replaced Milling.

The blanked workpiece shown in Fig. 2 replaced a machined part of slightly different dimensions. For the machined part, starting blanks 75 mm (3 in.) long by 17 mm ($\frac{11}{16}$ in.) wide by 4.0 mm ($\frac{5}{32}$ in.) thick were sawed from ground flat stock of A2 tool steel spheroidize-annealed to 14 to 18 HRC. The long edges of the blanks were ground to reduce the width of the blank from 17 to 15.9 mm ($\frac{11}{16}$ to 0.625 in.). Grinding was followed by four separate milling operations. This change in production method from milling to blanking reduced the machining time for 100 pieces from 28 to 0.23 h and decreased cost per piece by a factor of 122.

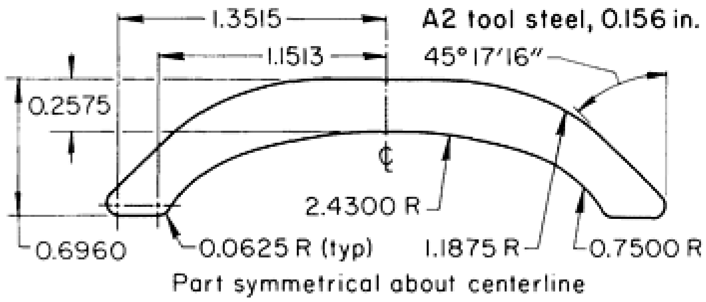

Fig. 2 Part produced by blanking for less than 1% of the per-piece cost of producing it by milling. The punch was modified to solve a stripping problem. Dimensions given in inches.

The blanking was done in a 280 kN (32 tonf) open-back inclinable mechanical press with a punch and die made from A2 tool steel at 60 to 62 HRC. To obtain acceptable edges on the workpiece, a punch-to-die clearance of 8 to 10% of stock thickness per side was used. Because of the force required for stripping, it was necessary to add a chisel-edge punch to spread the scrap skeleton and to prevent damage to the blanking punch. In addition, a minimum corner radius of 1.6 mm (0.062 in.) was necessary for efficient stripping, and the overall width of the part was increased to 17.7 mm (0.696 in.).

Dimensional accuracy in the blanking and piercing of high-carbon steel depends largely on the accuracy of the tooling. Initially, the practical accuracy is the same as that for the blanking and piercing of other metals. However, because the rate of tool wear is usually higher in the blanking and piercing of high-carbon steel (especially if pretempered) than for many other work metals, maintenance of tolerances can be more difficult and may require more frequent reconditioning of the tools.

The following example describes a spring for which it was impossible to attain the specified tolerances on one dimension without subsequently grinding. Variations in two dimensions, measured on 124 pieces during the production run, are shown in the bar graphs in Fig. 3.

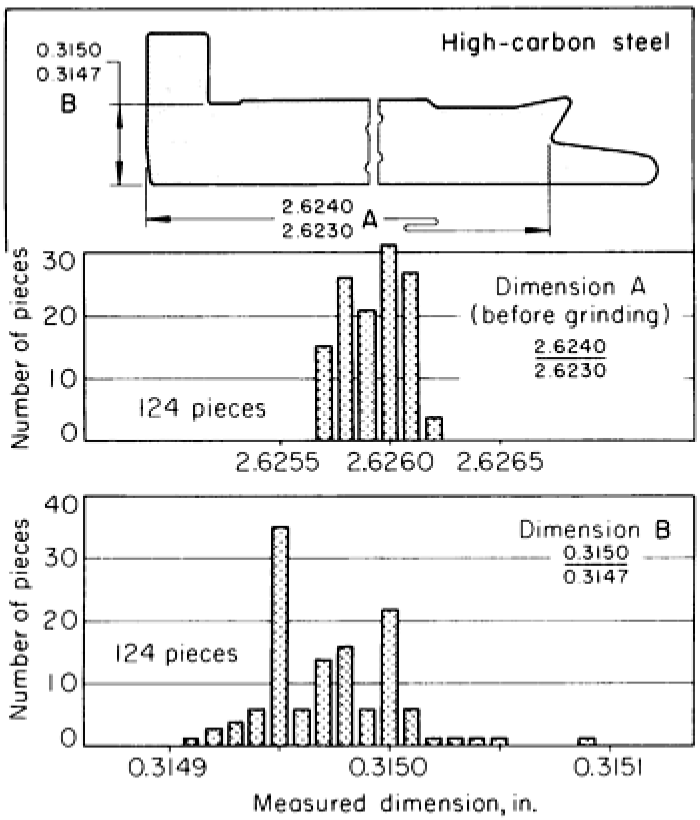

Fig. 3 Variations in two dimensions of blanked springs. Dimensions given in inches.

Example 3: Variations in Dimensions of Blanked Springs.

The data in Fig. 3 show variations in two dimensions measured on 124 blanked springs randomly selected from a production run of 50,000 pieces. The total tolerance on the length (dimension A) was 0.03 mm (0.001 in.), which was not practical for blanking. Therefore, the springs were blanked slightly oversize, and about 0.05 mm (0.002 in.) was removed by grinding the square end. The total tolerance on dimension B was 0.008 mm (0.0003 in.). As shown in Fig. 3, all but 11 of the springs conformed to this tolerance, and these 11 samples were all on the high side of 8.001 mm (0.3150 in.).

The springs were blanked from 25 mm (1 in.) wide, bright-finish, pretempered high-carbon steel (1.15 to 1.35% C, 84 to 87.5 HR15N). Thicknesses ranged, in steps of 0.013 mm (0.0005 in.) from 0.102 to 0.165 mm, ±0.005 mm (0.004 to 0.0065 in., ±0.0002 in.). The die was made of T1 high-speed steel at 64 to 65 HRC and operated in a 270 kN (30 tonf) open-back inclinable mechanical press having a 38 mm ($1\frac{1}{2}$ in.) stroke and an automatic feed.

The tolerances that can be held and the size and spacing of holes and slots that are practical in press dies are illustrated in the following example.

Example 4: Blanking and Piercing an Intricate Pattern.

The comb of an electric shaver (Fig. 4), made of pretempered spring steel, had an intricate pattern of slots and holes. Because more than 7 million of these combs were produced yearly, it was economical to construct the die needed to make them by blanking and piercing. Most of the dimensions on the part were held to a tolerance of ±0.025 mm (±0.001 in.). Similar parts of stainless steel were made by chemical machining.

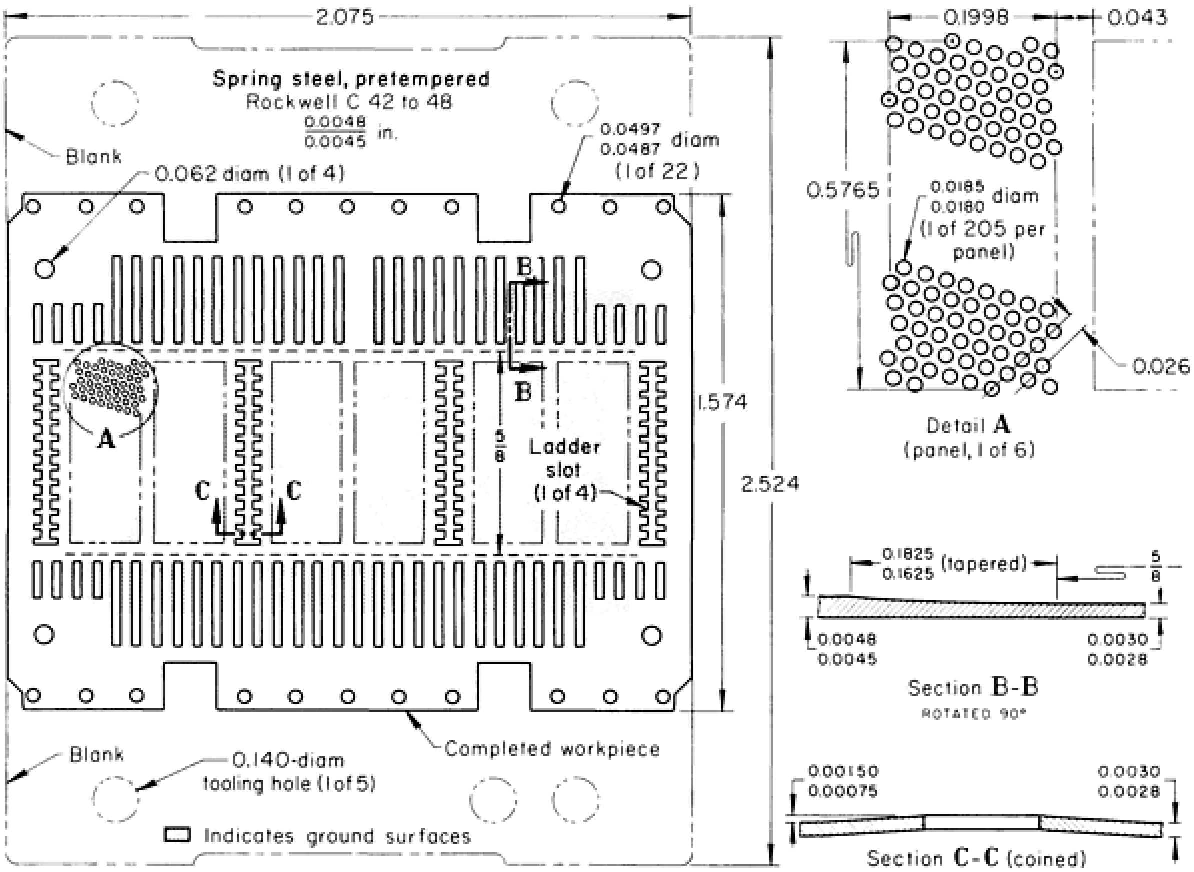

Fig. 4 Comb of an electric shaver made by blanking and piercing. Dimensions given in inches.

The stock was 56 mm ($2\frac{3}{16}$ in.) wide high-carbon spring steel, pretempered to 42 to 48 HRC. Thickness was 0.11 to 0.12 mm (0.0045 to 0.0048 in.). Blanks sheared from the stock were 52.70 mm (2.075 in.) wide by 64.11 mm (2.524 in.) long and included, at each end, 12.1 mm (0.475 in.) that was later trimmed. This trimmed stock contained five tooling holes, one of which was a foolproof hole that prevented incorrect placement of the blank in the die.

In the first piercing operation, the rectangular slots at each end of the cutting areas were pierced, along with the five 3.56 mm (0.140 in.) diam tooling holes in the trim area and four ladder slots that bordered the three cutting areas. After this operation, the three cutting areas were ground to a thickness of 0.071 to 0.076 mm (0.0028 to 0.0030 in.). This ground surface, 15.9 × 12.6 mm (0.625 × 0.495 in.), tapered to the original stock surface in 4.11 to 4.62 mm (0.162 to 0.182 in.).

In the third operation, 0.46 mm (0.018 in.) diam holes were pierced in the cutting areas at a centerline spacing of 0.572 mm (0.0225 in.) in one direction and 0.66 mm (0.026 in.) in the other direction. Each of the three cutting areas had 410 holes arranged in two panels of 205 holes each.

After the third operation, workpieces were deburred, and the area around each of the four ladder slots was coined to a depth of 0.019 to 0.038 mm (0.00075 to 0.0015 in.). The surface was buffed before plating, removing 0.008 mm (0.0003 in.) of stock. Finally, the comb was trimmed from the rough blank and four 1.6 mm (0.062 in.) diam holes for locating studs and 22 rivet holes 1.24 to 1.26 mm (0.0487 to 0.0497 in.) in diameter were pierced. The piece was plated after assembly with the comb support.

Dies were made of D2 tool steel and hardened to 58 to 60 HRC. Some additional wear resistance that could have been attained by hardening to 60 to 62 HRC was sacrificed in order to make the delicate punches more resistant to shock. The presses were 620 and 670 kN (70 and 75 tonf) mechanical presses operated at 5 or 6 strokes per minute to accommodate meticulous hand feeding of the workpieces. Production lots consisted of 50,000 pieces each.

Forming Pretempered Steel

The mold forming of high-carbon steel in the quenched-and-tempered (pretempered) condition (usually 47 to 55 HRC) is common practice. The severity of forming that can be done without cracking of the work metal depends mainly on thickness. When metal thickness is no more than about 0.38 mm (0.015 in.), it is possible to make relatively severe bends without fracturing the work metal. However, as metal thickness increases, the amount of forming that can be done on pretempered steel decreases rapidly.

The example that follows describes the production of parts by blanking, piercing, and forming in progressive dies. The hardness and abrasiveness of the work metal reduced die life well below that experienced with low-carbon steel or annealed high-carbon steel. Tabs were coined to a spherical radius after being bent to a 45° angle. This required resetting the die to overcome variations in each coil of stock.

Example 5: Lockwashers From 1074 Steel.

The lockwasher shown in Fig. 5 was made from 1074 pretempered steel with a hardness of 64 to 67 HR30N. Coil stock was 64 mm ($2\frac{1}{2}$ in.) wide and 0.38 mm (0.015 in.) thick. A progressive die with three working stations was used to cut the tabs to shape, bend, and coin the tabs to a spherical radius, and blank the part from the strip. Idle stations were placed between the working stations for added die strength. D2 tool steel was used for the cutting and forming die elements. Die life between sharpenings was about 25,000 pieces.

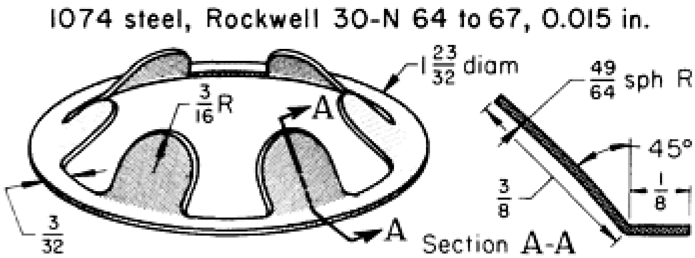

Fig. 5 Lockwasher that was blanked and formed of pretempered steel. To control tab dimensions, the dies had to be reset for each new coil of stock. Three progressive-die stations cut the tabs to shape and coined them to spherical radius. Dimensions given in inches.

Adjustment of the die setting was necessary for each coil of stock so that the tabs would be coined and bent to the proper angle. A 580 kN (65 tonf) mechanical press operating at 110 strokes per minute was used.

Forming Annealed Steel

Moderately severe forming can be done on cold-rolled stock that has not been quenched and tempered and on high-carbon steel that has been spheroidize-annealed. Such materials are usually hardened and tempered after forming to improve spring properties. Table 1 shows the effect of the carbon content of steel on bendability and demonstrates the major importance of sheet thickness.

Table 1 Typical effects of carbon content and sheet thickness on minimum bend radius of annealed steels

Thickness of sheet	Minimum bend radius

The following two examples describe the forming of parts from annealed stock or from cold-rolled stock that had not been hardened. The first example deals with parts that were redesigned to improve producibility in the press; the other example, with parts for which the forming severity required annealed or unhardened stock. (Annealed stock was also used in Example 8.)

Example 6: Bracket That Was Redesigned to Prevent Punch Breakage.

The bracket shown in Fig. 6 was made of 0.11 mm (0.042 in.) thick spheroidize-annealed 1070 spring steel at 70 to 82 HRB. It was blanked, pierced, and formed by a progressive die in a 530 kN (60 tonf) double-eccentric straight-side press at the rate of 210 pieces per minute.

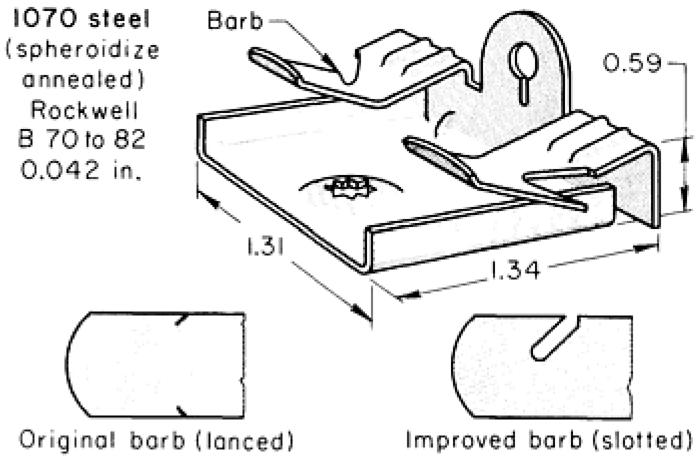

Fig. 6 Bracket produced by blanking, piercing, and forming in a progressive die. Improved design of the barb reduced die maintenance cost and press downtime and gave the barb more holding power in service. Dimensions given in inches.

The bracket was used to attach electric conduit and other building components to the flanges of beams and other structural members. In the original design of the bracket, the lanced barbs (Fig. 6) caused frequent breaking of a punch. The improved design, as shown in Fig. 6, produced a barb with better holding power and permitted the use of a stronger punch, reducing the cost of die maintenance and press downtime. After forming, the parts were heat treated to 44 to 48 HRC and phosphate coated.

Example 7: Use of a Progressive Die to Outline, Pierce, Form, and Blank.

The washer-wingnut shown in Fig. 7 replaced two parts--a washer and a wingnut. To produce the unit as one piece, spheroidize-annealed 1070 steel was used. The part was quenched and tempered after forming.

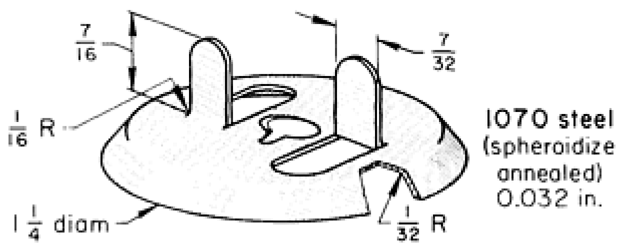

Fig. 7 Washer-wingnut that was made in a progressive die. The edges of the center-hole slot were offset to the pitch of the screw thread so that the part could serve as both a nut and a washer. Dimensions given in inches.

A progressive die was used to outline, pierce, form, and blank the part from coil stock. The metal around the center hole was slotted and spiral formed, as in making a speed nut, to engage threads. A 530 kN (60 tonf) double-eccentric straight-side press operating at 180 strokes per minute produced three wingnuts per stroke, or 540 per minute.

The progressive die was made of D2 tool steel and hardened to 58 to 60 HRC. Die life was 200,000 strokes between regrinds. An extreme-pressure lubricant was used on the strip. Annual production was 3.4 million pieces.

Hole Flanging

Flanges are formed around holes to increase bearing surface or to increase the number or threads that will fit in a tapped hole. The relationship among stock thickness, hole size, and flange height is discussed in the article "Press Bending of Low-Carbon Steel" in this Volume. In the following example, flanges were formed around holes that were large compared to the flange width in order to provide a bearing surface.

Example 8: Swivel Washer With Flanged Holes.

Annealed 1070 spring steel 0.25 mm (0.010 in.) thick was used to make the swivel washer shown in Fig. 8. After forming, the parts were heat treated to 46 to 48 HRC.

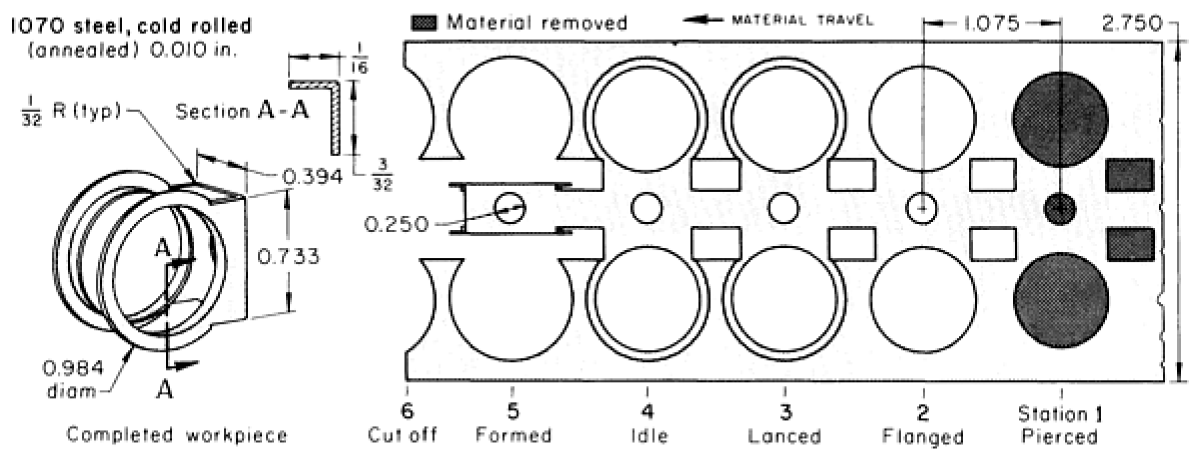

Fig. 8 Swivel washer, with flanged holes, that was made in a progressive die. Dimensions given in inches.

The strip layout for the six-station progressive die is also shown in Fig. 8. In the first station, two rectangular holes, one 6.35 mm (0.250 in.) diam pilot hole, and two 18.0 mm (0.710 in.) diam holes were pierced. The larger round holes were flanged to 20.3 mm (0.798 in.) in diameter by 1.6 mm ($\frac{1}{16}$ in.) in depth in the second station. The washer was lanced in the third station and formed in the fifth. The part was cut off in the sixth station. Station 4 was idle.

The die was made of A2 tool steel and was hardened to 60 to 61 HRC. It ran in a 130 kN (15 tonf) open-back inclinable press at 2000 strokes per hour. To maintain a minimum burr height, the die was sharpened after making 60,000 pieces. Total die life was more than 3 million pieces.

Multiple-Slide Forming

Small parts that are used in large quantities and require considerable forming are often produced on multiple-slide machines. In general, more severe forming can be done in the forming station of a multiple-slide machine than in a progressive die. Additional information on multiple-slide forming is available in the article "Forming of Steel Strip in Multiple-Slide Machines" in this Volume. The following example illustrates high-carbon steel parts produced in a multiple-slide forming machine.

Example 9: Blanking and Bending a Bracket in a Multiple-Slide Machine.

The mounting bracket shown in Fig. 9 was embossed, pierced, and notched in a progressive die in the press station of a multiple-slide machine. It was then cut off and bent. Production was at the rate of 100 pieces per minute. The work metal was coiled cold-rolled 1050 steel strip, 0.91 mm (0.036 in.) thick by 32 mm ($1\frac{1}{4}$ in.) wide.

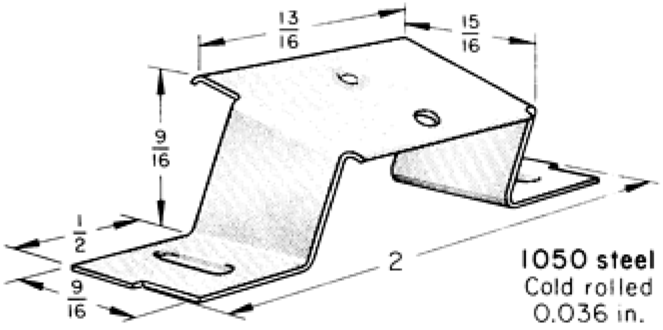

Fig. 9 Mounting bracket that was blanked and bent in a multiple-slide machine. Dimensions given in inches.

In the press station, two holes were pierced, two weld projections were embossed, one hole was flanged, the outline was notched, and the top surface was flanged to improve stiffness. The strip then moved to the forming station, where the part was cut off and bent to the final form shown in Fig. 9. All slides in this station moved in a horizontal plane. A front slide tool held the part against the center post and preformed the flanges. A cam action on the right and left slides formed the flanges against the post and the rear slide tool.

Vertical-Plane Machines. The machines that formed the parts described in the preceding example have slides that operate in the horizontal plane. There are also machines in which the center post is horizontal and the slides operate in a vertical plane normal to the center post.

Introduction

COATED STEEL sheet or strip is formed in the same presses as those used for forming uncoated steel. Forming procedures, however, must sometimes be modified, depending on the type of coating. During processing, scratching or breaking of the coating (sometimes, only marring the surface) must be avoided because these defects could cause rejection of the finished part.

Coated steels have formability characteristics that are different from those of uncoated steels. This article will discuss the effects of coatings on the formability of sheet steels and will provide some general guidelines for the forming of coated steels. The forming of bare (uncoated) steels is discussed in the articles "Press Forming of Low-Carbon Steel" and "Press Forming of High-Carbon Steel" in this Volume.

Press Forming of Coated Steel

Impact of Coating Processes on Substrate Formability

Coated steels can be categorized according to the formability of the substrate. It must be kept in mind, however, that the method used to apply the coating (whether it is zinc (galvanized), aluminum, tin, or terne or an organic coating) can affect the metallurgical structure of the substrate and therefore its properties.

The most prevalent coated steel that is currently in use is zinc-coated steel (galvanized). Steel can be galvanized by hot dipping or electroplating. Although applications for electrogalvanized steel are increasing, most of the galvanized steel currently being used is produced by hot dipping.

Hot-Dip Galvanizing. Hot-dip galvanized steel is produced by one of two basic processes, depending on the properties required. A low-temperature process (~455 to 480 °C, or 850 to 900 °F) is used when the steel is preannealed to achieve a soft, ductile structure and good formability.

Higher temperatures (675 to 870 °C, or 1250 to 1600 °F) are used for in-line annealing (that is, the steel substrate is annealed as the hot dip coating is applied). Because of the short duration of the in-line annealing process, steels processed by this method are less formable than steels that are coated at lower temperature. Depending on carbon content, steels coated by the high-temperature hot-dip process may or may not require postannealing to enhance formability. Low-carbon steels often require postannealing to restore full formability; extralow-carbon steels (0.01% C) normally do not require postannealing.

Electrogalvanizing is conducted at temperatures at or near ambient; therefore, the properties of electrogalvanized steel sheet are nearly identical to those of uncoated cold-rolled steel.

Other types of coatings discussed in this article include aluminum, tin, terne (lead-tin alloy), nickel and chromium, and organic coatings. Because aluminum is applied by hot dipping, aluminum-coated (aluminized) steel is subject to the same types of problems as hot-dip galvanized steel. Tin coatings can be applied by hot-dipping or electroplating; the latter is much more common. Terne is a hot-dip product. Nickel plating and chromium plating are applied by electroplating. The methods used to apply paints and other organic coatings vary, although most require curing at moderate temperature to achieve final properties. These coatings will be discussed in more detail in the following sections.

Press Forming of Coated Steel

Galvanized Steels

The formability of galvanized steels is reduced to some extent by the brittle iron-zinc alloy layer that is produced between the metallic zinc and the steel base during hot-dip galvanizing. The thickness of the alloy layer depends on the temperature-time cycle in galvanizing, but it is also affected by the percentage of other metals, especially lead and aluminum, in the molten-zinc bath. The decrease in formability is usually in direct proportion to the thickness of the iron-zinc alloy layer. Modern hot-dip galvanizing processes use special thermal cycles and low-lead low-aluminum coating materials to minimize formation of the iron-zinc alloy layer.

In deep drawing, the beneficial effects of the free-zinc layer on the surface of the work metal outweigh the adverse effect of the alloy layer, often permitting greater reductions and greater draw depths than with similar uncoated steel. The layer of soft metallic zinc prevents galling during forming by eliminating direct contact between the steel substrate and the punch.

Formability is also influenced by other factors; chief among these are the initial properties of the steel base; the amount of mechanical work before or after galvanizing; and the response of the steel to the heating cycle for galvanizing, to supplementary heat treatments, and to aging. These factors often have a greater effect on the formability of galvanized steel than the galvanized coating does.

Mill Products. Galvanized steel sheet for use in forming is generally purchased in one of four AISI grades:

- Commercial quality (CQ)
- Drawing quality (DQ)
- Drawing quality, special killed (DQSK)
- Drawing-quality special-killed extralow carbon

Drawing-quality special-killed extralow-carbon steel is available in both stabilized (interstitial-free) and nonstabilized grades. The grades listed above are available in either the dead-soft or the temper-rolled condition.

The thickness of the zinc coating per side, including the iron-zinc alloy layer, ranges from about 55 μm (2.15 mils) for the heaviest coating to 16.5 μm (0.65 mils) in eight coating classes. It is more common, however, to specify the desired coating by weight per unit of surface area. This is particularly true in the automotive industry; automakers are requesting closer weight control tolerances for more consistent welding and forming characteristics. Coating weight is commonly specified in the auto industry in terms of grams per square meter (g/m^2) per side.

One-side galvanized steels have also been developed for the automotive industry. These materials are used with the galvanized side facing inward; this gives the protection of galvanizing while maintaining the paintability and weldability of uncoated low-carbon steel on the outside of the panel.

Tool Design. Tools for forming zinc-coated steel parts are of conventional design and are made of cast iron and standard tool steels. However, parts formed of CQ continuous-annealed steel or of steel over 1.52 mm (0.060 in.) thick require more compensation for springback than conventional box-annealed steel and uncoated steel, which have lower yield strengths and hardnesses. Postheat-treated continuous-annealed and box-annealed DQ galvanized steels require the same tooling as uncoated steels in most forming operations.

Forming Applications. Galvanized steel is used for parts that differ widely in forming severity; typical formed parts include automobile frame and body parts, roofing, siding, gutters and downspouts, ductwork, signs, awnings, outdoor hardware, highway guardrails, and culverts. Information on the hot-dip galvanizing process is available in the article "Batch Hot Dip Galvanized Coatings" in *Surface Engineering*, Volume 5 of the *ASM Handbook*; the corrosion resistance of hot-dip galvanized steels is the subject of the article "Hot Dip Coatings" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

Electrogalvanized Steels. Because the intermediate layer of iron-zinc alloy is either absent or very thin on electrogalvanized steels, the formability of these materials is essentially the same as that of equivalent uncoated steels. There is no measurable thickness of iron-zinc alloy on the plated coil stock even after long storage at room temperature; the amount of alloy produced in heat treating the plated stock before forming is usually too small to affect formability. The plating ($\sim$2.5 to 7.5 μm, or 0.1 to 0.3 mil thick) is tightly adherent even under the most severe deformation. Table 1 lists the typical mechanical properties of galvanized and uncoated CQ, DQ, DQSK, and DQSK extralow-carbon steels.

Table 1 Typical substrate mechanical properties of four types of galvanized and uncoated steels

Type of steel	**Yield strength**		**Ultimate tensile strength**		**Elongation, in 50 mm (2 in.), %**	**Average normal plastic anisotropy, $\bar{r}$**	Average strain-hardening exponent, *n*

Source: Ref 1

Galvannealed steels are hot-dip products that use a zinc-iron alloy coating on both sides of the sheet. The alloy coating is produced by hot-dipping and then annealing or wiping the sheet.

An investigation of the formability of two different galvannealed materials found that the annealing treatment used to produce galvannealed steel resulted in averaging of the substrate, with resulting lower yield strength and higher elongation values (Ref 2). Ductility as measured by the strain-hardening coefficient *n* also increased. However, deep drawability as measured by the plastic-strain ratio *r* decreased. A higher *r* value indicates good resistance to thinning and therefore good deep-drawing properties. Figure 1 illustrates the effect of the galvannealing treatment on mechanical properties.

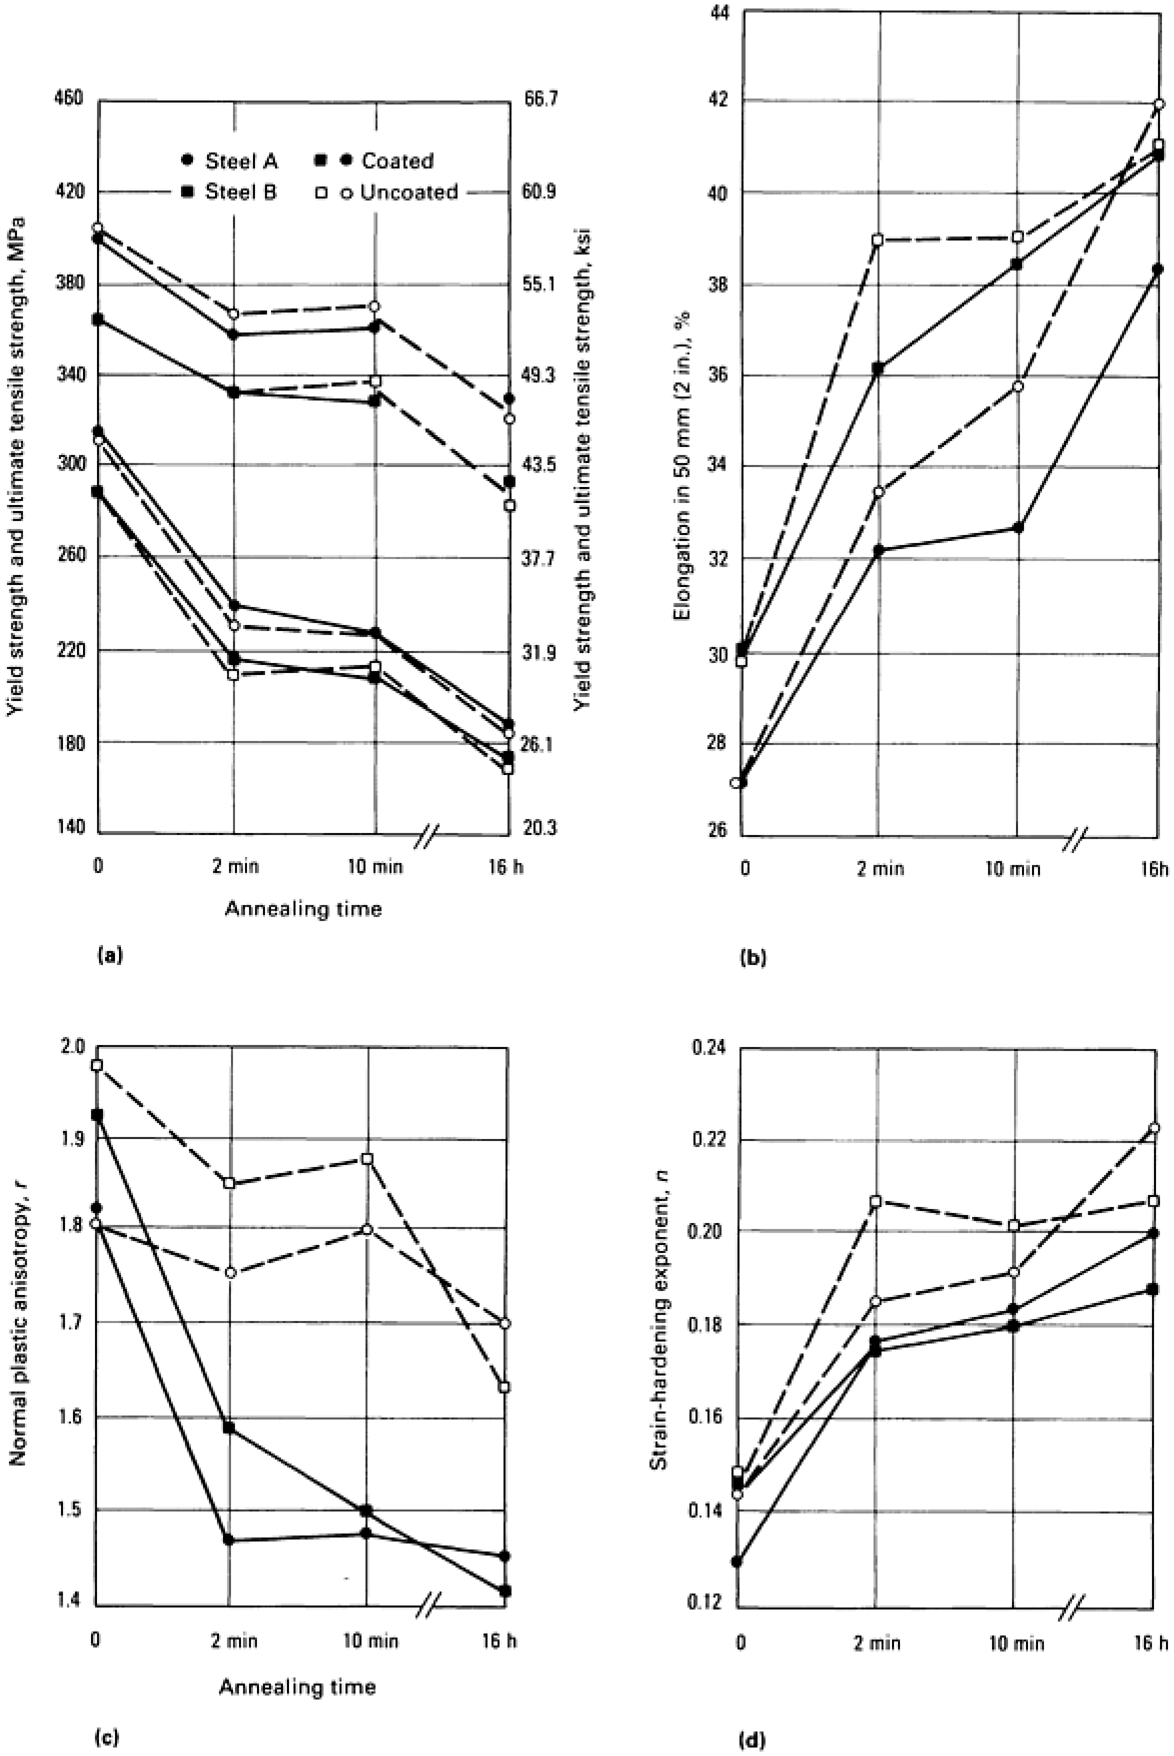

Fig. 1 Effect of the zinc-iron alloy layer on the mechanical properties of galvannealed steels. Data for hot-dip galvanized steel are shown for comparison with galvannealed steels after three annealing times. (a) Yield strength and ultimate tensile strength. (b) Elongation. (c) Normal plastic anisotropy *r*. (d) Strain-hardening

coefficient *n*. Short-term anneals (2 and 10 min) were at a temperature of 550 °C (1020 °F); 16 h anneal was at 420 °C (790 °F). Source: Ref 2.

Galfan-Coated Steels. A relatively recent development in hot-dip coatings is a Zn-5Al-mischmetal coating known as Galfan. Bend and deep-drawing tests have shown that this coating material is less susceptible to cracking upon forming than other hot-dip coatings (Ref 3). Figure 2 compares forming limit diagrams for hot-dip galvanized and Galfan-coated steels. The forming limit diagram shows the maximum strain a material can withstand during forming without necking.

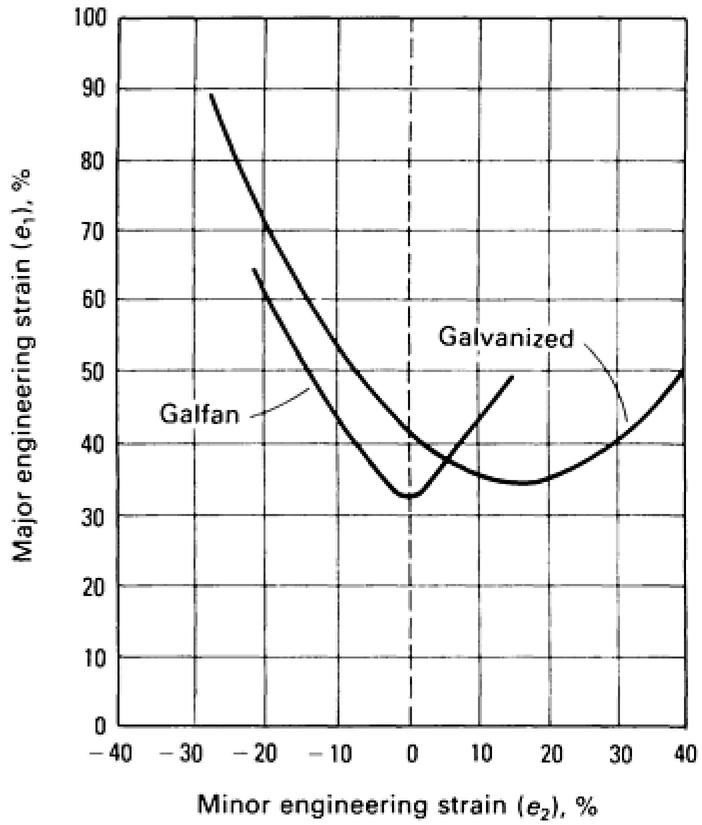

Fig. 2 Forming limit diagrams for hot-dip galvanized and Galfan-coated steel. Source: Ref 3.

Aluminum-Coated Steels

Moderately severe forming is done on hot-dip aluminum-coated (aluminized) steel. The same dies and pressworking practices used for uncoated steel are applicable to aluminum-coated stock. Drawing compounds are recommended for forming and drawing operations (see the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume).

There are two types of aluminum coatings that are commercially significant. Type 2 uses commercially pure aluminum for the coating, and Type 1 uses an aluminum alloy containing 5 to 11% Si. The microstructure of the Type 2 coating has a layer of aluminum, often with scattered iron-aluminum intermetallic particles, bonded to the steel substrate by an iron-aluminum intermetallic layer. This intermetallic layer forms a distinctive serrated boundary with the steel and is generally identified as Fe_2Al_5, although some investigations have found additional iron-aluminum compounds.

A different microstructure is produced when silicon is added to form a Type 1 coating. The intermetallic layer becomes narrower and smoother, and this results in increased formability of the coated product. The coating bath temperature can also be lowered with increasing silicon additions, and the growth of the intermetallic layer is further inhibited.

Alloy additions of beryllium, copper, and certain other elements have also been found to impede the growth of the intermetallic layer. Additions of these and other elements to the steel itself can also retard the growth of the alloy layer. The way in which these elements reduce the growth is not understood, although silicon appears to act after being incorporated into the intermetallic layer itself.

Formability of Mill Products. Forming operations of moderate severity can be done on CQ steel with a Type 1 or 2 coating. Sheet stock withstands bending 180° flat on itself in any direction, without fracture of the steel base, and bending 180° over two thicknesses of the material without flaking or peeling on the outside of the bend. When greater ductility is needed, DQ or DQSK steels with Type 1 coating are used, and they are supplied in a quality suitable for forming a specific part.

Requirements for corrosion resistance in service often limit the permissible severity of forming to less than that described in the preceding paragraph. Hairline cracks that develop in the aluminum coating lead to lower service life at high temperature or in atmospheric exposure. Table 2 gives minimum diameters for 180° bends for 25 cycles of exposure for 30 min at 595 °C (1100 °F) and cooling for 30 min (Type 1 coating) or for a service life of 1 year in a mild industrial atmosphere (Type 2 coating).

Table 2 Minimum bend radii for corrosion-resistant 180° bends in various thicknesses of aluminized steel sheet

Steel sheet thickness, *t*		Minimum bend radius	
mm	**in.**	**Type 1 coating**[(a)]	Type 2 coating[(b)]
1.61	0.0635	1.5*t*	**2.5*t***
1.31	0.0516	1.5*t*	**2*t***
1.00	0.0396	1.5*t*	**1.5*t***
0.85	0.0336	. . .	**1*t***
0.70	$\leq$**0.0276**	**0.5*t***	**0.5*t***

(a) Coating containing about 9% Si and weighing 150 g/m^2 (0.5 oz/ft^2). Minimum radii are for no rust on the outside of the bend after exposure in air for 25 cycles consisting of 30 min at 595 °C (1100 °F) and 30 min of cooling.

(b) Coating of commercially pure aluminum weighing 350 g/m^2 (1.15 oz/ft^2). Minimum bend radii are for no rusting at the outside of the bend after 1 year of exposure to a mild industrial atmosphere.

Adherence testing by reverse bending has shown good correlation in predicting the suitability for forming and drawing steel sheet with aluminum hot-dip coatings of different composition, structure, and thickness or coating weight. Compressive forces are more destructive than tensile forces to the adherence of the coating. In a 180° bend test, the coating always fails first on the compression side of the bend, if it fails at all. Similarly, in a coating failure occurring during a drawing operation, peeling always develops first on the compression side.

In applications involving tension only, as in an elongated tensile specimen, the alloy layer is fractured, but the fractures do not show at the outer surface of the coating. Microscopic examination has verified the ability of the more ductile outer layer to elongate and provide continuous coverage of the cracked alloy particles.

An investigation of the adhesion of Type 1 coatings of various thicknesses in severe press forming found that adhesion decreased as coating thickness increased (Ref 4). In three-station direct redrawing (Fig. 3), the aluminized coating peeled as coating weight exceeded 50 g/m^2 (0.16 oz/ft^2). The thickness of the intermetallic alloy layer was determined to be the primary cause of peeling at higher coating thicknesses (Ref 4).

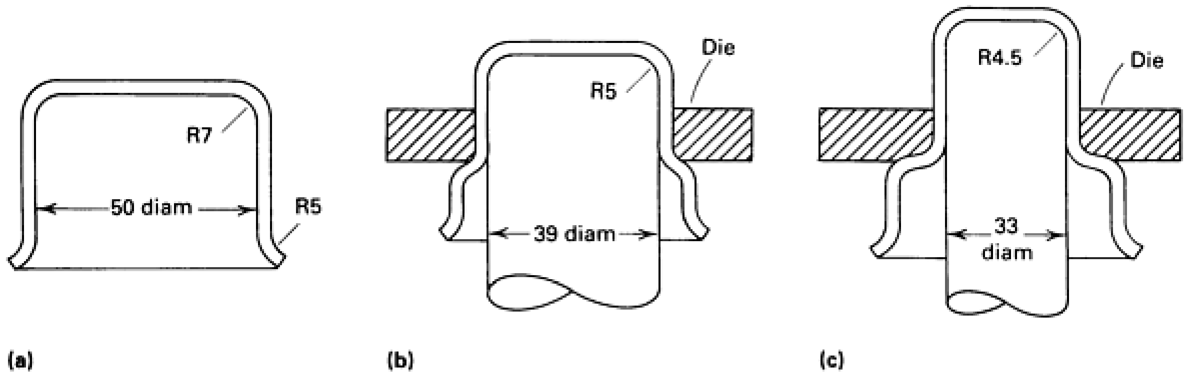

Fig. 3 Three-station direct redrawing used to investigate the formability of aluminized steels in Ref 4. (a) First draw. (b) First redraw. (c) Second redraw. Blank diameter was 90 mm (3.54 in.); blankholder force was 600 kgf (1320 lbf). Dimensions given in millimeters (1 in. = 25.4 mm). Source: Ref 4.

Examples of Application. Steels coated with Type 1 aluminum are used in applications in which resistance to heat and oxidation is important, such as in automotive exhaust systems or heat-treating equipment. Type 2 coatings are used for their resistance to atmospheric corrosion.

Tin-Coated and Terne-Coated Steels

The steels to which tin and terne coatings are applied vary in composition for different products and among different manufacturers, but are generally low-carbon grades similar to 1008 or 1010. Nearly all of the common forming methods are used on tin-coated and terne-coated low-carbon steel. Spinning is not ordinarily done on these materials, because of the likelihood of excessively thinning or fusing the coatings.

More than 95% of the steel sheet and strip that is coated with tin at the mill has an electroplated coating of tin; the remainder has a hot-dip coating. The properties of these products are determined by the requirements of the end use.

The thickness of tin on electroplated mill products ordinarily ranges from 0.4 to 2.3 μm (15 to 90 μin.) per side. Hot-dip products have coating thicknesses of 1.7 to 3.8 μm (66 to 150 μin.) per side.

Terne-coated steel products are hot-dip coated with a lead-tin alloy that contains 10 to 25% Sn by weight. Terne coatings range from the thinnest coating that gives complete coverage of the steel to about 1 to 1.8 μm (40 to 70 μin.) per side.

Effect of Coating on Formability. The thin, ductile surface layer of pure tin (or lead-tin alloy) increases die life and reduces lubrication requirements in forming, as do zinc and aluminum coatings. However, unlike the hot-dip zinc and aluminum coatings, the tin and lead-tin coatings have too thin an alloy layer to reduce the formability of the steel base noticeably. Therefore, in general, the formability of tin- or terne-coated steels is the same as that of uncoated steels.

The formability of electrolytic tin-coated sheets and long terne sheets is related to the quality designation of the steel. Commercial-quality sheets are suitable for moderate deformation and can be bent flat on themselves in any direction without fracture of the base steel or the coating. Drawing-quality, drawing-quality special-killed, and, less frequently, physical-quality sheets are used to meet specific deep-drawing and severe forming requirements.

Deep Drawing. A tin coating on steel produces a substantial improvement in the drawability of the base material. The effect of electrolytic tin plate of various thicknesses on the limiting drawing ratio of steel has been investigated for DQ and DQSK steels 0.71 mm (0.028 in.) thick. The results of lubricated Swift cup tests showed that the thinnest tin coating (0.076 μm, or 3 μin., per side) produced a considerable increase in the limiting drawing ratio, that is, an increase in drawability. The increase was greater for thicker coatings (Fig. 4). Unlubricated testing showed the same results, except that the improvement in drawability was not as pronounced (Fig. 4).

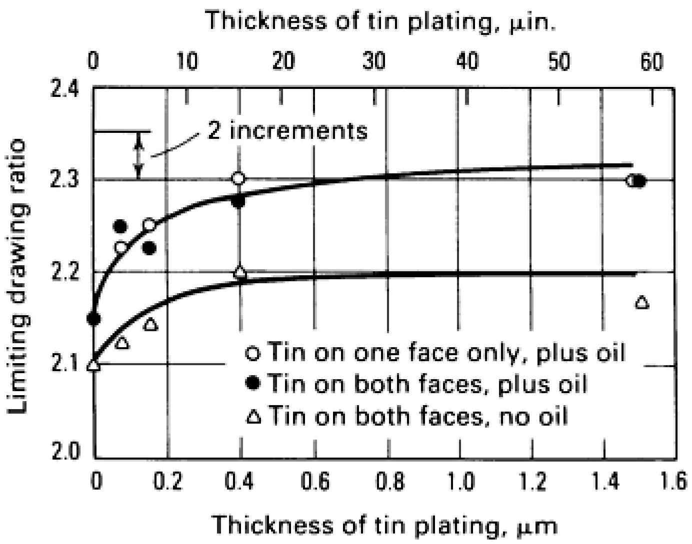

Fig. 4 Effect of tin coating thickness on limiting drawing ratio of steel sheet with and without lubrication.

Applications. Tin plate containers for various items are made at high speed by blanking, forming, rolling, lockseaming, and crimping. Other applications for which tin plate is formed include household utensils and appliances, commercial baking pans, automotive parts, toys, and hardware.

The behavior of terneplate in forming is generally the same as that of tin plate. Because of its high lead content, terneplate is toxic and therefore not suitable for food containers, but it is formed into containers for gasoline and paint. Terneplate is used in formed products such as roofing, door frames, and automotive parts because of its excellent resistance to atmospheric corrosion and its low cost.

Nickel-Plated and Chromium-Plated Steels

Press forming and roll forming are sometimes done on steel that has been electroplated in the coil with decorative copper-nickel or copper-nickel-chromium. More often, however, parts are formed to final shape before electroplating with these materials.

Conventional lubricants can be used in the press forming of this material, particularly in high-volume production. Sometimes, however, no lubricant is used in making decorative parts. Instead, surface contact between the work metal and tools is prevented by the use of strippable plastic coatings or adhesive-backed paper on the work metal, or of loose paper between the work metal and the punch or the die. These materials protect the decorative finish on the preplated steel, prevent galling, and provide a controlled amount of friction for forming. They can also be removed from the completed parts without harming the finish.

Polished die surfaces, or dies or die inserts made of rubber or plastic, also protect parts during forming. Coated blanks or parts can be interleaved with paper, cardboard, or plastic sheet material, or they can be placed in containers with separate compartments to protect the decorative surfaces from damage during storage or handling between forming operations.

Conventional lubricants are used in roll forming. Volatile materials that evaporate completely can be used where cleaning after forming presents problems. Mineral seal oil is preferred in some applications because it leaves only a light residue that may not require removal.

Standard Products. The substrate for these decorative preplated materials is usually 1008 or 1010 cold-rolled steel. Rimmed steel is used for forming applications in which there is only mild or moderate deformation. Aluminum-killed steel is used in applications in which strain lines or aging presents a problem. Drawing-quality steel may be needed where the utmost in severity of deformation is encountered, although its use entails some sacrifice in surface finish in the formed areas.

Stock thickness is usually from 0.20 to 1.27 mm (0.008 to 0.050 in.) for coils and up to 1.57 mm (0.062 in.) for cut sheets, which are usually used in the annealed condition. One manufacturer of preplated strip specifies a hardness of 50 to 60 HR30T on the raw material. Harder tempers can be used to meet special requirements.

Copper plating thickness and nickel plating thickness are usually 2.5 to 7.5 μm (0.1 to 0.3 mil) each, and the chromium plating is 0.075 to 0.25 μm (3 to 10 μin.) thick. A nickel deposit thicker than 7.5 μm (0.3 mil) gives greater corrosion resistance, but usually cannot be produced on coil stock.

Plating conditions are controlled to give a ductile deposit with minimum residual stress. The copper is buffed, and the nickel is buffed or given a satin finish.

Formability. The ductility of the plated steel may be different from that of the unplated coil stock, depending on the metal or metals deposited, plating bath and plating conditions, and the effects of aging or buffing. It may also be affected to some extent by work hardening from the extra coiling and uncoiling of stock during plating.

The plating procedure is usually selected and controlled to yield ductile electrodeposits and a plated product that (after buffing or aging for several days) has formability at least as good as the unplated raw material. Formability of this quality is obtained with buffed, ductile electrodeposits of copper or nickel, or a composite of the two, up to a total plating thickness of 64 μm (2.5 mils), with the normal bright chromium plate over these. Ductility is reduced by the use of nonductile electrodeposits from bright or contaminated plating baths or by the use of unfavorable plating conditions in depositing a heavier-than-normal chromium coating. The severity of forming permitted is usually limited by the need to avoid objectionable visible roughening of the plating or lowering of corrosion resistance in the regions of severe deformation, not by the ability to deform the preplated stock without cracking or rupturing.

Organic-Coated Steels

Steels that have been painted or plastic coated in the coil are formed by the commonly used press and roll methods, using the same equipment as for uncoated stock. The thickness of the steel base is usually 0.25 to 1.57 mm (0.010 to 0.062 in.) but may range from less than 0.20 to 1.9 mm (0.008 to 0.075 in.).

The tools used on uncoated steel can usually be used for painted or plastic-coated steel. However, die materials lower in strength, shock resistance, and wear resistance than those generally used in forming uncoated steel are satisfactory in many applications. Dies may have inserts of rubber or plastic to help protect the coating during forming.

Organic coatings promote long tool life because they generally provide a less abrasive surface than bare steel. This effect varies with the composition of the coating The abrasiveness of an organic coating increases with decreasing gloss.

To avoid scoring or marring of the organic coatings, die surfaces must be highly polished, and workpieces must be handled with care. For forming metals that have coatings only a few tenths of a mil thick, little or no increase in clearance is needed. However, the resilience and compressibility of the thicker dispersion coatings and vinyl-film laminates must be taken into consideration in the design of tooling to ensure that dimensional tolerances are maintained during forming.

Zincrometal is an organic-coated sheet steel that is widely used in the automotive industry. It consists of a mixed-oxide underlayer containing metallic zinc particles and a zinc-rich organic (epoxy) topcoat. The total coating thickness of Zincrometal is about 15 μm (0.6 mils). A solid lubricant has recently been incorporated into the coating to improve formability, which is similar to that of electrogalvanized steel (Ref 5).

Organic composite-coated sheet steels for the automotive industry are currently under development (Ref 6, 7, 8). These coil-coated products generally have an electroplated zinc alloy base layer and a chemical conversion coating under a thin organic topcoat containing a high percentage of metal powder. The thinness of the organic topcoat allows for good formability without damage to the coating (Ref 6, 7, 8).

Lubricants and Handling. Lubricants must be selected that do not affect the appearance or properties of the coating, and they must be easy to remove without damaging the coating. Adhesive-backed paper or strippable plastic films are sometimes used in place of or in conjunction with a lubricant.

Formability of organic-coated metals is generally limited to a severity that will not damage the appearance of the coating, reduce its protective value, or impair its adhesion (although some coatings are flexible enough to withstand deformation that fractures the underlying metal). The effect of the coating on formability, tooling, and forming procedure depends primarily on the type and thickness of the coating and the pretreatment of the base metal.

Table 3 lists a number of types of organic coatings and gives the normal thickness range and adhesion rating for each coating, with the minimum bend radius and formability rating for the coated sheet metal.

Table 3 Forming characteristics of organic precoated sheet steels

For coiled bare, hot-dip or electrogalvanized, and aluminized steels. Applied also to aluminum, copper, and brass substrates. For tin-coated steel, ratings apply only for epoxy coatings; other coatings have lower ratings. For copper and brass, ratings apply only when primers based on epoxy or phenolic resins are used. Data are based on the use of suitable chemical conversion treatments and primers; results may vary for different substrates. Conversion coatings and primers improve results with most coating-substrate combinations.

Type of coating	**Coating thickness**		**Coating adhesion**[a]	**Minimum 180° bend radius**[b]	Suitability for severe forming[a]

(a) Ratings: E, excellent; G, good; F, fair.

(b) *t*, thickness of sheet.

(c) Results are greatly affected by coating thickness.

(d) Coating of medium thickness is good for deep drawing.

(e) Coating can bridge cracks in the metal produced by severe forming; compressibility of the coating must be considered in forming to close tolerances.

(f) Results are greatly affected by substrate material and thickness.

(g) Bonds may be destroyed in extreme draws or sharp bends.

(h) Bond strength may be seriously reduced after slight deformation.

(i) Particularly susceptible to damage by scoring of coating during forming

The ranges of coating thickness shown in Table 3 represent the extreme limits that are technically feasible; most production coatings have much narrower limits of thickness. Primer thickness is not included in the values for coating thickness.

The surface condition of the metal base can influence the permissible severity of forming, particularly with thin (~25 μm, or 1 mil) coatings. Highly polished metal surfaces give a more uniform distribution of the surface stresses induced by tools during forming. This more effectively preserves the appearance and texture of the coating and would allow greater severity of deformation if it were not counteracted by the generation of heat over the entire surface of the coating that is in contact with the forming die.

A metal base with a relatively coarse surface finish subjects the high points of the coating (which for thin coatings are a reproduction of those of the metal beneath) to higher stresses and greater wear during forming. However, the smaller area of contact results in generation of less heat from friction.

Adhesion and Flexibility. The adhesion of commonly used coatings is rated in Table 3. The minimum bend radii and formability ratings in Table 3 are a measure of the combined effect of coating adhesion and flexibility. Vinyl plastisol coatings have such outstanding flexibility that they can bridge cracks produced in the metal base by severe forming.

To provide the adhesion generally required for forming, chemical conversion coatings, selected for the metal surface to be painted or plastic coated, are applied to coil stock or blanks by spray or immersion treatment. This treatment is usually followed by the application of a prime coat compatible with the final coating material. Bare steel is given an iron phosphate coating with a weight of 375 to 480 mg/m^2 (0.013 to 0.016 oz/ft^2). Zinc-coated steel receives a zinc phosphate coating--1.6 to 2.7 g/m^2 (0.005 to 0.009 oz/ft^2) on hot-dip coatings and 1.08 to 1.9 g/m^2 (0.0035 to 0.006 oz/ft^2) on electroplated coatings. Aluminum-coated steel is treated with a chromate coating weighing 215 to 270 mg/m^2 (0.0007 to 0.0008 oz/ft^2). These coating weights refer to area of stock and must be doubled when treatment of both sides of the stock is considered.

Organic coatings that are applied to untreated and unprimed metal surfaces have better flexibility than those applied to pretreated surfaces. However, without pretreatment or the use of a suitable primer, the degree of adhesion necessary to withstand forming forces or to have adequate service life and corrosion resistance usually cannot be assured. As indicated in Table 3, forming characteristics are generally improved by the use of a primer. An exception is tin-coated steel.

The thicker films of organosols, plastisols, and vinyl-film laminates have better flexibility than films of solution coatings in the 0.025 mm (1 mil) dry-film range. Because of their greater thickness, the reduction in thickness from elongation in bending is a smaller percentage than that for the thinner films of solution coatings. The stress of forming is absorbed within the thicker films and is not transferred to the interface with the metal, at which adhesion is established.

Solution coatings, because of increasing film strength, have less flexibility and adhesion near the upper thickness limit. The most severe forming can be done near the lower thickness limit, but such thin coatings may not fulfill service requirements. Although solution coatings of silicone-polyesters and thermosetting acrylics can be applied as thin as 2.5 μm (0.1 mil), as exterior coatings they are used almost exclusively in the heavier thicknesses shown in Table 3. Laminated plastic coatings may show excessive film strength and therefore less flexibility and adhesion at the upper end of the thickness range, and low tensile strength at the lower end. The color and gloss of an organic coating also affect coating flexibility, which decreases with increased pigment loading.

Hardness of organic coatings is in the range of HB to 3H pencil hardness for most of the commonly used paints and about Durometer A 85 to 90 for plastisol coatings and laminated plastics. Softer coatings are more likely to be damaged by scoring in the forming die. Die pressure transmitted through an organic coating to the interface can destroy adhesion. In heavy films and vinyl-film laminates, the elastic, compressible finish coating normally yields under die pressure, but the relatively brittle adhesive primer layer can be damaged by localized high die pressure.

Shearing, Blanking, and Piercing. Sharpness of cutting tools and direction and speed of cut affect the performance of coatings in the cut area. Dull cutting tools or high impact speeds cause high-energy impact on the coating surface and may shatter the bond in the surrounding areas, particularly in coatings of borderline adhesion strength. Flaking or lifting of the coating may result.

Bending. Minimum bend radii for organic-coated metals are given in Table 3. Slow bending will prevent breakage of the coating more effectively than rapid bending. When bending with contour forming rolls, the finish of the organic coating will be preserved, and less stress will be imposed on the steel base if the radii are bent over several rolls instead of one or two rolls.

Bending short flanges close to a cut edge or where the coating is scored by the bending tool at the peak of the bend can cause the coating to lift off the steel base. In both cases, the cohesive strength of the film has been weakened, and coatings with high film strength will attempt to return to the shape in which they were applied.

Deep Drawing. Suitability of the organic-coated metals for deep drawing (or severe forming) is rated in Table 3. The effect of speed of drawing or forming is generally the same as that described for bending.

The more steps used, the more severely a part can be drawn or formed without damaging the organic coating. However, the ductility and work-hardening behavior of the steel, as well as the flexibility of the coating system, must be considered in the design of a forming or drawing die.

Forming Temperature. Depending on the effect of temperature on the properties of the organic coating, heating up to 50 °C (120 °F) before forming will reduce the likelihood of coating fracture. Some coatings, such as silicone-polyester coatings with a high silicone content, can be formed at a temperature as high as 65 °C (150 °F). Heating can be done with infrared radiant heaters, hot air, or an open gas flame or by storing the coil stock in a heated room until fabrication.

Overheating must be avoided. Organic coatings, especially the thermosetting types, can be softened enough to make them subject to surface damage from die action and handling.

The design and surface finish of tools and the selection of handling procedures and equipment are important in forming organic-coated metals. Depending on the accuracy requirements and the coating thickness, allowance may have to be made for the coating thickness in dimensioning the forming tools. When accuracy requirements and coating thicknesses permit, the same dies can often be used for painted and plated metals.

To prevent scratching and scoring of prepainted surfaces, the die surfaces must be polished and sharp corners rounded off. In addition, damage during ejection and subsequent handling of the parts must be prevented.

Coated High-Strength Steels

The demand is increasing for high-strength steel sheet for stamped parts, particularly in the automotive industry. Although most current applications are for uncoated high-strength steels, the use of coated high-strength steels is expected to increase; corrosion resistance is of even greater concern for the thinner (and therefore lighter) high-strength steel sections used. Coated high-strength steels can be manufactured by any of the conventional coating processes and can be coated with any of the coating materials already described in this article. Table 4 lists typical substrate mechanical properties of galvanized and uncoated high-strength steels.

Table 4 Typical substrate mechanical properties of high-strength steels

The galvanizing of high-strength steels appears to have much the same effect as the zinc coating of carbon steels; that is, the free zinc at the surface acts as a lubricant during forming. Figure 5 compares the limiting drawing ratios of coated and uncoated high-strength steel sheets. The results of a comprehensive comparison of the formability of coated and uncoated high-strength steels are reported in Ref 9.

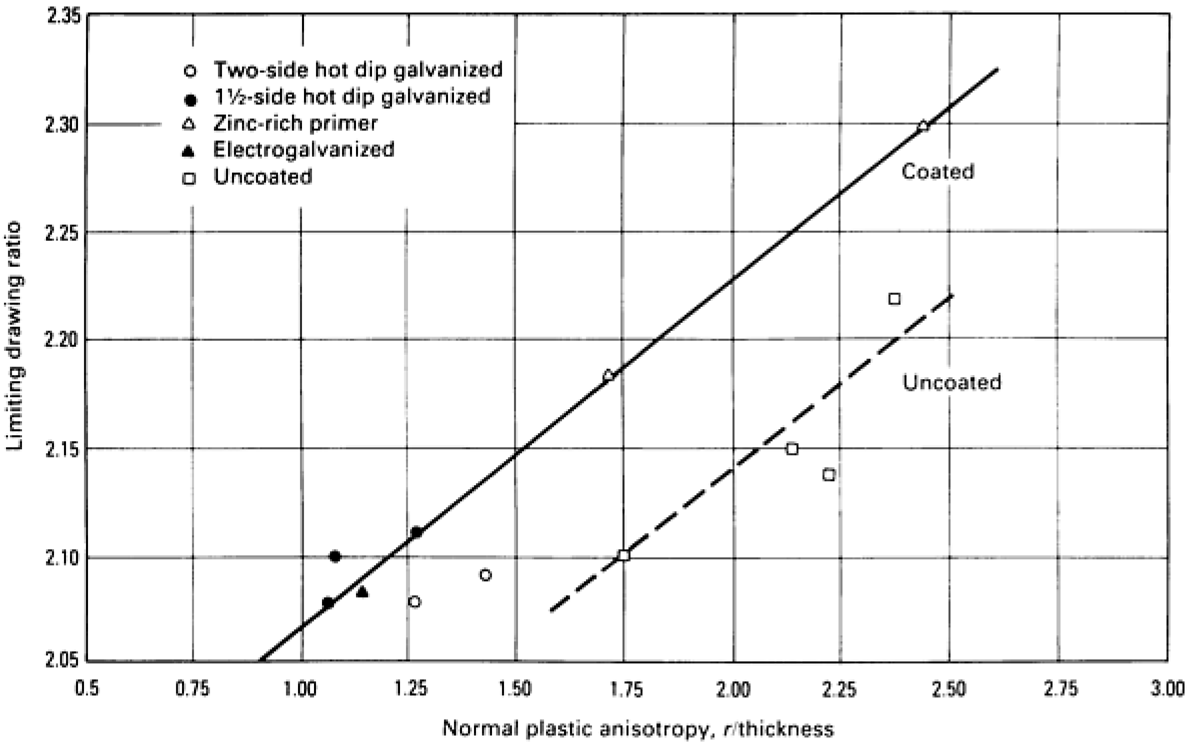

Fig. 5 Limiting drawing ratio for various coated and uncoated high-strength steels. One and a half side galvanized steel is produced by hot dipping, then wiping one side of the sheet to produce a zinc-iron alloy coating. Source: Ref 9.

Forming of Steel Strip in Multiple-Slide Machines

Revised by Deborah A. Blaisdell, The U.S. Baird Corporation

Introduction

MULTIPLE-SLIDE FORMING is a process in which the workpiece is progressively formed in a combination of units that can be used in various ways for the automated fabrication of a large variety of simple and intricately shaped parts from coil stock or wire. Operations such as straightening, feeding, trimming, blanking, embossing, coining, lettering, forming to shape, and ejecting can all be done in one cycle of a multiple-slide machine. Forming is generally limited to bending operations, but the four slides and center post permit the fabrication of very complex parts. Deep drawing is generally not done in the forming or press stations of a multiple-slide machine.

Acknowledgement

Portions of this article were adapted with permission from T. Hanson, *The Multiform Manual,* Heenan & Froude Ltd.

Applicability

Multiple-slide forming is used to produce shapes from coiled strip or wire. The maximum size of workpiece that can be formed from strip metal in a multiple-slide machine is 203 mm (8 in.) wide by 685 mm (27 in.) long. Parts made from wire up to 1015 mm (40 in.) long (or longer if a special machine is used) and up to 9.5 mm ($\frac{3}{8}$ in.) in diameter can be formed automatically from coil stock. This article deals with the forming of strip stock; the fabrication of wire forms is discussed in the article "Forming of Wire" in this Volume.

If the work metal is comparatively thin and the bending is not severe, tempered strip material can be formed. Plated or coated materials can be formed, but it is usually better to coat after forming because it is difficult to avoid marring coated surfaces during forming. However, nonmetallic inserts at appropriate points in the straightener, feeder, and forming tools can be used to reduce tool marks.

Springback must be considered in bending such materials as stainless steel, phosphor bronze, certain grades of brass and beryllium copper, or high-carbon steel. Adjustments can be made in the forming tools to provide the amount of overbending required for the accuracy of the finished work.

More than one piece can be made in each cycle of a multiple-slide machine. For example, a part that had been made in seven conventional press operations was replanned for the multiple-slide production of four pieces per cycle at 200 cycles per minute.

Forming of Steel Strip in Multiple-Slide Machines

Revised by Deborah A. Blaisdell, The U.S. Baird Corporation

Multiple-Slide Machines

Multiple-slide machines are made in a range of sizes, all similar in construction and principle. The larger machines have a longer die space, which enables more die stations to be used for the manufacture of complicated components. Generally, the number of strokes per minute decreases and the horsepower increases as the machine size increases.

The four forming slides of a typical multiple-slide machine are generally sufficient for ordinary part-forming needs. However, complex parts can be formed at two or three levels around the center post, thus doubling or tripling the number of forming positions available.

Figure 1 shows a plan view of the main units of a medium-size multiple-slide machine that uses a floor space of 3.7 × 1.5 m (12 × 5 ft), including the stock reel. Four shafts (A, B, C, and D), mounted to a flat-top bedplate, are driven at equal speed through spur gearing (E) by an electric motor. Each of the four shafts is fitted with a positive-action cam (F) that drives a slide (G) (only two of four are identified) on which the forming tools can be secured. In the center of the machine is a vertical post (H) into which the center post or former is fixed and around which the work material is bent. The formed workpiece is removed from the center post by a stripper mechanism, which usually consists of a hardened steel plate surrounding the center post and secured to a vertical rod operated by a cam (F) on the right-hand shaft to give up-and-down motion to the stripper. All of these parts constitute the forming station of the machine.

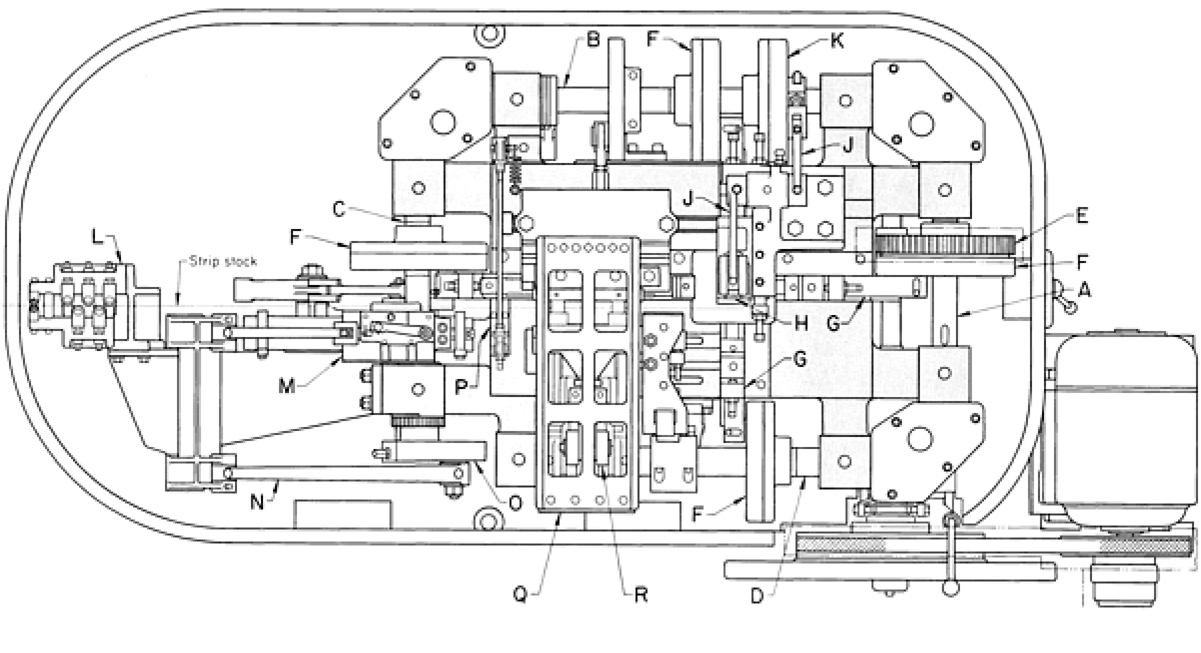

Fig. 1 Plan view of a multiple-slide machine showing major components. A to D, integrated shafts; E, spur gearing; F, positive-action cam; G, slide; H, vertical post; J, bell crank; K and R, cams; L, stock straightener; M, automatic gripper in feed slide; N, links; O, adjustable crank; P, stationary gripper with cam-operated jaws;

Q, horizontal press with dies; R, cam. See text for description of operation.

To the left of the machine proper is a stock straightener (L), shown in working position with strip stock passing through it. Intermittent feeding of the work metal is accomplished by an automatic gripper in the feed slide (M) and an adjustable crank (O), which is attached to a shaft (C). A separate gripper (P) is provided with cam-operated jaws, which grip the strip on the return stroke of the feed slide to prevent backward motion of the strip.

The work metal strip, fed through the machine in a vertical plane (on edge), passes horizontally through dies in a horizontal press (Q). A short, powerful stroke is given to the horizontal press slide by a cam on the front shaft (D) (see Fig. 2).

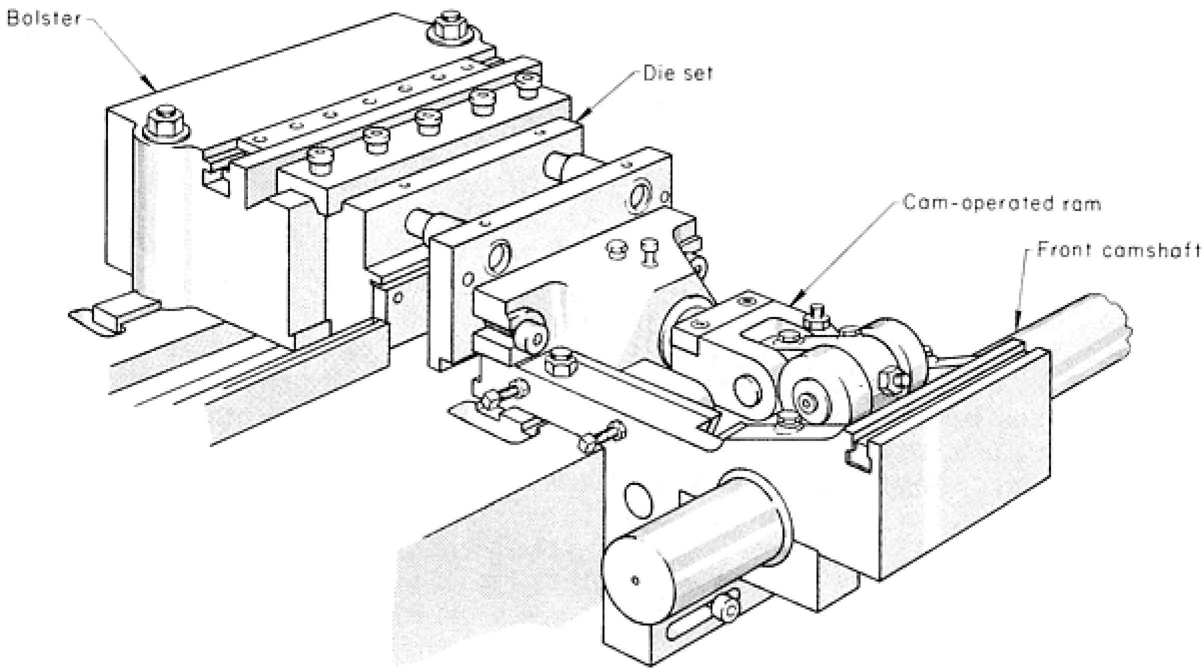

Fig. 2 Press station of a multiple-slide forming machine. See text for details.

Stock straighteners used on multiple-slide machines are similar to those described in the article "Presses and Auxiliary Equipment for Forming of Sheet Metal" in this Volume. The primary difference is that in a multiple-slide machine the rolls are mounted vertically to straighten the work metal as it passes through the machine on edge, instead of horizontally as in a conventional press.

The stock-feed mechanism of a multiple-slide machine is made of two separate units constituting the forward gripping and transporting device (M, Fig. 1) and a stationary gripping unit (P) to hold the strip when it is released on the return stroke of the feed. The stock-feed slide is reciprocated through a system of links from a crank disk keyed to the left-hand camshaft of the machine (M, O, and C, Fig. 1).

Press Station. The die used for piercing, trimming, embossing, and minor forming of the stock is mounted in the press station, which consists essentially of a horizontal press operated by a cam on the front shaft (Q and D, Fig. 1). It may consist of a single unit, as shown in Fig. 2, or additional units can be placed side by side, especially in the larger machines.

Die head units can also be operated from front, rear, or both in machines that are constructed symmetrically. Burr direction can be controlled at designer option.

Cams provide a positive movement to the press slide in both directions, so that the tools are withdrawn from the strip at the end of the working stroke. A dwell at completion of the in-stroke provides time for opposing motions. This permits working cleanly from each side of the stock. A means of adjusting the shut height of the die is provided. The entire unit can also be moved longitudinally along the bedplate to the desired position established by the feed length.

A bolster provides support for the die shoe, and a cam-actuated ram provides support and motion for the punch holder.

The cutoff unit, placed between the press and the front forming slide, is used for cutting work metal into blanks before they are bent to shape. The ends can be cut off straight, or the cut can be curved.

The cutoff unit consists basically of a horizontal slide that is operated through a lever from a cam on the front shaft. The unit can be adjusted along the bedplate in order to cut off the blank at the required distance from the center post. A positive cam action returns the slide so that the cutoff tool will not interfere with forming. Generally, the cutting die and stripper, through which the work metal is fed, are stationary, while the punch moves to cut off the blank.

It is sometimes desirable to install a second cutoff unit on the right-hand side of the center post. The two units trim the two ends of the blank to an accurate length. Because both ends of the blank are trimmed, slightly more stock is required when this method is used, but the inaccuracies of a long feed length are corrected.

The forming station consists of four slides, a center post, and a stripper mechanism. Shaped tools in the four slides progressively bend the workpiece around the center post. In most applications, the center post controls the shape of the workpiece. The first forming tool, usually on the front slide, holds the blank against the center post during cutoff.

Each of the four forming slides runs in its own slideway machined in the bedplate, and each slide is operated positively in both directions by cams. The front, rear, and right-hand slides are all similar in design; the left-hand slide is different because it must pass underneath the press unit.

The tool holder and slide have a mating key and keyway machined parallel to the slide motion so that the forming tool can be adjusted in this direction. A keyway in the top of the tool holder at right angles to the slide movement and a mating key on the end of the forming tool allow sidewise adjustment. The cam that operates each forming slide is made in two halves and has radially disposed slots so that it can be easily exchanged or timing can be adjusted.

The unit shown in Fig. 3 holds the center post rigidly in position for the forming tools to operate around and provides the means for stripping the completed parts off the center post. The center post is fitted and rigidly secured to a king post, which generally consists of a square or rectangular steel bar. The king post fits into a recess in an overhead horizontal slide and is clamped in position by a steel plate and screws. This arrangement holds the king post and center tool rigid and allows for easy adjustment of the vertical position of the center post. The center tool is held square with the forming tools at all times.

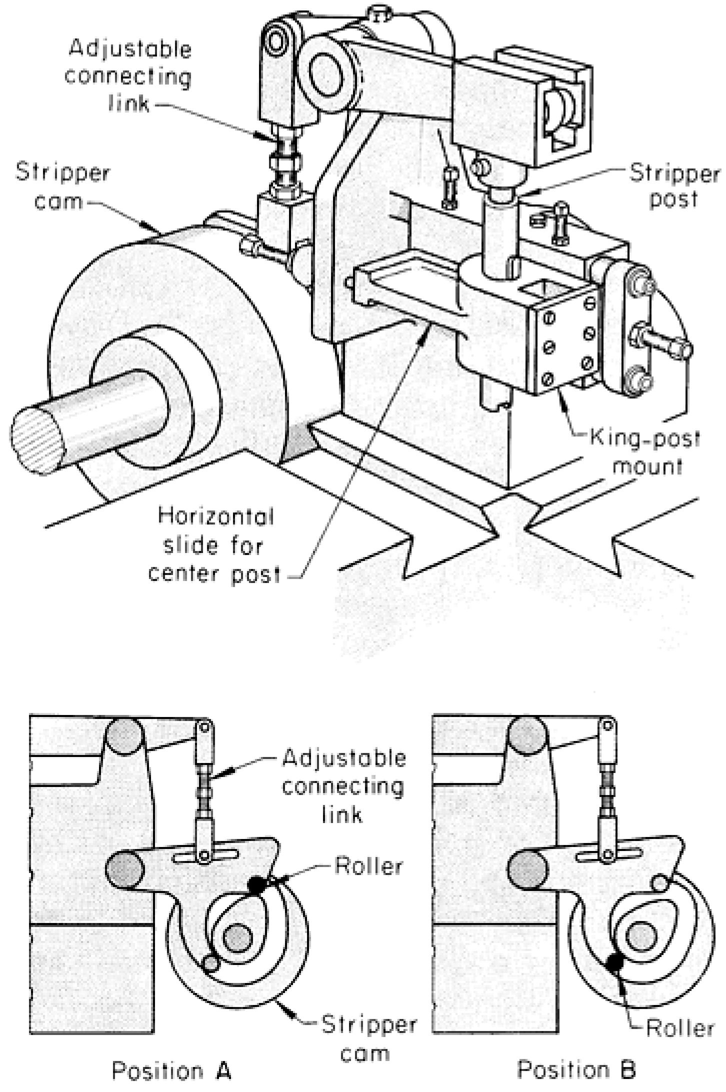

Fig. 3 Unit containing cam-operated stripping mechanism and horizontal slide for mounting of the center post assembly. See text for details.

The overhead slide, carrying the center post, moves parallel with the front and rear slides and is pushed backward by the action of the front tool holding the strip against the center post until the slide reaches a stop, when the metal is bent to shape. When the front tool retracts, the slide containing the center post is returned by spring pressure until a stop is reached. If desired, the slide can be held in a fixed position by adjustment of the two stops. The sliding center post arrangement minimizes interference between the cutoff die and the left-hand slide tools.

Workpieces are ejected from the center post by the downward movement of a suitably shaped stripper plate. The stripper plate is held on a vertical rod, which derives its motion through a system of levers from a positive-action cam on the rear shaft. During forming, the stripper plate is positioned above the forming tools. The vertical rod is guided by a bushing in the overhead slide.

The stripper-cam lever has provision for the roller to be in one of two positions. With the roller as shown in position A, Fig. 3, the cam acts as a normal ejector, moving quickly down and returning the stripper rod almost immediately. With the roller in position B, the rod is held down for a longer period and remains in the upward position only for a short time. This arrangement is used when a retractable mandrel is attached to the mechanism in place of a stripper plate. The mandrel can be held down for a long time while the forming takes place and can then be quickly retracted, as may be required in a further forming or closing operation.

Revised by Deborah A. Blaisdell, The U.S. Baird Corporation

Blanking

The blank that is bent to shape in the forming station has all of the prior operations done in the press station. Trimming the blank outline; piercing holes; embossing ribs, weld projections, and hole flanges; and stamping letters and numerals are done before the blank is cut off and formed. The blank is severed from the strip by cutting off, parting, or blanking methods.

Dies used in multiple-slide machines are either single-stage or progressive, depending on the complexity of the part being formed. Generally, a progressive die is used, even though it may be only a simple two-station pierce-and-pilot die.

The dies for producing the blank must be made as accurately for a multiple-slide machine as they are for a conventional press. However, the multiple-slide dies are of a simpler design and are less expensive than conventional press dies because most of the forming is done in a separate station and around the center post.

The strip layout and die construction are similar to those for progressive dies used in conventional presses. However, as noted previously in this article, the bending operations are usually done in the forming station and cutting off is usually done in the cutoff unit, unless a transfer unit is used to transport the blank from the press station to the forming station. Air jets are used where possible to eject the pierced slugs from the die.

The forming of lanced detents and flanged holes toward the punch side of the blank can be done by actuating the punches with cams on the rear camshaft. Additional movements of die units can be obtained from any of the three other camshafts.

Extended dies are progressive dies that are mounted in the press station and extend into the forming station. After the usual piercing, notching, and piloting operations, bending or forming is done by a combination of elements in the progressive die and those actuated by the front and rear camshafts. The stripper mechanism can be used to advance and retract a mandrel around which the part is bent. The moving or positioning of punches and dies by the camshafts can make it possible to use tools that are much simpler in design than those made for operations in conventional presses. The parts made in extended dies are generally those that can be retained on the strip until all operations are complete before the part is cut off.

Cutting off the blank is usually done with a blade and die mounted in the cutoff unit. The die is fixed to the housing across which the strip of work metal passes. The blade is secured to the slide so that when it is given a forward movement, the blank is sheared from the strip.

Basically, the cutoff tool consists of two flat pieces of metal: the cutoff die (A) and the blade (B), as shown in Fig. 4(a). A fixed stripper (D) holds the work metal (C) against the die, and when the blade moves across the face of the die, the metal is severed. Most of the parts illustrated in this article were cut from the strip by this method.

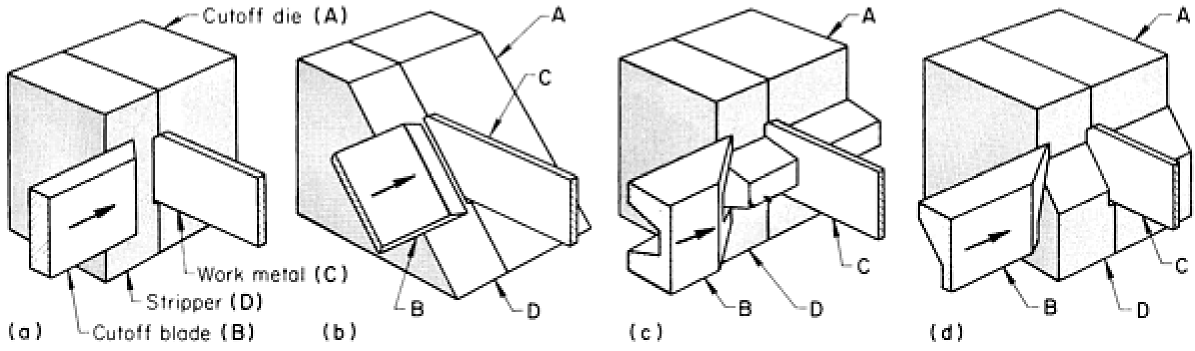

Fig. 4 Four arrangements of cutoff blades and dies for multiple-slide forming machines. See text for details.

The die and blade can be modified to give a shaped cut, as shown in Fig. 4(b) to (d). The shapes illustrated can be used when forming ringlike parts that have a smooth-fitting joint.

Shaped ends on a workpiece can be formed by two methods. The first consists of cutting the full contour of the ends of two adjacent parts in one machine stroke, as shown in Fig. 5(a). The second method consists of partly developing the contour in the press station and then using the cutoff station to complete the contour by parting the blank from the strip by shearing the connecting tab, as shown in Fig. 5(b).

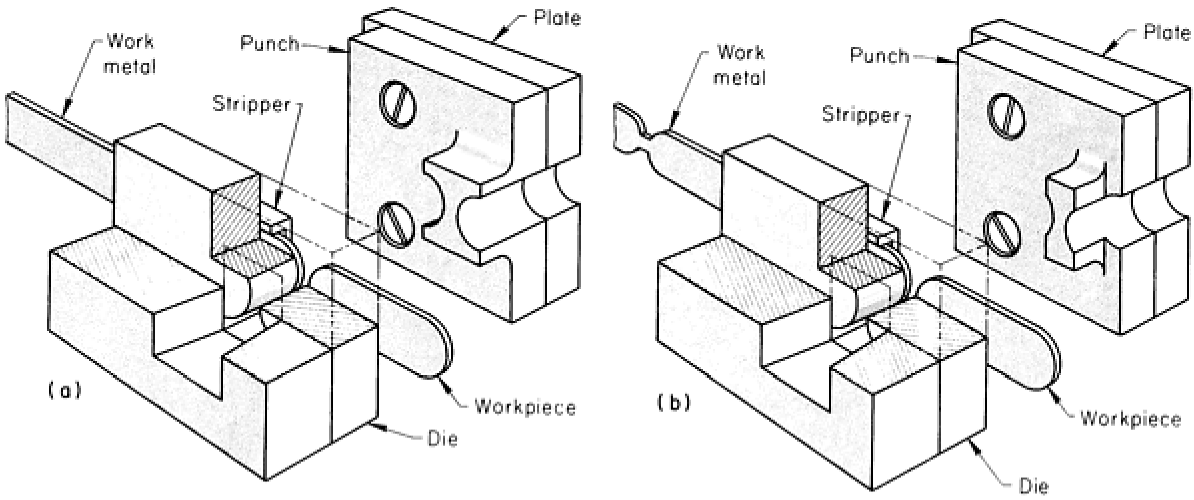

Fig. 5 Two types of parting dies used to shape the ends of blanks before forming. (a) Die for cutting the contour in one stroke. (b) Die for completing the contour by parting a partially developed blank from the strip.

Blending of the parting punch with the previously cut contour may necessitate the use of a punch with sharp corners, which could shorten punch life. If not properly blended, flats or other evidence of mismatch will appear on the severed workpiece.

As shown in Fig. 5, the parting punch is mounted on the plate at the rear of the strip. The die is fitted with a stripper into which the metal is guided across the front of the die. The die and the stripper are both mounted on the slide of the cutoff unit and move horizontally toward the punch, carrying the strip metal with them. When the work metal contacts the punch, the ends are sheared. The scrap is ejected through the die.

Normal press practice is for the die to remain stationary and the punch to move. This is reversed when parting in the cutoff unit so that the end of the metal can swing clear, which would not be possible if the die were at the back of the strip.

Another way in which shaped ends can be produced is to provide a cutoff unit at each side of the front forming tool, each unit being fitted with a die to cut one end. When pilots cannot be used in the die or when a long blank is being cut, the second unit helps in solving tooling problems.

Short Blanks. When the length of the blank is short and the end is very close to the forming slides, the cutoff blade can be fastened to the front tool. The blade is fitted and secured to the front tool; an adjustment screw provides for positioning of the blade. The cutoff die is positioned to mate with the blade.

Transfer of blanks from the cutoff unit to the forming station is generally unnecessary, because the blank can be moved into the forming station before it is cut from the strip. However, it is sometimes desirable to cut the blank from the strip at the last station in the progressive die, as in ordinary press blanking. In such a cycle, a transfer unit such as that shown in Fig. 6(a) is used, which transfers the blank to the forming station. The transfer head is actuated by a stub shaft located below the left-hand camshaft (C, Fig. 1).

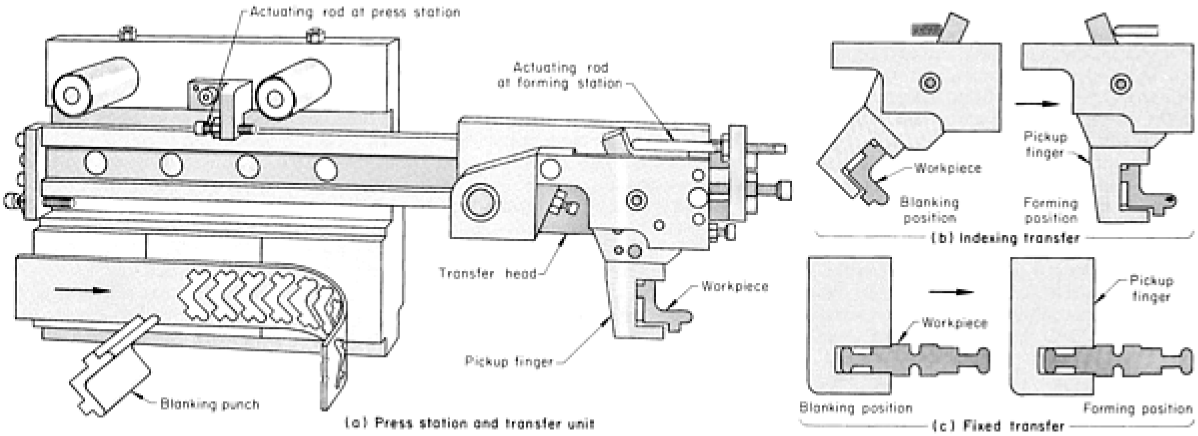

Fig. 6 Mechanism for indexing and fixed transfer of blanks from the press station to the forming station of a multiple-slide machine.

After the blanking punch has retracted, the blank is held in the die cavity. The blank is then pushed out of the die cavity with a plunger that is moved forward by a cam fixed to the rear shaft and into the waiting pickup finger. The blank is transported horizontally to the forming station, where the first forming tool pushes the blank out of the pickup finger and against the center post. While the forming tools are bending the blank around the center post, the transfer head moves back to the press station for another blank.

A blank can be picked up in the blanking station in one position and indexed to the forming position during the transfer motion (Fig. 6b). This permits the strip layout to be designed for optimal stock use. Bends can also be positioned favorably with respect to the rolling direction.

The transfer of blanks from the blanking position to the forming position without reorientation is shown in Fig. 6(c). The pickup finger is mounted in the transfer head so that no swiveling or indexing takes place.

Timing of the transfer-head motion is important. The finger must be in position for loading or unloading, but must not interfere with the blanking punch or the forming slides.

Forming of Steel Strip in Multiple-Slide Machines

Revised by Deborah A. Blaisdell, The U.S. Baird Corporation

Forming

As the work metal strip leaves the press station, it passes through the cutoff unit and between the center post and the first forming tool (usually the front tool). Simultaneously with the cutting off of the blank, the front forming tool moves forward and holds the blank firmly against the center post. By continued movement of the front tool, the blank is bent around the center post. Tools on the two side slides move in to make further bends, and these can be followed by a fourth tool on the rear slide to complete the forming. The sequence in which the slides move is not fixed, nor is it always necessary to use all four slides when forming a part.

Holding blanks firmly in position against the center post is necessary while they are being severed from the stock and also during the initial forming operation in order to prevent slipping and to ensure against premature bending or kinking across a weak section. The work metal is likely to bulge when a U-shape part is being formed. Such a bulge is not removed when the tools are fully closed, because the surplus metal cannot flow while the blank is held firmly by the two corners of the bending tool. In some applications, a spring-loaded plunger in the first forming tool is positioned slightly in advance of the bending portions and prevents the blank from bulging when the bends are started. A positive blankholder is essential for holding forms having a weak section between the bends or for preventing slipping or dragging of a blank around the corner when bending takes place. A partly formed blank also must be held while being moved to the lower level and until a form tool can grip it.

There are two general types of mechanically operated blankholders. One type makes use of the standard stripping mechanism, and the other is operated by a cam and lever from one of the shafts.

Part Ejection. After all tools are retracted, the formed part is ready for ejection by the stripper plate. During forming, the stripper plate is positioned at the top and clear of the forming tools. After forming, the stripper plate moves down and ejects the part from the center post. The stripper can also move a partly formed component into a second, or even a third, forming level on the center post.

Multiple-Part Forming. Forming of more than one part per cycle of the machine should be considered when planning the tools for production, but the increased loading must be within the capacity of the equipment. The way in which the outline of the part is developed depends largely on its finished shape. If a part can be made of strip stock by piercing, cutting off, and forming, then more than one part can be made in each cycle by slitting the strip into two or more ribbons. For parts having shaped ends (for example, semicircular), the strip can be slotted and the blank then cut off. Slotting the strip may eliminate the need for sharp corners on the punch and die, thus increasing their service lives. Parts with more complex outlines require more complex trimming punches. The blank is severed from the strip by either cutoff or parting methods.

Some parts, such as those having the basic shape of an L, are easier to form into a U-shape and then part after forming. The bottom forming level of a multiple-slide machine can be used for parting. The parting punch is positioned on the rear tool slide, and the die on the front tool. The center post has a clearance hole for the punch.

Forming Level. Forming can be done around the center post at the same level at which the blank enters the forming station (single-level forming) or at one or two positions below that level (two- or three-level forming). Parts can be finish formed at the lower level, resistance welded into ringlike parts, or finish formed and then cut into two or more pieces. The partly completed workpieces are usually moved to the lower level by the stripper mechanism.

Single-level forming is used when all of the bends can be made with one set of forming tools, usually with one forward stroke per machine cycle. Sometimes, a bend can be made by partly forming, retracting the tool, doing some work by another tool, and then advancing the first tool to finish the bend. Auxiliary forming tools actuated by separate cams or lever arrangements can be used to do more work on a piece. Wide blanks are usually formed at one level because of the length of center post needed to support more than one part and because of the limited space available mounting tools.

During two-level forming, two components are on the center post--one at the top level and the other at the bottom level. Work is done simultaneously on each piece by the forming tools. Forming is often done at both levels simultaneously by providing each slide with a tool that is shaped to perform an operation on each piece. The workpiece at the lower level is pushed off of the center post by the downward movement of the partly completed piece from the top level.

One of the simplest applications of two-level forming is the manufacture of bushings and ferrules by forming the center and the ends of the blank at the top level and finish forming to final diameter at the bottom level. A more complicated application of two-level forming is described in the following example.

Example 1: Two-Level Forming of a Hose Clamp.

The hose clamp shown in Fig. 7 was made from cadmium-plated steel 9.5 mm ($\frac{3}{8}$ in.) wide at two levels on the center post in a multiple-slide machine. At the press station, the three holes were pierced and a score mark or slight kink was formed between two holes to ensure that the two holes would coincide after the metal had been folded back on itself. Pilots in the press station ensured accurate location of the strip for cutoff and forming. The forming tools used for the two levels are shown at left in Fig. 7.

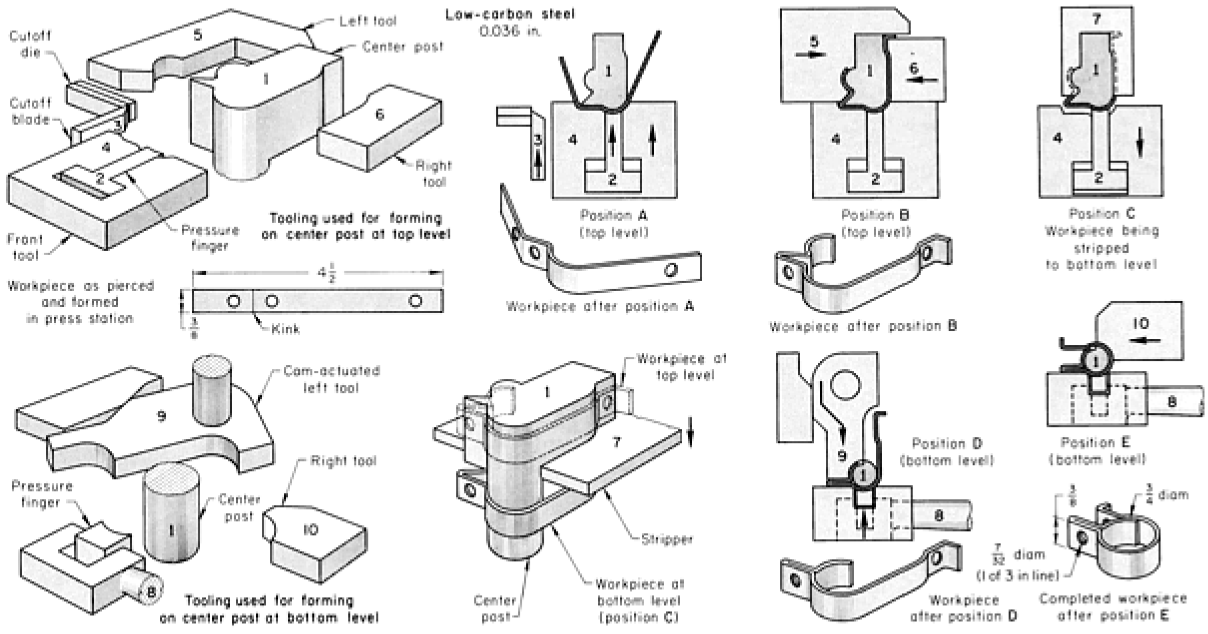

Fig. 7 Forming tools used and sequence of operation in the forming of a low-carbon steel hose clamp. Dimensions given in inches.

At position A in Fig. 7, the cutoff blade (3) sheared the blank from the strip while it was held against the center post (1) by the pressure finger (2). The front tool (4) formed the blank as shown. The side tools (5 and 6) are shown pressing the stock around the center post in position B. With the front and side tools retracted in position C, the pressure finger held the formed part against the center post while the stripper (7) moved the part to the lower level, where the spring-loaded lever arm and pressure finger (8) held the part.

In position D at the bottom level, the pivoting rear tool (9) formed the part around the center post (circular in shape at this level). The rear tool also set the folded-over metal against an extension of the front tool (4). The final forming operation by the right tool (10) was as shown in position E.

In the next cycle, the stripper pushed a new workpiece down to the bottom level, as the completed hose clamp was pushed off of the center post. The cycle time was about 60 components per minute.

Lockseaming. Metal strip is used to make large quantities and varieties of small open-end boxes, tubes, and cylinders to be used as ferrules for paint brushes, radio shields, and many other common products. All of these are made with some locking method for joining the ends of the metal.

In lockseaming or can seaming, one end of the metal is formed over the other and flattened into a tight joint. Other methods of locking two ends of metal together in multiple-slide machine include interlocking dovetails, raised tabs inserted through slots and then flattened or twisted, a tongue inserted into a lanced slot and then swaged, and lancing and forming through two stock thicknesses.

Lockseaming can be done at either one or two levels around the center post. Single-level forming is used where the tubes are long or where projecting lugs would be too weak to push the finished part off of the center post. In this method, the rear and side tools must be advanced two or three times during each cycle of the machine.

Two-level forming with an attachment that gives a positive movement to the seaming tools is a more efficient method of making lockseams. The sliding head containing the center post can be used to make several sizes of lockseam tubes by setting the rear and side tools a fixed distance from the strip line, then changing only the front tool and the center post. The following example describes a two-level forming operation for external lockseaming to make a short cylindrical tube.

Example 2: Two-Level External Lockseaming to Produce a Round Tube.

The external lockseam of the tube shown in Fig. 8 was formed at two levels in a multiple-slide machine. At position A, the strip had been fed between the center post (1) and the pressure finger (2) and sheared by the cutoff die (3) and blade (4). At the same time, the right-hand end of the blank had a small flange formed by the fixed tool (5) and the blade (6). Position B shows the blank formed into a U-shape by the front tool (7). Forming of the cylinder by the side tools (8 and 9) is shown in position C. The two ends extend at right angles to the surface, one end being longer than the other. The right tool (10), moved by the cam (11), supported the previously bent flange as the left tool (8) formed the longer end. At position D, the left tool (12), actuated by the cam (13), bent the long end over the shorter end.

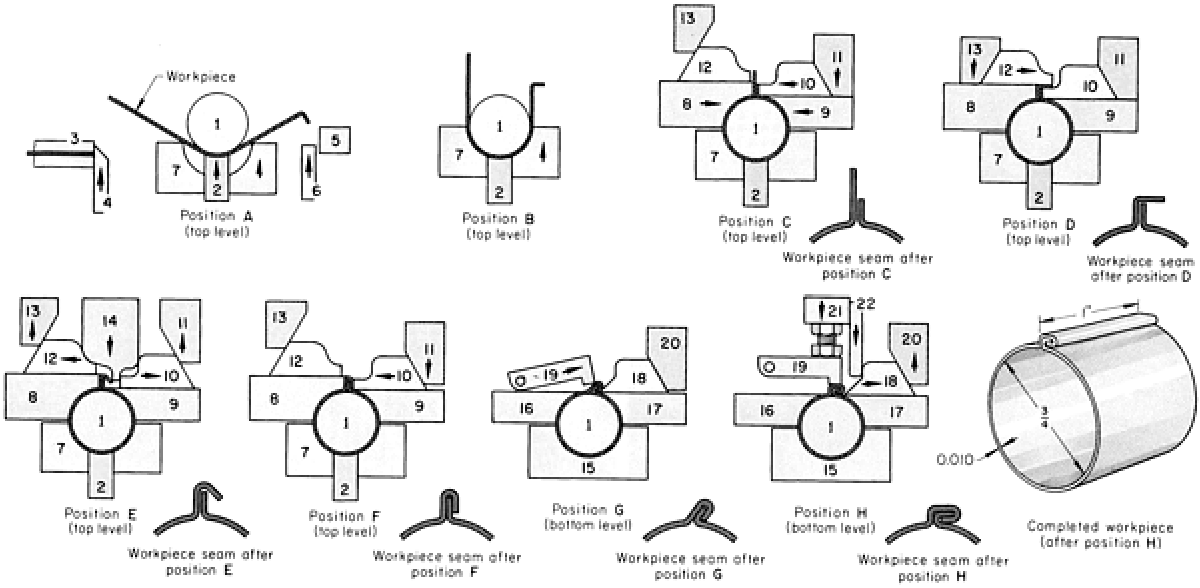

Fig. 8 Two-level forming of an external lockseam to produce a cylindrical part. Dimensions given in inches.

At position E, the cams (11 and 13) retracted, allowing the side tools (10 and 12) to be pushed aside by the advancing rear tool (14), thus permitting the end of the seam to be bent. The rear tool retracted, and the cam (11) advanced to move the side tool (10) to flatten the seam against the left tool (8), as shown in position F. The part then was transferred to the lower level by the stripper (not shown).

At the bottom level, the front tool (15) and the side tools (16 and 17) held the cylinder on the center post. The front tool also backed up the center post during the final forming operations. As shown in position G, the anvil (18) supported the seam while the swinging tool (19) moved forward to bend the seam at an angle. The anvil is moved by the cam (20). Final flattening of the seam is shown in position H. As the rear tool (21) advanced, the cam projection (22) contacted the anvil, pushing it clear as the swinging tool (19) closed the seam.

Two workpieces were on the center post at this stage, and both were formed at the same time. One, formed through position F, was at the top level; the other was at the bottom level. Both were held tightly on the center post. The completed piece was pushed off of the center post and into a container.

Internal lockseams can be made by forming an external seam, as shown in Fig. 8, and then re-forming the part to make the seam flush with the outer surface. The part is moved to the lower level, where a vertical slot in the center post provides space for the seam as it is pushed inward.

Forming of Steel Strip in Multiple-Slide Machines

Revised by Deborah A. Blaisdell, The U.S. Baird Corporation

Assembly Operations

By means of auxiliary feeding attachments, one or more components can be assembled to a part being formed during the same machine cycle. Hopper feeding units can sort and orient machined or previously formed parts for feeding into the part being formed in the multiple-slide machine. These devices can be arranged to feed horizontally adjacent to any forming slide, or can be operated vertically.

Hopper feeding involves the automatic sorting and transfer of components placed randomly in a hopper of suitable design and shape for delivery by gravity to a track, correctly positioned and in ordered sequence to a machine.

Production Practice. Figure 9 shows the assembly of a flat steel spring into a small steel bracket at the lower level of a two-level multiple-slide machine operation. The bracket was made from 12.7 mm ($\frac{1}{2}$ in.) wide stock 0.76 mm (0.030 in.) thick. In the press station, the two holes were pierced, and the lug was slit and raised. The bracket was bent to shape around the center post at the top level by the action of the front, rear, and right forming tools. It was then moved to the bottom forming level by the stripper and held in position against the center post by a spring-loaded retainer. A sliding pin mounted in the retainer was used to flatten the lug against the spring steel strip.

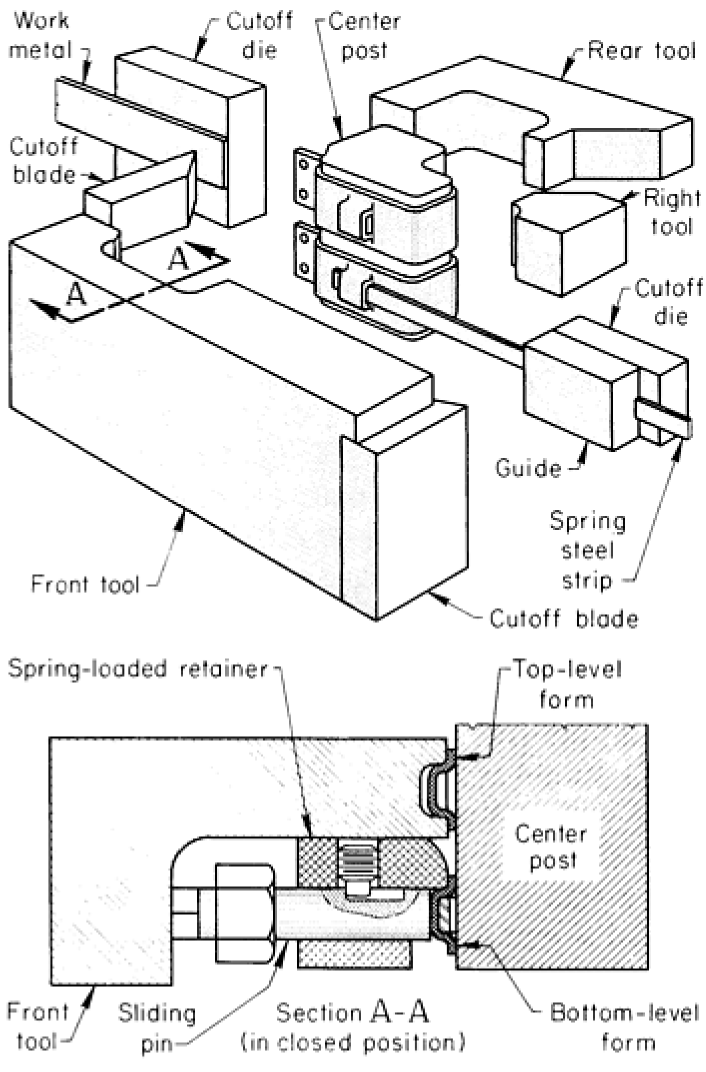

Fig. 9 Assembly of spring steel strip into a bracket at the bottom level of a two-level multiple-slide forming operation.

The spring steel strip was fed into the recess formed by the lug. The front tool then moved in, contacted the sliding pin, flattened the lug, secured the strip to the bracket, and at the same time severed the spring steel strip by a blade mounted to the front tool.

On the next cycle, the assembly was ejected from the center post by the downward movement of the succeeding component. The lower part of the spring-loaded retainer was cut away to clear the strip as it was fed into the lug and to permit ejection.

Forming of Steel Strip in Multiple-Slide Machines

Revised by Deborah A. Blaisdell, The U.S. Baird Corporation

Multiple-Slide Rotary Forming Machines

The multiple-slide rotary forming machine with open planetary gearing is simple in concept and design. In this type of machine, the slides are driven by a central gear wheel, and the central forming motions are controlled by cams.

Figure 10 shows a schematic of a multiple-slide rotary forming machine. The material is first uncoiled from the reel, then pulled through the straightening station (A) by the material feeder (B). It is then fed to the press (C) and forming slides (D), where the workpieces are formed and ejected. Recessed rails guide the material between the feeder and the stamping station, as well as between the cutting and forming stations. Here, the blanks are either completely stamped out in the press and then pushed into the bending station by the following material, or they remain attached to the strip by means of a web that is not completely separated until it reaches the final forming station. Material feed, stamping presses, forming slides, and operation of the central tool are synchronously coupled to each other.

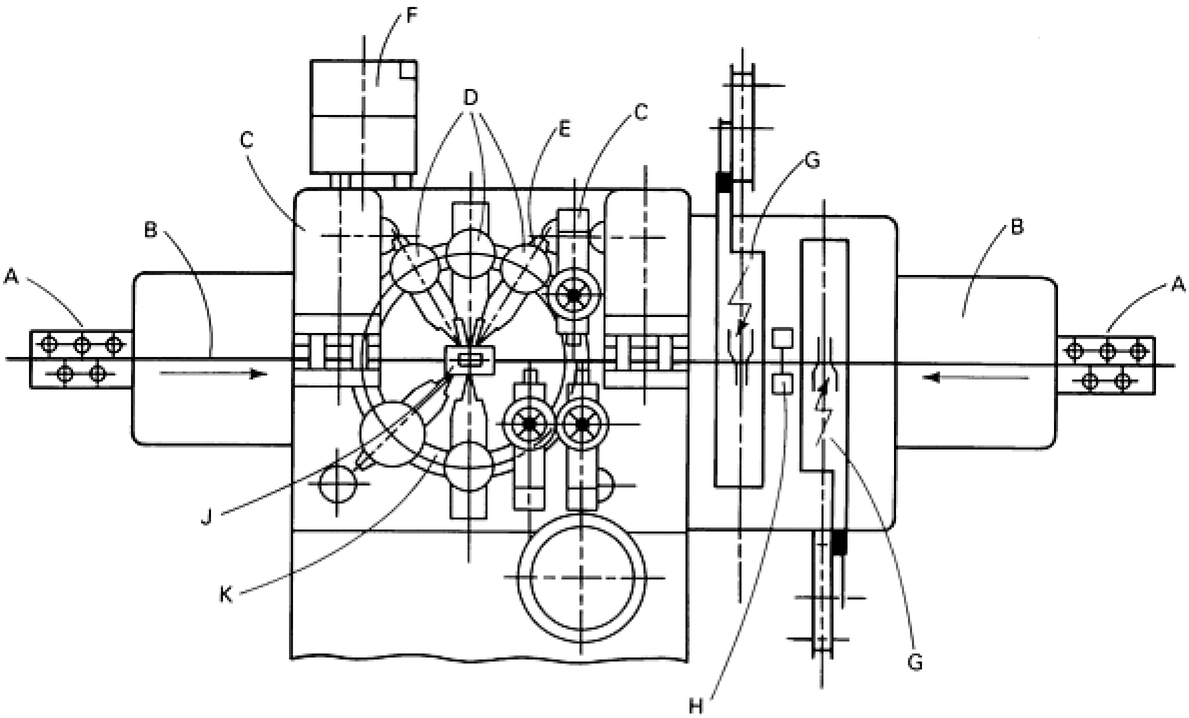

Fig. 10 Schematic of a multiple-slide rotary forming machine. A, straightening stations; B, feed mechanism; C, stamping stations; D, forming tools; E, thread tapping unit; F, station for feeding and assembling; G, welding stations; H, sizing unit; J, standard forming tool guide; K, central gear wheel. See text for description of operation.

Auxiliary Equipment. A second material feed and press, a part-feeding mechanism, three thread-tapping units, and two welding units can be added to a multiple-slide rotary forming machine (Fig. 10). It is possible to have additional material feeds from the front and rear sides. Additional cam motions allow forming slides and standardized tools to be mounted on the rear side of the bed in the forming area. Machined assembly surfaces on the bed and cover plate offer further possibilities for fastening attachments.

Standardized Tooling. The forming tool guide (the basic tool) consists of the tool plate with a central slider for one or more tools (Fig. 11). Forming tools are suspended in the tool holders mounted on the forming slides, which can be easily inserted or removed. In operation, the tool guide is enclosed by a cover plate, with an opening at its center for ejection of the working piece. Control cams drive the forming slides and consist of two complementary disk cams.

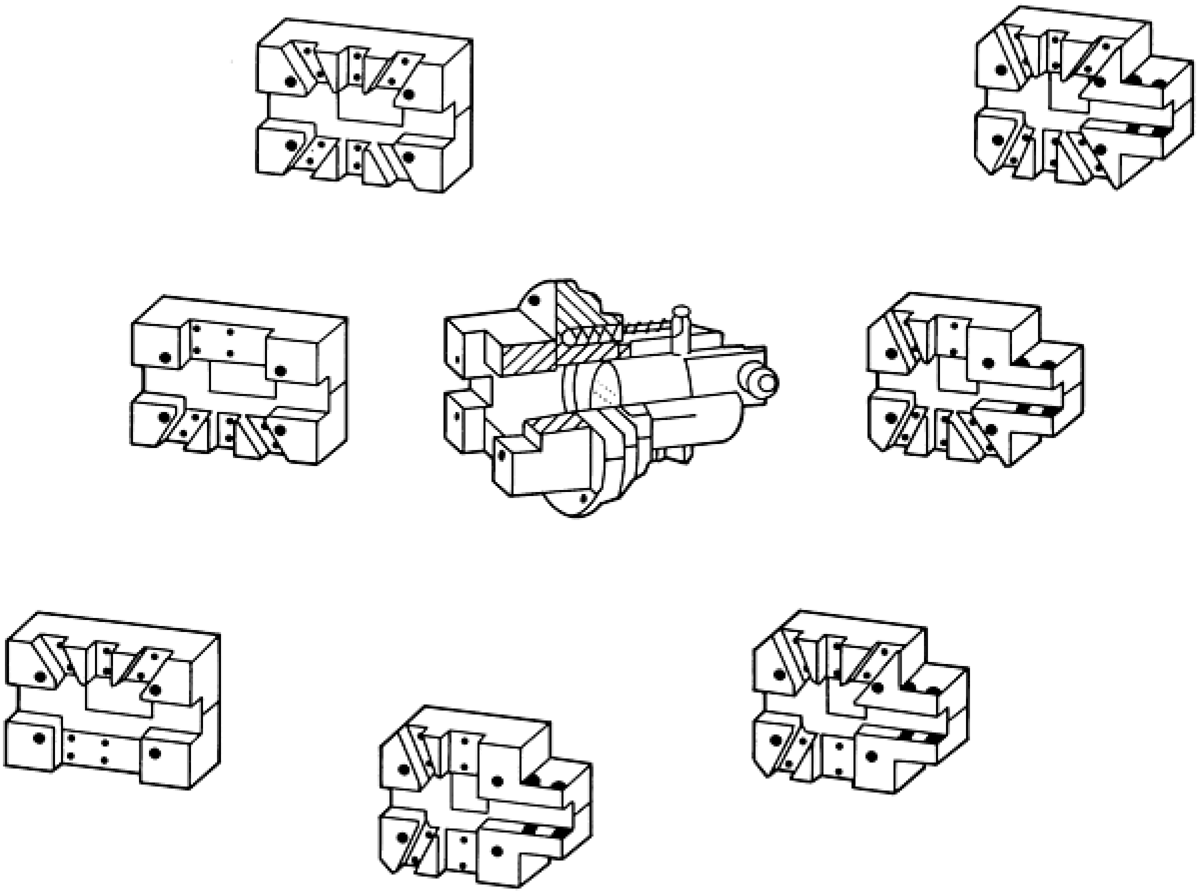

Fig. 11 Standard forming tool guides for multiple-slide rotary forming machines.

Deep Drawing

Introduction

DEEP DRAWING of metal sheet is used to form containers by a process in which a flat blank is constrained while the central portion of the sheet is pressed into a die opening to draw the metal into the desired shape without folding of the corners. This generally requires the use of presses having a double action for hold-down force and punch force. The process is capable of forming circular shapes, such as cooking pans, box shapes, or shell-like containers. The term deep drawing implies that some drawing-in of the flange metal occurs and that the formed parts are deeper than could be obtained by simply stretching the metal over a die. Clearance between the mate punch and the female die is closely controlled to minimize the free span so that there is no wrinkling of the sidewall. This clearance is sufficient to prevent ironing of the metal being drawn into the sidewall in the deep-drawing process. If ironing of the walls is to be part of the process, it is done in operations subsequent to deep drawing.

Suitable radii in the punch bottom to side edge, as well as the approach to the die opening, are necessary to allow the metal sheet to be formed without tearing. In most deep-drawing operations, the part has a solid bottom to form a container and a retained flange that is trimmed later in the processing. In some cases, the cup shape is fully drawn into the female die cavity, and a straight-wall cup shape is ejected through the die opening. To control the flange area and to prevent wrinkling, a hold-down force is applied to the blank to keep it in contact with the upper surface of the die. A suitable subpress or a double-action press is required. Presses can be either hydraulic or mechanical devices, but hydraulic presses are preferred because of better control of the rate of punch travel.

Any metal that can be processed into sheet form by a cold-rolling process should be sufficiently ductile to be capable of deep drawing. Both hot- and cold-rolled sheet products are used in deep-drawing processes. The cold-work effects introduced during processing of the sheet products for deep-drawing applications must be removed (by annealing, for example), and the as-delivered coils should be free of any aging. This would imply that an aluminum-killed drawing-quality steel, for example, would be preferred over a rimmed steel. After the deep-drawing operation, ductility can be returned to that of the original sheet by in-process annealing, if necessary. In many cases, however, metal that has been deep drawn in a first operation can be further reduced in cup diameter by additional drawing operations, without the need for intermediate annealing.

The properties considered to be important in sheet products designed for deep drawing include:

- Composition, with a minimum amount of inclusions and residual elements contributing to better drawability
- Mechanical properties, of which the elongation as measured in a tension test, the plastic-strain ratio *r* (see the section "Drawability" in this article), and the strain-hardening exponent *n* are of primary importance. The strength of the final part as measured by yield strength must also be considered, but this is more a function of the application than forming by deep drawing
- Physical properties, including dimensions, modulus of elasticity, and any special requirements for maintaining shape after forming

Once a metal has been deep drawn into a suitable form, it can be further processed to develop additional shape. The first shape is usually a round cylinder, or a modification of this--a square box with rounded corners, for example. This latter shape is related to the cylinder in that the four corners are essentially quarter segments with straight walls between each segment.

For small cylinders, a relationship between the diameter of a circular blank and the bottom diameter of the cup shape to be formed is sometimes used to measure deep drawability. The most commonly referred to cup test for deep drawing is the Swift cup test, which uses a 2 in. (50 mm) diam flat-bottomed punch to form test blanks. For ductile low-carbon steel, aluminum, and brass sheets, a 102 mm (4 in.) circular blank can be formed in a single draw. Increased plastic strain ratio *r* and ductility allow larger blanks to be drawn successfully; the limit is reached when the bottom punches out, rather than forming a cup shape. The blank diameter divided by the punch diameter gives the limiting draw ratio (LDR), which for the above examples would be 2. More information on the Swift cup test is available in the article "Formability Testing of Sheet Metals" in this Volume.

Of the commonly formed metals, brass and austenitic stainless steels show high limiting draw ratios (up to 2.25). A few samples have reached a value of 2.5 to produce a cup with a sidewall height of nearly 64 mm (2.5 in.). This is possible, although the total length of the cup cross section would be 179 mm (7 in.), which is more than the blank diameter because of the deep-drawing forces. The interstitial-free steels, which have average *r* values of 2.5 or higher, can be deep drawn to limiting draw ratios near 2.5. With these extremely deep draws, sidewall delayed splitting must be prevented by such means as stress-relief annealing immediately following the drawing operation.

The thickness of the work metal does not change appreciably in deep drawing; therefore, the surface area of the final part is about the same as that of the initial blank. As the metal in the flange area is drawn into the die opening over the approach radius, it is subjected to radial tension and, concurrently, to circumferential compression. This explains why a 127 mm (5 in.) diam blank with a surface area of 126 cm^2 (19.6 $in.^2$) can form a cup shape 64 mm (2.5 in.) deep that has a total surface area of about 121 cm^2 (18.8 $in.^2$).

With proper balance among the punch force, the hold-down force, and the strength of the metal sheet being formed, a cup shape can be developed. At the start of this process, the metal in the free area between the punch bottom and the flange hold-down is stretched and wrapped over the nose of the punch and the approach radius of the die. During this stretching, strain hardening strengthens the metal. If it is not capable of such strengthening or if its strength at any location is exceeded at any time during the forming, the bottom of the cup shape will break out. Contributing to this strengthening is a high *r* value, which is a measure of resistance to through-thickness changes in the metal sheet. If the metal has a high resistance to thinning and thickening, the bottom radius and the upper sidewall areas retain close to their original thickness, and the radial and circumferential strains obtainable in the drawn-in flange are increased to accommodate the deep-drawing process.

After the bottom has been stretch formed, the clearance between the punch and die is such that the metal in the cup side is free to move without excessive rubbing on the die walls. It has been found that slight roughening of the punch radius and minimizing the lubrication of this area contribute to deeper drawability; however, the die opening should be smooth and well lubricated with a suitable drawing compound.

Fundamentals of Drawing

A flat blank is formed into a cup by forcing a punch against the center portion of a blank that rests on the die ring. The progressive stages of metal flow in drawing a cup from a flat blank are shown schematically in Fig. 1. During the first stage, the punch contacts the blank (Fig. 1a), and metal section 1 is bent and wrapped around the punch nose (Fig. 1b). Simultaneously and in sequence, the outer sections of the blank (2 and 3, Fig. 1) move radially toward the center of the blank until the remainder of the blank has bent around the punch nose and a straight-wall cup is formed (Fig. 1c and d). During drawing, the center of the blank (punch area, Fig. 1a) is essentially unchanged as it forms the bottom of the drawn cup. The areas that become the sidewall of the cup (1, 2, and 3, Fig. 1) change from the shape of annular segments to longer parallel-side cylindrical elements as they are drawn over the die radius. Metal flow can occur until all the metal has been drawn over the die radius, or a flange can be retained.

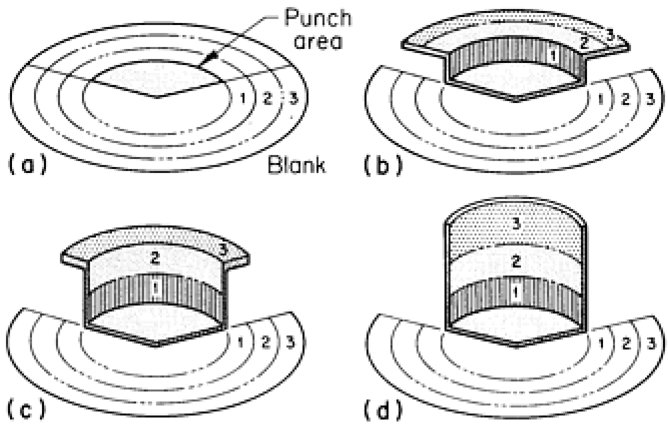

Fig. 1 Progression of metal flow in drawing a cup from a flat blank.

A blankholder is used in a draw die to prevent the formation of wrinkles as compressive action rearranges the metal from flange to sidewall. Wrinkling starts because of some lack of uniformity in the movement or because of the resistance to movement in the cross section of the metal. A blankholder force sufficient to resist or compensate for this nonuniform movement prevents wrinkling. Once a wrinkle starts, the blankholder is raised from the surface of the metal so that other wrinkles can form easily. The force needed to hold the blank flat during drawing of cylindrical shells varies from practically zero for relatively thick blanks to about one-third of the drawing load for a blank 0.76 mm (0.030 in.) thick. Thinner blanks often require proportionally greater blankholder force.

Conditions for drawing without a blankholder depend on the ratio of the supported length of the blank to its thickness, the amount of reduction from blank diameter to cup diameter, and the ratio of blank diameter to stock thickness. For thick sheets, the maximum reduction of blank diameter to cup diameter in drawing without a blankholder is about 25%. This ratio approaches zero for thin foil-like sheet. If a blankholder is employed, the maximum reduction is increased to about 50% for metals of maximum drawability and 25 to 30% for metals of marginal drawability in the same equipment.

Drawability

In an idealized forming operation--that is, one in which drawing is the only deformation process that occurs--the blankholder force is just sufficient to permit the work material to flow radially into the die cavity without wrinkling.

Deformation takes place in the flange and over the lip of the die. No deformation occurs over the nose of the punch. The deep-drawing process can be thought of as analogous to wire drawing in that a large cross section is drawn into a smaller cross section of greater length.

The drawability of a metal depends on two factors:

- The ability of the material in the flange region to flow easily in the plane of the sheet under shear
- The ability of the sidewall material to resist deformation in the thickness direction

The punch prevents sidewall material from changing dimensions in the circumferential direction; therefore, the only way the sidewall material can flow is by elongation and thinning. Thus, the ability of the sidewall material to withstand the load imposed by drawing down the flange is determined by its resistance to thinning, and high flow strength in the thickness direction of the sheet is desirable.

Taking both of these factors into account, it is desirable in drawing operations to maximize material flow in the plane of the sheet and to maximize resistance to material flow in a direction perpendicular to the plane of the sheet. Low flow strength in the plane of the sheet is of little value if the work material also has low flow strength in the thickness direction.

The flow strength of sheet metal in the thickness direction is difficult to measure, but the plastic-strain ratio r compares strengths in the plane and thickness directions by determining true strains in these directions in a tension test. For a given metal strained in a particular direction, r is a constant expressed as:

$$r = \frac{\epsilon_w}{\epsilon_t} \qquad \textbf{(Eq 1)}$$

where ϵ_w is the true strain in the width direction and ϵ_t is the true strain in the thickness direction.

Sheet metal is anisotropic, that is, the properties of the sheet are different in different directions. It is therefore necessary to use the average of the strain ratios measured parallel to, transverse to, and 45° to the rolling direction of the sheet to obtain an average strain ratio $\bar{r}$, which is expressed as:

$$\bar{r} = \frac{r_L + 2r_{45} + r_T}{4} \qquad \textbf{(Eq 2)}$$

where r_L is the strain ratio in the longitudinal direction, r_{45} is the strain ratio measured at 45° to the rolling direction, and r_T the strain ratio in the transverse direction.

If flow strength is equal in the plane and thickness directions of the sheet, $\bar{r}$= 1. If strength in the thickness direction is greater than average strength in the directions in the plane of the sheet, $\bar{r}$> 1. In this latter case, the material resists uniform thinning. Generally, the higher the $\bar{r}$value, the deeper the draw that can be achieved (Fig. 2).

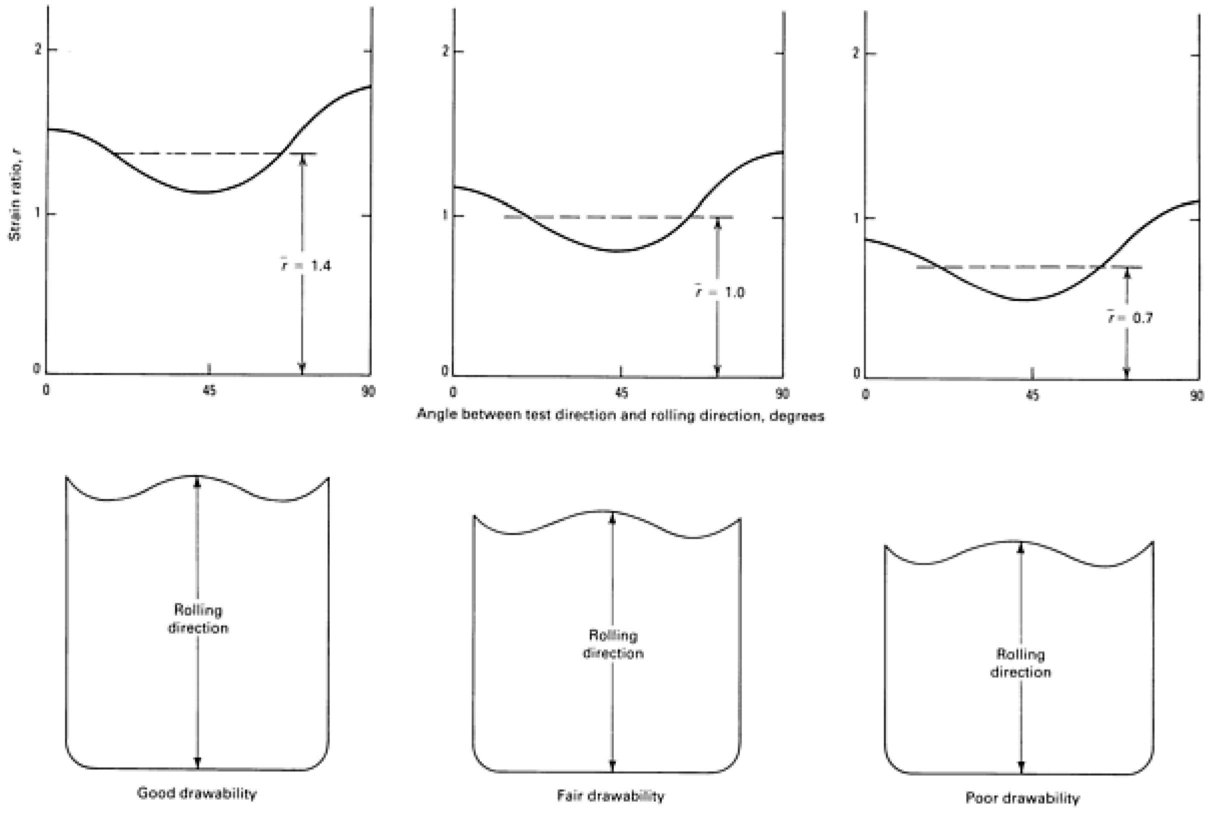

Fig. 2 Variation of strain ratio *r* with direction in low-carbon steel (top curves) and effect of average strain ratio $\bar{r}$ on drawability of cylindrical cups (bottom). Each cup represents the deepest cup that can be drawn from material with the indicated $\bar{r}$.

Because the average strain ratio $\bar{r}$ gives the ratio of average flow strength in the plane of the sheet to average flow strength normal to the plane of the sheet, it is a measure of normal anisotropy. Variations of flow strength in the plane of the sheet are termed planar anisotropy. The variation in strain ratio in different directions in the plane of the sheet, Δr, is a measure of planar anisotropy, and Δr can be expressed as:

$$\Delta r = \frac{r_L + r_T - 2r_{45}}{2} \quad \textbf{(Eq 3)}$$

where Δr is the variation in strain ratio and the other terms are as defined in Eq 2.

A completely isotropic material would have $\bar{r} = 1$ and $\Delta r = 0$. These two parameters are convenient measures of plastic anisotropy in sheet materials. More information on formability is available in the article "Formability Testing of Sheet Metals" in this Volume.

Earing in deep-drawn parts is related to planar anisotropy. The sheet metal therefore may be stronger in one direction than in other directions in the plane of the sheet. This causes the formation of ears on the drawn part even when a circular blank is used. In practice, enough extra metal is left on the drawn cup so that the ears can be trimmed. More information on the effects of anisotropy is available in the section "Effects of Material Variables" in this article.

Draw Ratios. Drawability can also be expressed in terms of a limiting draw ratio or percentage of reduction based on results of Swift cup testing (see the article "Formability Testing of Sheet Metals" in this Volume). The limiting draw ratio is the ratio of the diameter *D* of the largest blank that can be successfully drawn to the diameter of the punch *d:*

$$\mathrm{LDR} = \frac{D}{d} \quad \textbf{(Eq 4)}$$

Percentage of reduction would then be defined as:

$$\text{Percentage of reduction} = \frac{100\,(D - d)}{D} \quad \textbf{(Eq 5)}$$

Additional information on formability testing and other measures of formability is available in the article "Formability Testing of Sheet Metals" in this Volume.

Deep Drawing

Presses

Sheet metal is drawn in either hydraulic or mechanical presses. Descriptions of these machines are given in the article "Presses and Auxiliary Equipment for Forming of Sheet Metal" in this Volume.

Double-action presses are required for most deep drawing because a more uniform blankholding force can be maintained for the entire stroke than is possible with a spring-loaded blankholder. Double-action hydraulic presses with a die cushion are often preferred for deep drawing because of their constant drawing speed, stroke adjustment, and uniformity of clamping pressure. Regardless of the source of power for the slides, double-action straight-side presses with die cushions are best for deep drawing. Straight-side presses provide a wide choice of tonnage capacity, bed size, stroke, and shut height.

Factors in Press Selection

Drawing force requirements, die space, and length of stroke are the most important considerations in selecting a press for deep drawing. The condition of the crankshaft, connection bearings, and gibs is also a factor in press selection.

Drawing Force. The required drawing force, as well as its variation along the punch stroke, can be calculated from theoretical equations based on plasticity theory or from empirical equations. The maximum drawing force $F_{d,max}$ required to form a round cup can be expressed by the following empirical relation:

$$F_{d,max} = n\pi d t s_u \quad \textbf{(Eq 6)}$$

where s_u is the tensile strength of the blank material (in pounds per square inch or megapascals), d is the punch diameter (in inches or millimeters), t is the sheet thickness (in inches or millimeters), and $n = \sigma_D/s_u$, the ratio of drawing stress to tensile strength of the work material. Equation 6 would yield $F_{d,max}$ in either pounds or kilonewtons, depending on the other units used.

The drawing force required to form a round shell can be estimated using Fig. 3. The nomograph shown in Fig. 3 is based on, first, a free draw with sufficient clearance so that there is no ironing and, second, on a maximum reduction of about 50% (note also that only English units of measure are used). Figure 3 gives the load required to fracture the cup or the tensile strength of the work metal near the bottom of the shell. An example of its use is the determination of the force required for deep drawing 0.125 in. thick steel stock with a tensile strength of 50,000 psi into a shell 10 in. in diameter:

- Using Line 1, connect point 10 on scale 2 to point 0.125 on scale 4
- Line 1 intersects scale 3 at 4.0, which is the approximate cross-sectional area (in.^{2}) of the shell wall
- Connect this point using line 2 to point 50,000 on scale 1
- Project a line to the right to intersect scale 5 at 98 tons, which is the required drawing force

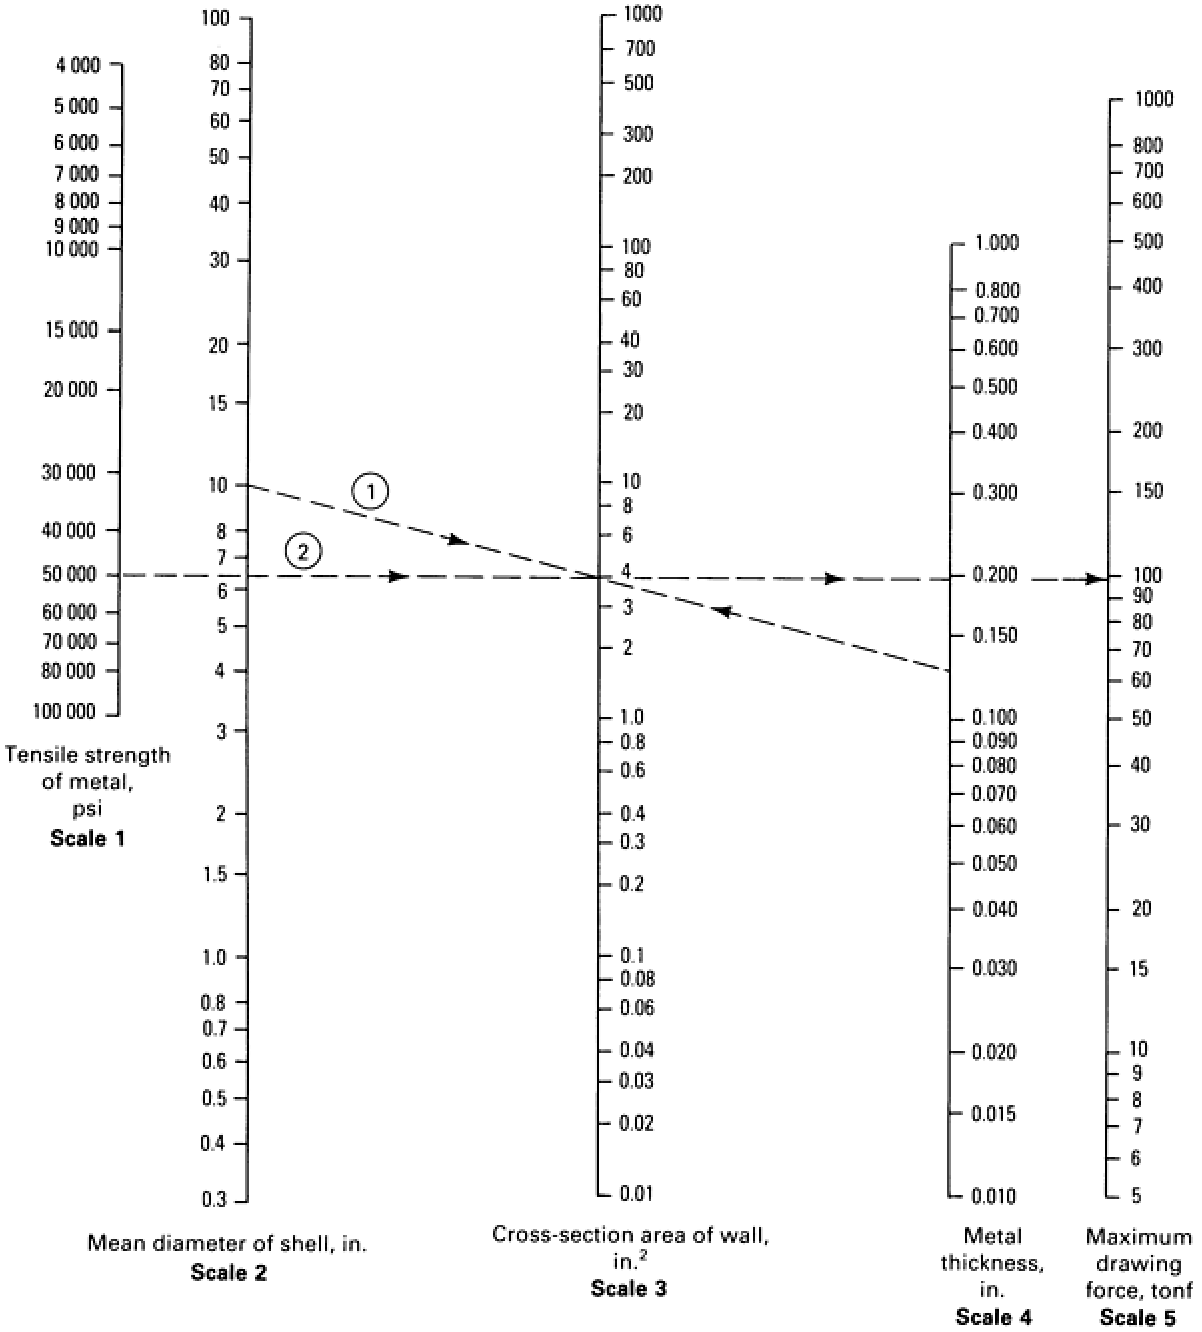

Fig. 3 Nomograph used for estimating drawing force based on several parameters. See text for description of use.

The force required to draw a rectangular cup can be calculated using Eq 7:

$$F_{d,max} = ts_u\,(2\pi R k_a + L k_b) \qquad \textbf{(Eq 7)}$$

where R is the corner radius of the cup (in inches), L is the sum of the lengths of straight sections of the sides (in inches), k_a and k_b are constants, and the other quantities are as defined in Eq 6. Values for k_a range from 0.5 for a shallow cup to 2.0 for a cup with a depth five to six times the corner radius; k_b values range from 0.2 (for easy draw radius, ample clearance, and no blankholder force) to a maximum of 1.0 (for metal clamped too tightly to flow).

When blankholder cylinders are mounted on the main slide of the press, the blankholder force must be added to the calculated drawing force. When a die cushion is used to eject workpieces, the main slide works against this force; therefore, such setups require more drawing force than would be calculated using Eq 6 or 7.

In toggle draw presses, the blankholder force is taken on the rocker shaft bearings in the press frame, so that the crankshaft bearings sustain only the drawing load. In other types of presses, both the drawing and blankholding loads are on the crankshaft, and allowances are made when computing press capacity. For round work, the allowance for blankholding should be 30 to 40% of the drawing force. For large rectangular work, the drawing force is relatively lower than that for round work, but the blankholding force may be equal to the drawing force. Where stretching is involved and the blank must be gripped tightly around the edge (and a draw bead is not permissible), the blankholding force may be two or three times the drawing force.

Blank size governs the size of the blankholder surfaces. Some presses with sufficient force cannot be considered for deep drawing, because the bed size and shut height are inadequate.

Depth of Draw. The length of stroke and the force required at the beginning of the working portion of the stroke are both important considerations. Parts that have straight walls can often be drawn through the die cavity and then stripped from the punch and ejected from the bottom of the press. Even under these ideal conditions, the minimum stroke will be equal to the sum of the length of the drawn part, the radius of the draw die, the stock thickness, and the depth of the die to the stripping point, in addition to some clearance for placing the blank in the die.

Workpieces with flanges or tapered walls must be removed from the top of the die. In drawing these workpieces, the minimum press stroke is twice the length of the drawn workpiece, plus clearance for loading the die. In an automatic operation using progressive dies or transfer mechanisms, at least one-half the stroke must be reserved for stock feed because the tooling must clear the part before feeding begins for the next stroke. For automatic operation, it is common practice to allow a press stroke of four times the length of the drawn workpiece. Therefore, some equipment is not suited to automatic operation, or it is necessary to use manual feed with an automatic unloader, or conversely, because of a shortage of suitable presses.

Slide Velocity. When selecting a press, it is also necessary to check slide velocity through the working portion of the stroke (see the section "Effect of Press Speed" in this article).

Means of Holding the Blank. Double-action presses with a punch slide and a blankholder slide are preferred for deep drawing. Single-action presses with die cushions (pneumatic or hydraulic) can be used, but are less suitable for drawing complex parts. Draw beads are incorporated into the blankholder for drawing parts requiring greater restraint of metal flow than can be obtained by using a plain blankholder or for diverting metal flow into or away from specific areas of the part (see the section "Restraint of Metal Flow" in this article).

Selection Versus Availability. The ideal press equipment for a specific job is often not available. This makes it necessary to design tools and to choose product forms of work metal in accordance with available presses and supplementary equipment. For example, if available presses are not adequate for drawing large workpieces, the manufacturing sequence must be completely changed. It may be necessary to draw two sections and weld them together. In addition, operations that could otherwise be combined, such as blanking, piercing, drawing, and trimming, may have to be performed singly in separate presses.

On the other hand, some manufacturers have placed more than one die in a single press because of the availability of a large press and the shortage of smaller presses. This procedure can cause lower production because all blanks must be positioned before the press can be operated. However, storage of partly formed workpieces and additional handling between press operations are eliminated. Where several small dies are used to reduce overall tool cost, there is economic justification for the use of small-capacity presses. If small presses are not available, it is often more economical to use compound dies. This is particularly true if overall part production is likely to exceed original estimates.

The availability of auxiliary equipment may also influence the type of press and tooling used. For example, if equipment is available for handling coils, plans will be made accordingly. However, if coil-handling equipment is not available and straight lengths of sheet or strip are to be processed, a compatible tooling procedure must be used, even though it might not be the most economical procedure.

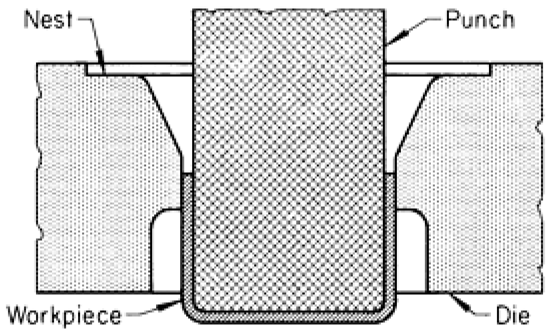
Dies

Dies used for drawing sheet metal are usually one of the following basic types or some modification of these types:

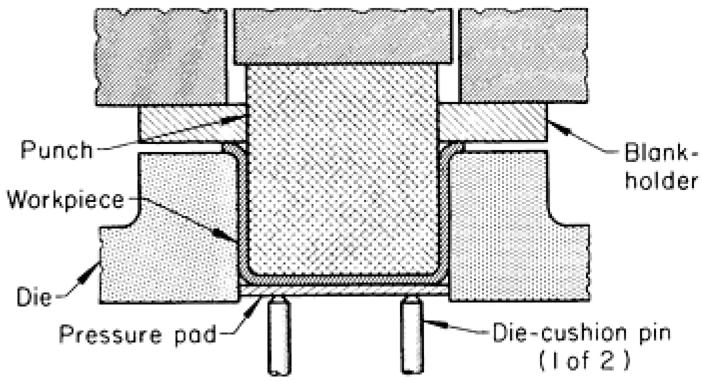
- Single-action dies
- Double-action dies
- Compound dies
- Progressive dies
- Multiple dies with transfer mechanism

Selection of the die depends largely on part size, severity of draw, and quantity of parts to be produced.

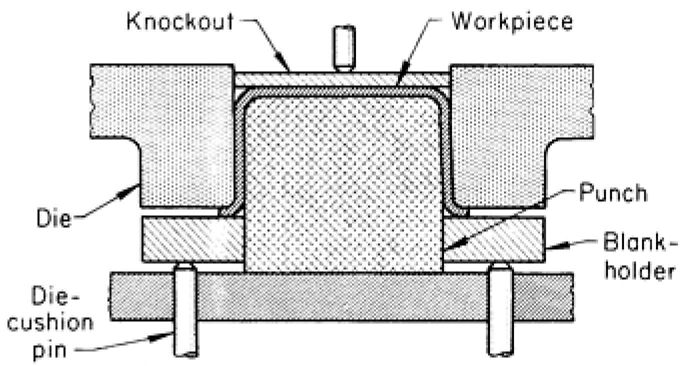
Single-action dies (Fig. 4a) are the simplest of all drawing dies and have only a punch and a die. A nest or locator is provided to position the blank. The drawn part is pushed through the die and is stripped from the punch by the counterbore in the bottom of the die. The rim of the cup expands slightly to make this possible. Single-action dies can be used only when the forming limit permits cupping without the use of a blankholder.



(a) Single-action die



(b) Double-action die



(c) Double-action die, inverted type

Fig. 4 Components of three types of simple dies shown in a setup used for drawing a round cup. See text for discussion.

Double-action dies have a blankholder. This permits greater reductions and the drawing of flanged parts. Figure 4(b) shows a double-action die of the type used in a double-action press. In this design, the die is mounted on the lower shoe; the punch is attached to the inner, or punch slide; and the blankholder is attached to the outer slide. The pressure pad is used to hold the blank firmly against the punch nose during the drawing operation and to lift the drawn cup from the die. If a die cushion is not available, springs or air or hydraulic cylinders can be used; however, they are less effective than a die cushion, especially for deep draws.

Figure 4(c) shows an inverted type of double-action die, which is used in single-action presses. In this design, the punch is mounted on the lower shoe; the die on the upper shoe. A die cushion can supply the blankholding force, or springs or air or hydraulic cylinders are incorporated into the die to supply the necessary blankholding force. The drawn cup is removed from the die on the upstroke of the ram, when the pinlike extension of the knockout strikes a stationary knockout bar attached to the press frame.

Compound Dies. When the initial cost is warranted by production demands, it is practical to combine several operations in a single die. Blanking and drawing are two operations commonly placed in compound dies. With compound dies, workpieces can be produced several times as fast as by the simple dies shown in Fig. 4.

Progressive Dies. The initial cost and length of bed needed for progressive dies usually limit their application to relatively small workpieces. Figure 5 shows a typical six-station progression for making small shell-like workpieces on a mass-production basis. However, larger parts, such as liners for automobile headlights, have been drawn in progressive dies.

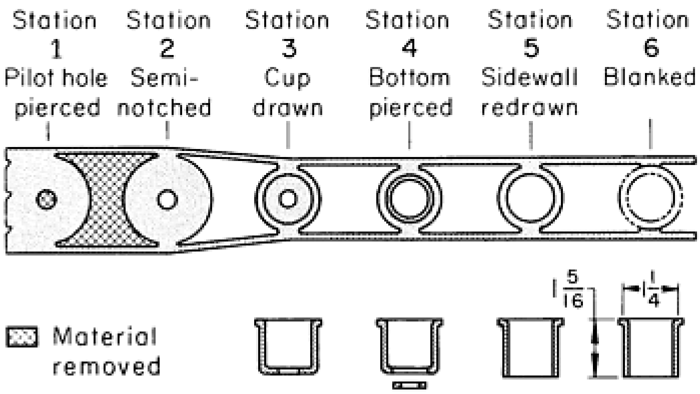


Fig. 5 Production of a small ferrule in a six-station progressive die. Dimensions given in inches.

The total number of parts to be produced and the production rate often determine whether or not a progressive die will be used when two or more operations are required. There are, however, some practical considerations that may rule against a progressive die, regardless of quantity:

- The workpiece must remain attached to the scrap skeleton until the final station, without hindering the drawing operations
- Drawing operations must be completed before the final station is reached
- In deep drawing, it is sometimes difficult to move the workpiece to the next station
- If the draw is relatively deep, stripping is often a problem
- The length of press stroke must be more than twice the depth of draw

Assuming that a progressive die can be used to make acceptable drawn parts, cost per piece is usually the final consideration. Progressive-die drawing is generally considered to be economical if savings in material and labor can pay for the die in 1 year. Ordinarily, the savings achieved by the use of a progressive die results from decreased labor.

Multiple dies, in conjunction with transfer mechanisms, are often used instead of progressive dies for the mass production of larger parts. Multiple dies and transfer mechanisms are practical for a wider range of workpiece sizes than progressive dies are. Although the eyelet-type transfer method is the most widely used for making parts less than 25 mm (1 in.) in diameter, transfer dies are practical for much larger workpieces. The seven-station operation for making the 165 mm ($6\frac{1}{2}$ in.) outside diameter cylindrical shell shown in Fig. 6 represents a typical sequence for the transfer-die method. The workpiece is mechanically transferred from one die to the next. One advantage of the transfer-die method, as opposed to the progressive-die method, is the greater flexibility permitted in processing procedure, mainly because in transfer dies the workpiece does not remain attached to the scrap skeleton during forming. Because of this, precut blanks can be drawn by the transfer method.

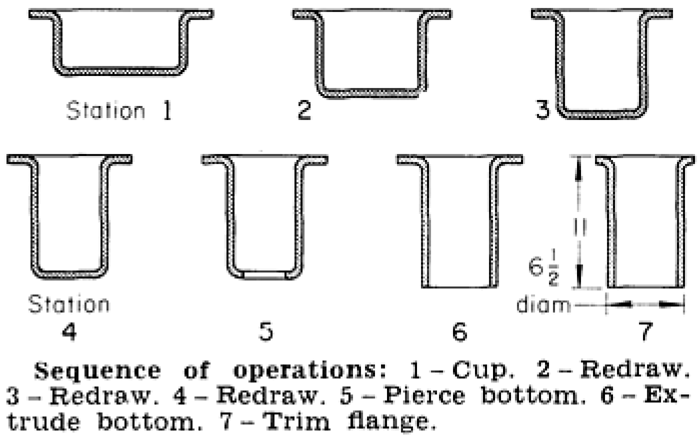

Fig. 6 Seven-station drawing and piercing of a cylindrical part in a multiple die and transfer mechanism. Dimensions given in inches.

Preforms can also be used as blanks. For example, oil pans for automobiles are blanked and partly drawn in a compound die, then finish formed, pierced, and trimmed by the transfer method.

Dies for producing a given part usually cost more for the transfer-die method than for a separate-die operation, but about the same as for a progressive-die operation. The cost of adapting the transfer unit to the part is not included in the die cost. Similarly, the production rate for the transfer method is usually greater than that for a single-die operation, but 10 to 25% less than that for drawing in a progressive die. Many parts can be produced equally well by all of these methods. Under these conditions, tool cost, rate of production, and total quantity of parts to be drawn determine the choice of procedure.

Die and Punch Materials. The selection of material for dies and punches for drawing sheet metal depends on work metal composition, workpiece size, severity of the draw, quantity of parts to be drawn, and tolerances and surface finish specified for the drawn workpieces. To meet the wide range of requirements, punch and die materials ranging from polyester, epoxy, phenolic, or nylon resins to highly alloyed tool steels with nitrided surfaces, and even carbide, are used. Detailed information on tool materials is available in the articles "Selection of Material for Press-Forming Dies" and "Selection of Material for Deep-Drawing Dies" in this Volume.

Effects of Process Variables

The process parameters that affect the success or failure of a deep-drawing operation include punch and die radii, punch-to-die clearance, press speed, lubrication, and type of restraint of metal flow used (if any). Material variables, such as sheet thickness and anisotropy, also affect deep drawing. These are discussed in the section "Effects of Material Variables" in this article.

Effect of Punch and Die Radii

As the blank is struck by the punch at the start of drawing, it is wrapped around the punch and die radii; the stress and strain that develop in the workpiece are similar to those developed in bending, with an added stretching component. The bends, once formed, have the radii of the punch and die corners. The bend over the punch is stationary with reference to both punch and shell wall. The bend over the die radius, however, is continuously displaced with reference to both the punch radius and the blank, and it also undergoes a gradual thickening as the shell is drawn. The force required to draw the shell at the intermediate position has a minimum of three components:

- The force required for bending and unbending the metal flowing from the flange into the sidewall
- The force required for overcoming the frictional resistance of the metal passing under the blankholder and over the die radius
- The force required for circumferential compression and radial stretching of the metal in the flange

Because of the variation in metal volume and in resistance to metal flow, the punch force increases rapidly, passes through a maximum, and gradually decreases to zero as the edges of the flange approach and enter the die opening and pass into the shell wall. With the cup diameter remaining constant, the maximum press load and the length of stroke required to draw the cup depend on the size of the blank. The punch force-stroke relations for drawing blanks of various diameters from brass sheet 1.5 mm (0.060 in.) thick, using a 50 mm (2 in.) diam punch, are shown in Fig. 7.

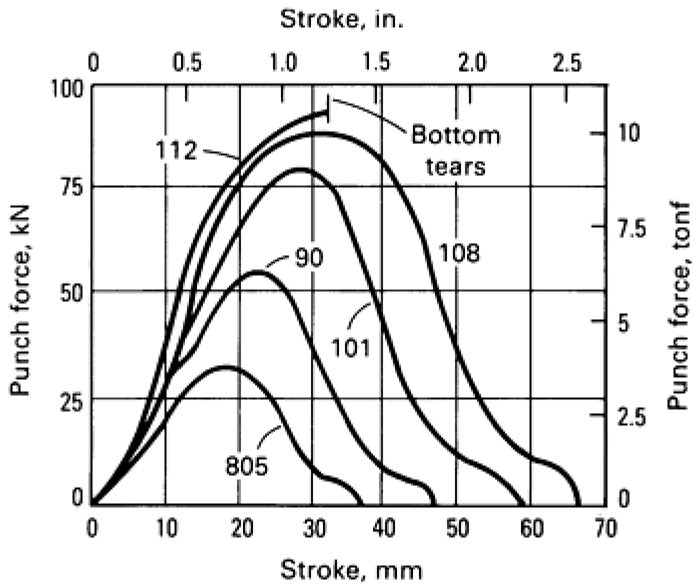

Fig. 7 Force-stroke relations for drawing blanks of various diameters from 1.5 mm (0.060 in.) thick alloy C27400 (yellow brass, 63%) sheet using a 50 mm (2 in.) diam punch. Numbers indicate blank diameter in millimeters.

Under the conditions shown in Fig. 7, during cupping, the shell bottom is subjected to tensile stress in all directions, while the lower portions of the shell wall, particularly the radiused portion connecting the bottom with the wall, are primarily subjected to longitudinal tension. The stress in the metal being drawn into the shell wall consists of combined compressive and tensile stresses. Separation of the shell bottom from the wall is likely if a reduction is made that requires a force greater than the strength of the shell wall near the bottom (Fig. 7).

The punch and die radii and percentage of reduction determine the load at which the bottom of the shell is torn out. Drawing is promoted by increasing punch and die radii. For a given drawing condition, the punch force needed to move the metal into the die decreases as the die radius increases, as shown in Fig. 8.

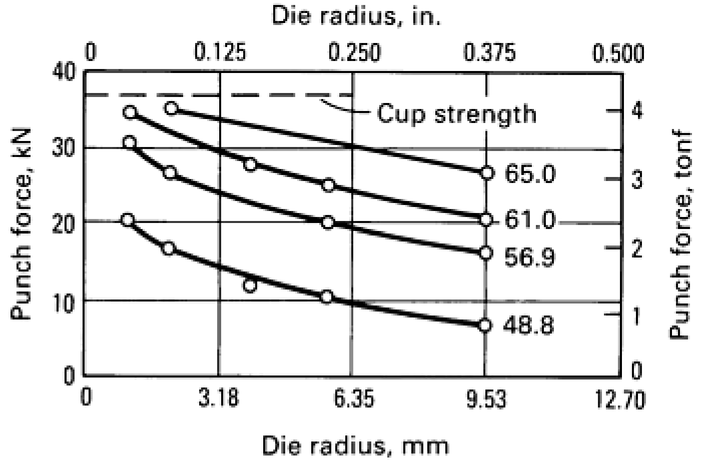

Fig. 8 Effect of die radius on punch force required for cupping various diameters of 1 mm (0.040 in.) thick alloy C27400 (yellow brass, 63%) blanks using a 30.5 mm (1.2 in.) diam punch with a nose radius of 0.61 mm (0.024 in.). Numbers indicate blank diameter in millimeters.

The reduction of drawing force in a double-action die by modification of the effective die radius can be accomplished in two convenient ways, as shown in Fig. 9. In the conical lead-in die (Fig. 9a), the cutout is effective in reducing frictional loads by removal of the portions of the die surface that are usually heavily loaded and increase friction. In Fig. 9(b), the sheet metal is formed into a conical shape before appreciable drawing begins. This has the effect of reducing the area of contact over the die radius by an amount proportional to α/90° (where $\alpha$is the angle to declination of the hold-down surface to the horizontal, as shown in Fig. 9b).

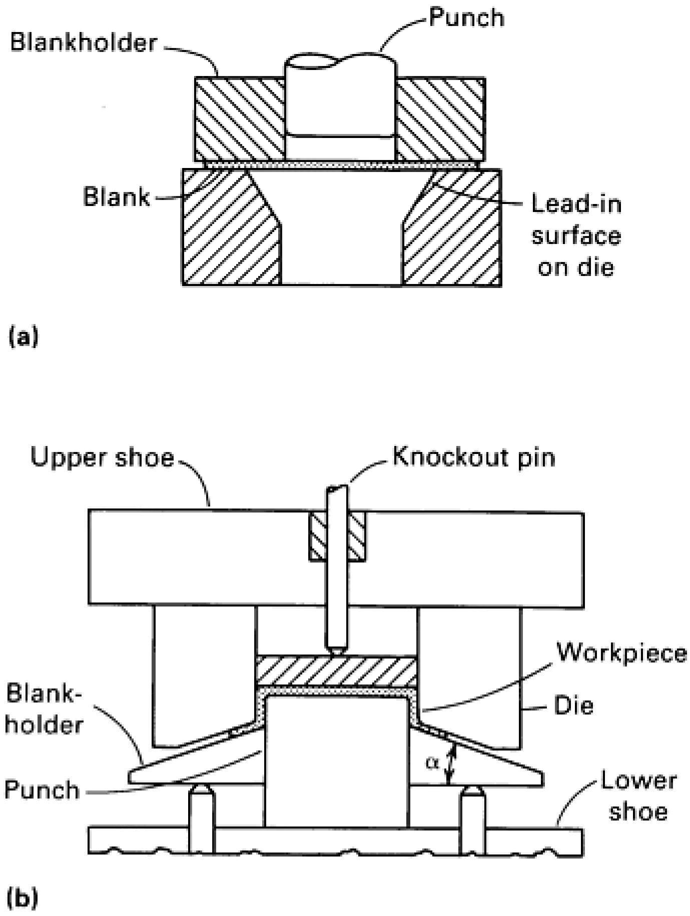

Fig. 9 Two ways of reducing the required drawing forces. (a) Conical lead-in die. (b) Conical blankholder. See text for details.

If the punch nose radius can be increased from one to five times metal thickness, the load in the sidewall of the shell will decrease so that the reduction in blank diameter will increase from 35% to about 50% (for steel). The shell can therefore be drawn deeper before the sidewall tears.

If the shell bottom radius is less than four times the sheet thickness, it is usually desirable to form it with a larger-radius punch and then to restrike to develop the specified radius. This will minimize bottom failures. However, the bottom corner radius usually cannot be increased beyond ten times the sheet thickness without the likelihood of wrinkling. The metal in dome-shaped parts is likely to pucker in the unconfined area between the punch nose and die radius. High blankholding forces or draw beads are often used to induce combined stretching and drawing of the metal when forming dome shapes.

The deep drawing of stainless steel or high-strength alloy boxes with sides longer than 50 times stock thickness may result in a stability problem called oil canning. The deflection of the sides by snap action can be eliminated by drawing the part in two operations with slightly different punches and an intermediate anneal. The first-draw punch will have a larger nose radius than the second; therefore, in the second drawing operation, the metal can be stretched to eliminate the oil-canning effect. Stretching of the metal in parts with long sidewalls can be improved by gradually increasing the punch nose radius from the corner toward the center. A constant nose radius is used on the second-draw punch.

Effect of Punch-to-Die Clearance

The selection of punch-to-die clearance depends on the requirements of the drawn part and on the work metal. Because there is a decrease and then a gradual increase in the thickness of the metal as it is drawn over the die radius, clearance per side of 7 to 15% greater than stock thickness (1.07 to 1.15t) helps prevent burnishing of the sidewall and punching out of the cup bottom.

The drawing force is minimal when the clearance per side is 15 to 20% greater than stock thickness (1.15 to 1.20t) and the cupped portions of the part are not in contact with the walls of the punch and die. The force increases as the clearance decreases, and a secondary peak occurs on the force-stroke curve where the metal thickness is slightly greater than the clearance and where ironing starts.

Redrawing operations require greater clearance, in relation to blank thickness, than the first draw in order to compensate for the increase in metal thickness during cupping. A sizing redraw is used where the diameter or wall thickness is important or where it is necessary to improve surface finish to reduce finishing costs. The clearance used is less than that for the first draw.

Table 1 lists clearances for cupping, redrawing, and sizing draws of cylindrical parts from metal of various thicknesses. As the tensile strength of the stock decreases, the clearance must be increased.

Table 1 Punch-to-die clearance for drawing operations

Metal thickness, *t*		Clearance-to-metal-thickness relationship for:		
mm	**in.**	**Cupping**	**Redrawing**	Sizing draws
Up to 0.38	Up to 0.015	1.07-1.09t	1.08-1.10t	**1.04-1.05*t***
0.41-1.27	0.016-0.050	1.08-1.10t	1.09-1.12t	**1.05-1.06*t***

1.29-3.18	0.051-0.125	1.10-1.12*t*	1.12-1.14*t*	**1.07-1.09*t***
3.2 and up	**0.126 and up**	**1.12-1.14*t***	**1.15-1.20*t***	**1.08-1.10*t***

Clearance between the punch and die for a rectangular shell, at the sidewalls and ends, is about the same as, or slightly less than, that for a circular shell. Clearance at the corners may be as much as 50% greater than stock thickness to avoid ironing in these areas and to increase drawability.

Restraint of Metal Flow

Even in the simplest drawing operation, as shown in Fig. 4(a), the thickness of the work metal and the die radius offer some restraint to the flow of metal into the die. For drawing all but the simplest of shapes, some added restraint is generally required in order to control the flow of metal. This additional restraint is usually obtained by the use of a blankholder, as illustrated in Fig. 4(b) and 4(c). The purpose of the blank-holder is to suppress wrinkling and puckering and to control the flow of the work metal into the die.

Drawing Without a Blankholder. A blank is not susceptible to wrinkling, and a blankholder need not be used, if the ratio of supported length to sheet thickness is within certain limits. In Fig. 10, the supported length *l* is the length from the edge of the blank to the die cavity (point of tangency). The sheet thickness is denoted as *t*. The *l*/*t* ratio is influenced little by other geometrical conditions, and it differs little for the various metals commonly drawn. When the *l*/*t* ratio does not exceed 3 to 1, a cup can be drawn from annealed brass, aluminum (to half-hard), and low-carbon steel without a blankholder. For slightly harder work metals, such as hard copper or half-hard brass, this ratio should not exceed 2.5 to 1.

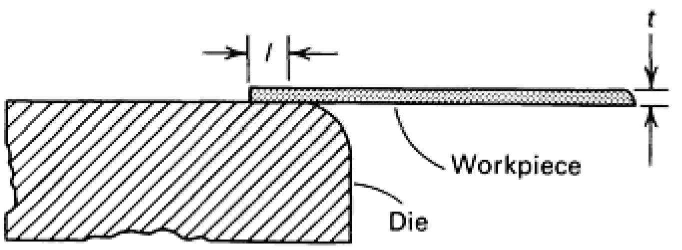

Fig. 10 The ratio of supported length *l* to sheet thickness *t* determines whether or not a blankholder is required for deep drawing.

An elliptical or conical die opening, such as that shown in Fig. 9(a), can be used where the die radius required to draw the part reduces the length of the blank-supporting surface to less than three times stock thickness. The distance between the die opening and the punch should not exceed ten times stock thickness.

A 30° elliptical radius derived from a circle created by a given draw radius increases the strain on the metal being drawn by 4.2%, but it decreases the metal out of control by 47% of the length of the original draw radius. This shape has been helpful in the drawing of tapered shells from a flat blank. For these draws, it is desirable to increase the strain slightly to prevent puckers and to reduce the metal out of control for the same reason.

A 45° elliptical radius derived as above reduces the strain on the metal being drawn by 1.03% and reduces the metal out of control by 33% of the length of the original draw radius. The 45° ellipse is useful only when a large radius will draw the part, but produces wrinkles. A smaller radius will not permit the draw.

A 60° elliptical radius does not measurably reduce drawing strain and accounts for only a 9% reduction of metal out of control. Its use on draw dies is not economically feasible when the small gains derived are considered in relation to the cost of producing the contour. The drawing of thick metal without a blankholder is frequently done when the blank diameter is no greater than 20 times stock thickness.

Blankholders. The purpose of a blankholder is to prevent wrinkles from forming in the flange of a part during drawing. The formation of wrinkles interferes with, or prevents, the compressive action that rear-ranges the metal from flange to sidewall. Much greater reductions are possible when a blankholder is used.

Blankholders can be used in double- and single-action presses. In a double-action press, the blankholder advances slightly ahead of the punch and dwells at the bottom of its stroke throughout the drawing phase of the punch cycle. The blankholder dwell usually extends to a point on the punch upstroke at which positive stripping of the shell is ensured. By using a die cushion and an inverted die, similar action can be obtained in a single-action press. A die cushion in a double-action press supports the blank and holds it against the punch during the drawing operation; it then lifts the finished part out of the die.

A blankholder must allow the work metal to thicken as the edge of the blank moves inward toward the working edge of the die. The amount of thickening is expressed by:

$$\frac{t_1}{t} = \sqrt{\frac{D}{D_1}} \qquad \textbf{(Eq 8)}$$

where t is the blank thickness, t_1 is the thickness of the flange at any instant during the drawing operation, D is the blank diameter, and D_1 is the diameter of the flange at any instant during the drawing operation (or the mean diameter of the workpiece without the flange). As the metal flows, paths of least resistance are taken; therefore, the actual value of t_1, will be less than that calculated from the formula.

Types of Blankholders. The simplest type of blankholder is fixed to the die block and has a flat hold-down surface, as shown in Fig. 11(a). A disadvantage of this type of blankholder is that maintenance of the optimal gap between the die surface and the flat hold-down surface requires careful adjustment. As shown in Fig. 11, the blankholder does not quite contact the work metal as drawing begins; restraint begins and increases as the flange portion thickens. A gap that is either too small or too large increases force and reduces drawability. For optimal results, the gap should be slightly smaller than the flange thickness, allowing 50 to 75% of the final thickening before the work metal contacts the blankholder.

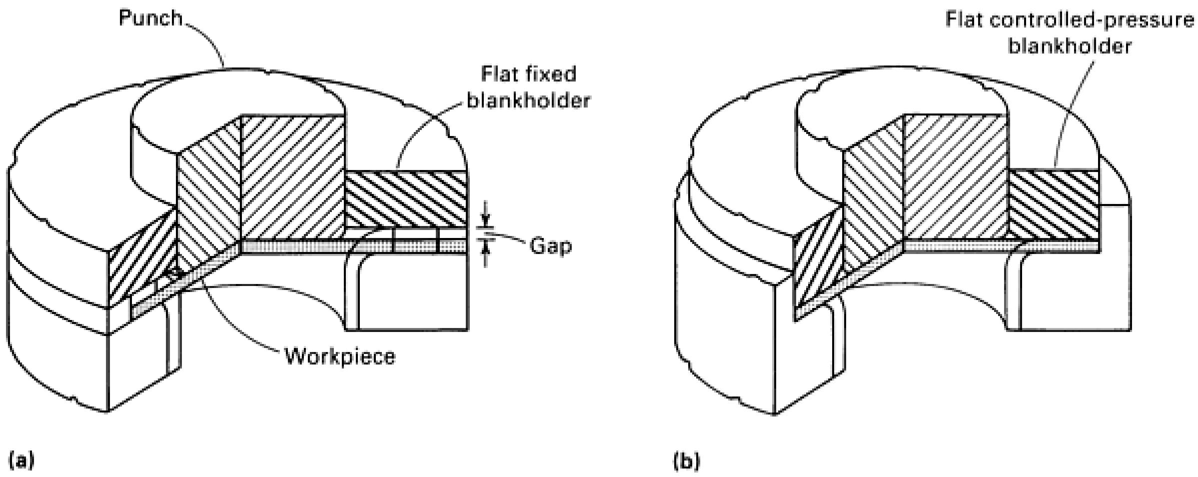

Fig. 11 Setups showing the use of two types of blankholders. See text for details.

The flat controlled-pressure blankholder shown in Fig. 11(b) is generally preferred in production operations because it can be adjusted to a predetermined and closely controlled value by hydraulic or pneumatic pressure. Springs, unless extremely long, are not suitable for supplying pressure to a blankholder during deep drawing, because the force exerted by a spring increases rapidly as it is compressed. The force on hydraulic or pneumatic die cushions will increase about 20% when compressed the full stroke length. Some hydraulic systems have pressure control valves that supply a more nearly constant pressure during the entire stroke.

The fixed-type blankholder (Fig. 11a) draws a cup without a flange and ejects it through the bottom of the die. The blankholder shown in Fig. 4(b) and 4(c) and in Fig. 11(b) can be used for drawing a cup with or without a flange. Cups without a flange can be pushed through the die if a pressure pad is not needed to support the blank.

Blankholder Force. Compressive forces on the metal in the area beyond the edge of the die cause the work metal to buckle. If this buckled or wrinkled metal is pulled into the die during the drawing operation, it will increase the strain in the area of the punch nose to the point at which the work metal would fracture soon after the beginning of the draw. Blankholder force is used to prevent this buckling and subsequent failure. The amount of blankholder force required is usually about one-third that required for drawing. Thickness of the work metal must also be considered when simple shapes are being drawn; the thinner the work metal, the more blankholder force that is required.

There are no absolute rules for calculating blankholder force for a given drawing operation; most blankholder force values are found empirically. Blankholder force should be just sufficient to prevent wrinkling, and it depends on draw reduction, work metal thickness and properties, the type of lubrication used, and other factors. For a particular application, blankholder force is best determined experimentally.

Draw beads help prevent wrinkles and control the flow of metal in the drawing of shells. The use of draw beads increases the cost of tools, product development, and tool maintenance. However, they are often the only means of controlling metal flow in the drawing of odd shapes. Draw beads are ordinarily used for the first draw only; therefore, production rates are the same as when conventional blankholders are used. For low production, draw beads are often made by laying a weld bead on the die after the optimal location has been determined.

Restraint of the metal flow, to the extreme of locking the flange of the blank to prevent motion, is needed for some draws. A deep shell with sloping walls can be made by drawing, followed by several redraws. This results in a stepped workpiece. The final sizing draw is a stretching operation that is done with the flange secured by a locking bead in the blankholder. This kind of blankholder is also used in making shallow drawn panels. Additional information on the design and use of draw beads is available in the article "Press Forming of Low-Carbon Steel" in this Volume.

Effect of Press Speed

Drawing speed is usually expressed in meters per minute (m/min) or linear feet per minute (ft/min). Under ideal conditions, press speeds as high as 23 m/min (75 ft/min) are used for the deep drawing of low-carbon steel. However, 6 to 17 m/min (20 to 55 ft/min) is the usual range--up to 17 m/min (55 ft/min) for single-action presses and 11 to 15 m/min (35 to 50 ft/min) for double-action presses. Ideal conditions include:

- Use of a drawing-quality work metal
- Symmetrical workpieces of relatively mild severity
- Adequate lubrication
- Precision carbide tools
- Carefully controlled blankholding pressure
- Presses that are maintained to a high level of accuracy

When one or more of the above conditions is less than ideal, some reduction in press speed is required. If all, or nearly all, are substantially less than ideal, press speed may have to be reduced to 6 m/min (20 ft/min). When the operation includes ironing, the drawing speed is usually reduced to about 7.6 m/min (25 ft/min) regardless of other factors.

The punch speed in hydraulic presses is relatively constant throughout the stroke. In mechanical presses, punch speed is that at mid-stroke because the velocity changes in a characteristic manner throughout the drawing stroke from maximum velocity to zero. The only adjustment in speed that can be made is to decrease flywheel speed or to use a press with a shorter stroke that operates at the same number of strokes per minute. This proportionately decreases maximum punch speed.

Speed is of greater significance in drawing stainless steels and heat-resistant alloys than in drawing softer, more ductile metals. Excessive press speeds have caused cracking and excessive wall thinning in drawing these stronger, less ductile metals. Nominal speeds for drawing various metals are given in Table 2.

Table 2 Typical drawing speeds for various materials

Material	Drawing speed	
	m/min	ft/min
Aluminum	45.7-53.3	**150-175**
Brass	53.3-61	**175-200**
Copper	38.1-45.7	**125-150**
Steel	5.5-15.2	**18-50**
Stainless steel	9.2-12.2	**30-40**

Effect of Lubrication

When two metals are in sliding contact under pressure, as with the dies and the work metal in drawing, galling (pressure welding) of the tools and the work metal is likely. When extreme galling occurs, drawing force increases and becomes unevenly distributed, causing fracture of the workpiece.

The likelihood of pressure welding depends on the amount of force and the work metal composition. Some work metals are more "sticky" than others. For example, austenitic stainless steel is more likely to adhere to steel tools than low-carbon steel is.

Lubricants are used in most drawing operations. They range from ordinary machine oil to pigmented compounds.

Selection of lubricant is primarily based on the ability to prevent galling, wrinkling, or tearing during deep drawing. It is also influenced by ease of application and removal, corrosivity, and other factors, as described in the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume.

If a lubricant cannot be applied uniformly by ordinary shop methods, its purpose is defeated, regardless of its ability to prevent pressure welding. In general, as the effectiveness of a lubricant increases, the difficulty of removing it also increases. For example, grease or oil can be easily removed, but special procedures (frequently including some hand scrubbing) are required for removing lubricants that contain zinc oxide, lithopone, white lead, molybdenum disulfide, or graphite.

A lubricant is sometimes too corrosive for use on certain metals. For example, copper alloys are susceptible to staining by lubricants that contain large amounts of sulfur or chlorine compounds. Lubricants containing lead or zinc compounds are not recommended for drawing stainless steel or heat-resistant alloys, because the compounds, if not thoroughly removed, can cause intergranular attack when the work-pieces are heat treated or placed in high-temperature service. Suitable safety precautions are necessary with toxic or flammable lubricants.

Some metals, such as magnesium and titanium, are drawn at elevated temperature, which complicates selection of the lubricant. Most oil-base and soap-base lubricants can be successfully used to 120 °C (250 °F), but above this temperature, the choice narrows rapidly. Some special soap-base lubricants can be used on work metals to 230 °C (450 °F). Molybdenum disulfide and graphite can be used at higher temperatures.

Any lubricant must remain stable, without becoming rancid, when stored for a period of several months at various temperatures. The cost of application and removal of the lubricant, as well as its initial cost, must be considered because all of these items can add substantially to the cost of the drawn workpieces.

In some plants, when a new application is started, a heavily pigmented drawing lubricant is used, regardless of the difficulty of applying and removing it. Lubricant is then downgraded as much as possible to simplify the operation and to reduce costs. In other plants, the reverse of this practice is used; that is, a simple lubricant, such as machine oil, is used at first, and lubricant is then upgraded when necessary.

The difficulty of removing drawing lubricants is an important consideration in production operations. In a number of applications, changes in drawing techniques (such as increasing the number of draws) or in workpiece design (larger radii, for example) have been made solely to permit the use of an easier-to-remove drawing lubricant. Methods of removing lubricants are discussed in the section "Cleaning of Workpieces" in this article.

Typical lubricants used in drawing steel are given in Table 3 according to severity of draw or the percentage of reduction from blank to cup diameter. Zinc phosphate conversion coating of the steel to be drawn is helpful for any drawing operation, and the importance of phosphate coating increases as the severity of the draw increases. Methods of application and other details on the use of phosphate conversion coatings are discussed in the article "Phosphate Coatings" in *Surface Engineering*, Volume 5 of the *ASM Handbook.*

Table 3 Lubricants commonly used for the drawing of low-carbon steel

Severity is indicated by the percentage of reduction in diameter in drawing a cylindrical shell.

Type or composition of lubricant	**Ease of removal by:**		Protection against rusting
	Water-base cleaners	**Degreasers or solvents**	
Water-base lubricants			
Low severity (10% or less)			
Water emulsion of 5-20% general-purpose soluble oil or wax	Very good	Good	**Fair**
Moderate severity (11-20%)			
Water solution of 5-20% soap	Very good	Very poor	**Fair**
Water emulsion of heavy-duty soluble oil (contains sulfurized or chlorinated additives)	Very good	Good	**Fair**
High severity (21-40%)			
Soap-fat paste, diluted with water (may contain wax)	Fair	Poor	**Fair**
Water emulsion of heavy-duty soluble oil (contains a high concentration of sulfurized or chlorinated additives)	Very good	Good	**Fair to poor**

Maximum severity (>40%)			
Pigmented soap-fat paste, diluted with water	Poor	Very poor	**Good**
Dry soap or wax (applied from water solution or dispersion); may contain soluble filler such as borax	Good	Very poor	**Good**
Oil-base lubricants			
Low severity (10% or less)			
Mill oil, residual	Good	Very good	**Fair**
Mineral oil	Good	Very good	**Fair**
Vanishing oil	Removal not required		**. . .**
Moderate severity (11-20%)			
Mineral oil plus 10-30% fatty oil	Good	Very good	**Fair**
Mineral oil plus 2-20% sulfurized or chlorinated oil (extreme-pressure oil)	Good to fair	Good	**Fair to poor**
High severity (21-40%)			
Fatty oil	Fair	Fair	**Fair**
Mineral oil plus 5-50% of:			
(a) Nonemulsifiable chlorinated oil	Poor	Good	**Very poor**
(b) Emulsifiable chlorinated oil	Good	Good	**Very poor**
Concentrated phosphated oil	Fair	Fair	**Fair**
Maximum severity (>40%)			
Blend of pigmented soap-fat paste with mineral oil	Poor	Poor	**Fair**
Concentrated sulfochlorinated oil (may contain some fatty oil):			

(a) Nonemulsifiable	Very poor	Fair	**Poor**
(b) Emulsifiable	Good	Fair	**Poor**
Concentrated chlorinated oil:			
(a) Nonemulsifiable	Very poor	Fair	**Very poor**
(b) Emulsifiable	**Good**	**Fair**	**Very poor**

Materials for Deep Drawing

Sheet steels and other sheet metals with higher strengths and better formability have recently become available. Developments such as vacuum processing and inclusion shape control have been especially beneficial in increasing the drawability of steels. Other metals and alloys that can be deep drawn include aluminum and aluminum alloys, copper and alloys, some stainless steels, and titanium.

Low-carbon sheet steels are the materials that are most commonly deep drawn and are commonly used, for example, in the automotive industry. Materials such as 1006 and 1008 steel have typical yield strengths in the range of 172 to 241 MPa (25 to 35 ksi) and elongations of 35 to 45% in 50 mm (2 in.). These materials have excellent formability and are available cold or hot finished in various quality levels and a wide range of thicknesses. Table 4 lists mechanical properties of the various qualities of carbon steel sheet.

Table 4 Typical mechanical properties of low-carbon sheet steels

Quality level	**Tensile strength**		**Yield strength**		**Elongation, % in 50 mm (2 in.)**	**Plastic-strain ratio, *r***	**Strain-hardening exponent, *n***	Hardness, HRB
	MPa	**ksi**	**MPa**	**ksi**				
Hot rolled								
Commercial quality	358	52	234	34	35	1.0	0.18	**58**
Drawing quality	345	50	220	32	39	1.0	0.19	**52**
Drawing quality, aluminum killed	358	52	234	34	38	1.0	0.19	**54**
Cold rolled, box annealed								
Commercial quality	331	48	234	34	36	1.2	0.20	**50**
Drawing quality	317	46	207	30	40	1.2	0.21	**42**

Drawing quality, aluminum killed	303	44	193	28	42	1.5	0.22	**42**
Interstitial-free	**310**	**45**	**179**	**26**	**45**	**2.0**	**0.23**	**44**

Other low-carbon steels that are commonly deep drawn are grades 1010 and 1012. These materials are slightly stronger than 1006 and 1008 and are slightly less formable. They are often specified when drawing is not severe and strength of the finished part is of some concern.

Grain size affects the drawability of these materials, and it may affect the selection of a grade. Grain sizes of ASTM 5 or coarser may result in excessive surface roughness as well as reduced drawability.

Surface finish also influences drawability. The dull finish normally supplied on drawing steels is designed to hold lubricants and to improve drawability. Brighter finishes may be required if, for example, parts are to be electroplated.

Effects of Materials Variables

Anisotropy. As mentioned earlier in this article, there are two types of anisotropy that must be considered: planar anisotropy, in which properties vary in the plane of the sheet, and normal anisotropy, in which the properties of the material in the thickness direction differ from those in the plane of the sheet.

Planar anisotropy (variations in normal anisotropy in the plane of the sheet) causes undesirable earing of the work material during drawing. Between the ears of the cup are valleys in which the material has thickened under compressive hoop stress rather than elongating under radial tensile stress. This thicker metal sometimes forces the die open against the blankholder pressure, allowing the metal in the relatively thin areas near the ears to wrinkle. Die design, draw reduction, and type of lubricant used all affect earing (see the section "Effects of Process Variables" in this article).

Sheet Thickness. In deep drawing, the pressure on the dies increases proportionally to the square of sheet thickness. The pressure involved is concentrated on the draw radius, and increasing sheet thickness will localize wear in this area without similar effect on other surfaces of the die.

Thick stock has less tendency to wrinkle than thin stock. As a result, blankholder pressures used for the drawing of thick sheet may be no greater, and may even be less, than those used for thinner blanks.

Direct Redrawing

In direct redrawing in a single-action die, the drawn cup is slipped over the punch and is loaded in the die, as shown in Fig. 12. At first, the bottom of the cup is wrapped around the punch nose without reducing the diameter of the cylindrical section. The sidewall section then enters the die and is gradually reduced to its final diameter. Metal flow takes place as the cup is drawn into the die so that the wall of the redrawn shell is parallel to, and deeper than, the wall of the cup at the start of the redraw. At the beginning of redrawing, the cup must be supported and guided by a recess in the die or by a blankholder to prevent it from tipping, because tipping would result in an uneven shell.

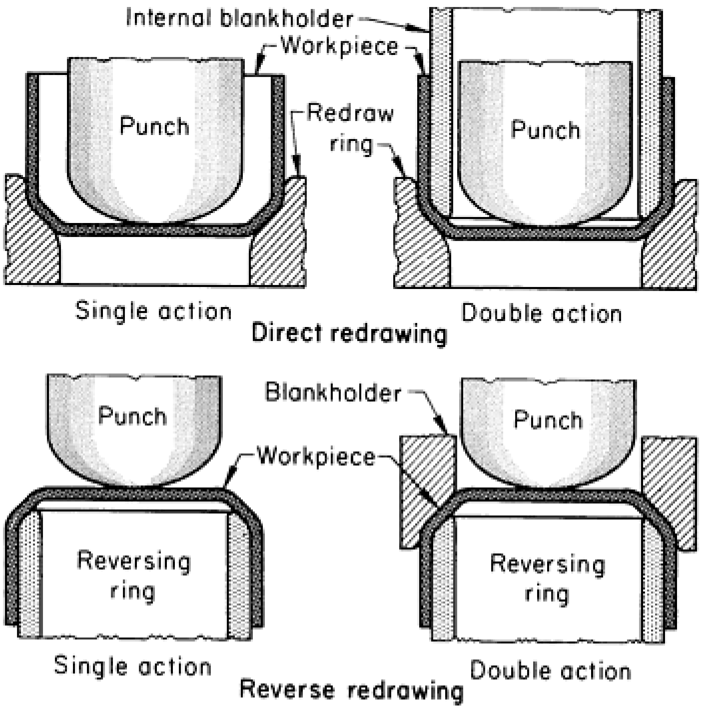

Fig. 12 Direct and reverse redrawing in single-action and double-action dies

In a single-action redraw, the metal must be thick enough to withstand the compressive forces set up in reducing the cup diameter without wrinkling. Wrinkling can be prevented by the use of an internal blankholder and a double-action press (upper right, Fig. 12), which usually permits a shell to be formed in fewer operations than by single-action drawing without the use of a blankholder.

Internal blankholders (Fig. 13) are slip fitted into drawn shells to provide support and to prevent wrinkling during direct redrawing. The blankholder presses on the drawn shell at the working edge of the die before the punch contacts the bottom of the shell and begins the redraw. It dwells against the shell as the metal is drawn into the die by the punch, preventing wrinkles.

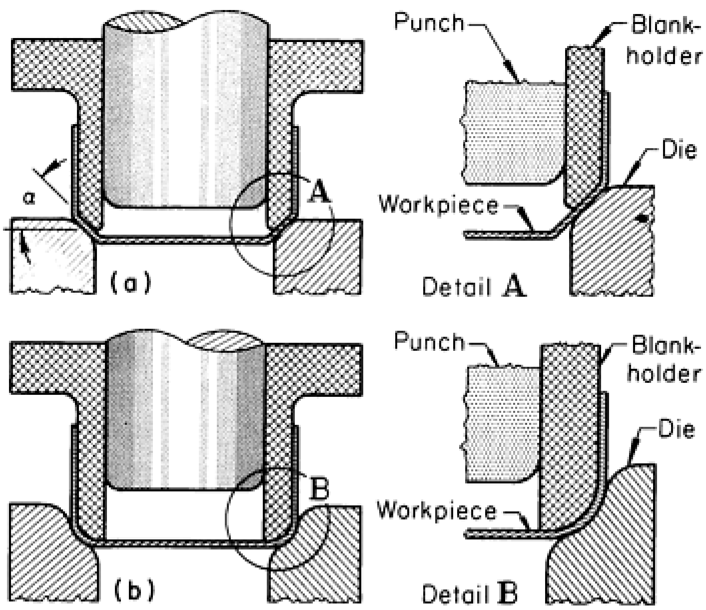

Fig. 13 Setups using internal blankholders for restraint of work metal in redrawing shells. See text for details.

The bottom of the cup to be redrawn can be tapered (Fig. 13a) or radiused (Fig. 13b), with the tip of the blankholder and the mouth of the die designed accordingly. An angle of 30° is used for metal thinner than 0.8 mm ($\frac{1}{32}$ in.), and 45° is used for thicker work metal. A modification of the above is a blankholder fitted against an S-curve die (Fig. 13b). The main disadvantage of an S-curve die is that it is more expensive to make and maintain. Near the bottom of a redrawn shell, there is usually a narrow ring, caused by the bottom radius of the preceding shell, that is thinner and harder than the adjacent metal. Redrawing may be required for reasons other than the severity of the drawn shape--for example, to prevent thinning and bulging.

Redrawing can also be done in a progressive die while the part is still attached to the strip. Where space permits the extra stations, the amount of work done in each station will be less than that done in a single die. This reduces the severity of the draw and promotes high-speed operation.

Reverse Redrawing

In reverse redrawing, the cupped workpiece is placed over a reversing ring and redrawn in the direction opposite to that used for drawing the initial cup. As shown in the two lower views in Fig. 12, reverse redrawing can be done with or without a blankholder. The blankholder serves the same purposes as in direct redrawing.

The advantages of reverse redrawing as compared with direct redrawing include:

- Drawing and redrawing can be accomplished in one stroke of a triple-action hydraulic press, or of a double-action mechanical press with a die cushion, which can eliminate the need for a second press
- Greater reductions per redraw are possible with reverse redrawing
- One or more intermediate annealing operations can often be eliminated by using the reverse technique
- Better distribution of metal can be obtained in a complex shape

In borderline applications, annealing is required between redraws in direct redrawing, but is not needed in reverse redrawing.

The disadvantages of reverse redrawing are:

- The technique is not practical for work metal thicker than 6.4 mm ($\frac{1}{4}$ in.)
- Reverse redrawing requires a longer stroke than direct redrawing

Usually, metals that can be direct redrawn can be reverse redrawn. All of the carbon and low-alloy steels, austenitic and ferritic stainless steels, aluminum alloys, and copper alloys can be reverse redrawn.

Reverse redrawing requires more closely controlled processing than direct redrawing does. This control must begin with the blanks, which should be free from nicks and scratches, especially at the edges.

The restraint in reverse redrawing must be uniform and low. For low friction, polished dies and effective lubrication of the work are needed. Friction is also affected by hold-down pressure and by the shape of the reversing ring. Radii of tools should be as large as practical--ten times the thickness of the work metal if possible. Reverse redrawing can be done in a progressive die as well as in single-stage dies if the operations are divided to distribute the work and to reduce the severity of each stage.

Tooling for Redrawing

Tooling for redrawing depends mainly on the number of parts to be redrawn and on available equipment. In continuous high production, a complete die is used for each redraw; the workpieces are conveyed from press to press until completed. In low or medium production, it is common practice to use a die with replaceable draw rings and punches. A die of this type used for three redrawing operations is shown in Fig. 14; the three redraws were made by changing to successively smaller draw rings and punches. The cup was drawn in a compound blank-and-draw die from a blank 1.7 mm (0.067 in.) thick and 171 mm ($6\frac{3}{4}$ in.) in diameter.

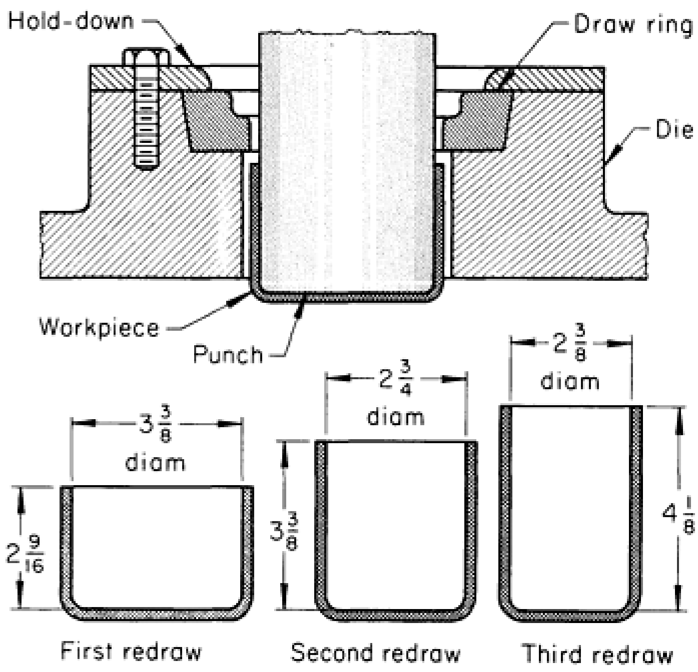

Fig. 14 Die in which draw rings and punches can be replaced for producing three successive redraws. Dimensions given in inches

Drawing of Boxlike Shells

Square or rectangular shells can be formed by redrawing circular shells when there is no flange. When flanges are required, the difficulty of producing acceptable boxlike shapes by drawing is increased. For deep-drawn square or rectangular shells (for example, where the depth is greater than either length or width), the best approach for forming a narrow flange is to allow sufficient stock and to form the flange after redrawing from a cylindrical shell.

Shallower boxlike shapes (for example, with proportions similar to the box illustrated in Fig. 15) can be drawn with a flange, which is then trimmed to the desired width. Calculations for the area of a blank used for a circular workpiece cannot be used for a square or rectangular box. These require metal in the bottom, ends, sides, and flange, as shown when a box is unfolded (flat pattern, Fig. 15). The excess metal at the corners (shaded areas, Fig. 15) is a problem.

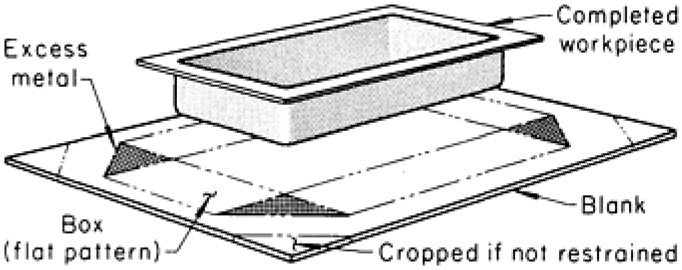

Fig. 15 Flanged rectangular box drawn from a blank with restraint at the corners. See text for details.

A seamless square or rectangular shell is made by drawing metal into the corners. The metal not needed for the corners is pushed into the walls adjacent to the corner radius and into earlike extensions of the corners. The compressive stresses set up when the metal in the corners is rearranged cause the metal to be thicker in the corners than in the sidewall or in the original blank.

The more difficult draws are made more easily by using a carefully developed blank. There are methods of developing the shape at the corners of a blank for a square or rectangular shell so that there is a minimum of excess metal. However, by cropping the corners as shown in Fig. 15 and by using a blankholder, satisfactory parts can generally be made. Draw beads in the blankholding surface surrounding the die are frequently used.

Drawing of Workpieces With Flanges

Regardless of whether the drawn workpiece is circular, rectangular, or asymmetrical, producing acceptable small-width flanges on workpieces is seldom a problem. Flanged workpieces are usually drawn in two or more operations, frequently with restriking as a final operation.

Cylindrical workpieces with wide flanges are troublesome to draw because of excessive wrinkling or fracturing in the sidewall due to lack of metal flow. Even though the metal is restrained by a blankholder, it is difficult to obtain acceptable flatness without special procedures.

Wide flanges on relatively large workpieces can be made flat by coining after drawing. Another means of dealing with wrinkling, when design permits, is to provide ribs in the flange. This controls the wrinkling by allowing space for the excess metal. Ribs are usually spaced radially around the flange, although circular, concentric ribs also are effective.

Rectangular, boxlike workpieces that have flanges are difficult to redraw in such a manner that the flange is unaffected in redrawing operations. Therefore, it is common practice to draw the part first to a shallower depth and with larger bottom radii than needed for shaping the final contour. The part is then re-formed in a final operation.

Asymmetrical workpieces that have flanges are often difficult to draw, particularly when neither draw beads in the die nor ribs in the workpiece can be permitted. Under these conditions, considerable development is usually required to determine the blankholder pressure that will result in the desired metal flow without using a larger blank than necessary.

Drawing of Hemispheres

In the drawing of a hemisphere, metal flow must be closely controlled for balance between excessive thinning in one area and wrinkling in another. In the top illustration in Fig. 16, the punch has begun to stretch the round blank, which is restrained by the blankholder, and the crown section of the hemisphere is being formed. At this stage, the crown section is subjected to biaxial tension, which results in metal thinning. With correct pressure on the blankholder, thinning is in the range of 10 to 15%. More than 15% thinning is likely to result in fracture of the crown section. In the top illustration in Fig. 16, the portion of the blank under the blankholder has not begun to move.

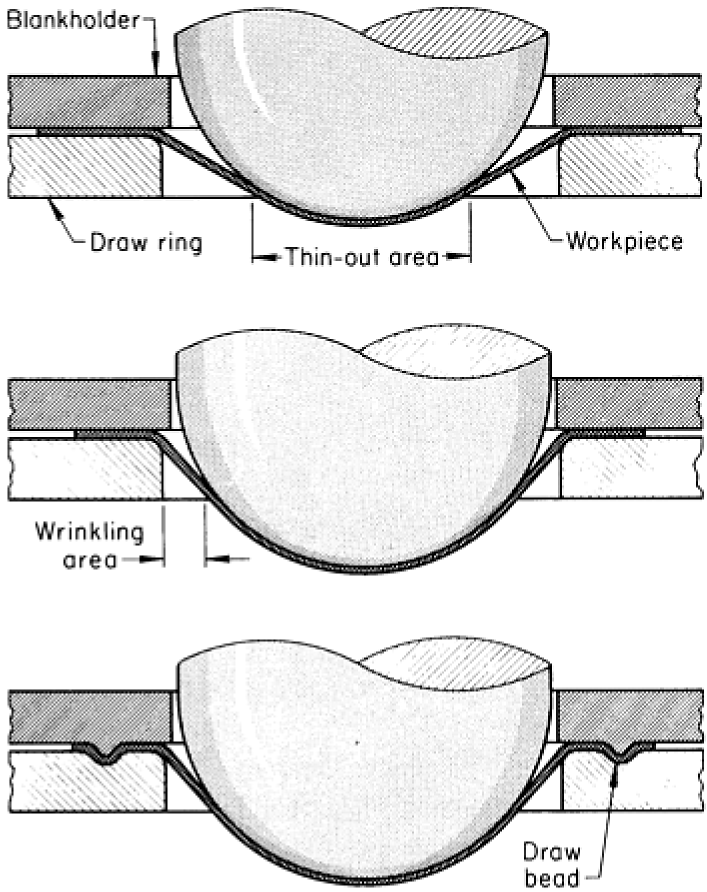

Fig. 16 Drawing of a hemisphere with and without a draw bead. See text for more information.

As the drawing operation continues, the metal begins to move from the blankholder, and a different problem develops (center illustration, Fig. 16). Here the metal has been drawn into a partial hemisphere with unsupported metal in a tangential slope between the punch and the clamped surface. Unlike the drawing of straight-sided shapes, the wide gap (wrinkling area, Fig. 16) prevents the use of the draw ring bore as the means of forcing the metal against the punch surface; therefore, the probability of wrinkling increases. Because the metal cannot be confined between the punch and die, wrinkling is likely to occur in this area.

To prevent wrinkles, the metal must flow from the flange area and, at the same time, must be securely held in tension. This requires an additional stretching force, derived from the portion of the blank that remains clamped. The area of metal between the clamping surfaces is gradually reduced as the punch advances, but the draw radius offers some resistance because the metal must follow a sharper bend as it moves into the die.

One means of controlling wrinkling is by the use of draw beads, as shown in the bottom illustration in Fig. 16. Another means is by a sharp draw radius. Small radii are susceptible to metal pickup and, depending on sharpness, can produce undesirable circumferential grooves in the hemisphere if the punch does not move at a steady rate.

Reducing Drawn Shells

Necking and nosing are used for reducing the diameter of a drawn cup or shell for a part of its height.

Necking. By the die reduction method, the work metal is forced into compression, resulting in an increase in length and wall thickness. The thicknesses of a shell before and after necking are related by:

$$t_2 = t_1 \sqrt{\frac{d_1}{d_2}} \quad \textbf{(Eq 9)}$$

and heights before and after necking by the formula:

$$h_2 = h_1 \sqrt{\frac{d_1}{d_2}} \quad \textbf{(Eq 10)}$$

where t_1 is the shell thickness before necking, t_2 is the shell thickness in the necked area after necking, d_1 is the mean diameter of the shell before necking, d_2 is the mean diameter after necking, h_1 is the unit of height before necking, and h_2 is the unit of height after necking.

Figure 17 shows the flow of metal in a necking operation. As the metal flows, paths of least resistance are taken. Therefore, the actual values for t_2 will be less, and for h_2 greater, than those calculated from Eq 9 and 10.

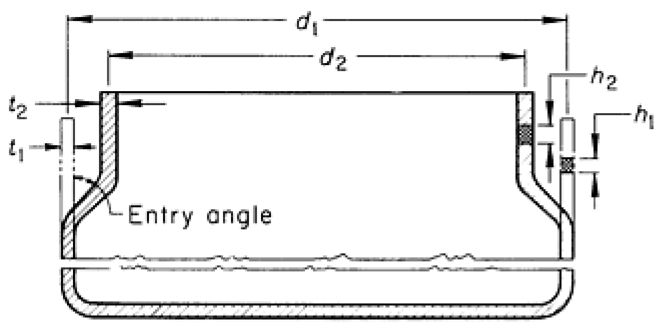

Fig. 17 Flow of metal in the reduction of a drawn shell by necking. See text for details.

Necking results are uniformly better if the workpiece has been slightly cold worked. This provides added strength to resist bulging in the column section and buckling in the section being reduced. The entry angle on the necking die is important because the probability that the metal will collapse is decreased as the angle with the vertical becomes smaller. This angle should be less than 45° (Fig. 17). If the angle is greater than 45°, a series of reductions may be necessary with localized annealing between reducing operations. With a die entry angle less than 45°, thin-wall tubes can be reduced as much as 15% in diameter; thick-wall tubes can be reduced as much as 20%.

Nosing reduces the open end of a shell by tapering or rounding the end (usually by cold reduction) and is primarily used in making ammunition. Shells are often machined before, instead of after, nosing. Shells are usually cold reduced as much as 30% of their original diameter by nosing.

Ironing is the intentional reduction in wall thickness of a shell by confining the metal between the punch and the die wall. When ironing occurs, the force needed to displace the punch often increases to a secondary maximum in the force-displacement curve. The second force maximum can be of such magnitude that the shell will break. However, after ironing has started and metal has been wrapped around the punch, the force is uniform and frequently less than that for redrawing operations.

Ironing is seldom used with redrawing operations unless the amount of wall thinning is relatively small, because it results in excessive die wear, causes workpiece breakage, and increases press tonnage requirements. If a shell with constant wall thickness is needed, however, it can be obtained only by ironing.

Deep Drawing

Expanding Drawn Workpieces

There are several methods for expanding portions of drawn workpieces in a press. Because the wall thickness is reduced during expansion, it is not advisable to increase the diameter for ductile metal shells (such as low-carbon steel or copper) more than 30%. If a diameter increase of more than 30% is required, the operation should be done in two or more stages, with annealing between stages.

Expanding With a Punch. In expanding with a punch, as in Fig. 18, the portion to be expanded is first annealed. Localized annealing, instead of annealing the entire cup, helps retain strength in the remainder of the cup. Regardless of whether or not the strength is required in the finished part, maximum column strength is desirable to prevent buckling as the punch enters the cup.

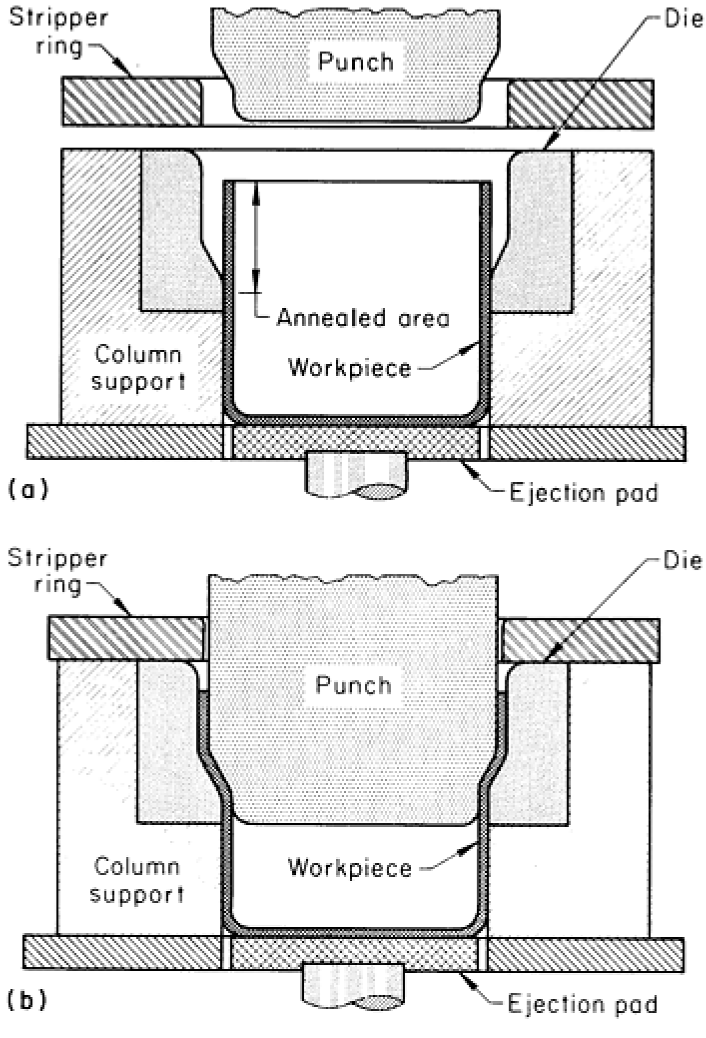

Fig. 18 Expansion of the mouth of a drawn shell with a punch.

After the cup has been placed in the die (Fig. 18a), the punch moves downward and expands the top of the cup (Fig. 18b). During the return stroke, the workpiece is stripped from the punch by the stripper ring and is ejected from the die by the ejection pad.

In an expanding operation of this kind, die dimensions are predetermined within reasonably close limits during the design stage. However, the possibility of later design changes must always be considered. Depending on the shape and location of the expanded section, a height reduction of the cup may occur that will require some modification of the die and punch after tryout.

Expanding with segmented dies is often used for forming sidewalls of drawn shells or sections of tubing. The forming segments are contracted by compression springs and expanded radially by a tapered punch. The die is made of two or more segments held apart by compression springs. As the press ram descends, cams move the die segments together. The punch then moves the inner segments outward, thus forming the contours in the sidewall. The presence of gaps between the forming segments is one of the disadvantages of this method and is the reason an alternative method, such as rubber-pad forming, is sometimes selected.

Deep Drawing of Pressure Vessels

Various grades of steel--many of them high-strength alloys--are deep drawn to make cylinders for compressed gases. Joints (when they are made) are around the girth of the vessel, rather than longitudinal. The integrity of the vessel is critical. Commercial-quality hot-rolled steels in the as-rolled condition are generally used. The work metal is usually induction heated or induction annealed to minimize scale.

For propane gas, pressure tanks must have high strength at minimum weight. In one application, the weight of such a tank was reduced from 59 to 32 kg (130 to 70 lb) by changing from 1025 steel to a high-manganese deep-drawing steel (Fe-0.2C-1.6Mn-0.025P-0.3S). Before drawing, the high-manganese steel had a minimum yield strength of 345 MPa (50 ksi) and a minimum tensile strength of 483 MPa (70 ksi).

Bottles for dispensing small quantities of liquefied gases or gases under high pressure are commonly made of drawing quality low-carbon steel to take advantage of the improved mechanical properties produced by deep drawing. The bottles range in size from 12.7 mm ($\frac{1}{2}$ in.) in diameter by 32 mm ($1\frac{1}{4}$ in.) long to 38 mm ($1\frac{1}{2}$ in.) in diameter by 152 mm (6 in.) long.

Deep Drawing Using Fluid-Forming Presses

Fluid forming (also termed hydroforming) is a deep drawing process that uses only one solid die half. Forming pressure is applied by the action of hydraulic fluid against a flexible membrane, which forces the blank to assume the shape of the rigid tool.

Fluid forming can be used for deep drawing and in fact offers advantages over other forming methods. One of these is that the draw radius can be varied by changing the pressure of the hydraulic fluid during the forming operation. This makes it possible to have, for example, a large draw radius at the start of the operation that decreases as the draw continues. Thus, reductions of up to 70% in a single pass are possible when drawing cylindrical cups; for rectangular shaped parts, a height of six to eight times the corner radius can be obtained in a single operation.

Presses for fluid forming sometimes use a telescoping ram system. Figure 19 shows a schematic of one type of press used for fluid forming. Figure 20 illustrates the deep drawing process on a press of this type. More information on fluid-forming equipment and processes is available in the article "Rubber-Pad Forming" in this Volume.

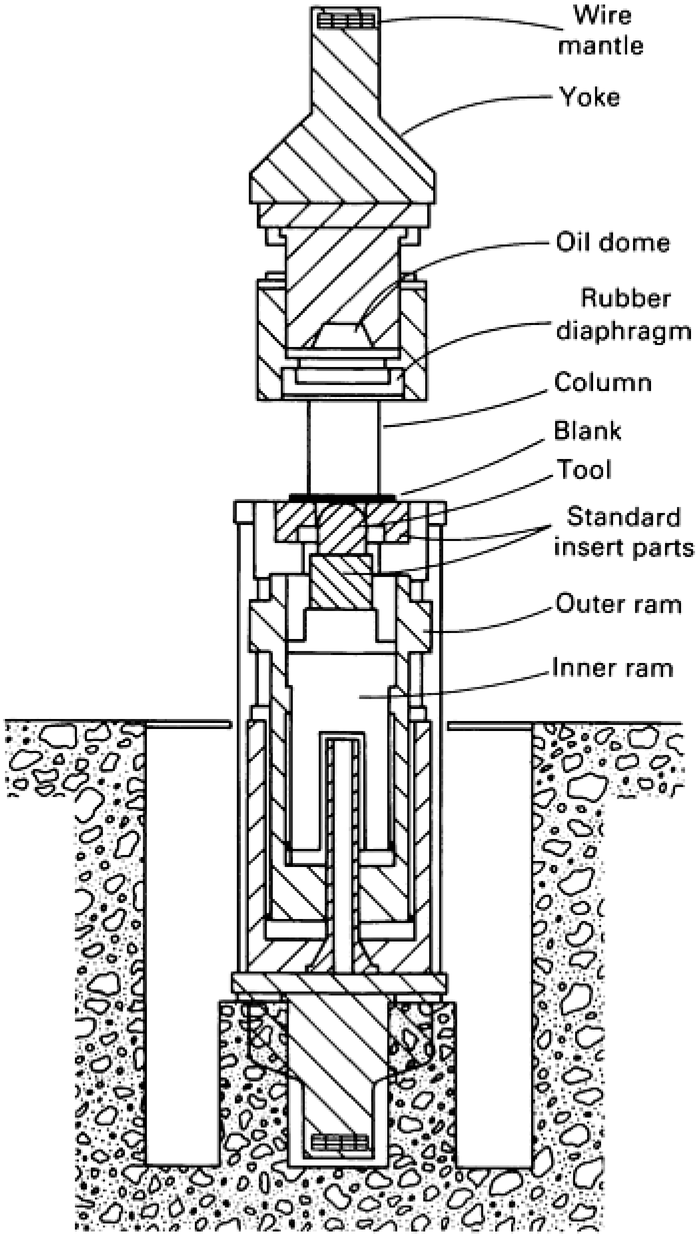

Fig. 19 Schematic of one type of fluid-forming press used for deep drawing.

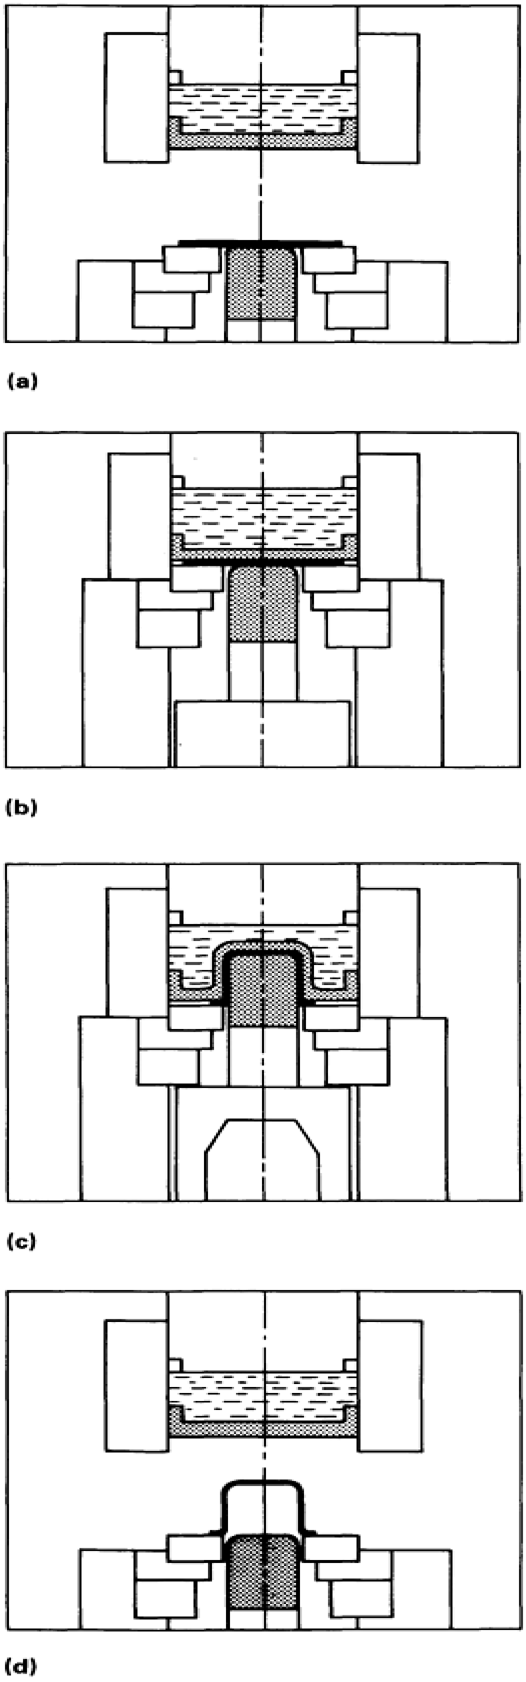

Fig. 20 Deep-drawing process using the fluid-forming press shown in Fig. 19. (a) The blank is placed on the blankholder. (b) The outer ram moves upward, carrying the blank. (c) Oil is pumped into the inner ram system, pressing the punch upward. (d) Outer ram is returned to its initial position, and the punch is retracted to allow removal of the formed part.

Ejection of Workpieces

In drawing operations, the drawn workpiece may adhere to either the punch or the die. Adherence is increased by depth of draw, straightness of workpiece walls, and viscosity of lubricant. The simplest means of ejecting a small workpiece is by compressed air through jets in the punch or the die. Timed air blast is widely used for ejecting relatively small workpieces--for example, where cup diameter is no greater than 102 to 127 mm (4 to 5 in.). In some production drawing operations, the workpiece is ejected by compressed air, and another timed blast of air from the side removes the piece by sending it down a chute or into a container. However, for larger workpieces or for those that are deep, some other means of ejection is required.

Mechanical methods of ejection include:

- Edge stripping by means of a lip on the draw ring (Fig. 21a) or by a spring-actuated stripper (Fig. 21b)
- The use of a blankholder in combination with an upper ejector (Fig. 22)
- The use of a lower ejector in combination with an upper stripper ring (Fig. 23)

Numerous other mechanical methods using cams or links have been devised to meet specific requirements. These methods are usually modifications of those described above. For example, thin shells are sometimes stripped from punches near the top of the press stroke by a cam-actuated rod that extends through the punch. This method is often used to avoid damage to the open end of the shell, which can occur when the piece is ejected by other methods. The major factors influencing the method of ejection are workpiece design (especially the presence or absence of a flange), work metal composition and thickness, and the type of equipment available.

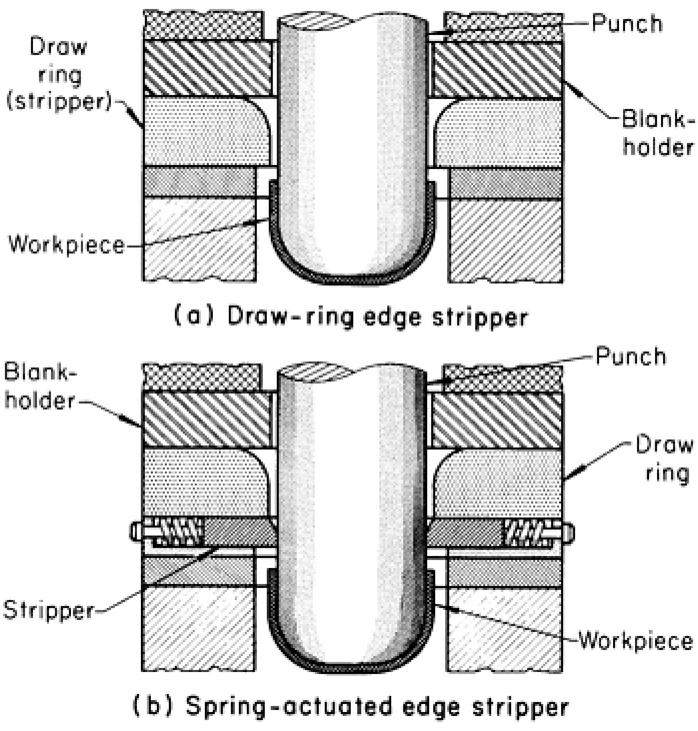

Fig. 21 Setups showing two methods of ejecting a drawn workpiece through the bottom of the press by edge stripping.

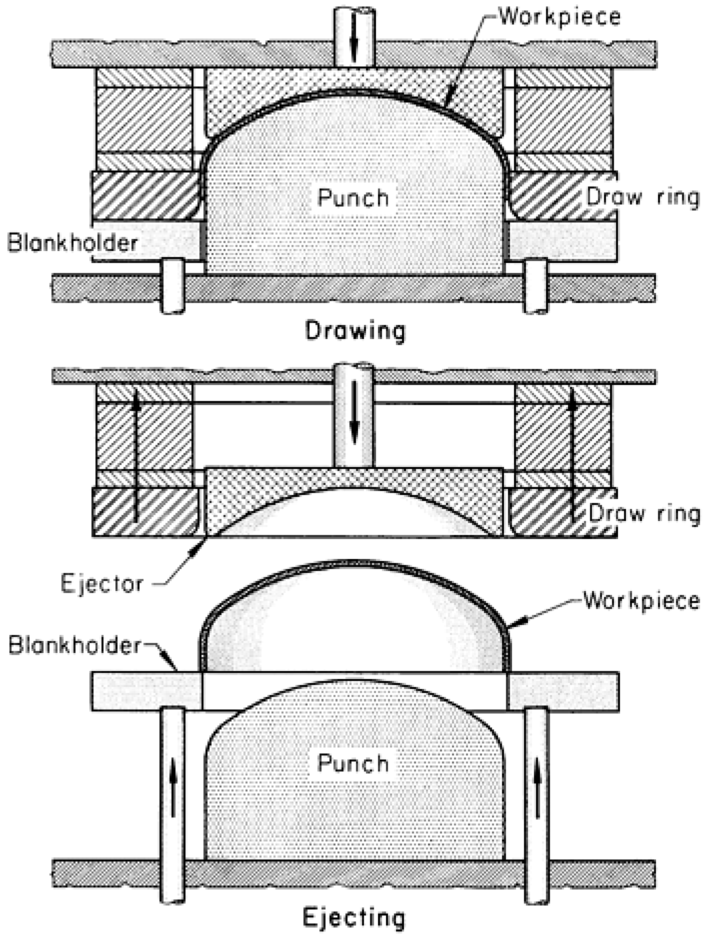

Fig. 22 Use of a blankholder and ejector for stripping of a drawn workpiece from inverted dies.

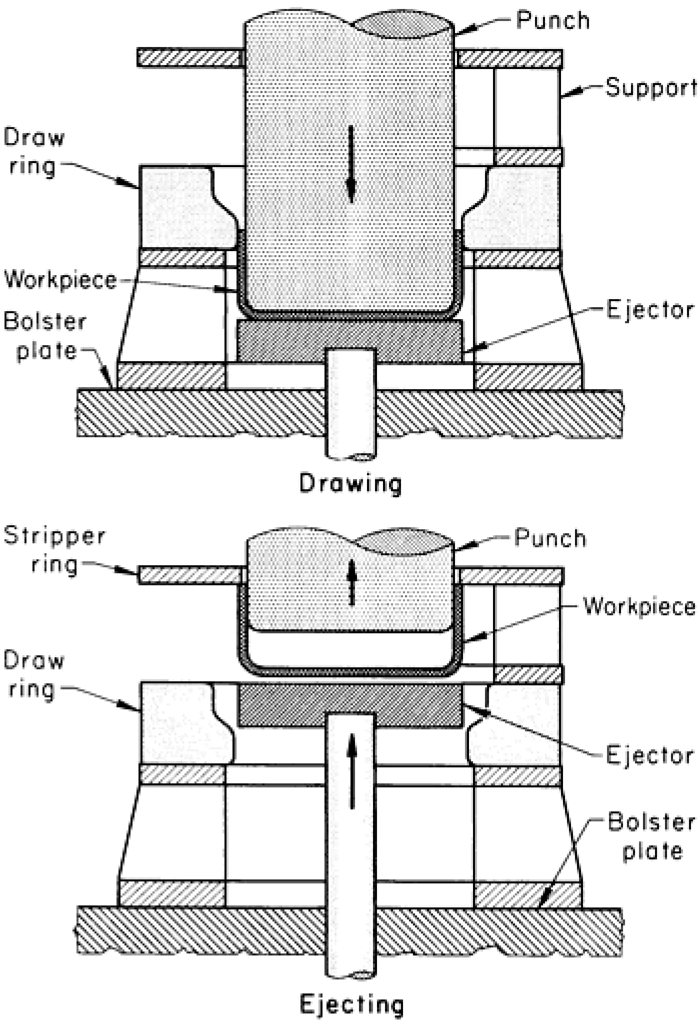

Fig. 23 Setup in which drawn workpiece is lifted from the die by an ejector and is stripped off the punch by a fixed stripper ring.

Trimming

Trimming in a lathe (using a cutting tool), roll trimming in a lathe, rotary shearing, die trimming (regular and pinch), and trimming on special machines are the methods most commonly used for trimming drawn workpieces.

Methods for Specific Shapes. Cylindrical workpieces such as the one shown in Fig. 24(a) can be trimmed by at least four different methods:

- In a lathe, with a cutting tool, but production cost is high
- By roll trimming in a lathe or in a rotary shear. Production cost is lower than that for trimming with a cutting tool, but the finish of a rolled edge is poor and maintenance cost of the rolls is high
- By pinch trimming in the press at the bottom of the drawing stroke. This involves almost no increase in production cost, but requires a more expensive die. This method produces a thinned edge at the trim line, which may be unacceptable
- In a shimmy die or trimming machine, but production quantities must be high to warrant the investment

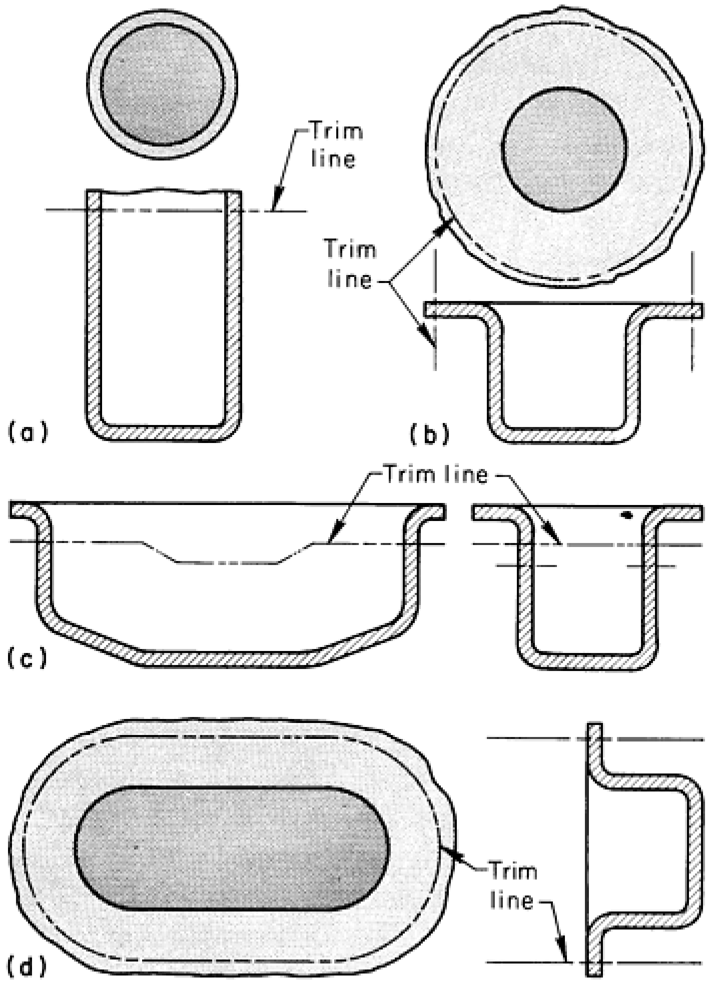

Fig. 24 Typical trim lines on drawn parts. See text for details.

Cylindrical workpieces with flanges, such as the one shown in Fig. 24(b), can also be trimmed in a lathe, although shapes such as this are ideal for trimming in a die and can be die trimmed for about 5% of the cost of trimming in a lathe. Rotary shearing can also be used for trimming circular drawn parts with flanges if the dimensional tolerance is 0.76 mm (0.030 in.) or more.

Drawn workpieces with an irregular trim line, as in Fig. 24(c), can be trimmed in a die for low-production requirements, or with a shimmy die or trimming machine for high-production requirements. The cost of a trimming die is about half that for a special trimmer (excluding the cost of the original machine). However, the trimming cost per piece with the special trimmer will be only about half the per-piece cost with multiple dies, and the trimmed edges will be better.

Flanged workpieces such as the one shown in Fig. 24(d) can be trimmed in a die for 5% of the cost of trimming in a rotary shear. In low production, drawn workpieces of such a shape are frequently trimmed in a nibbler and filed to conform to a template. This means of trimming costs up to 60 times as much as die trimming.

Developed Blanks Versus Final Trimming

The most important factor that influences a choice between using a developed blank or a final trimming operation is whether or not the shape of the drawn edge is acceptable. A semideveloped blank is sometimes necessary to draw an acceptable part, and the edge must be trimmed to meet dimensional tolerances.

The next consideration is the cost of blanking versus final trimming. This would include the adaptability of the process to the available equipment, based on expected production requirements. The principal advantage of a developed blank is that strip or coiled work metal can be used. The use of strip eliminates the need for shearing the work metal to a rough-blank shape, as is sometimes required when final trimming is used. The developed-blank approach is usually more economical than final trimming because a blanking die is frequently less expensive than a final-trimming die.

When using developed blanks, the draw dies are made, and several blanks are drawn to select the optimal developed shape before the blanking die is made. This causes a delay in placing the draw die into production. However, with proper planning and scheduling, this should not be a problem.

Another disadvantage of developed blanks occurs when variations in work metal properties and thickness are sufficient to affect the uniformity of the drawn workpiece. Under these conditions, closer tolerances are obtained by final trimming. It is possible to develop blank contours accurately enough so that the outline of the drawn part is within tolerance, thus avoiding a final-trimming operation.

Cleaning of Workpieces

In general, the more effective the lubricant, the more difficult it is to remove. Therefore, an overly effective drawing lubricant should be avoided.

The cleaning method depends on the work metal composition, the lubricant, the degree of cleanliness required, workpiece shape, and sometimes the length of time between application of lubricant and its removal. Some metals will be attacked by cleaners that are not harmful to others. For example, strong alkaline cleaners are suitable for cleaning steel and many other metals, but they are likely to attack aluminum alloys. Detailed information is available in the articles on the surface engineering of specific metals in *Surface Engineering*, Volume 5 of the *ASM Handbook.*

Unpigmented oils and greases can be removed from steel workpieces by several simple shop methods, including alkaline dipping, emulsion cleaning, and cold solvent dipping. These methods are usually sufficient for in-process cleaning. However, if the workpieces are to be painted, a more thorough cleaning by emulsion spray or vapor degreasing is required. For plating, electrolytic cleaning plus etching in acid (immediately prior to plating) is required. These latter methods usually follow a rough cleaning operation.

Pigmented drawing lubricants and waxes greatly increase cleaning problems. At a minimum, in-process cleaning usually requires slushing in a hot emulsion or vapor degreasing. If the lubricant is not removed for several days after application, soaking in a hot alkaline cleaner or an emulsion cleaner may be required. Particularly for complex workpiece shapes, some hand or power brush scrubbing may be needed. If the workpieces are to be painted or plated, additional cleaning will be required, as described above. Detailed information on the choice of cleaning method is available in the article "Classification and Selection of Cleaning Processes" in *Surface Engineering*, Volume 5 of the *ASM Handbook.*

Dimensional Accuracy

Dimensional accuracy in deep drawing is affected by the variation in work metal thickness, variation in work metal condition (chiefly hardness), drawing technique (particularly the number of operations), accuracy of the tools, rate of tool wear, and press condition. Control of dimensions begins with the purchase of sheet to closer-than-commercial thickness tolerance, which adds substantially to the cost. Close control of sheet hardness also costs more. In-process annealing may be required to minimize springback or warpage; it will not be needed if tolerances are more liberal. Annealing, handling, and cleaning operations are costly.

As tolerances become closer, it is often necessary to add more die stations to minimize the amount of drawing in any one station. Close tolerances may demand restriking operations that would not be necessary for parts with more liberal tolerances. Additional operations increase tool costs and decrease productivity, thus increasing the cost per piece.

The initial cost of tools increases as tolerances become closer because of greater cost for precision machining and grinding or more costly tool materials. In addition, tool life before reconditioning and total tool life decrease as tolerances become closer. Maintenance costs and downtime of presses are also greater.

When required, extremely close tolerances can be maintained on some parts (Fig. 25). In most deep drawing, the accuracy shown in Fig. 25 is either impossible or impractical. The more usual practice when dimensional accuracy is important is to check critical dimensions at specified intervals during a production run and to plot the variation. Data from this method of quality control show the capabilities of the process under shop conditions and the magnitude of drift during a production run. When results (either initially or during a run) are unacceptable, one or more of the controls discussed at the beginning of this section can be applied.

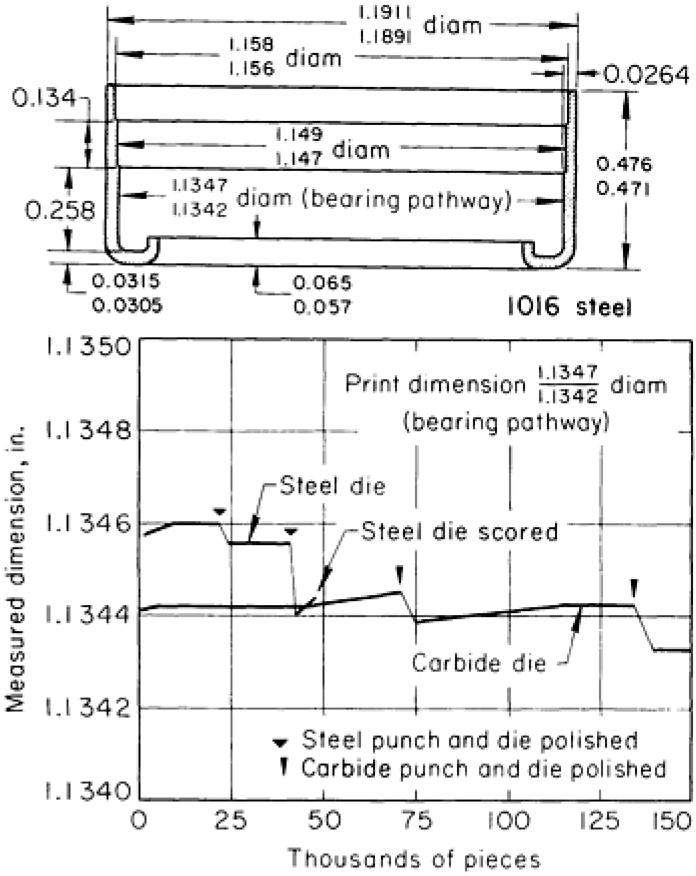

Fig. 25 Variation in bearing pathway diameter of a needle bearing cup drawn using high-speed tool steel and carbide dies.

Safety

Deep drawing, like other press operations, involves potential hazards to operators and other personnel in the work area. No press, die, or auxiliary equipment can be considered ready for operation until these hazards are eliminated by the installation of necessary safety devices. Operators should be properly instructed in safe operation of equipment.

Introduction

STRETCH FORMING is the forming of sheet, bars, and rolled or extruded sections over a form block of the required shape while the workpiece is held in tension. The work metal is often stretched just beyond its yield point (generally 2 to 4% total elongation) to retain permanently the contour of the form block.

The four methods of stretch forming are:

- Stretch draw forming (Fig. 1a and b)
- Stretch wrapping, also called rotary stretch forming (Fig. 1c)
- Compression forming (Fig. 1d)
- Radial draw forming (Fig. 1e)

These methods are discussed separately in subsequent sections of this article.

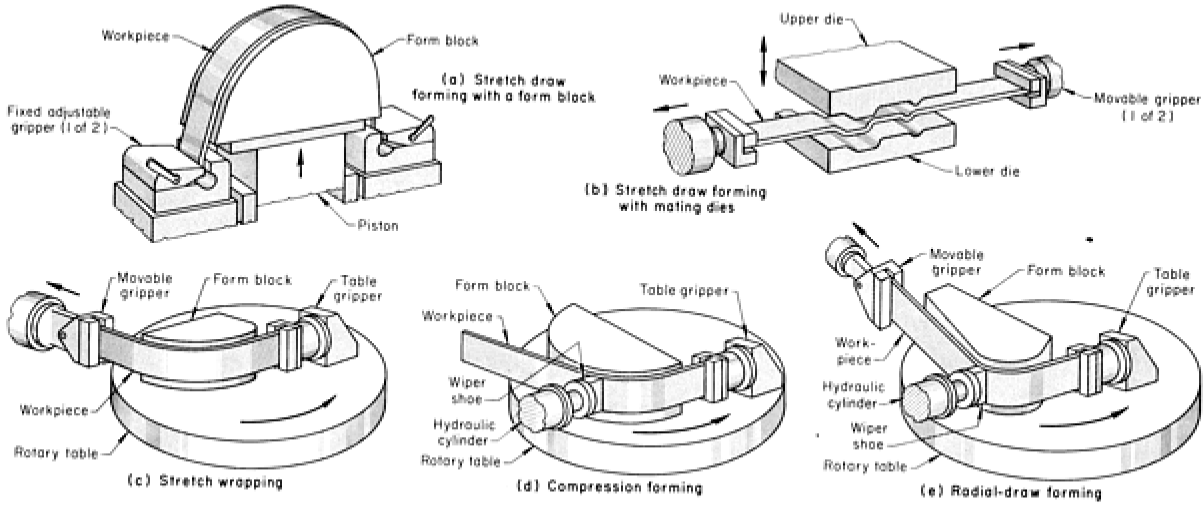

Fig. 1 Fundamentals of the techniques involved in the four methods of stretch forming

---

Applicability

Almost any shape that can be produced by other sheet-forming methods can be produced by stretch forming. Drawn shapes that involve metal flow, particularly straight cylindrical shells, and details that result from such compression operations as coining and embossing cannot be made. However, some embossing is done by the mating-die method of stretch draw forming (Fig. 1b).

Stretch forming is used to form aerospace parts from steel, nickel, aluminum, and titanium alloys and other heat-resistant and refractory metals. Some of these parts are difficult or impossible to form by other methods--for example, the titanium alloy gas-turbine ring shown in Fig. 2. The procedure for making such a ring is described in Example 5 in this article.

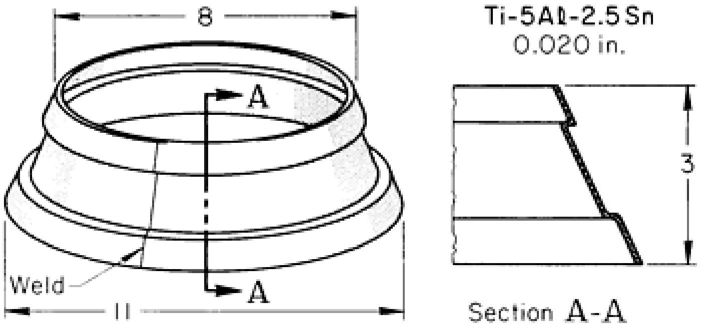

Fig. 2 Titanium alloy gas-turbine ring that was produced by compression forming. Dimensions given in inches

Stretch forming is also used to shape automotive body panels, both inner and outer, and frame members that could be formed by other processes but at higher cost. An example is the automobile roof shown in Fig. 3, which was stretch draw formed using a blank that weighed 2.9 kg (6.4 lb) less than would have been needed for a conventional press-forming process. Architectural shapes and aerospace forms that call for compound curves, reverse bends, twists, and bends in two or more planes are also produced by stretch forming.

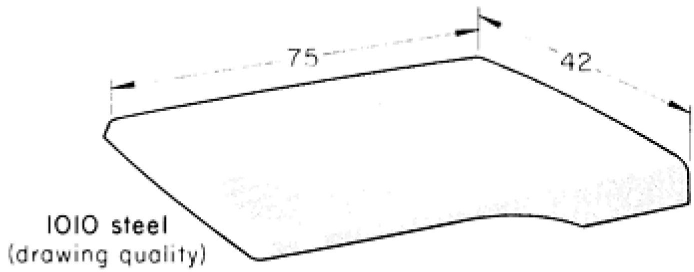

Fig. 3 Stretch draw formed automobile roof. Dimensions given in inches

Advantages. Stretch forming has the following advantages over conventional press-forming methods:

- About 70% less force is needed than that required for conventional press forming
- Stretch forming can reduce material costs by as much as 15%. Although allowance must be made on the stock for gripping, it is gripped on two ends only. The allowance for trimming is usually less than that in conventional press forming
- Because stretch forming is done on the entire area of the workpiece, there is little likelihood of buckles and wrinkles. Tensile strength is increased uniformly by about 10%
- Hardness is increased by approximately 2%
- Springback is greatly reduced. There is some springback, but it is easily controlled by overforming
- Residual stresses are low in stretch-formed parts
- Form blocks are made of inexpensive materials, such as wood, plastic, cast iron, or low-carbon steel, and are about one-third the cost of conventional forming dies. If the workpiece is formed hot, the dies must be able to withstand the forming temperature. However, most stretch forming is done at room temperature
- Changeover is simple. Only one form block and two sets of grippers are involved. To make the same part from a different metal or another stock thickness, the same form block and grippers are used, but the tension of the stretch mechanism is adjusted

Limitations. Stretch forming is subject to the following limitations:

- It is seldom suited to progressive or transfer operations
- It is limited in its ability to form sharp contours and reentrant angles. It is at its best in forming shallow or nearly flat contours
- If the piece is not pinched between mating dies, there is no opportunity to coin out or iron out slight irregularities in the surface of the metal
- In some applications, especially in stretch wrapping, the process is slower than competitive processes, and it is not suited to high-volume production. However, stretch draw forming with mating dies can be done as rapidly and automatically as conventional press operations. In fact, punch presses are used with dies incorporating draw beads or other means of gripping the blank in order to perform some stretch-forming operations
- Metals with yield strength and tensile strength very nearly the same, such as titanium, necessitate the use of automatic equipment for determining the amount of strain for uniform results
- Optimal results are achieved with rectangular blanks. The aircraft industry uses trapezoidal blanks, but gives greater attention to each piece than is warranted in high-volume production
- Deep forming in the direction of the free edges is not practical

Machines and Accessories

Stretch wrapping, compression forming, and radial draw forming use rotary tables (some with sliding leaves) for mounting the form blocks, a ram gripping and tensioning or wiping device, and a mechanically or hydraulically actuated table gripper (Fig. 4). Machines used for these operations have capacities to 8900 kN (1000 tonf).

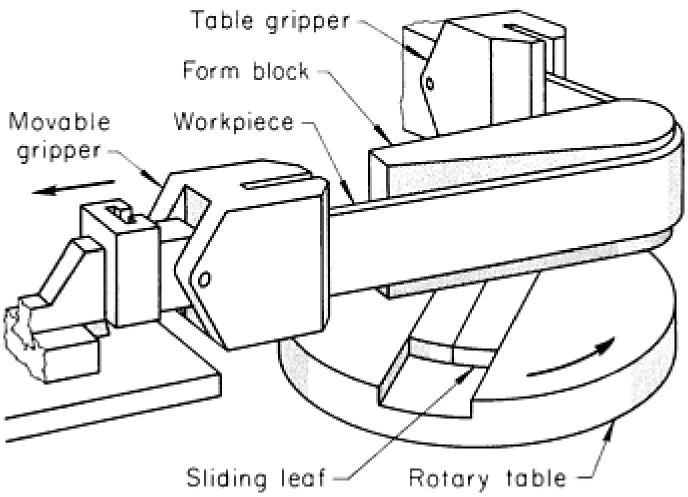

Fig. 4 Stretch-forming machine with rotary table and sliding center leaf

Stretch draw forming is done in three types of machines. In one type, the form block mounted on a hydraulic cylinder is pushed into the blank, which is held in tension by a pair of pivoting grippers. In another type, the form block is fixed to the table, and the blank is drawn around it by a pair of grippers actuated by slides or a hydraulic cylinder. The third type of machine is a single-action hydraulic press equipped with a means of closing and moving a pair of grippers (see Fig. 7); a mating die is used instead of a form block. The hydraulic presses ordinarily used in stretch draw forming have capacities of 1800 to 7100 kN (200 to 800 tonf).

Accessory Equipment. Grippers and wiping shoes or rollers are made to conform to the rolled or extruded shape that is to be stretch formed. Jaws used for gripping sheet in stretch draw forming can be segmented or contoured to apply equal stretch to all parts of the sheet as it is formed.

The vertical adapter shown in Fig. 5 is used with a rotary table; it is fastened to the hydraulic cylinder used for applying tension to the blank. The adapter allows wiper shoes, rollers, and grippers to move up or down as needed in order to accommodate work with bends in two or more planes. Lead screws or hydraulic cylinders position the grippers or wiping devices at the correct position for the forming operation (see Examples 5 and 6).

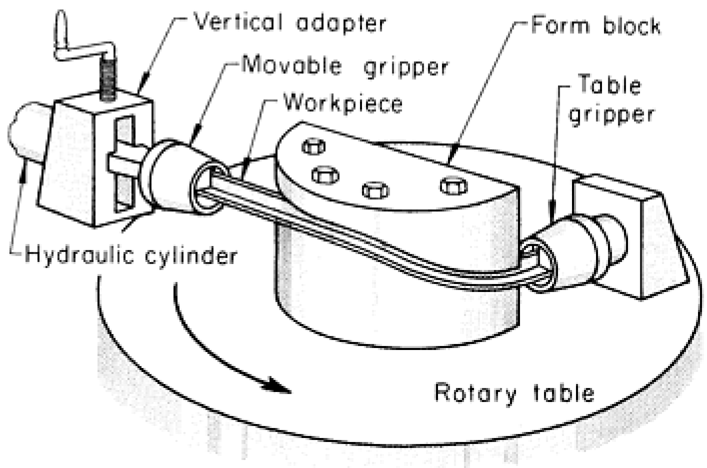

Fig. 5 Use of a vertical adapter on the tension unit to accommodate work with bends in two or more planes

A yield detector and tension-control device (Fig. 6) provide a means of automatically applying the same amount of stress to every workpiece in a production lot. This is important with metals (for example, titanium) that have yield strength and tensile strength too close for ordinary control of tension for stretch forming (see the article "Forming of Titanium and Titanium Alloys" in this Volume). With this type of control, scrap in the stretch forming of titanium can be reduced to 2%.

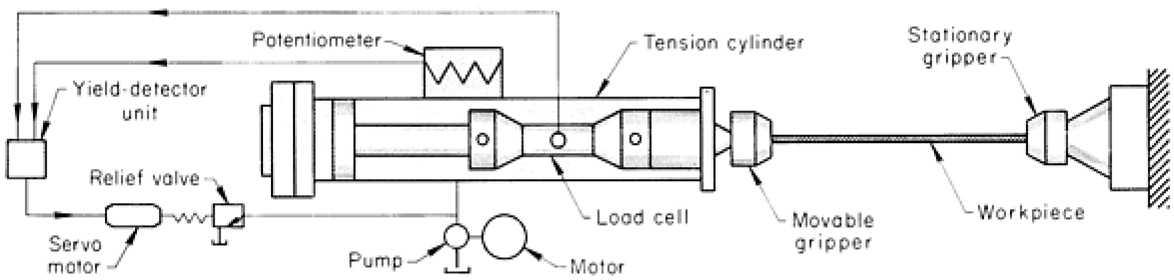

Fig. 6 Components and signal-flow diagram of an automatic tension-control system used in stretch forming

The tension control uses two inputs in a null system for its output signal. One input comes from a load cell that gives a signal proportional to the stretch force on the workpiece. The other signal comes from a potentiometer that measures the elongation of the workpiece. As long as the signals are proportional, the metal is not stretched beyond its yield point, and the two inputs balance. When the yield point is reached, the input from the load cell stops increasing or increases at a much lower rate, while the potentiometer input continues to rise. This upsets the null balance, and an output signal is given, which can be interpreted as percentage of strain beyond the yield point.

Table restretch units are small short-stroke hydraulic cylinders and clamps that can be bolted to the rotary table to give a final stretch set to workpieces that need to be stretched from both ends or restretched after heat treatment. The capacity of a table restretch unit is usually equal to that of the main tensioning gripper.

Stretch Draw Forming

Stretch draw forming is done with either a form block or a mating die.

The Form-Block Method. Bars and structural shapes, although usually radial draw formed, can be stretch draw formed by the form-block method. Also known as drape forming, the form-block method uses either a fixed or a moving form block. A fixed form block is attached to the machine base. Each end of the blank is held by a gripper attached to a hydraulic cylinder. The grippers move to stretch the blank over the form block. Alternatively, the moving form block is attached to a hydraulic piston. A blank is held by grippers while tension is applied to it, and the form block then moves to form the part, as shown in Fig. 1(a).

The mating-die method uses a two-piece die mounted in a single-action hydraulic press (Fig. 7). This method combines the advantages of stretch forming and conventional press forming. The stretch forming sets the contours of moderately formed workpieces, and the press forming gives definition to sharply formed contours, such as beads or feature lines on automobile body parts.

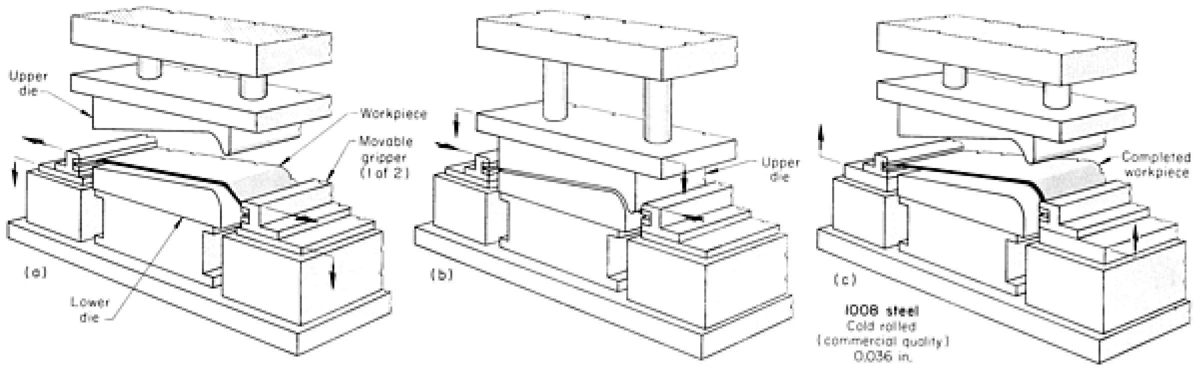

Fig. 7 Production of an automobile rear-deck lid in a stretch draw forming press. (a) Sheet metal blank is tensioned by grippers moving apart. Grippers move down, stretching the workpiece over the lower die. (b) Upper die descends onto the workpiece, pressing the metal into both dies to form the part. (c) After forming, the press opens, and the part is released from the grippers.

Grippers preform the blank over the lower die to the curvature of the part (Fig. 7a). There is very little metal flow; the stretching action and the die form the general outline of the part. The upper die then descends to produce the details and to set the contours (Fig. 7b).

Automatic material-handling equipment can be adapted to the machine for production runs. Production rates are comparable to those obtainable for drawing in conventional single- and double-action presses. Stretch draw press tooling for large parts, such as automobile roof panels, weighs only one-third that for a conventional double-action press, as indicated in Table 1.

Table 1 Comparison of conventional and stretch presses

Press	**Capacity**				**Tooling weight**		Press height	
	Punch		**Gripper (blankholder)**					
	kN	**tonf**	**kN**	**tonf**	**kg**	**tons**	**mm**	in.
Conventional	8000	900	5300	600	20,000	22	7320	**288**

Stretch	**2200**	**250**	**760**	**85**	**6300**	**7**	**5100**	**200**

Exposed parts, such as automobile outer body panels, frequently have a maximum surface roughness specification of 1.1 μm (45 μin.), and stretcher strain marks and other defects, which are still noticeable after painting, must be prevented. One method of avoiding strain marks is the use of segmented or curved grippers, which equalize the amount of stretching. The following example describes the production of a rear-deck lid by stretch draw forming with a mating die.

Example 1: Stretch Draw Forming of an Automobile Rear-Deck Lid.

Automobile rear-deck lids were produced in a stretch draw press using mating dies, as shown in Fig. 7. The blanks were commercial-quality cold-rolled 1008 steel 0.91 mm (0.036 in.) thick, 1450 mm (57 in.) wide, and 1600 mm (63 in.) long. Residual mill oil was the only lubricant. The production rate was 360 pieces per hour, and annual production was 400,000 deck lids.

Tension was applied to the sheet by the grippers as they moved apart. (Generally, hydraulic cylinders are used to apply the force in this operation.) The tensioned sheet (still held by the grippers) was then lowered to stretch over the lower die. Finally, the upper die was lowered, pressing the sheet into both dies to form the lid.

The cycle time was 7 s. The finished parts showed uniformly good quality without wrinkles or buckles. Approximately 0.9 kg (2 lb) more sheet steel would have been needed to produce this part in a conventional double-action press.

Lancing. If stretch drawing is used to form severe contours, the stretch limits of the metal may be exceeded in the zones of deep forming, resulting in fracture of the metal. This can be avoided by lancing the metal in areas to be discarded later so that the metal can flow in the severely formed zones. Single-operation production of a truck-cab roof having a combination of gradual curves and sharp contours is described in the following example.

Example 2: Stretch Draw Forming of a Truck-Cab Roof With Reinforcing Beads.

By using stretch draw forming with mating dies, the truck-cab roof panel shown in Fig. 8 was produced in one operation. Panels were formed from cold-rolled drawing-quality aluminum-killed 1008 steel. The blanks were 1520 × 813 × 0.89 mm (60 × 32 × 0.035 in.).

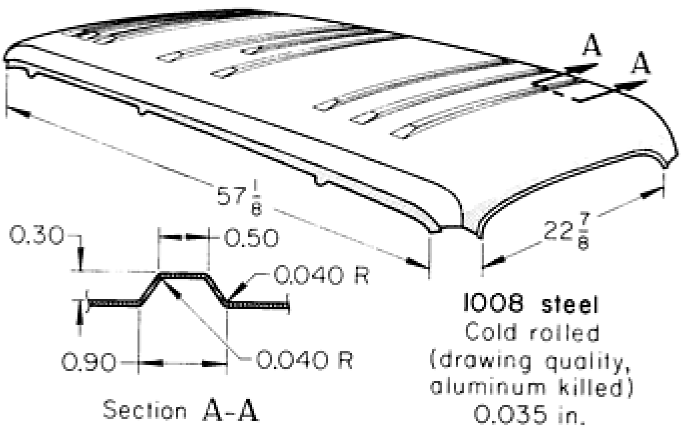

Fig. 8 Beaded truck-cap roof that was stretch draw formed with mating dies. Dimensions given in inches

With automatic material-handling equipment to load and unload the machine, the production rate was 100 to 150 pieces per hour. Annual production was 25,000 pieces.

The forming dies were of cast iron, with flame-hardened surfaces where severe forming occurred. Design changes that would make the dies obsolete were not expected for 4 or 5 years. Radii on the roof beads were 1.0 mm (0.040 in.).

Other examples of stretch draw forming using the mating-die and form-block methods are described in the article "Forming of Aluminum Alloys" in this Volume.

Stretch Wrapping

In stretch wrapping, just enough tension is applied to one end of a workpiece to exceed the yield strength of the material, while the form block revolves into the workpiece with the turning of the table, as shown in Fig. 1(c). The other end of the workpiece is held in a table gripper or clamped to the end of the form block. The hydraulic cylinder applying tension to the workpiece is free to swivel so that the tension is always tangential to the last point of contact. Thus, the work metal wraps in tension around the form block without the scuffing or friction that occurs with other forming methods. The result is an accurately formed piece with little springback; therefore, form blocks can be made to accurate size.

Because there is no scuffing, form blocks can be made of soft metal, wood, or plastic, although common die materials such as cast iron are often used. Form blocks made of hardwood, masonite, and epoxy have also been used. The contour of the form block can vary throughout the bend, and the workpiece will follow it accurately if there are no concave surfaces on the form block.

Form blocks for the stretch wrapping of rolled and extruded sections are machined to the shape of the section as well as the contour of the finished part. Thus, the shaped form block supports the section during forming. Additional support is sometimes needed for open or hollow sections. A segmented filler, a filler made of low-melting alloy, or a strip of easy-to-form metal can provide this support. Return bends can be made by using additional form blocks on sliding leaves of the turntable and by reversing the table direction to produce the part, as shown in Fig. 9.

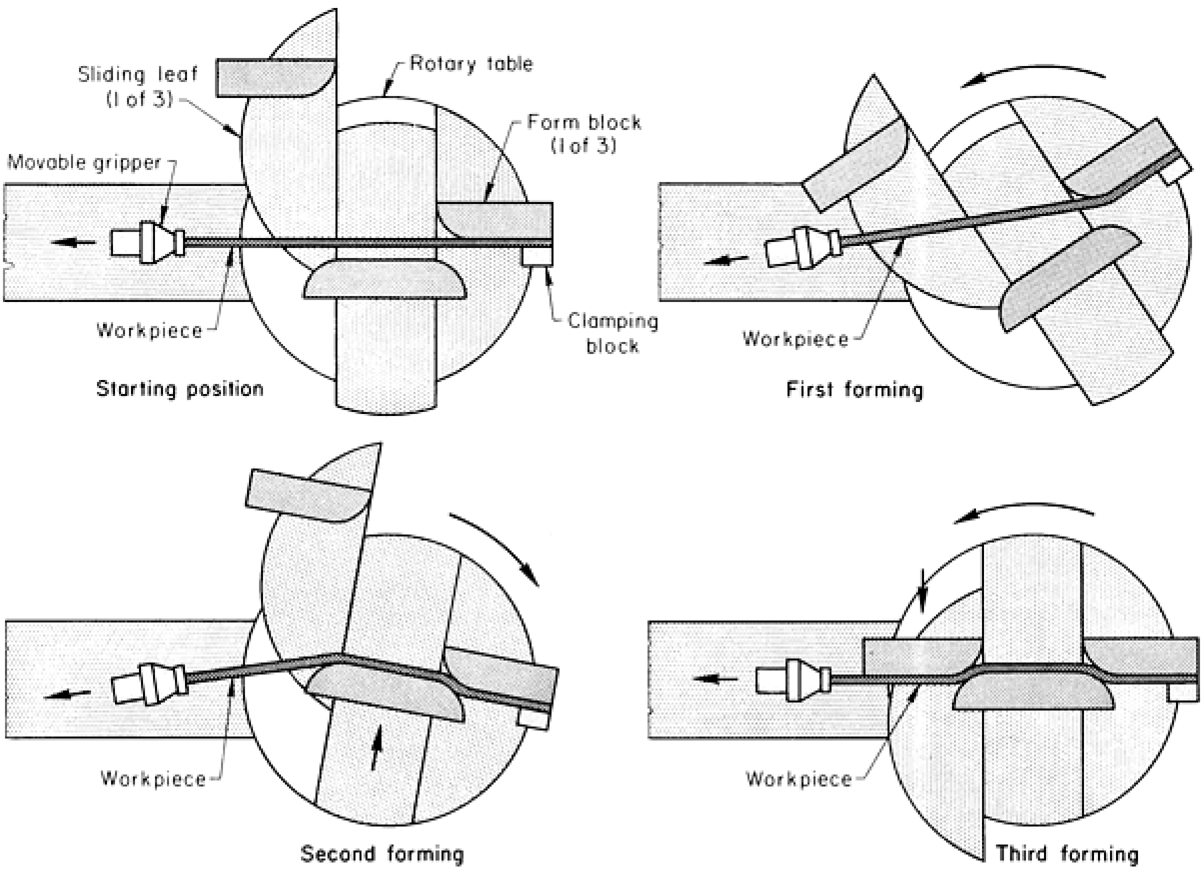

Fig. 9 Stretch wrapping of a part around three form blocks to make two reverse bends

Machines for stretch wrapping consist basically of a variable-speed power-driven rotary table and a double-action pressure-controlled hydraulic cylinder. The form block is bolted to the table. Grippers are connected to the hydraulic cylinder so that tension can be applied to the workpiece, as in Fig. 1(c). The fabrication of a typical part by stretch wrapping is described in the following example.

Example 3: Forming of an Aircraft Leading-Edge Wing Panel by Stretch Wrapping.

A corrugated leading-edge wing panel of aluminum alloy 6061-O was stretch wrapped in a stretch-forming machine with a vertical-axis turntable. The sheet, with corrugations in the direction of airflow, was gripped at each end with grippers shaped to fit the corrugations. The tension applied was slightly above the yield strength of the work metal. The form block, bolted to the turntable, rotated slowly into the workpiece, causing it to form smoothly into the shape of the wing without flattening the corrugations. While the form block was moving in the sheet, the hydraulically restrained gripper maintained tension slightly above the yield point. The form block was made to the required final shape without allowance for springback because only a small amount of springback occurred.

Compression Forming

In compression forming, the workpiece is pressed against the rotating form block instead of being wrapped around it. The process is typically used for maintaining or controlling workpiece cross-sectional dimensions throughout the contour, for bending to radii small enough to exceed the elongation limits of the metal if formed by stretch wrapping, and for bending sections too heavy for the capacity of the available stretch wrap machinery.

Compression forming can generally be done in the same machine as stretch wrapping, but the hydraulic cylinder is used to apply pressure instead of tension to the workpiece. The cylinder is locked in place to keep it from swiveling, and the ram head is furnished with a roller or a shoe to press the workpiece against the form block. A clamp or table gripper holds the end of the workpiece against the form block, and as the table rotates, the shoe or roller on the hydraulic cylinder presses the workpiece into the contour of the block, as shown in Fig. 1(d).

Compression forming can often make bends to a smaller radius than stretch wrapping in a part that has a deep cross section. If the same bend were produced by stretch wrapping, fracturing or overstressing of the outer fibers would result. The total load needed to form large-section pieces, such as crossrails and bumpers, can be as little as 2% of that needed to form them in a punch press. The total energy applied to the workpiece would of course be the same (neglecting efficiency); the smaller compression-forming force is applied for a longer period of time. The wiping shoe or roller can hold the cross-sectional size and shape to close tolerance throughout the contour. Parts that are too heavy in cross section for stretch wrapping can often be compression formed.

Blanks for stretch forming are usually made longer than the finished part so that the surface damaged by the gripper jaws can be trimmed off. However, end details, locating surfaces, and other considerations occasionally necessitate the use of a blank cut to the length of the finished part, and dimensional tolerances still must be met, as in the following example.

Example 4: Use of an Adjustable Form Block to Compression Form a Developed Blank.

Because both ends of the piece shown in Fig. 10 had previously produced details, the part could not be trimmed after forming. Instead of a table gripper or clamp, the blank was fastened to the form block by bolts through two 21 mm ($\frac{13}{16}$ in.) diam holes pierced in one end. The blank was cut slightly shorter than the required length because the length increased from 3.602 to 3.613 m (141.81 to 142.25 in.) during forming.

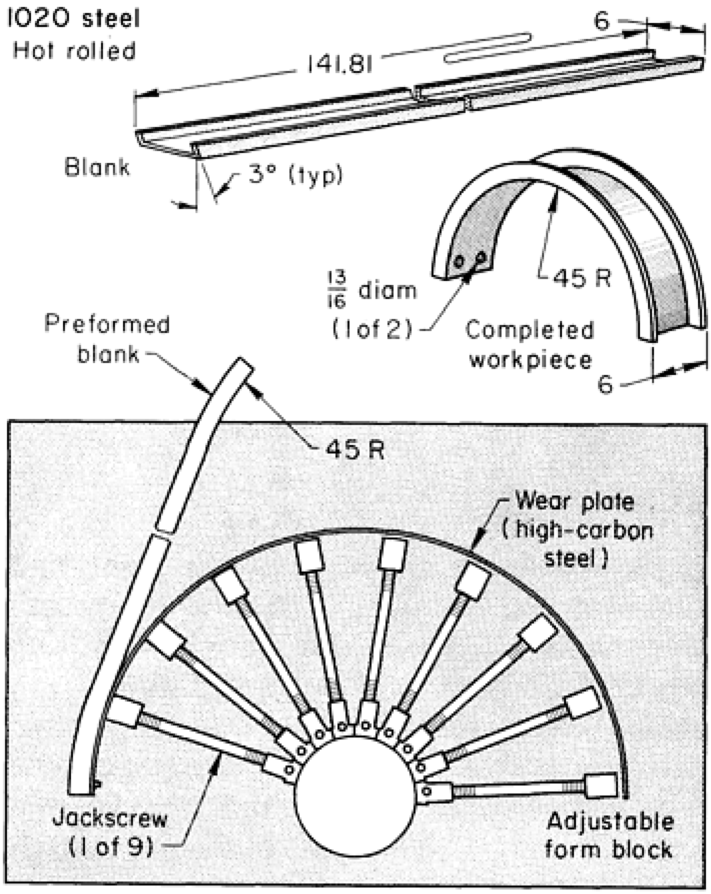

Fig. 10 Steel channel that was compression formed without trim allowance using an adjustable form block. Dimensions given in inches

The 1020 steel structural shape that was being compression formed had considerable springback, which varied with each heat of steel. To obtain uniform results, the form block was made adjustable. As shown in Fig. 10, the wear plate, made of 19 mm ($\frac{3}{4}$ in.) thick by 203 mm (8 in.) wide high-carbon steel, was backed up with jackscrews that could be adjusted to change the effective radius. One end of the wear plate was fastened to the base plate, and the other end was free to move in and out of any position, supported by the jackscrews. When a new lot of steel was delivered, an experimental piece was run to determine springback, and the jackscrews were adjusted accordingly.

The work material was a hot-rolled channel 152 mm (6 in.) wide, weighing 15.6 kg/m (10.5 lb/ft), approximating a 1020 steel in composition. The piece was compression formed on a radial draw former into a half circle with a 1145 mm (45 in.) radius. The two holes in the end of the piece were used to connect this section with a fishplate on one end of a mating piece to form an assembled ring. The sequence of operations was as follows:

- Saw ends with a 3° bevel to developed length (3.602 m, or 141.81 in.)
- Deburr
- Pierce two 21 mm ($\frac{13}{16}$ in.) diam holes
- Form both ends to 1145 mm (45 in.) radius for 152 to 203 mm (6 to 8 in.) of length on a press brake
- Bolt the workpiece to the form block by the two pierced holes. Compression form to 1145 mm (45 in.) radius
- Galvanize after forming
- Flatten as necessary (galvanizing sometimes causes warpage)

A straight mineral oil was used as the lubricant. The overall tolerance on the formed curve was 1.5 mm (0.060 in.) total indicator reading.

Production time was 3 min per piece with two operators, and setup time was 1 h. The production-lot size was 250 pieces.

Two-plane curvature. When a part must have curvature in two or more planes, a vertical adapter, either hydraulic powered or screw actuated, is used to permit the ram gripper to move up and down as the work requires. Thus, the work material can be fed into a spiral or other form involving rising and failing curvatures. In the following example, a vertical adapter with a wiper shoe was used to form a low-angle helix that was later welded into a ring.

Example 5: Producing a Ring From a Helix to Counteract Springback.

Because springback in the forming of a titanium alloy engine ring made it difficult to weld the workpiece into a true circle after forming, the stock was compression formed into a low-angle helix by using a vertical adapter with a wiper shoe. The form block was smaller in diameter than the finished ring, and when the workpiece was removed from the form block, springback was just sufficient to permit welding into a true ring. The setup used for forming the ring is shown in Fig. 11.

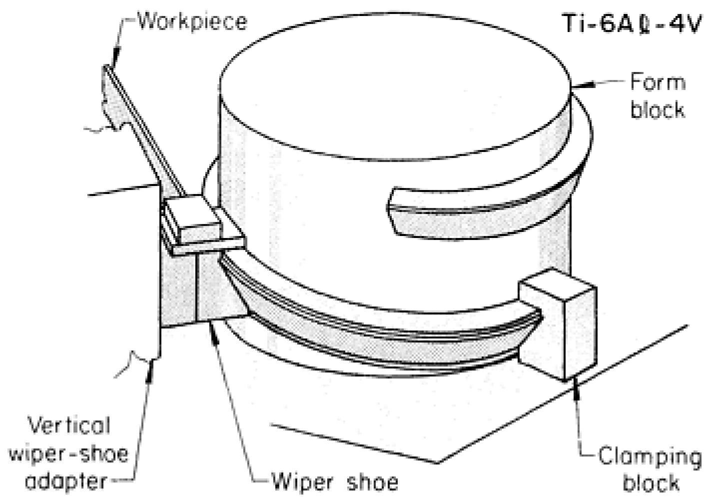

Fig. 11 Use of a vertical wiper-shoe adapter to form a helical shape. After forming, springback of the titanium alloy used brought the formed piece into a circular shape, which could be welded into a ring.

Stretch Forming

Radial Draw Forming

Radial draw forming is a combination of stretch wrapping and compression forming, as shown in Fig. 1(e). As in stretch wrapping, one end of the workpiece is gripped by stationary jaws attached to the rotary table. The other end is gripped by jaws on the hydraulic cylinder. The cylinder exerts tension on the workpiece as the form block on the rotary table revolves into it. A second hydraulic unit, fitted with a wiper shoe or roller, presses the workpiece into the contour of the form block at the point of tangency. The hydraulic unit applying the compression force can be moved as necessary to keep the wiper shoe in contact with the workpiece. On large machines, an operator sometimes rides a platform on the second unit to observe the point of contact.

Joggles in rolled or extruded sections can be formed after the part has been radial draw formed, without removing the part from the form block. When contour forming is completed, the part is held in tension while the compression unit is repositioned, and the joggle is formed by the wiper shoe. The wiper shoe is sometimes used to apply pressure to a loose joggle block (Fig. 12) if the wiper shoe will not provide the correct shape for the joggle. In either case, the shape of the joggle is also machined into the form block. The vertical adapter shown in Fig. 5 can be used in the radial draw forming of bends in two or more vertical planes.

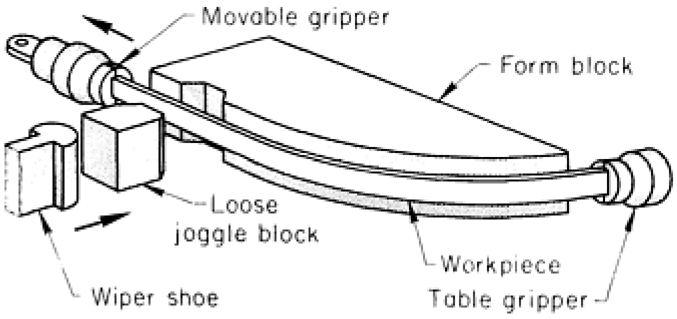

Fig. 12 Forming a joggle with a loose block and a wiper shoe after radial draw forming

Architectural sections, extruded shapes, and other sections sometimes have to twist on themselves if they are contour formed through any plane other than the plane of symmetry. In radial draw forming, this can be done by permitting the workpiece to rotate axially as the part follows the twisting contour of the form block. Rotation is obtained by slightly loosening the lock ring on the body of the gripper head, allowing the head to rotate about its own centerline. The following example illustrates the forming of an angle section by this method.

Example 6: Twisting of an Angle Section During Contour Forming.

An L-shaped section for the gunwale of an air-sea rescue craft (Fig. 13) had to be twisted as it was radial draw formed. It was made of aluminum alloy 2024-T4. Forming had to be done in several planes. The locking ring of the gripper was loosened, permitting the head to rotate as the part was formed.

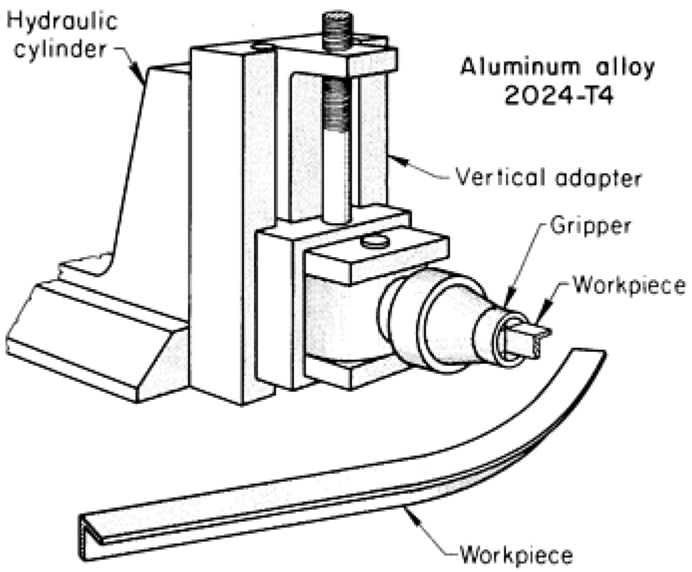

Fig. 13 Gunwale section that was produced from an L-section by a combination of twisting, stretching, and forming in several planes

The usual production-lot size was 500 pieces. Parts were formed at the rate of 10 per hour.

Radial draw forming operations on an extruded section and on a sheet are illustrated in the article "Forming of Aluminum Alloys" in this Volume.

Stretch Forming

Stretch-Forming Machines for Large Parts

Drape-forming machines are designed to be used on relatively small lengths and widths. The stretching and bending of greater lengths and widths require the increased capacity of stretch-forming machines. Stretch-forming machines bend the workpiece around the die to elongate the material fibers while simultaneously preventing wrinkles and minimizing springback.

These machines are available in two basic types:

- Moving jaws only, to stretch the blanks around a stationary form block
- Moving jaws combined with a moving-die (form-block) table

Transverse or longitudinal models and combination transverse-longitudinal models are available. Selection of the appropriate machine (jaw width, distance between jaws, and force capacity are key specifications) is determined by the configuration and dimensions of the workpiece.

Transverse Machines. The jaws of transverse machines, on which the workpieces are stretched and bent transversely, must be as long as the workpiece to provide substantial area for gripping. The transverse machine shown in Fig. 14 has a movable die table that can be tilted 15° above or below the horizontal. The jaws can be swiveled 30° in a horizontal plane and 90° in a vertical plane so that the direction of stretching can be aligned with the contour of the die. Rated at 6700 kN (750 tonf), the machine has a 2080 mm (82 in.) stroke, a 25 to 3660 mm (1 to 144 in.) jaw distance, and a 25 to 457 mm/min (1 to 18 in./min) forming speed. This equipment is primarily used for forming large sheets, such as fuselage skins and the leading edges of airplane wings. Large, cumbersome extrusions, such as wing spars, can be formed by changing or adapting the jaws.

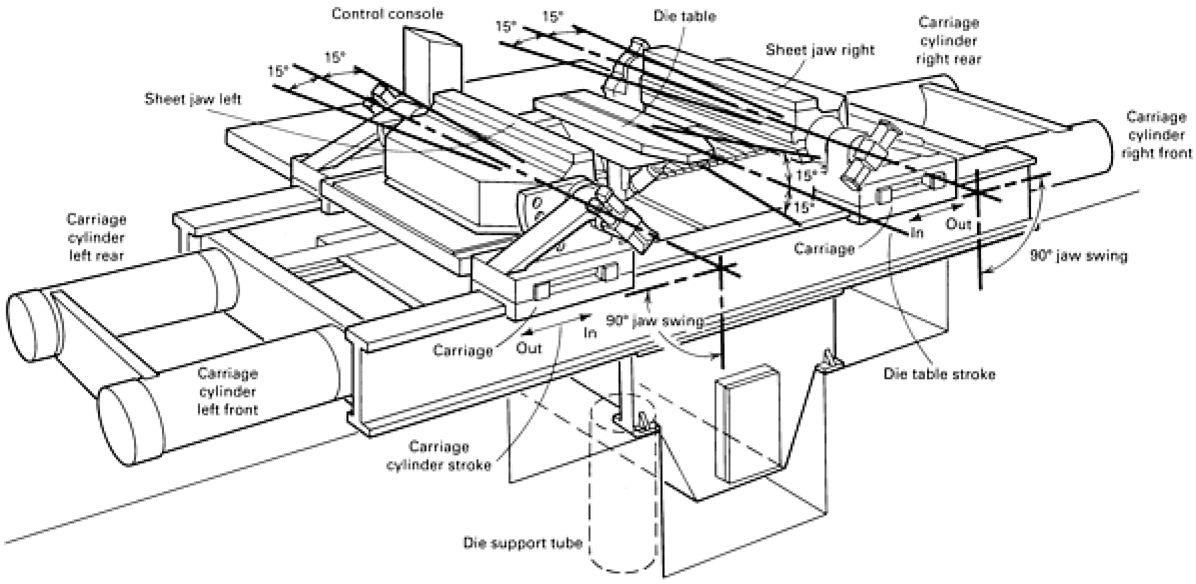

Fig. 14 Transverse stretch-forming machine having both movable and tiltable die table and swiveling, movable jaws

Longitudinal Machines. The longitudinal stretch-forming machine shown in Fig. 15 can be swiveled 90°, but cannot be raised or lowered. The 2540 mm (100 in.) wide, hydraulically powered, leadscrew-actuated jaws are made in sections for curvature to various radii. These jaws can be swiveled both horizontally and vertically. Each individual jaw develops a 6700 kN (750 tonf) tensile force, and the jaws in tandem are capable of forming 12 × 2.4 in (40 × 8 ft) sheet metal skins. The addition of adapter jaws bolted to the standard jaws allows the machine to form long extruded frame members weighing up to 450 kg (1000 lb).

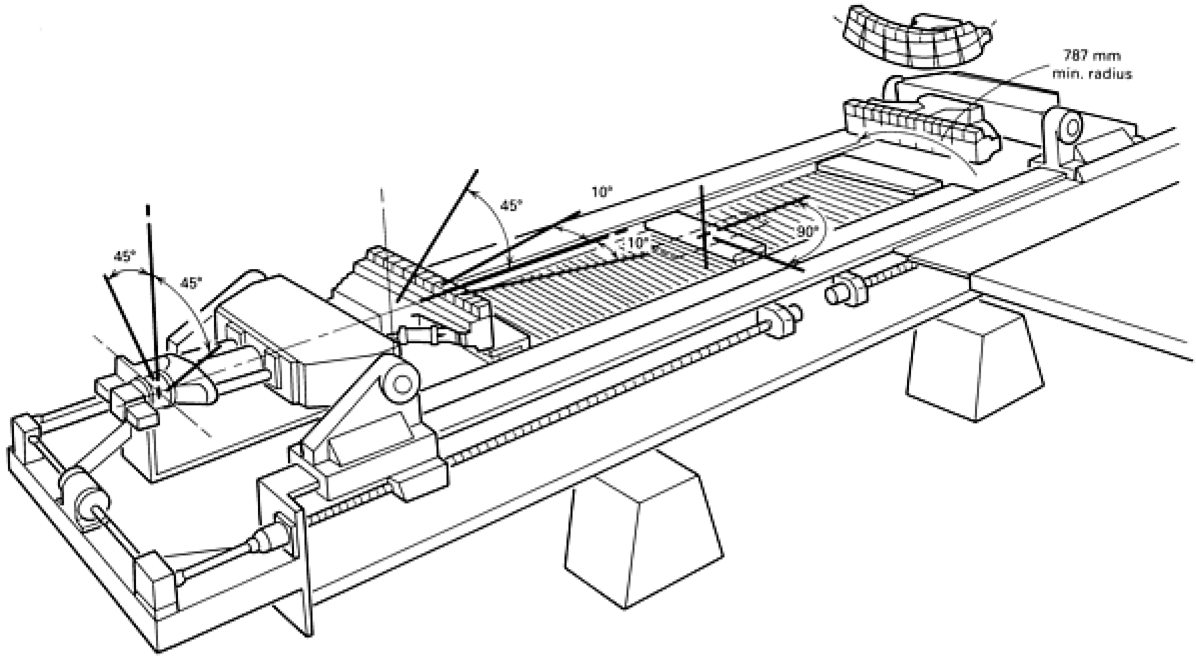

Fig. 15 Longitudinal stretch-forming machine with leadscrew-actuated jaws that can be curved and swiveled both horizontally and vertically

Accuracy

High-strength alloys, stainless steel, and titanium can be stretch formed to overall tolerances of ±0.25 mm (±0.010 in.) on workpieces bent to about a 178 mm (7 in.) radius. With springback allowance, bends can be controlled to $\pm\frac{1}{2}$°. Cross-sectional dimensions have been held to ±0.05 mm (±0.002 in.) by close control of raw material, as in the following example.

Example 7: Maintaining Close Tolerances on Grooves While Forming a Guide-Vane Shroud.

Because a cover strip had to slide easily, but without play, into the grooves of a stainless steel guide-vane shroud after the vanes were assembled, the width of the grooves had to be held within 0.10 mm (0.004 in.), as shown in Fig. 16. Strip was selected that had thickness variation within ±0.013 mm (±0.005 in.) because of the close groove tolerances that had to be met. The two U-bends forming the grooves were made in a press brake, and the guide slots were pierced in another operation. The shrouds were then contoured to a 190 mm ($7\frac{1}{2}$ in.) radius by stretch forming. The width of the work strip and the width of the grooves were held within the specified tolerances without using a filler for support.

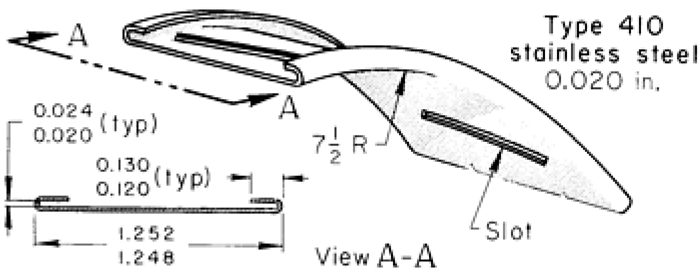

Fig. 16 Guide-vane shroud that was stretch formed without noticeable distortion to the 0.51/0.61 mm (0.020/0.024 in.) groove dimension. Dimensions given in inches

The shrouds were produced at a rate of 10 per hour. A typical production run was between 200 and 1000 pieces.

Tolerance Specifications. As shown in the preceding example, it may be necessary to control stock to a small thickness variation if close tolerances on the workpiece must be met. Ordinarily, it is good practice to allow about 25% of the finished-part tolerance as the stock thickness tolerance or the tolerance on any preformed dimension that could affect the accuracy of the stretch-formed dimension. In Example 7, the smallest tolerance was ±0.05 mm (±0.002 in.), and the stock thickness variation was controlled to ±0.013 mm (±0.0005 in.) (25% of workpiece tolerance).

Titanium is stretch formed both hot and cold (see the article "Forming of Titanium and Titanium Alloys" in this Volume). In cold stretch forming, shrinkage at right angles to the stretch is ordinarily controlled to ±0.79 mm ($\pm\frac{1}{32}$ in.) on bends with 229 mm (9 in.) radii. Angular variation on stretch bends in all materials is held to $\pm\frac{1}{2}$°.

In one plant, large rectangular tubing of copper alloy is stretch formed with a filler or with a flexible mandrel similar to those described in the article "Bending and Forming of Tubing" in this Volume. Tubes as large as 102 to 203 mm (4 to 8 in.) square and up to 4.9 mm (16 ft) long with 3.2 to 9.5 mm ($\frac{1}{8}$ to $\frac{3}{8}$ in.) walls can be formed. When mandrels are not used, distortion appears as concavity in the face away from the form block and some tapering toward the concave face, as shown in Fig. 17. These tubes are stretch formed to large radii with a ±0.81 mm ($\pm\frac{1}{32}$ in.) tolerance on the radius of the bend.

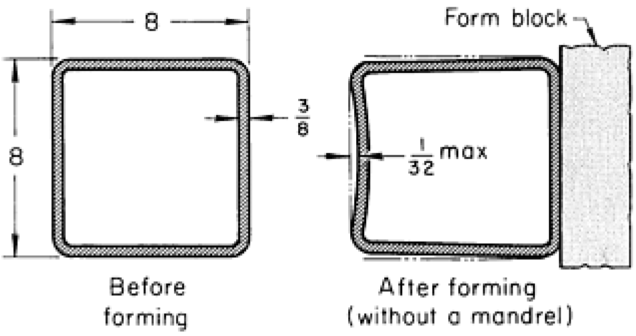

Fig. 17 Typical distortion of square copper alloy tubes in stretch forming. Dimensions given in inches

In the bending of large tubing, the bend is usually so shallow that the elastic limit of the metal is not reached without gross overbending, unless stretch-forming methods are used. As with conventional methods, overbending leads to unpredictable results. Tolerances on shallow bends can seem deceptively large. To hold a 3.0 m (10 ft) radius within ±0.79 mm ($\pm\frac{1}{32}$ in.) in a 10° arc means holding an overall tolerance of more than ±0.13 mm (±0.005 in.).

Surface Finish

Little can be done in stretch forming to improve surface finish because tool contact with the surface is incidental. However, some practices can be implemented to help preserve the original finish:

- Avoid overstretching. With most materials, 2 to 4% stretch is sufficient to achieve the results desired in stretch forming. The overstretching of some metals, such as aluminum, simply because they are ductile is a common mistake. This leads to the appearance of stretcher strains or other surface relief effects

- Plastic wiper shoes can be used in the compression forming or radial draw forming of aluminum alloys to avoid marring the surface. With stainless steel workpieces, well-finished plastic wiper shoes are used with drawing compounds similar to those used for severe deep drawing

An extra-fine finish is necessary in order to protect the surfaces of aluminum alloys directly in contact with the form block. Special practices used to preserve the finish include cleaning to eliminate abrasive dust particles, the use of polyvinyl chloride instead of a lubricant, and the use of special carrier sheets for protection of the surface during forming.

Stretch Forming Versus Alternative Methods

The following example compares stretch draw forming with alternative forming or drawing processes for a part manufactured by an automotive supplier. Stretch forming was competitive for the product considered.

Example 8: Stretch Draw Forming Versus Conventional Drawing.

An automotive plant that produced quarter-pillar lock panels from 0.89 mm (0.035 in.) thick commercial-quality 1008 steel by conventional drawing investigated the relative merits of stretch draw forming for this product. In drawing, an 8900 kN (1000 tonf) double-action press with conventional draw dies produced 525 pairs of panels per hour. In stretch draw forming, a 7200 kN (800 tonf) 2.74 × 1.52 m (108 × 60 in.), straight-side, single-action mechanical press with 1.22 m (48 in.) long stretch grippers was used. The production rate was the same as that for the conventional press when automatic loading and unloading were used, and the production cost was less. The process was changed to stretch draw forming.

In high-production forming, the principal disadvantage of stretch forming is the slowness of the hydraulic units used on the grippers, unless pumps of excessively high capacity are used. Mechanical units are available that have rapid response.

Operating Parameters

Size and configuration of the workpiece, material composition, type of forming operation used, machine and tooling used, and production requirements are among the variables that influence stretch forming. Operating parameters, such as force requirements, and the lubricant used must be determined prior to forming.

Force Requirements. The application of excessive tension in stretch forming can cause breakage of the workpiece. On the other hand, too little tension can result in poor contouring, wrinkling, or springback of the formed part. The force capacity of the machine required for stretch forming a part can be calculated by:

$$F = \left(\frac{Y_s + UTS}{2}\right) A \quad \textbf{(Eq 1)}$$

where F is the stretch-forming force (in pounds of force), Y_s is the yield strength of the material (in pounds per square inch), UTS is the ultimate tensile strength of the material (in pounds per square inch), and A is the cross-sectional area of the workpiece (in square inches). To convert from English units (pounds of force) to metric units (newtons), the force in pounds is multiplied by 4.448.

The estimate of the force required for stretch forming obtained with Eq 1 is generally an average. To compensate for work hardening, friction, more complex contours, and other variables, the force obtained mathematically should be increased by an additional 25% for some applications.

Lubrication. In most stretch forming, little or no lubrication is needed, because the movement between the work metal and the form block is minimal. On sheet steel, residual mill oil is usually sufficient, although some operators spray the stock with a light lubricating oil as it enters the forming area. Lubricants are sometimes intentionally avoided because they attract and retain dust particles that could mar the workpiece surface.

In the compression forming of copper alloys, low-carbon steel, and stainless steel, in which a shoe rubs hard against the part or there is considerable movement against the form block, white lead thinned with SAE 30 engine oil can be brushed on the workpiece before forming. In some shops, molybdenum disulfide is similarly used on low-carbon steel. Both lubricants resist heat and pressure and reduce friction. Polyvinyl chloride sheet can be used in place of a lubricant (and to embed dust particles) in the forming of microwave reflectors.

Introduction

SPINNING is a method of forming sheet metal into seamless, axisymmetric shapes by a combination of rotation and force. On the basis of techniques used, applications, and results obtainable, the method can be divided into two categories: manual spinning and power spinning. This article will discuss the spinning of sheet; tube spinning is covered in the article "Tube Spinning" in this Volume.

Manual Spinning

Manual spinning involves no appreciable thinning of the work metal. The operation is accomplished with the use of a lathe, and it consists of pressing a tool against a circular metal blank that is rotated by the head-stock. The blank is usually forced over a mandrel of a predetermined shape, but simple shapes can be spun without a mandrel. Various mechanical devices are used to increase the force that can be applied to the workpiece.

Any metal that is ductile enough to be cold formed by other methods can be spun. Most spinning is done without applying heat to the workpiece; the metal is sometimes preheated to increase ductility or to allow thicker sections to be spun.

Applicability

Manual spinning is used to form flanges, rolled rims, cups, cones, and double-curved surfaces of revolution (such as bells). Several typical shapes formed by manual spinning are shown in Fig. 1. Products include light reflectors, tank ends, covers, housings, shields, and components for musical instruments. Manual spinning is also extensively used for the production of aircraft and aerospace components, often with mechanical assistance for increased force.

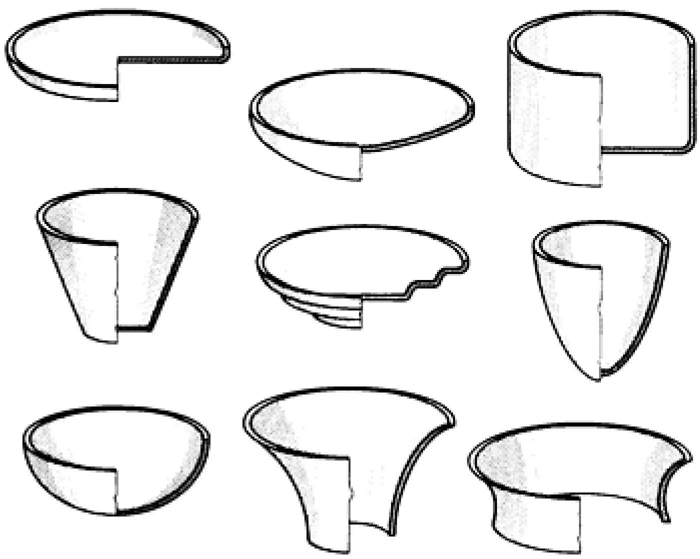

Fig. 1 Typical conical, cylindrical, and dome shapes that can be formed by manual spinning.

The practical maximum thickness of low-carbon steel that can be spun without mechanical assistance is 3.2 mm ($\frac{1}{8}$ in.). In this thickness, the diameter can be as great as 1.8 m (72 in.). Diameters can be greater when the sheet steel is thinner, but the maximum practical diameter is often limited by the availability of equipment. The upper limit of thickness increases as work metal ductility increases or as strength decreases. For example, the manual spinning of aluminum as thick as 6.4 mm ($\frac{1}{4}$ in.) is feasible.

Advantages and Disadvantages

Manual spinning has several advantages over a competitive process such as press forming:

- Tooling costs less, and investment in capital equipment is relatively small
- Setup time is shorter
- Design changes in the workpiece can be made at minimum expense
- Changes in work metal composition or thickness require a minimum of tool changes

The disadvantages of manual spinning include:

- Skilled operators are required, because uniformity of results depends greatly on operator skill
- Manual spinning is usually slower than press forming
- Available force is more likely to be inadequate in manual spinning than in press forming

Equipment

A simple tool and workpiece setup for manual spinning is shown in Fig. 2(a). The mandrel is mounted on the headstock of a lathe. The circular blank (workpiece) is clamped to the mandrel by the follower block. An antifriction center is used between the follower and the tailstock spindle, and pressure is applied at the tailstock by means of a screw or by air or hydraulic pressure, depending on the size and type of lathe. The tool rest and pedestal permit the support pin (fulcrum) to be moved to various positions by swinging the tool rest and moving the support pin from one hole to another as needed. Spinning is done by manually applying the friction-type spinning tool as a pry bar.

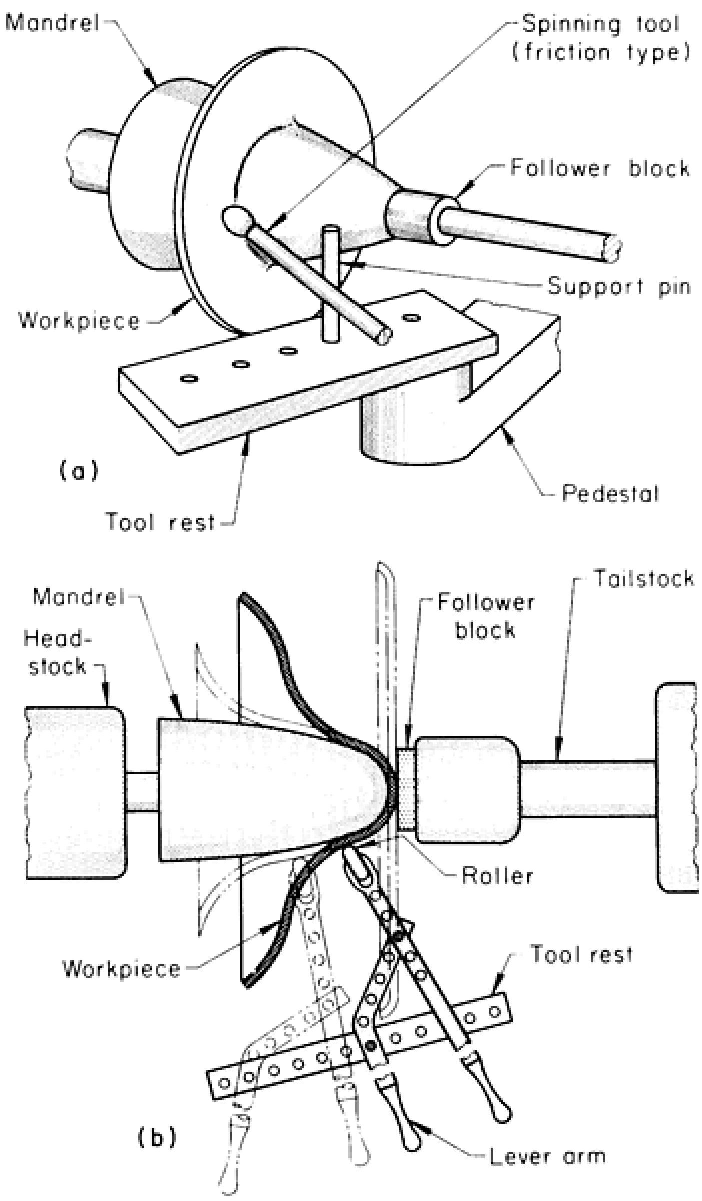

Fig. 2 Manual spinning using a lathe. (a) Simple setup using a hand tool applied as a pry bar. (b) Setup using scissorlike levers and roller spinning tool.

Figure 2(b) shows a more complex setup for manual spinning. In this configuration, the spinning tools (rollers) are mounted in the fork sections of long levers, and the tool support has a series of holes for the rapid changing of tool position. The tool is manipulated by pulling, pushing, or pivoting the two scissorlike handles, with the roller against the workpiece.

Lathes. Several sizes of standard horizontal spinning lathes are available that can spin blanks ranging from 6.4 mm to 1.8 m ($\frac{1}{4}$ to 72 in.) in diameter. Special pit lathes permit the spinning of blanks as large as 4.9 m (192 in.) in diameter. Standard lathes can be fitted with special chucks for making oval parts. Lathes should be equipped with variable-speed drives to permit quick changes of speed as judged necessary by the operator.

Mandrels, also known as form blocks or spin blocks, are usually made of seasoned hard-maple wood. Most hardwood mandrels are constructed by gluing strips of 25 to 50 mm (1 to 2 in.) thick maple into the main block to create a cross-laminated structure, then turning the glued structure to the desired shape. Such mandrels are stronger and more durable than mandrels turned from a solid block. Some wooden mandrels are steel reinforced at the ends and at small radii to ensure maintenance of radii in the spun workpieces. Sharp corners can be produced in workpieces by spinning them over mandrels cornered with steel; but minimum inside radii of 1.6 mm ($\frac{1}{16}$ in.) are more common than sharp corners, and 3.2 mm ($\frac{1}{8}$ in.) minimum radii are preferred where possible.

Some mandrels are constructed of alternating wood and steel plates or rings in order to obtain a more economical yet durable mandrel. Other materials include fiber compositions, steel, cast iron, aluminum, magnesium, and plastic-coated wood. Few mandrels are made entirely of heavy metals such as steel and cast iron, except for close-tolerance work. Cored castings of these metals are then preferred, because of the weight savings. Solid steel or cast iron mandrels must be statically balanced, and for use at high speed, they should also be dynamically balanced.

Spinning Tools. Simple spinning tools are usually made by forging carbon or low-alloy tool steels (such as W1 or O1) to the desired shape, hardening the working ends to about 60 HRC, and polishing them. Several typical shapes are illustrated in Fig. 3. Tools of shaped aluminum bronze are also satisfactory, especially for the spinning of steel. Hardwood tools have performed satisfactorily in spinning thin-gage ductile metals.

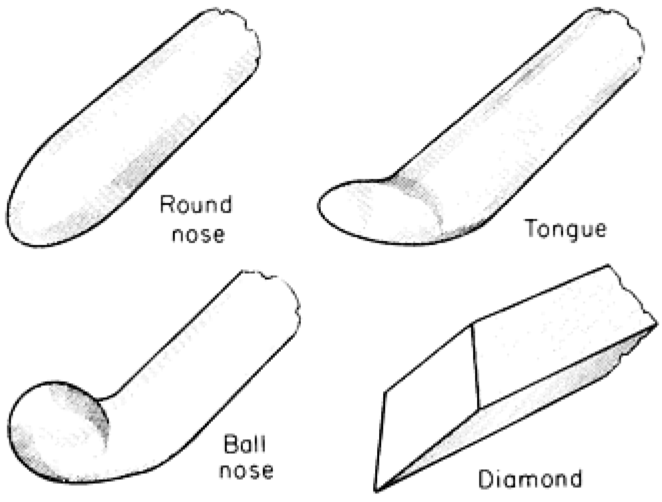

Fig. 3 Typical shapes of working ends of tools used for manual spinning. Round nose, tongue, and ball nose tools are for spinning; the diamond tip is for trimming.

With the lever arrangement (Fig. 2b), the tools usually consist of rollers (sometimes called tool rings) mounted in forks. Most rollers are made of hardened tool steel or of aluminum bronze.

Manual Spinning Practice

Because of the low tooling cost, manual spinning is extensively used for prototypes and for production runs of 1000 pieces or fewer. Larger lots can usually be produced at lower cost by power spinning or press forming.

For example, the part in the middle of the second row in Fig. 1 is a stainless steel cover for a food-processing machine, produced in one plant at the rate of 100 per year. The parts were produced satisfactorily by manual spinning with only two hardwood mandrels, the cost of which was only a fraction of the tooling cost for the press forming of the same shape.

Conical parts (such as the shape on the left in the middle row in Fig. 1) are ideal for spinning because only one tool is required; drawing in dies would require four or five operations. Many such cones, depending on their included angle, can be spun in one operation at a moderate production rate. Therefore, manual spinning is often used for quantities up to medium production (<1000 units). For large-quantity production, power spinning is generally less expensive than manual spinning.

Control of quality, including freedom from wrinkles and scratches and maintenance of dimensional accuracy, is largely a function of operator skill. Dimensional tolerances increase as the diameter of the blank increases, as indicated in Table 1. These tolerances are typical of demands for commercial products and parts for aerospace applications.

Table 1 Typical dimensional tolerances for manual spinning

Diameter of blank		Tolerance			
		Commercial		Aerospace	
m	in.	mm	in.	mm	in.
Up to 0.305	Up to 12	±0.4	$\pm\frac{1}{64}$	±0.20	±0.008
0.33-0.90	13-36	±0.8	$\pm\frac{1}{32}$	±0.38	±0.15
0.94-1.37	37-54	±1.6	$\pm\frac{1}{16}$	±0.51	±0.020
1.4-2.4	55-96	±3.2	$\pm\frac{1}{8}$	±0.76	±0.030

Speeds that are best suited to manual spinning depend mainly on work metal composition and thickness. For example, a given blank of stainless steel is successfully spun at 60 m/min (200 surface feet per minute, or sfm), and speed is determined by "operator feel" to be maximum for the conditions. Under otherwise identical conditions, changing to an aluminum blank will permit speeds of 120 to 180 m/min (400 to 600 sfm). Similarly, if the thickness of the stainless steel blank were decreased to one-half the original thickness (no other changes), speed could be safely doubled or tripled.

Selection of optimal speed depends largely on "operator feel." In many spinning operations, speed is changed (usually increased) during the operation by means of a variable-speed drive on the headstock.

Lubricants should be used in all room-temperature spinning operations, regardless of work metal composition, workpiece shape, or type of spinning tools used. The usual practice is to apply the lubricant to the blank with a swab or brush before loading the blank into the machine. In some cases, additional lubricant is added during operation as judged necessary by the operator. The need for additional lubricant depends on the tenacity of the lubricant used and on blank-rotation speed.

The most important property of a lubricant used for spinning is its ability to adhere to the rotating blank. Ordinary cup grease is often used. It can be heated to reduce its viscosity, thus making it easier to apply to the blank. Upon application to the cold blank, the viscosity of the grease increases. In addition, cup grease can be easily removed.

Other lubricants used for spinning include soaps, waxes and tallows (and proprietary mixtures of two or more of these materials), and pigmented drawing compounds. All of these, however, are more difficult to remove than simple grease. Therefore, the more tenacious lubricants are not used if an easier-to-remove lubricant will provide acceptable results.

Power Spinning

Power spinning is also known as shear spinning, because in this method metal is intentionally thinned by shear forces as high as 3.5 MN (400 tonf). Power spinning is used in two broad areas of application: cone spinning and tube spinning. In cone spinning, the deformation of the metal from the flat blank is in accordance with the sine law (see the section "Mechanics of Cone Spinning" in this article).

Virtually all ductile metals can be processed by power spinning. Products range from small hardware items made in large quantities (metal tumblers, for example) to large components for aerospace applications in unit or low-volume production.

Blanks as large as 6 m (240 in.) in diameter have been successfully power spun. Plate stock up to 25 mm (1 in.) thick can be power spun without applying heat. When heated, blanks as thick as 140 mm ($5\frac{1}{2}$ in.) have been successfully spun.

Conical and curvilinear shapes are those most commonly produced from flat (or preformed) blanks by power spinning. The mechanics of the process should be known and the rules followed when planning manufacturing processes that include power spinning.

Mechanics of Cone Spinning

The application of shear spinning to conical shapes is shown schematically in Fig. 4. The metal deformation is such that forming is in accordance with the sine law, which states that the wall thickness of the starting blank, t_1, and that of the finished workpiece, t_2, are related as follows:

$$t_2 = t_1 (\sin \alpha)$$

where α is one-half the apex angle of the cone. When spinning in accordance with the sine law, the axial thickness is the same as the thickness of the starting blank (Fig. 4).

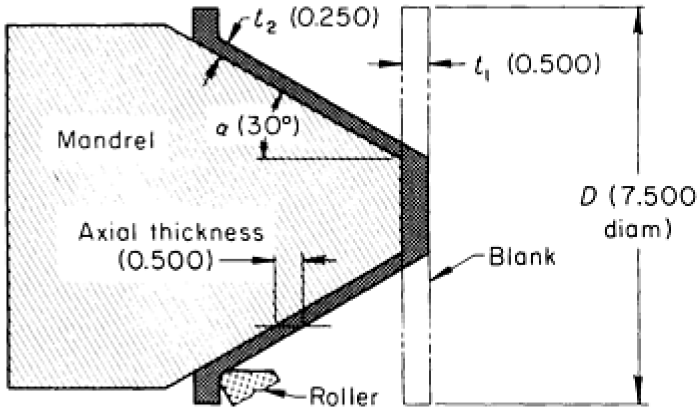

Fig. 4 Setup and dimensional relationships for the one-operation power spinning of a cone. *D*, mandrel diameter; t_1, original (blank) thickness; t_2, spun thickness; α, included angle. Dimensions given in inches.

When spinning cones to small angles (<35° included angle), the best practice is to use more than one spinning pass with a different cone angle for each pass, as illustrated in Fig. 5. When using this technique, the workpiece is annealed or stress relieved between passes.

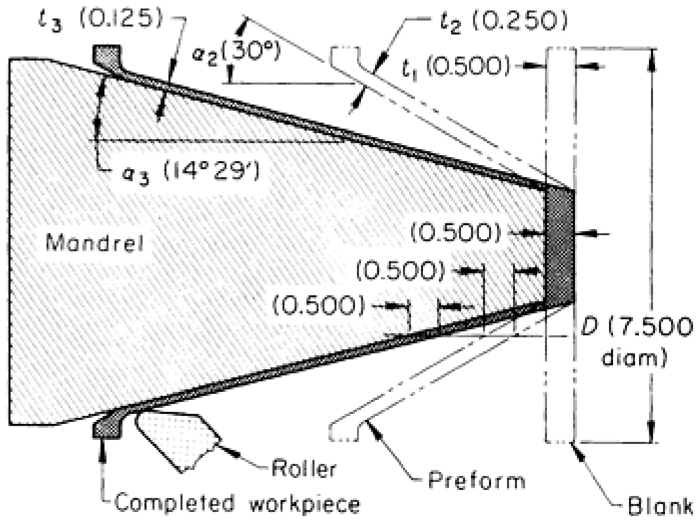

Fig. 5 Setup and dimensional relationships for the two-operation spinning of a cone to a small angle (35° included angle). Dimensions given in inches.

This practice permits a high total reduction while maintaining a practical limit of 50 to 75% between process anneals. The reduction between successive annealing operations is determined by the maximum acceptable limits of deformation for the metal being spun (Table 2); this value is obtained by multiplying t_1 by a factor (0.5 for 50%, 0.25 for 75%, and so on) and then dividing the result by t_1 to obtain the sine of the required half angle.

(a) Hot spun

Even in multiple-pass spinning, the original blank diameter is retained, and the exact volume of material is used in the final part. At any diameter of either the preform or the completed workpiece, the axial thickness equals the thickness of the original blank. For example, if a flat plate has a diameter of 190 mm ($7\frac{1}{2}$ in.) and a thickness of 12.5 mm ($\frac{1}{2}$ in.), the spun preform has this same 12.5 mm ($\frac{1}{2}$ in.) axial thickness, but the wall thickness is only 6.4 mm ($\frac{1}{4}$ in.) (t_1, Fig. 5), thus satisfying the sine law. Similarly, the final workpiece has an axial thickness of 12.5 mm, ($\frac{1}{2}$ in.), but in accordance with the sine law, it has a wall thickness of only 3.2 mm ($\frac{1}{8}$ in.) (t_3, Fig. 5).

Effects of Deviation From the Sine Law. Deviation from the sine law is usually expressed in terms of overreduction or underreduction. In overreduction, the final thickness of the workpiece is less than that dictated by the sine law; in underreduction, the thickness is greater. In overreduction, the flange will lean forward; in underreduction, the flange will lean backward. If a thin blank is spun with severe underreduction, the flange will wrinkle. This phenomenon corresponds to a deep-drawing operation in which the blankholder pressure is insufficient.

In power spinning, overreduction has an additional effect on the shape of the workpiece. As the workpiece is overreduced, back extrusion can occur (Fig. 6). For a given amount of reduction, the likelihood of back extrusion increases with increasing mandrel angle (Fig. 6).

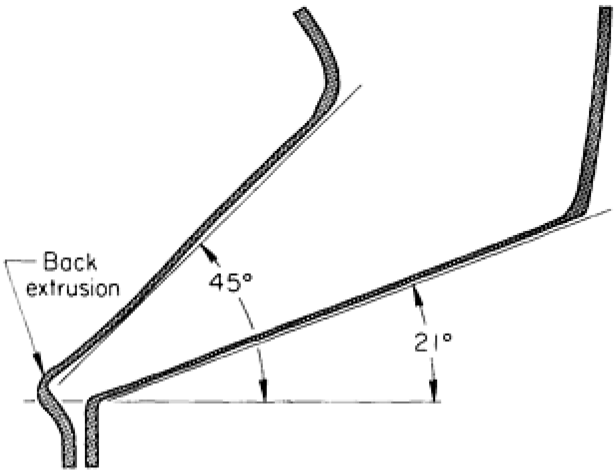

Fig. 6 Back extrusion as a result of overreduction in the power spinning of low-carbon steel.

The phenomenon of back extrusion in spinning is explained in terms of the compressive stress in the spun workpiece that pushes the spun section backward. If the tailstock of the machine is removed, it is possible to obtain curvilinear shapes on a conical mandrel by varying the amount of overreduction during spinning.

Machines for Power Spinning

Most power spinning is done in machines specially built for the purpose. The significant components of such a machine are shown in Fig. 7. Although Fig. 7 illustrates the power spinning of a conical shape, similar machines are used for the spinning of tubes (see the article "Tube Spinning" in this Volume).

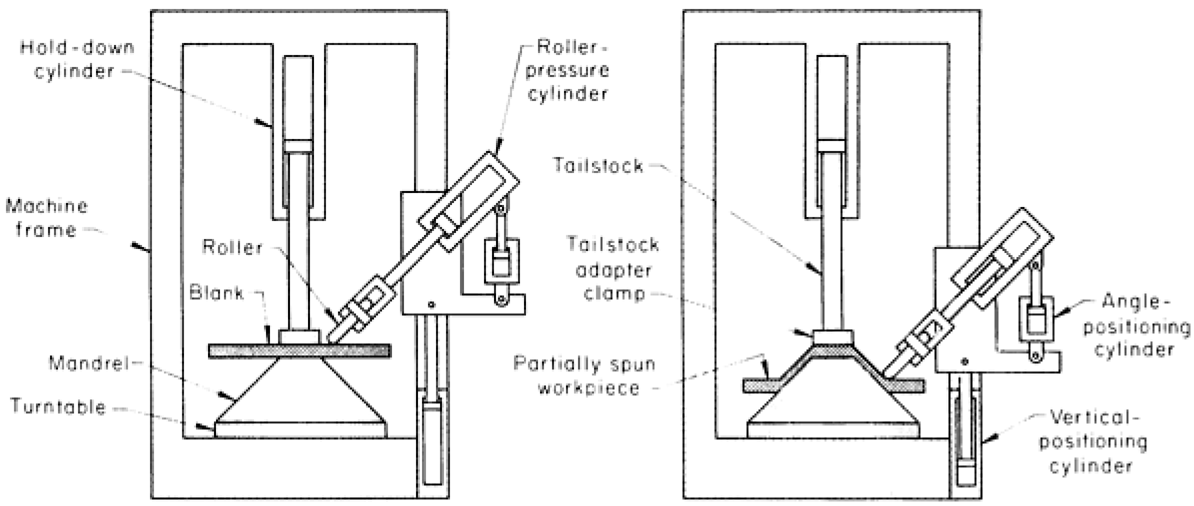

Fig. 7 Schematic of power spinning in a vertical machine.

Machines for power spinning are usually described by specifying the diameter and length (in inches) of the largest workpiece that can be spun and the amount of force that can be applied to the work. It is also common practice to specify that the machine can spin a given thickness of metal at a 50% reduction in thickness in one pass.

The capacity of spinning machines ranges from 455 × 380 mm (18 × 15 in.) at 18 kN (4000 lbf) to machines capable of spinning workpieces as large as 6 m (240 in.) in diameter × 6 m (240 in.) long. Force on the work can be as great as 3.5 MN (800,000 lbf). Machines have been built that spin steel 140 mm ($5\frac{1}{2}$ in.) thick.

Spinning machines can be vertical or horizontal. Machines used for spinning workpieces 1.8 m (70 in.) or more in diameter are usually vertical because they are better suited to handling large work.

Machines for power spinning can be automated to various degrees. Most spinning machines use template guides that control the shape and accuracy of the workpiece. Most machines used for production spinning are semiautomatic; that is, they are loaded and unloaded by the operator, but the entire spinning cycle is controlled automatically. Machines can also be equipped with automatic loading and unloading devices, thus making them fully automatic.

Tools for Power Spinning of Cones

Mandrels, rollers, and other tools are subjected to more rigorous service in power spinning than in manual spinning; therefore, more careful consideration must be given to design and materials of construction.

Mandrels. A typical mandrel profile is illustrated in Fig. 8. Dimensions *A* and *B* and angle α can vary as required. Usual practice is to have, first, an integral flange to permit the mandrel to be bolted to the headstock and, second, a boss of suitable diameter and at least 16 mm ($\frac{5}{8}$ in.) in thickness that fits into the headstock of the machine (Fig. 8). Radius *R* can vary from a minimum of 0.8mm ($\frac{1}{32}$ in.) to a round nose.

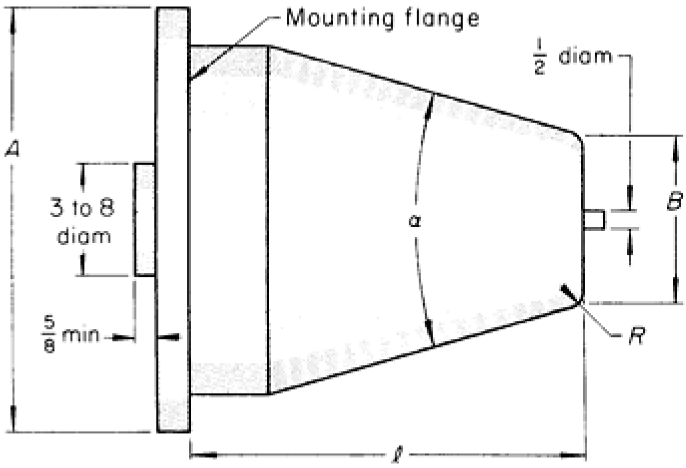

Fig. 8 Typical profile of a mandrel for the power spinning of cones. Dimensions given in inches.

Mandrel wear or failure is frequently a problem in the power spinning of conical shapes. The mandrels used in production spinning must be hard in order to resist wear, and they must resist the fatigue resulting from normal eccentric loading. Failure is often caused by spalling (flaking off). Mandrels can also be damaged by the rollers plunging into the workpiece at the start of metal flow. The need for plunging can sometimes be eliminated by machining a ring on the preform to a depth equal to the depth the rollers would otherwise be plunged. This technique permits the rollers to enter the machined space before they start moving along the mandrel, thus eliminating the severe stress on the mandrel as spinning is begun.

Materials selection for the mandrels used in cone spinning depends primarily on the number of identical workpieces to be spun. Based on quantity, the most commonly used materials are:

- Gray iron (as-cast) for the low-production spinning of soft metals (10 to 100 pieces)
- Alloy cast iron (sometimes flame hardened in areas susceptible to high wear), for spinning 100 to 250 pieces
- 4150 or 52100 steel hardened to about 60 HRC, for spinning 250 to 750 pieces
- Tool steels such as O6, A2, D2, or D4 hardened to 60 HRC or slightly higher, for high production

The finish of the mandrels should be no rougher than 1.5 μm (60 μin.). The various diameters should be within ±0.025 mm (±0.001 in.) concentric with each other within approximately 0.05 mm (0.002 in.) total indicator reading.

Rollers. Three types of rollers are shown in Fig. 9. Rollers are usually 305 to 510 mm (12 to 20 in.) in outside diameter, depending on the type and size of the spinning machine. Roller widths are usually 50 to 75 mm (2 to 3 in.), and inside diameters range from 255 to 380 mm (10 to 15 in.). The shape of the rollers depends largely on the shape of the workpiece to be spun. Full-radius rollers (Fig. 9a) are usually used to produce curvilinear shapes, while those illustrated in Fig. 9(b) and 9(c) are preferred for the spinning of cones.

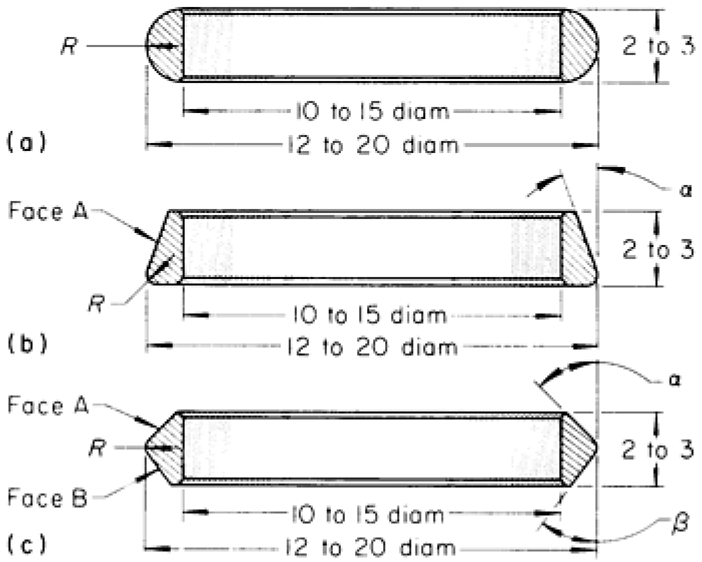

Fig. 9 Typical rollers used in the spinning of cones and hemispheres. (a) Full-radius roller. (b) Corner roller. (c) Thinning roller. Dimensions given in inches.

Angle α shown in Fig. 9(b) and 9(c) is necessarily varied to suit the work being spun (particularly the angle of the cone). This angle is intended for clearance and should be such that the work metal does not touch face A (Fig. 9b) or either face A or face B (Fig. 9c). The radius *R* should not be less than the final wall thickness.

The type of roller illustrated in Fig. 9(b) is widely used in cone spinning. A typical setup, using two of these rollers opposed, is illustrated in Fig. 10. When two rollers are used to spin a part from flat plate, the rollers are set the same. However, when spinning is done from a preformed shape, common practice is to make one the lead roller and to set it ahead of the other by 1.6 to 3.2 mm ($\frac{1}{16}$ to $\frac{1}{8}$ in.). If more than two rollers are used, this increment is continued between successive rollers. The angle between the axis around which the rollers revolve and the workpiece (angle α, Fig. 10) is usually about 10°, while the angle between the same roller axis and the peripheral face of the roller (angle β, Fig. 10) may vary and is shown in Fig. 10 as approximately 30°.

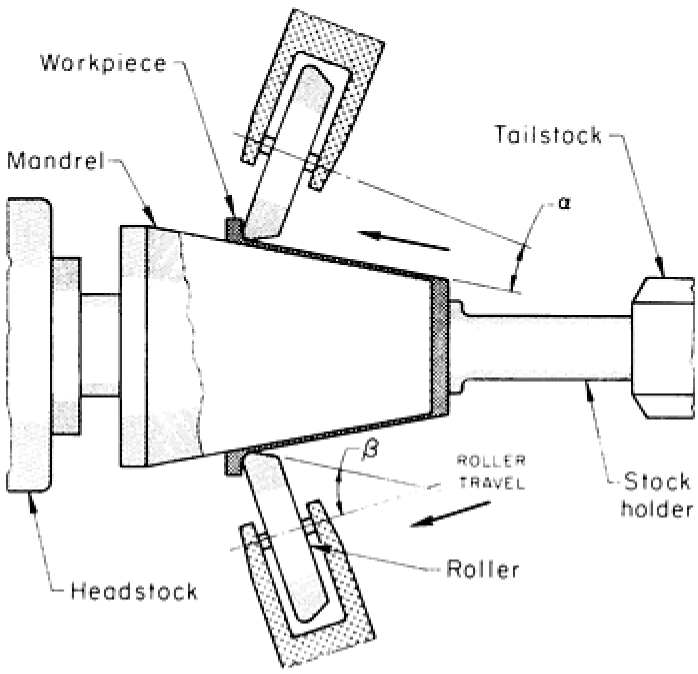

Fig. 10 Relative positions of rollers and workpiece in the spinning of a cone.

Rollers are made from a variety of hard materials. The five materials most widely used for the power spinning of conical shapes, in order of ascending wearability and cost, are W2 tool steel, O6 tool steel, D2 tool steel, D4 tool steel, and carbide. Choosing among these materials is usually done on the basis of quantity of workpieces to be spun. The less costly W2 and O6 tool steels are generally suitable for low-to-medium production quantities. Tool steels D2 and D4 are preferred to high production quantities. Carbide is seldom used except for specialized applications in which the need has been proved and the high cost can be justified.

Rollers made from any of the above tool steels should be hardened to 60 to 65 HRC. All rollers should be polished to a maximum surface roughness of 0.25 μm (10 μin.).

Auxiliary tools for cone spinning include tailstock adapters, tracer templates, tracer followers, and stripping devices. A tailstock adapter clamps the work to the mandrel (Fig. 7) and is made of carbon or alloy steels or of tool steel. The clamping face of the tailstock adapter must be ground square to the spindle axis.

Tracers are used to spin workpieces that vary in wall thickness or shape. Tracer templates are made of low-carbon steel, such as 1020, that is, 3.2 to 4.8 mm ($\frac{1}{8}$ to $\frac{3}{16}$ in.) thick. Large templates have lightening holes for easier handling. Tracer templates are made to the same standards of accuracy as dies and similar tools. Tracer followers can be ball bearings or hardened tool steel fingers, depending on cone shape.

Stripping devices can be full rings or fork-type fingers, attached to the roller carrier. The need for stripping devices depends on the size and shape of the workpiece.

The use of preforms is common in cone spinning when the included angle of the cone is less than 35° or when the percentage of wall reduction is high. Preforms are usually prepared by cold forming in a die, although hot forging or machining or a combination of both can be used. Some preforms are made by spinning.

Speeds and Feeds for Cone Spinning

Most metals spin best at high speeds. The minimum speed considered to be practical is about 120 m/min (400 sfm), but speeds this low are seldom used except for the spinning of small-diameter workpieces. Machine spindles sometimes cannot rotate fast enough with such workpieces to achieve the desired surface speed. Speeds of 305 to 610 m/min (1000 to 2000 sfm) are most widely used, regardless of work metal composition, workpiece shape, or reduction per pass.

Feed. Most cone-spinning operations are done at feeds of 0.25 to 2 mm/rev (0.01 to 0.08 inches per revolution, or ipr). In practice, however, feeds are usually calculated in millimeters per minute (mm/min) or inches per minute (ipm). Most machines used in cone spinning are equipped with electronic or hydraulic devices that steplessly change the rate of feed as the diameter on which the rollers are working changes continuously. The rate of feed usually ranges from 38 to 380 mm/min ($1\frac{1}{2}$ to 15 ipm).

Feed rate is important, because it controls the workpiece finish and the fit of the workpiece to the mandrel. With all other factors constant, an increase in feed rate will make the workpiece fit tighter on the mandrel, and the finish of the workpiece will coarsen. On the other hand, a decrease in feed rate will cause a loose fit, and workpiece finish will improve. The diameter of the mandrel should be the same as the inside diameter required on the workpiece (no allowance for springback), and the workpiece should be spun to fit the mandrel. The fit may be loose, snug, or tight.

To find the optimal combination of speed, feed, and pressure, a few pieces should be spun experimentally when a new job is set up. During continuous operation, the temperature of the mandrels and spinning tools changes; therefore, after the first hour or so, it is often necessary to adjust the pressure, speed, and feed for uniform results.

Power Spinning of Hemispheres

The use of preforms to control percentage of reduction has enabled power spinning to be applied to the forming of hemispheres, ellipses, ogives, and in general, any curvilinear surface of revolution. However, the design of the preform for curvilinear shapes is more complicated than that for conical shapes. In the spinning of conical shapes, it is possible to find an axial thickness of the spun part that corresponds to the thickness of the blank (Fig. 5). No such relationship exists for a curvilinear surface. In the path from the pole to the equator, the axial thickness of the metal on a hemisphere changes from stock thickness at the pole to infinity at the equator (the inverse of sin 0° being infinity). The blank thickness must be back tapered to compensate for the change in thickness that will take place during spinning. This is shown in Fig. 11; the machined taper started at 3.8 mm (0.150 in.) in thickness (in the center of the blank) and ended at 7.6 mm (0.300 in.) in thickness at the circle where the 30° radial line of the sphere was projected to the blank. At the corresponding 45° line, the blank thickness was 5.38 mm (0.212 in.); at the 15° line, 14.73 mm (0.580 in.). Below the 30° line, however, the reduction was greater than permissible for the material, and the operation was planned as if spinning a cylinder. The blank for this portion had a flange with a thickness proportional to the percentage of reduction.

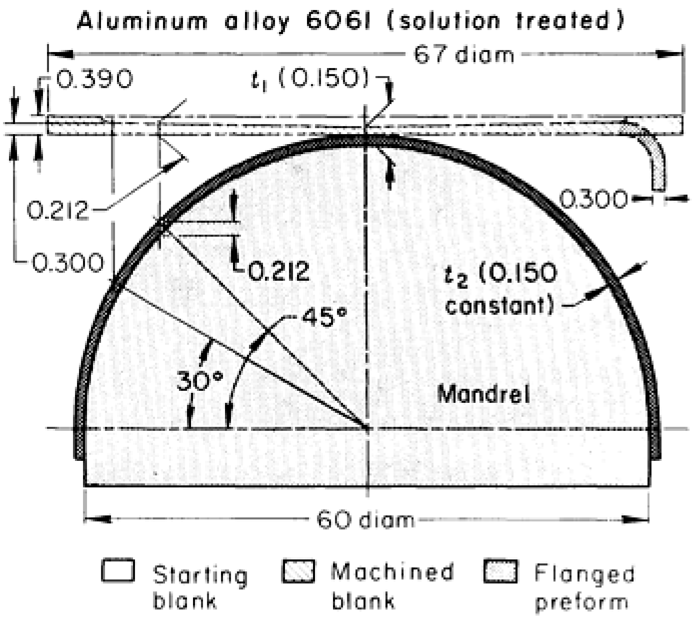

Fig. 11 Hemisphere spun from a machined and preformed blank. Dimensions given in inches.

A usable blank can be designed by first finding in Table 2 the allowable reduction for the work metal to be used. A beginning stock thickness should be selected that, with the maximum reduction, will give the thickness desired on the sphere. The ratio of finished stock thickness to original stock thickness is then taken as the sine of an angle, which will be the angle of the surface at the latitude at which preforming must start. Beyond this point, the reduction required to make the hemisphere will be greater than is permissible for the work metal. There will be no reduction at the pole, because at that point blank thickness and final thickness will be the same. At 45° from the pole, final part thickness will be 0.707 times the original thickness (sin 45° = 0.707). At a corresponding circle on the blank, therefore, the original thickness must be 1.414 times the final part thickness. Other latitudes can be similarly chosen, and necessary stock thickness at a corresponding circle on the blank determined. Preforming must start at the circle corresponding to the limiting latitude (the point where the maximum permissible reduction has taken place). In a cross-section view, the circles resulting from the above method will appear as points, and the thickness of the stock at these points can be determined. When the points are laid out, a dozen or more points are connected to yield the final part shape.

In modern shops, such calculations are usually performed with the aid of a computer. It is common practice in such systems to use 1200 to 1500 points on a shape such as a large hemisphere.

The thickness of the starting blank can be obtained by multiplying the known thickness of the finished part by an appropriate factor. Similarly, by dividing the starting blank thickness by the appropriate factor, the thickness of the finished part is obtained. The factors are related to the percentage of reduction and are the reciprocal of the difference between the percentage reduction (expressed as a decimal) and one, as follows:

- For 50% reduction, use a factor of 2
- For 66 $\frac{2}{3}$% reduction, use a factor of 3
- For 75% reduction, use a factor of 4

- For 80% reduction, use a factor of 5

Use of this system is illustrated in the following example.

Example 1: Forming a 1.5 m (60 in.) Diam Hemisphere by Power Spinning.

Large hemispheres (Fig. 11) were power spun from solution-treated aluminum alloy 6061 using the following calculations. From Table 2, it was determined that a 50% reduction could be made with this alloy. Preliminary calculations for thickness of the starting blank were as follows:

$$
\begin{aligned}
t &= \text{final wall thickness} \cdot \text{factor for percentage reduction} \\
&= 3.81 \text{ mm } (0.15 \text{ in.}) \cdot 2 \\
&= 7.62 \text{ mm } (0.300 \text{ in.})
\end{aligned}
$$

In calculating the blank thickness at various points on the sphere, it was found that at the pole, or 90° point, the thickness had to be reduced to 3.81 mm (0.150 in.) and that some reduction was required out to a point directly above the 30° tangency on the hemisphere, where the thickness of the starting blank had to be 7.62 mm (0.300 in.). Beyond this point, a flange would be preformed by spinning, and an additional thickness would be required. It was estimated that an increase in blank thickness of 30% would be enough, and initial blank thickness established at 9.91 mm (0.390 in.).

Machining of the blank to graded thickness was done in a tracer-controlled vertical boring mill, with the blank held on a vacuum chuck. After machining, the flange was preformed to the desired contour by conventional power spinning, accomplishing a reduction in wall thickness that provided a uniform 7.62 mm (0.300 in.) wall.

Final spinning was accomplished in one pass of the rollers after the alloy was given a controlled amount of room-temperature aging (usually 13 to 18 h). During final spinning one roller led the other by a vertical offset of 1.6 to 3.2 mm ($\frac{1}{16}$ to $\frac{1}{8}$ in.), using 19 mm ($\frac{3}{4}$ in.) radius tool rings at a feed of about 2.3 mm/rev (0.09 ipr). Speed varied from 300 rpm maximum down to 40 rpm at the flange.

The procedure described in Example 1 has also been successfully applied to the forming of hemispheres and ellipses 152 mm to 1.8 in (6 to 70 in.) in diameter from 17-7 PH and type 410 stainless steels, from alloy steels such as 4130 and 4140, and from aluminum alloys 5086, 2014, and 2024 (as well as 6061). In one case, the procedure was used for the hot spinning of an ogive 762 mm (30 in.) in diameter and length from molybdenum.

Hot Spinning of Hemispheres. The use of heat for decreasing the strength and increasing the ductility of the work metal is sometimes required because the machine capacity is insufficient for cold forming the thickness to be spun or because the room-temperature ductility of the work metal is too low. Hot spinning is done only when necessary, because heating, subsequent cleaning, and increased tool deterioration all contribute to increased cost.

Lubricants and Coolants for Power Spinning

Power spinning requires the use of a fluid that serves as both a lubricant and a coolant. Because of the large amount of heat generated, a water-base fluid is most commonly used. Usually, a colloidal suspension of zinc in lithium soap or molybdenum disulfide paste is mixed with water to function as the lubricant. These lubricant-coolant combinations are satisfactory for most metals, although zinc-free lubricants and coolants should be used for the spinning of stainless steel to avoid surface contamination.

Various oils and oil mixtures, such as 10% lard oil in kerosene, have also been successfully used for power spinning. Regardless of composition, the fluid must be free flowing and applied by pumps in copious amounts, or both workpieces and tools will be damaged from heat.

When spinning aluminum or stainless steel, the workpieces or mandrels or both are sometimes coated with the lubricant before spinning. During spinning, workpieces and tools are flooded with a coolant, such as an emulsion of soluble oil in water.

Effects of Spinning on Work Metal Properties

Power spinning is a severe cold-working operation and therefore has a marked effect on the mechanical properties of the work metal. A well-defined and directional grain flow pattern is produced by power spinning. The surface finish of a spun workpiece is usually good enough so that no additional machining is required after spinning. Spun finishes are commonly about 1.5 μm (60 μin.), although finishes as smooth as 0.5 μm (20 μin.) have been produced by power spinning.

Strength and Hardness. In spinning, tensile and yield strengths increase, and ductility decreases. The magnitude of effect depends on the amount of wall reduction and on the susceptibility of the metal to work hardening.

In many applications, the increase in strength caused by spinning is highly desirable because it eliminates the need for heat treating. In other applications, the change in mechanical properties is not desired, and the workpieces must be annealed after spinning.

To measure the work hardening in the deformation zone, Rockwell F (HRF) readings were taken on the cross section of a spun copper workpiece that was reduced 43%. The results are shown in Fig. 12. It is evident that the area near the roller contact has higher hardness than the area at the mandrel side.

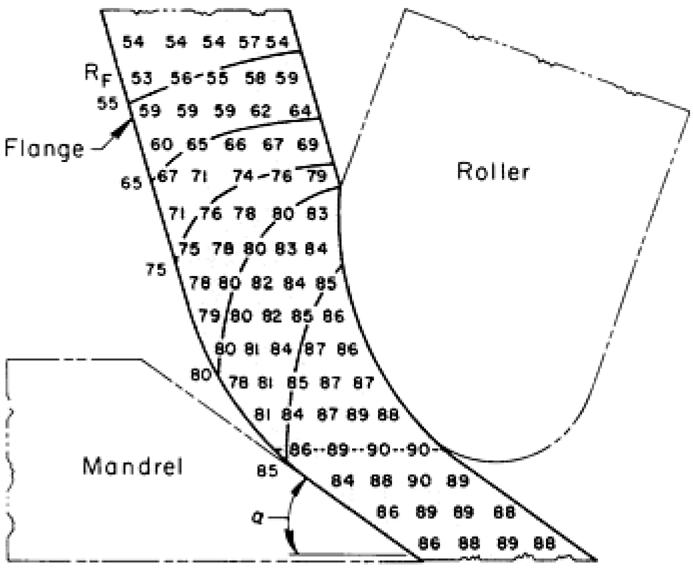

Fig. 12 Hardness distribution (HRF) in a copper workpiece reduced 43% by spinning.

Assembly by Spinning

Spinning is frequently used for less conventional applications than those described earlier in this article and in the article "Tube Spinning" in this Volume. It is often the least expensive means of joining two or more parts to form an assembly. For example, a tube can be inserted through a hole in a plate, and the protruding end of the tube can then be spun to secure it to the plate. Small parts are assembled by this technique with a special tool rotated by a drill press.

Introduction

RUBBER-PAD FORMING, also known as flexible-die forming, employs a rubber pad or a flexible diaphragm as one tool half, requiring only one solid tool half to form a part to final shape. The solid tool half is usually similar to the punch in a conventional die, but it can be the die cavity. The rubber acts somewhat like hydraulic fluid in exerting nearly equal pressure on all workpiece surfaces as it is pressed around the form block.

Rubber-pad forming is designed to be used on moderately shallow, recessed parts having simple flanges and relatively simple configurations. Form block height is usually less than 100 mm (3.9 in.). The production rates are relatively high, with cycle times averaging 1 min or less.

The advantages of the rubber-pad forming processes compared to conventional forming processes are:

- Only a single rigid tool half is required to form a part
- One rubber pad or diaphragm takes the place of many different die shapes, returning to its original shape when the pressure is released
- Tools can be made of low cost, easy-to-machine materials due to the hydrostatic pressure exerted on the tools
- The forming radius decreases progressively during the forming stroke, unlike the fixed radius on conventional dies
- Thinning of the work metal, as occurs in conventional deep drawing, is reduced considerably
- Different metals and thicknesses can be formed in the same tool
- Parts with excellent surface finish can be formed as no tool marks are created
- Set-up time is considerably shorter as no lining-up of tools is necessary

The disadvantages are:

- The pad or diaphragm has a limited lifetime that depends on the severity of the forming in combination with the pressure level
- Lack of sufficient forming pressure results in parts with less sharpness or with wrinkles, which may require subsequent hand work
- The production rate is relatively slow, making the process suitable primarily for prototype and low-volume production work

Equipment. The hydraulic presses used in most flexible-die forming are similar to those described in the article "Presses and Auxiliary Equipment for Forming of Sheet Metal" in this Volume. Some processes use special machines, which are described in this article in the discussions of the specific processes. In most applications, only one solid tool half is specially made. The tool half can be made of epoxy resin, zinc alloys, hardwood, or other inexpensive material, as well as aluminum, cast iron, or steel.

Equipment is available with cycling rates as high as 1500 per hour. Some flexible-die forming methods have been applied to high-volume production, such as the forming of deeply recessed taillight reflectors for automobiles, and the deep drawing of toaster shells (Example 3).

The application of rubber pads in press-brake dies is discussed in the article "Press-Brake Forming" in this Volume. In the past, flexible-die forming methods were designated by specific processes: Guerin process, Verson-Wheelon process, trapped-rubber process, Marform process, Hydroform process, SAAB process, and Demarest process. Modern technology has reduced this list, categorizing the methods into three basic groups: rubber pad, fluid cell, and fluid forming. Detailed applications of these rubber-die forming processes to specific metals are available in the articles "Forming of Stainless Steel," "Forming of Aluminum Alloys," "Forming of Copper and Copper Alloys," and "Forming of Titanium and Titanium Alloys" in this Volume.

Rubber-Pad Forming

The Guerin process is synonymous with the term rubber-pad forming. An improvement over the Guerin process is the Marform process, which features the addition of a blankholder and die cushion to make this process suitable for deeper draws and to alleviate the wrinkling problems common to the Guerin process. Another variation of the Guerin process is the trapped-rubber process, in which the forming force is provided by a hammer instead of a hydraulic press. Like the Marform process, the trapped-rubber process can be used for deeper draws and results in less scrap due to wrinkling than the basic Guerin process. The design and construction of the ASEA Quintus rubber-pad presses are further refinements of the Guerin and Marform processes.

Guerin Process

The Guerin process is the oldest and most basic of the production rubber-pad forming processes. Its advantages are simplicity of equipment, adaptation to small-lot production, and ease of changeover.

Some metals that are commonly formed by the Guerin process are listed in Table 1. Titanium can be formed only if the workpiece and the form block are both heated. The resulting deterioration of the rubber pad often makes the process too costly, as compared to forming by conventional dies.

Table 1 Metals commonly formed by the Guerin process

Metal	Maximum thickness[(a)]	
	mm	in.
Mild forming		
Aluminum alloys		
2024-O, 7075-W	4.7	**0.187**
2024-T4	1.6	**0.064**
Austenitic stainless steels		
Annealed	1.3	**0.050[(b)]**
Quarter hard	0.8	**0.032[(c)]**
Titanium alloys	1.0	**0.040[(d)]**
Stretch flanging		
Aluminum alloy 2024-T4	1.6	**0.064**
Austenitic stainless steels		

Quarter hard	**0.8**	**0.030**

(a) Typical; varies with type of equipment and part design.

(b) Up to 2.0 mm (0.078 in.) when compression dams are used (see the section "Accessory Equipment" and Fig. 2 in this article).

(c) Only very mild forming.

(d) When heated to 315 °C (600 °F)

Presses. For maximum forming capability, the force capacity of the press and the area of the rubber pad must be suitable for the operation under consideration. The rubber pad is generally about the same size as the press ram, but it can be smaller (Example 2).

Tools. The principal tools are the rubber pad and the form block, or punch (Fig. 1). The rubber pad is relatively soft (about Durometer A 60 to 75) and is usually three times as deep as the part to be formed. The pad can consist of a solid block of rubber, or of laminated slabs cemented together and held in a retainer, as shown in Fig. 1. The slabs can also be held loose in a flanged retainer. The retainer is generally made of steel or cast iron, and it is approximately 25 mm (1 in.) deeper than the rubber pad. It is also strong enough to withstand the forming pressures generated (up to 140 MPa, or 20 ksi, in some applications, although an upper limit of 14 MPa, or 2 ksi, is more common).

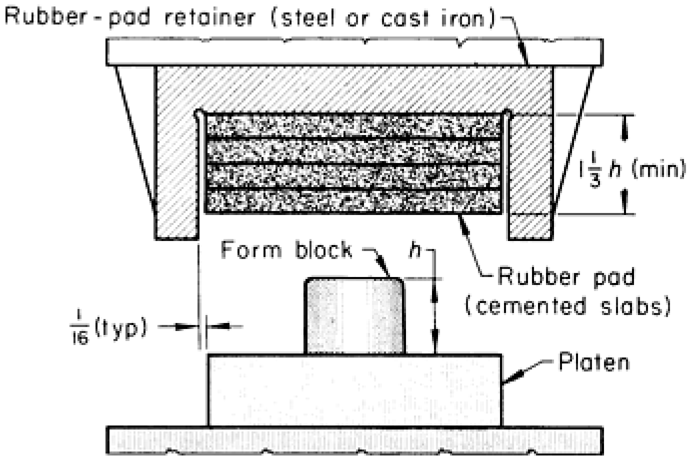

Fig. 1 Tooling and setup for rubber-pad forming by the Guerin process. Dimensions given in inches.

The minimum pad thickness is $1\frac{1}{3}$ times the height of the form block, as shown in Fig. 1. Pad thicknesses generally vary from 152 to 305 mm (6 to 12 in.), and the most commonly used thickness is 203 to 229 mm (8 or 9 in.).

Form blocks are made of wood, plastic, masonite, cast iron, steel, or alloys of aluminum, magnesium, zinc, or bismuth. The softer materials are used in making prototypes or experimental models or in small production runs. The life of a wood, plastic, or soft-metal form block can be extended by facing it with steel. Form blocks are fitted with locating pins to hold the blanks in position while they are being formed.

The form block is loosely mounted on a platen, or pressing block (Fig. 1), which fits closely into the rubber-pad retainer to avoid extrusion of the rubber during the forming process. Several form blocks are often mounted on one platen so that several parts can be formed simultaneously with one stroke of the press. Two or three platens can be used with each press; they can be slid or rotated from under the press ram for loading and unloading.

Accessory equipment includes draw clips, cover plates, wiping plates, forming rings and forming bars, and dams and wedge blocks. These are used to increase the pressure on the workpiece in specific locations and to aid in the forming of difficult shapes.

Draw clips are fastened to the edge of a blank to equalize the drawing force on a flange and to keep it from wrinkling. Wiping plates, usually hinged to the pressing block, mechanically transfer the pressure of the rubber pad to hard-to-form flanges. Forming rings and forming bars work in the same way, except that they encircle the part and therefore are not hinged. Dams are shaped and positioned so that with the sidewall of the form block they form a trap. The dam has a face sloping toward this trap so that rubber is cammed against the sidewall as the rubber pad moves down, thus increasing the pressure in that area. Wedge blocks use the same kind of camming action to apply mechanical pressure to the side of a workpiece. Examples 1 and 4 in this article illustrate the use of dams. Cover plates are used to hold blanks flat during forming or to protect previously formed areas from distortion.

Procedure. The rubber-pad retainer is fixed to the upper ram of the press, and the platen, containing the form block, is placed on the bed of the press. A blank is placed on the form block and is held in position by two or more locating pins. The pins must be rigidly mounted in the form block so that the rubber will not drive them down into the pinhole or push them out of position; and they must be no higher than necessary to hold the blank, or they will puncture the rubber pad. In some applications, nests can be used to locate the blank during forming.

As the ram descends, the rubber presses the blank around the form block, thus forming the workpiece. The rubber-pad retainer fits closely around the platen, forming an enclosure that traps the rubber as pressure is applied. The pressure produced in the Guerin process is ordinarily between 6.9 and 48 MPa (1 and 7 ksi). The pressure can be increased by reducing the size of the platen. Pressures as high as 140 MPa (20 ksi) have been developed through the use of small platens in high-capacity presses (see Example 1).

The pressure is not a function of the number of parts being formed, but of the platen area. To obtain maximum production with each stroke of the press, therefore, as many form blocks as possible are mounted on a single platen. The depth of the finished parts formed by this process seldom exceeds 38 mm ($1\frac{1}{2}$ in.). However, deeper parts can be formed by using a press with a high force capacity and a rubber pad with a small surface area. In one application, such a setup produced 140 MPa (20 ksi) of pressure and was able to form a flange 70 mm ($2\frac{3}{4}$ in.) deep.

Straight flanges can be easily bent by the Guerin process if they are wide enough to develop adequate forming force. If the flanges are not wide enough, accessory tools must be used.

Minimum widths for flanges of stainless steel and aluminum alloys that can be bent by rubber-pad forming are listed in Table 2. Angles on flanges in soft metal can generally be held to a maximum variation of ±1°. In hard metals, such as half-hard stainless steels, which have more springback than annealed stainless steels, a ±5° tolerance can be met only with special care. An envelope (all-around) tolerance of ±0.38 mm (±0.015 in.) is possible on the contour of soft-metal pieces, but on hard metal, the tolerance must be increased to ±0.51 mm (±0.020 in.).

Table 2 Minimum formable flange widths for the rubber-pad forming of stainless steels and aluminum alloys

Alloy and/or temper	Minimum flange width[(a)]	
	mm	in.
Stainless steels		
Annealed	4.8 + 4.5t	$\frac{3}{16}$ **+ 4.5*t*[(b)]**

Quarter hard	16	$\frac{5}{8}$
Aluminum alloys		
2024-O, 7075-O	1.6 + 2.5*t*	$\frac{1}{16}$ **+ 2.5*t*(b)**
2024-T3, 2024-T4	**3.2 + 4*t***	$\frac{1}{8}$ **+ 4*t*(b)**

(a) Using minimum permissible bend radius; a larger bend radius requires a wider flange.

(b) *t*, sheet thickness

Stretch flanges and shrink flanges can be formed around curves and holes if the deformation is slight to moderate. If forming is severe, auxiliary tools must be used to support the work and to prevent wrinkling.

Shallow Drawing. Cover plates are often used to hold webs flat while flanges are being formed. In the following example, a pressure of 140 MPa (20 ksi) was used to form a part so well that only minimal hand reworking was required. To obtain the 140 MPa (20 ksi) pressure, a rubber pad 508 mm (20 in.) in diameter (surface area: ~0.19 m^2, or 300 in.^{2}) was mounted in a 27 MN (3000 tonf) hydraulic press. The bed size of the press was 1520 mm (60 in.) front-to-back and 1570 (62 in.) left-to-right. Stroke length was 457 mm (18 in.), and shut height was 1270 mm (50 in.). The press had a turntable that held two form blocks; therefore, one block could be unloaded and loaded while the other was under the press ram. The rubber pad was 203 mm (8 in.) thick and made in two pieces. One piece was 178 mm (7 in.) thick and had a hardness of Durometer A 80 to 85. The second piece, which was replaceable, was 25 mm (1 in.) thick and had a hardness of Durometer A 70 to 75.

Example 1: Shallow Drawing of a Fuselage Tail Cap by the Guerin Process.

The fuselage tail cap shown in Fig. 2 was rubber-pad formed at 140 MPa (20 ksi) using the 27 MN (3000 tonf) hydraulic press and the 508 mm (20 in.) diam pad described above. The cap was originally made by spinning, but at a rate of only one piece per hour. Changing to high-pressure rubber-pad forming by the Guerin process increased the production rate to 12 pieces per hour.

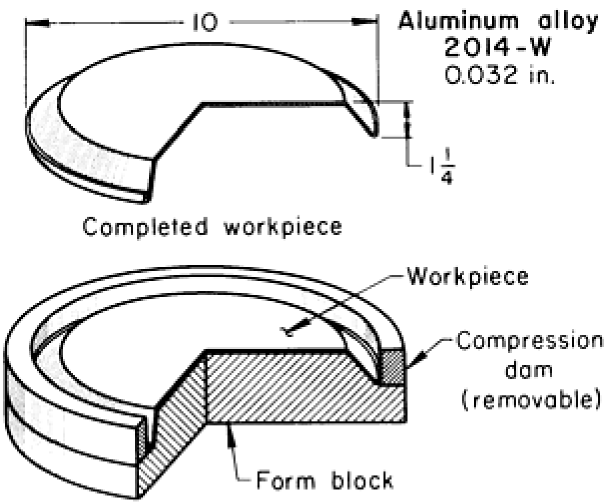

Fig. 2 Fuselage tail cap that was formed by the Guerin process in a high-pressure setup. Dimensions given in inches.

A blank of aluminum alloy 2014-O, 0.81 mm (0.032 in.) thick, was solution heat treated to the W temper and was lubricated with heavy-duty floor wax. The part was formed before age hardening was complete. A compression dam surrounded the form block (Fig. 2) and was used to concentrate pressure on the flange.

Matched Laminations. In the following example, accurately matched laminations were made by forming one over the other on a form block by the Guerin process.

Example 2: Forming of a Two-Piece Cockpit Rail on a Single Form Block.

By using a rubber pad instead of a conventional die, it was possible to form the two mating parts of a cockpit rail section on a single form block. One of the two parts is shown in Fig. 3. The second part was formed over the first after it had been formed.

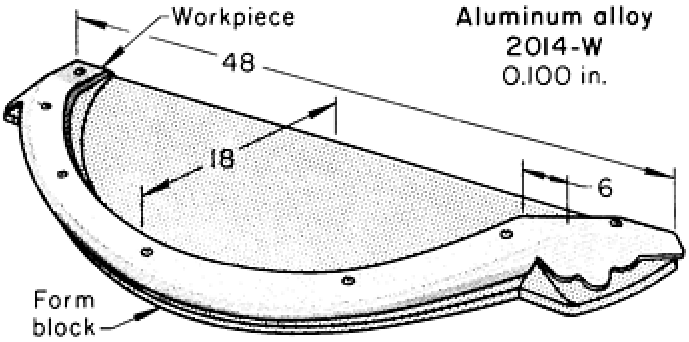

Fig. 3 Cockpit rail section that was formed on a single form block by the Guerin process. Dimensions given in inches.

A fully developed blank, 2.54 mm (0.100 in.) thick, was cut from aluminum alloy 2014-O and solution heat treated. Forming was done by the Guerin process with a minimum pressure of 52 MPa (7.5 ksi). No lubricant was used. The form block (Fig. 3) was made of masonite and was plastic faced. The production rate was 20 pieces per hour.

Blanking. With the Guerin process, rubber pads can be used for blanking and piercing as well as for forming. Rubber pads produce better edges on the workpiece than band sawing, and almost as good as those made by routing. An edge radius up to the thickness of the metal can be produced on some heavy-gage metals. The rubber-pad method can blank aluminum alloy 2024-O up to 0.81 mm (0.032 in.) thick and, for some shapes, up to 1.0 mm (0.040 in.) thick. The minimum hole diameter or width of cutout is 50 mm (2 in.). A minimum of 38 mm ($1\frac{1}{2}$ in.) trim is needed for external cuts.

The form block has a sharp cutting edge where the blank is to be sheared. In hard-metal blocks, this edge can be cut into the form block, as shown in Fig. 4(a) and 4(b). Form blocks of soft metal, plastic, or wood need a steel shear plate for the cutting edge (Fig. 4c); the shearing edge should be undercut 3 to 6°.

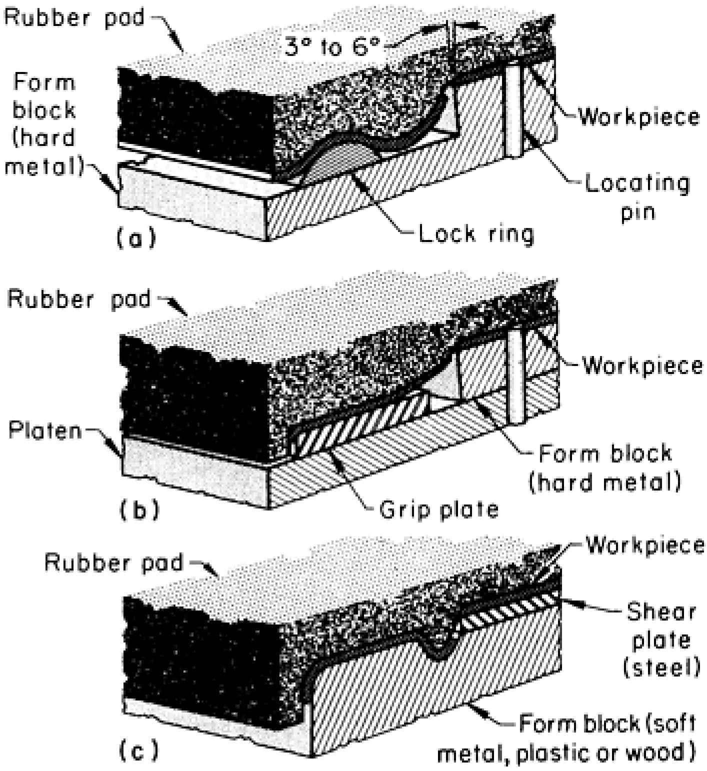

Fig. 4 Three techniques for blanking by the Guerin process categorized by clamping method. (a) Lock ring. (b) Grip plate. (c) Raised extension of the form block.

The trim metal beyond the line of shear must be clamped firmly so that the work metal will break over the sharp edge instead of forming around it. This clamping is done by a lock ring (Fig. 4a), a grip plate (Fig. 4b), or a raised extension of the form block (Fig. 4c).

These clamping devices also localize pressure at or near the cutting line. A rounded edge on the finished blank can be produced by locating the lock ring or grip plate a small distance from the shear edge (Fig. 4a and 4b). The metal droops in the unsupported area and forms around the sharp corner before it shears. The result is a smooth, rounded edge.

Drawing of shallow parts is often done by a modification of the Guerin process in which the contour is recessed (for example, a die cavity) into the form block rather than being raised on it. The blank is securely clamped between the rubber pad and the surface around the recess before forming begins.

Clamping the work metal before drawing and the amount of pressure used are both important for successful drawing. The work metal must be securely clamped to prevent it from flowing irregularly and subsequently forming wrinkles, but not so tightly that the metal cannot flow at all, which will cause thinning, or even tearing, of the work metal. To avoid this, either the edges can be lubricated or a protecting block with an undercut slot to accommodate the flange (Fig. 5) can be placed over the edges of the workpiece. The width of the block and undercut must provide the correct balance between clamping force and drawing force. The undercut should be 0.08 to 0.15 mm (0.003 to 0.006 in.) higher than the thickness of the work metal.

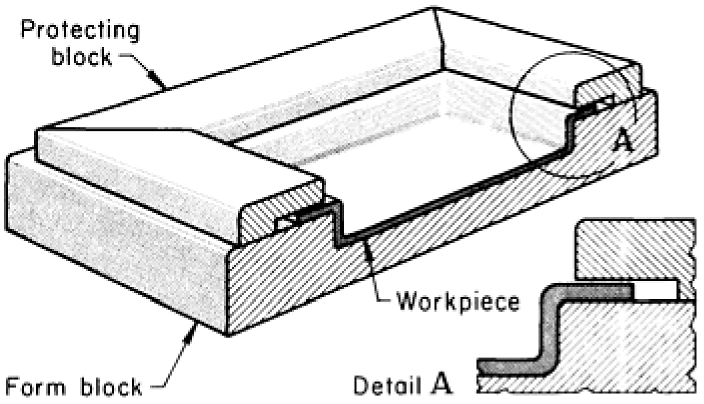

Fig. 5 Use of a protecting block to prevent work metal irregularities in shallow drawing by the Guerin process.

Marform Process

The Marform process was developed to apply the inexpensive tooling of the Guerin and Verson-Wheelon processes (see the section "Verson-Wheelon Process" in this article) to the deep drawing and forming of wrinkle-free shrink flanges. A blankholder plate and a hydraulic cylinder with a pressure-regulating valve are used with a thick rubber pad and a form block similar to those used in the Guerin process. The blank is gripped between the blankholder and the rubber pad. The pressure-regulating valve controls the pressure applied to the blank while it is being drawn over the form block.

While forming a soft aluminum alloy blank, the diameter can usually be reduced 57%, and reductions as high as 72% have been obtained. A shell depth equal to the shell diameter is normal when the minimum stock thickness is 1% of the cup diameter. Depths up to three times shell diameter have been reached with multiple-operation forming. The minimum cup diameter is 38 mm (1½ in.).

Foil as thin as 0.038 mm (0.0015 in.) can be formed by placing the blank between two aluminum blanks about 0.76 mm (0.030 in.) thick and forming the three pieces as a unit. The inner and outer shells are discarded.

Presses. The Marform process is best suited to a single-action hydraulic press in which pressure and speed of operation can be varied and controlled. A Marform unit comes as a package that can be installed in a hydraulic press having ample stroke length and shut height. However, a press that incorporates a hydraulic cushion system into its bed has been designed specifically for Marforming.

The rubber pressures used depend on the force capacity of the press and the surface area of the rubber pad. Recent installations range from 34 to 69 MPa (5 to 10 ksi).

Tools. The rubber pad used in Marforming is similar to that used in the Guerin process. It is normally 1½ to 2 times as thick as the total depth of the part, including trim allowance. The rubber pad can be protected from scoring by the use of a throw sheet, which is either cemented to the pad or thrown over the blank.

Well-polished steel form blocks are used for long runs and deep draws. Aluminum alloy form blocks must be hard coated to prevent galling for draws deeper than 38 mm (1½ in.). Masonite form blocks can be used if they can withstand the abuse and wear of forming a particular part in a given quantity. When a cast shape is more economical, aluminum or zinc alloy form blocks can be used.

Blankholder plates are usually made of low-carbon steel. The contact surface is ground flat and polished to avoid scratching of the blank. Clearance between the form block and the mating hole in the blankholder is 0.76 to 1.52 mm (0.030 to 0.060 in.) per side. The edge should have a 1.6 mm ($\frac{1}{16}$ in.) radius.

A radius plate is necessary when the machine pressure is insufficient for forming the flange radius within tolerance. The part is drawn first without the plate, then redrawn using the plate to form the exact radius. The radius plate is usually 13 mm (½ in.) thick and 25 mm (1 in.) wider than the workpiece. A sealing ring is used to prevent the rubber pad from extruding out of the container.

Procedure. The blank rests on the blankholder plate above the form block. The rods supporting the seal ring and blankholder plate (Fig. 6) are supported on a variable-pressure hydraulic cushion. As the press ram is lowered, the blank is clamped between the rubber pad and the blankholder before forming begins. As the rubber pad continues to descend, the blank is drawn over the form block while the pressure control valve in the hydraulic cushion releases fluid at a controlled rate. The pressure in the hydraulic cushion must be adjusted to prevent wrinkles from forming in the flange but to permit the blank to be drawn into a smooth shell. The part is stripped from the form block by the blankholder. The following example describes an application of the process.

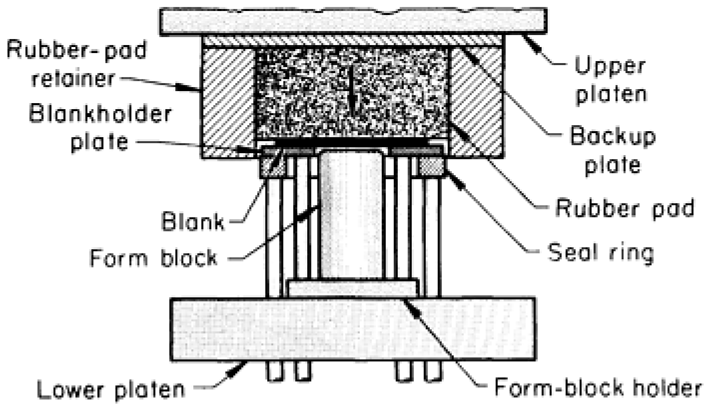

Fig. 6 Tooling and setup for rubber-pad forming by the Marform process.

Example 3: Deep Drawing of Toaster Shells by the Marform Process.

The toaster shell shown in Fig. 7 was deep drawn in large quantities (80,000 pieces) from 0.76 mm (0.030 in.) thick deep-drawing-quality 1010 steel. The blanks were lubricated by brushing with a soap compound. Available pressure was 41 MPa (6 ksi). The depth of the trimmed shell was 127 mm (5 in.). The reduction time per piece was 22 s.

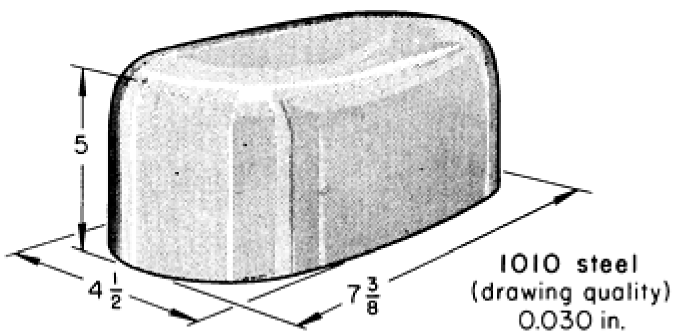

Fig. 7 Toaster shell that was deep drawn by the Marform process. Dimensions given in inches.

Drop Hammer Forming With Trapped Rubber

A process similar to the Guerin process, for forming shallow workpieces, is a trapped-rubber process, which uses a drop hammer in place of the hydraulic press; the primary differences are the faster forming speed and the impact force of the hammer. The use of rubber pads in drop hammer forming is illustrated in the article "Drop Hammer Forming" in this Volume.

Figure 8 shows the effects of forming flanges on aluminum alloys 5052-O and 2024-O by the drop hammer (trapped-rubber) and Guerin processes. When flanges deeper than 32 mm (1¼ in.) are made by the Guerin process, stretch flanges can tear and shrink flanges can wrinkle. However, when the drop hammer process is used, fewer deformities occur (Fig. 8).

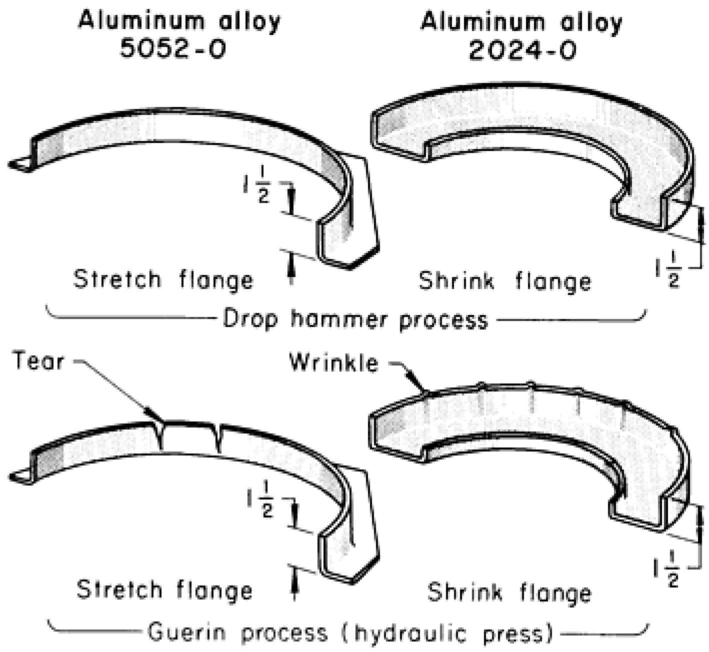

Fig. 8 Effect of impact in forming stretch and shrink flanges by the drop hammer (or trapped-rubber) and Guerin processes. Dimensions given in inches.

ASEA Quintus Rubber-Pad Press

ASEA presses, generally designed with force capacities of 50 to 500 MN (5600 to 56,000 tonf), are constructed of wire-wound frames and have separate guiding columns (Fig. 9). By winding the press frames with prestressed wire, only compressional stresses are present in the large castings or forgings of the yokes and columns, even when subjected to maximum forming pressure. Therefore, when the press is loaded, the frame remains in slight compression, and the major structural components never operate in the tensile mode.

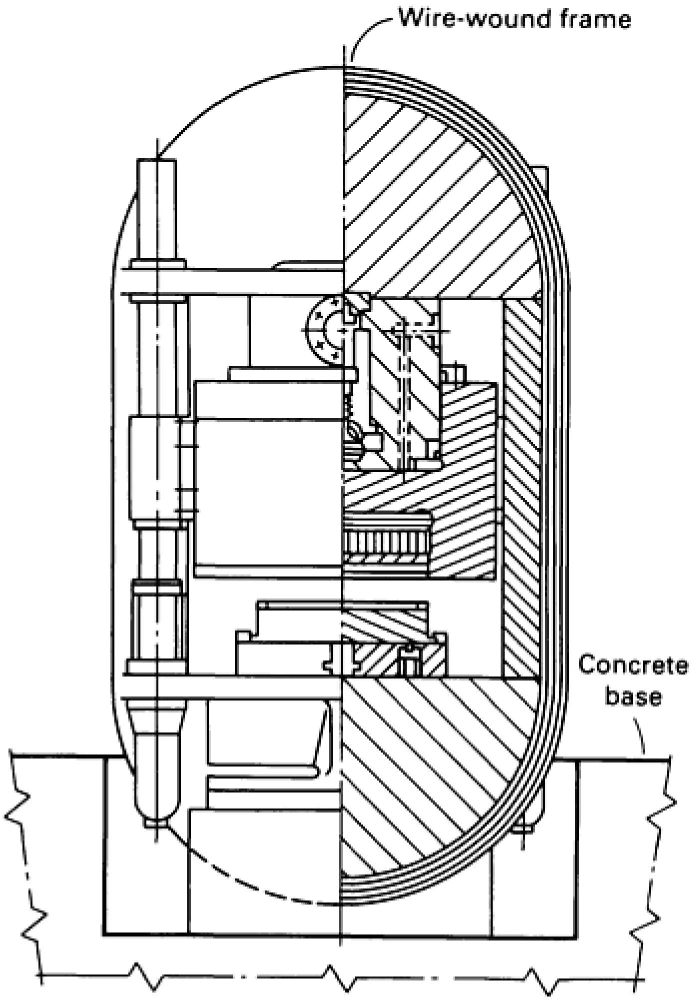

Fig. 9 Schematic of ASEA Quintus rubber-pad hydraulic press with wire-wound frame.

The press is equipped with a forged-steel rubber-pad retainer that has a replaceable insert to allow for forming at even higher pressures. Although the maximum tool height is sacrificed by using these high-pressure inserts, cutting the work area in half doubles the maximum forming pressure of the press when needed.

Standard table sizes range from 0.7 × 1.0 m (28 × 39 in.) to 2 × 3 in (79 × 118 in.). These presses provide forming pressures to 100 MPa (15 ksi). Hard and brittle materials such as titanium, along with the die, can be heated outside the press by an infrared heater; blanks can also be heated by conduction from the table through the heat transferred through the die (Fig. 10).

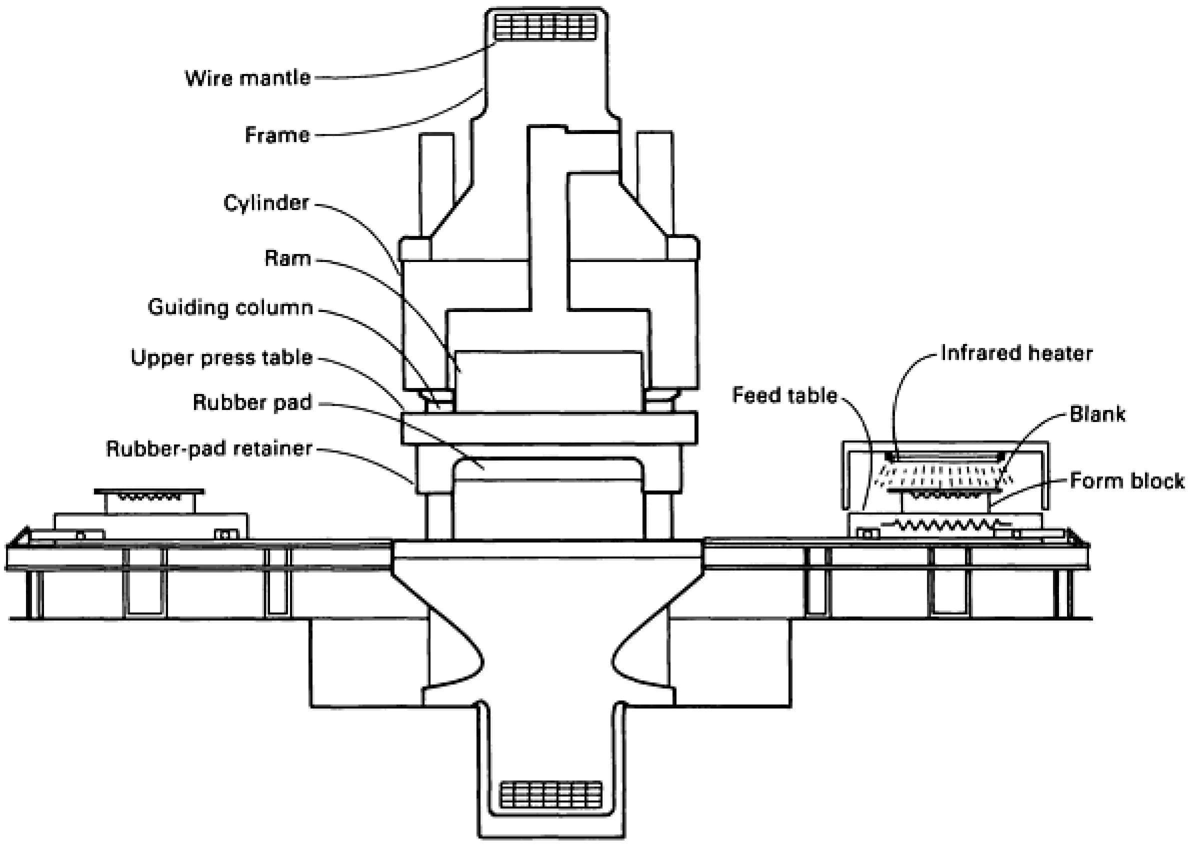

Fig. 10 Schematic of ASEA Quintus rubber-pad press with provision for heating hard and brittle materials using infrared heater or heating elements contained in feed table.

Fluid-Cell Forming

Initially developed as the Verson-Wheelon process, the fluid-cell process uses a fluid cell (a flexible bladder) backed up by hydraulic fluid to exert a uniform pressure directly on the form block positioned on the press table. This process can be classified in terms of the presses used (Verson-Wheelon and ASEA Quintus) as well as a specialized method (Demarest process) for producing cylindrical and conical parts. The Verson-Wheelon press has cylindrical press housings of laminated, prestressed steel that serve as pressure chambers. The ASEA Quintus press has a forged steel cylinder that is wound with high strength steel wire to create a prestressed press frame with extremely good fatigue properties.

Fluid-cell forming can be used for recessed parts that are beyond the capabilities of rubber-pad forming, for all flange configurations (including C-shaped flanges), and for complex parts with reentrant features and intricate joggles. Maximum form block height is 425 mm (16.7 in.), and typical cycle time is 1 to 2 min.

Verson-Wheelon Process

The Verson-Wheelon process was developed from the Guerin process. It uses higher pressure and is primarily designed for forming shallow parts, using a rubber pad as either the die or punch. A flexible hydraulic fluid cell forces an auxiliary rubber pad to follow the contour of the form block and to exert a nearly uniform pressure at all points.

The distribution of pressure on the sides of the form block permits the forming of wider flanges than with the Guerin process. In addition, shrink flanges, joggles, and beads and ribs in flanges and web surfaces can be formed in one operation to rather sharp detail in aluminum, low-carbon steel, stainless steel, heat-resistant alloys, and titanium.

Presses. The Verson-Wheelon press has a horizontal cylindrical steel housing, the roof of which contains a hydraulic fluid cell (Fig. 11). Fluid-cell bladders can be of neoprene or polyurethane composition. Hydraulic fluid is pumped into the cell, causing it to inflate or expand. The expansion creates the force needed to flow the rubber of the work pad downward, over and around the form block and the metal to be formed.

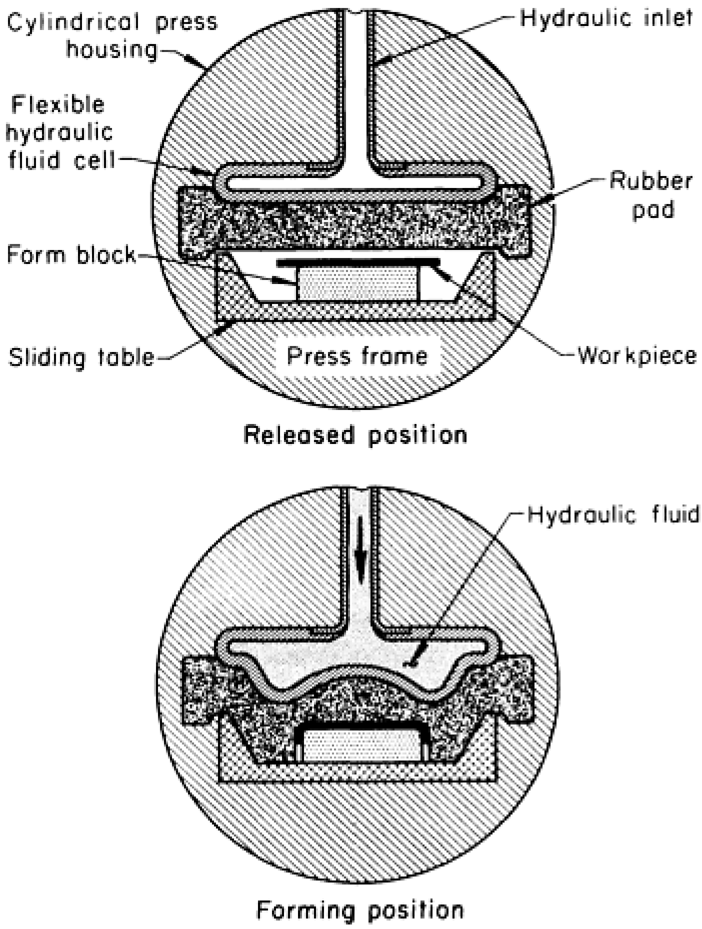

Fig. 11 Principal components of the Verson-Wheelon process.

Below the chamber containing the rubber pad and the hydraulic fluid cell is a passage, extending the length of the press, that is wide and high enough to accommodate a sliding table containing form blocks. At each end of the passage is a sliding table that is moved into position for forming.

The rubber pad used in the Verson-Wheelon process has a hardness of about Durometer A 35. It is usually protected from sharp corners on the form block and blank by a throw sheet or work pad that is harder and tougher than the pad itself. The throw sheet is much less costly to replace than the rubber pad below the fluid cell.

Verson-Wheelon presses are available with forming pressures ranging from 35 to 140 MPa (5 to 20 ksi) and force capacities of 22 to 730 MN (2500 to 82,000 tonf). Sliding tables range in size from 508 × 1270 mm (20 × 50 in.) to 1270 × 4170 mm (50 × 164 in.). The larger machine can form parts having flange widths to 238 mm ($9\frac{3}{8}$ in.).

Heating elements can be used with the sliding tables for producing parts made of magnesium. The maximum temperature is 315 °C (600 °F), and special heat-resistant throw pads are used to protect the hydraulic fluid cell.

Tools. The form blocks for the Verson-Wheelon process are made in much the same way as those for the Guerin process. Compression dams or deflector bars can be used to direct pressure into local areas for forming shrink flanges or return bends, as described in Example 4.

Aluminum alloy or zinc alloy form blocks are recommended. Because of the high pressures, masonite or wood form blocks may break down from repeated use. More than one form block can be used at a time; the quantity depends on the size and shape of the form block.

Damage to the rubber pad can be reduced by removing all burrs and sharp edges from the blank. Form blocks should be smooth; all sharp corners and projecting edges should be well rounded; high tooling pins should be eliminated; deep narrow crevices or gaps between parts of form blocks should be eliminated; holes in blocks should be plugged during forming.

Procedure. The sliding table containing the form blocks is loaded and slid into the press. Hydraulic fluid is pumped into the cell, expanding it and driving the rubber pad down against the workpiece and around the form blocks. The pressure is released, and the table of formed pieces is slid out, unloaded, and reloaded for another cycle.

Repositioning the form blocks after a few cycles will distribute the wear on the rubber pad and lengthen its life. The use of a hard-rubber (or occasionally leather) pad slightly larger than the blank assists in the uniform forming of flanges and prevents wrinkles.

The cycle time for the Verson-Wheelon process is longer than that of conventional presses, such as those used with the Guerin process. To reduce cell filling and draining time, it is good practice to load the table to capacity or to have dummy blocks on the sliding table when only one part is being formed.

In the following example, the time to form a part in a Verson-Wheelon press was less than when the part was made by the Guerin process. The higher forming pressure completely formed the part in one operation (whereas the Guerin process had required two operations) and reduced hand work after machine forming.

Example 4: Verson-Wheelon Versus Guerin Process for the Forming of a Complex Part.

The complex part shown in Fig. 12 was originally formed by the Guerin process in a 40 MN (4500 tonf) hydraulic press from 1.0 mm (0.040 in.) thick alclad aluminum alloy 7075-W. The improved method used a Verson-Wheelon press that could exert a pressure of 69 MPa (10 ksi) and had a capacity of 360 MN (41,000 tonf). A pressure of 48 MPa (7 ksi) was needed to form the part. The same tool was used for both processes.

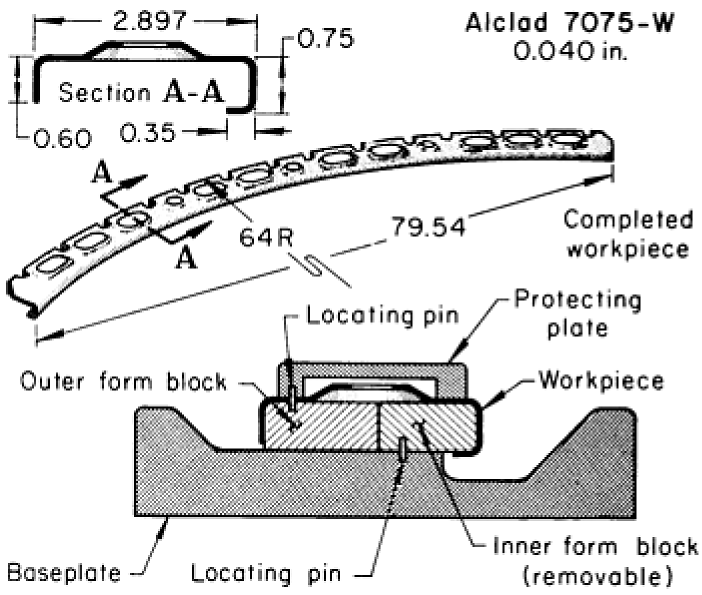

Fig. 12 Complex part that was formed in a Verson-Wheelon press. Dimensions given in inches.

In the Guerin process, forming was done in two operations. Joggles and stringer tabs were set by hand after forming. In the first press operation, the outer flange was formed, and the inner and return flanges were partly formed. In the second press operation, the forming was completed with rubber strips confined by the dams.

In the Verson-Wheelon process, the outer, inner, and return flanges and the joggles were formed in one operation. This translated into a 30% labor-cost advantage for the Verson-Wheelon process over the Guerin process for this workpiece.

The heat-treated aluminum alloy 6061 form block was mounted to a baseplate, with the inner and outer rims acting as dams. Because of the return flange on the inside radius of the part, the aluminum alloy form block was split longitudinally, and the outer half was fastened to the baseplate (see tooling setup in Fig. 12). The inner half, bushed and located on pins projecting from the baseplate, was removed from the base with the finished part. Locating holes in the blank and the outer form block matched locating pins in the cover plate.

The 127 × 2240 mm (5 × 88 in.) blank was routed, and lightening holes were individually pierced and flanged, in a punch press in both processes before rubber-pad forming. After forming, the part was aged to the T6 temper. The production lot was 20 pieces. Several thousand pieces were produced on the form blocks.

Secondary Operations. Even though higher forming pressures are used, many pieces made by the Verson-Wheelon process (as well as by the Guerin process) need hand work to remove wrinkles and to add definition to details. A further refinement in the use of throw pads is a shaped rubber pad. Pad laminations are built up around a cavity that approximates the shape of the part, so that flow of the rubber is less severe and forming pressure is more evenly distributed than with the conventional flat rubber pad. The shape of the cavity is only approximate and can be used for similar parts.

Demarest Process

Cylindrical and conical parts can also be formed by a modified rubber bulging punch. The punch, equipped with a hydraulic cell, is placed inside the workpiece, which is in turn placed inside the die. Hydraulic pressure expands the punch. Forming with an expanding punch using the Demarest process is described in the following example.

Example 5: Use of Expanding Punches to Form Aircraft Fuel-Tank Sections.

Aluminum alloy workpieces, rolled and welded into cones (Fig. 13a), were formed into aircraft fuel-tank sections with expanding rubber punches (Fig. 13b). The cones were lowered into cast iron dies, which weighed 1600 kg (3500 lb) each and were designed to withstand 10 MPa (1.5 ksi) of forming pressure.

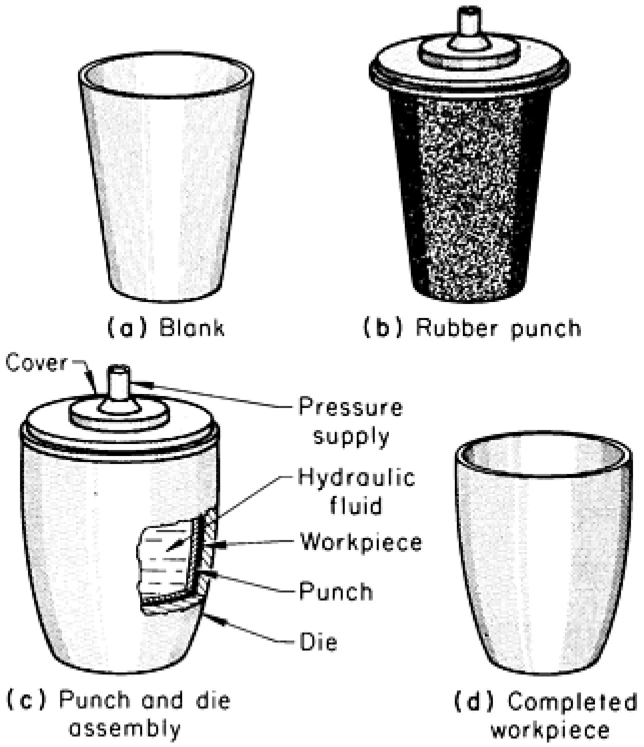

Fig. 13 Forming of a fuel-tank section from a blank using the Demarest process.

The rubber punch was lowered into the workpiece, and a steel cover was clamped over the whole assembly (Fig. 13c). The punch was expanded under 2800 kPa (400 psi) of hydraulic pressure, which formed the work metal into the curved shape of the die (Fig. 13d).

The time taken for the entire process, including dismantling of the die and unloading of the workpiece, was 3 min. In contrast, spinning requires 15 to 20 min.

ASEA Quintus Fluid Cell Process

The ASEA Quintus fluid cell process is a further development of the Guerin process, allowing deeper and more complex parts to be formed. It uses a flexible rubber diaphragm backed up by oil as either the male or female tool half. The pressurized diaphragm forces the blanks to assume the shape of the solid-tool halves. The high uniform hydrostatic pressure permits the forming of shallow- to medium-depth parts with complex shapes to final shape, practically eliminating the subsequent hand forming usually required to apply the Guerin process.

Presses. The ASEA Quintus fluid cell press (Fig. 14) consists of a horizontally placed cylindrical press frame, two rectangular, independently operated press tables on each side of the press, and all electric and hydraulic equipment necessary to operate the press placed on top of and alongside the press. The press frame is a forged steel cylinder that has been wound under pre-stress with high strength steel wire, so that only compressional stresses can occur in the steel forgings, even at maximum pressure. Therefore, the fatigue properties of the Quintus wire-wound frame are excellent and the risk of fracture virtually eliminated.

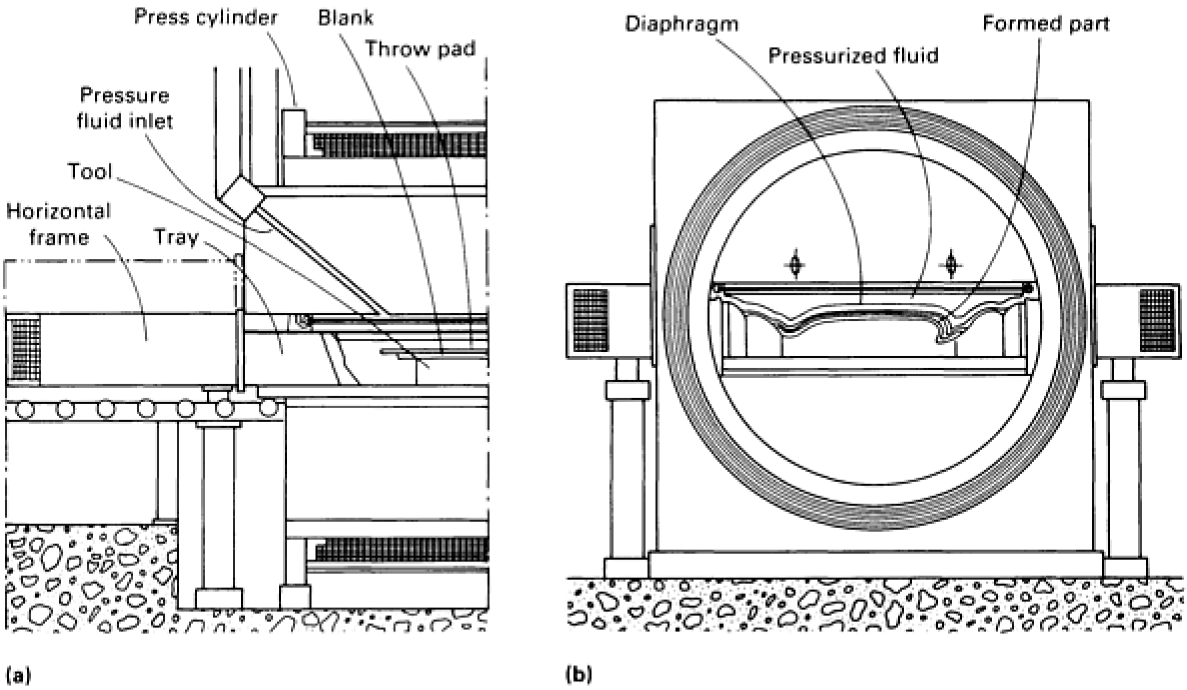

Fig. 14 Illustration of the principal components of a new generation ASEA Quintus fluid cell press. (a) Tray containing blanks inserted into press prior to pressurizing. (b) Pressurized fluid cell diaphragm forming a blank.

A diaphragm (bladder) of natural rubber is located inside the press and covers the entire surface of the press table. Hydraulic fluid is pumped into the cell created by the frame and the diaphragm, and the diaphragm is forced by the increased pressure to expand into the table, which forces the blank to assume the shape of the form block, thus forming the part. Once forming is done, the table is shuttled out to one side of the cylindrical press frame, and the table on the other side can be shuttled inside the press to allow forming of parts placed on that table.

In the new generation of ASEA Quintus fluid cell presses, the flexible diaphragm can be changed in less than 30 min. No rubber pad is required, and the diaphragm, which is made of natural rubber, can be repaired on-site should a sharp corner of a tool or blank penetrate the roll-up pad that rolls out to cover the press table when it is shuttled into the press.

ASEA Quintus fluid cell presses are available with maximum forming pressures ranging from 100 to 200 MPa (14 to 29 ksi) and force capacities up to 1400 MN (157,000 tonf). The forming tables range in size from 700 × 2000 mm (27.5 × 78.7 in.) to 2000 × 5000 mm (78.7 × 196.8 in.). The large presses can accommodate tools as high as 425 mm (16.7 in.) and consequently form parts as deep or flanges as wide as 425 mm (16.7 in.).

Tools. Because of the uniform hydrostatic pressure exerted by the press on the tools, they can be made of low-strength and low-cost tool materials such as hardwood, bakelite, epoxy, zinc-alloy, and so on, as well as of stronger materials such as aluminum, cast iron, and steel. Depending on the shape of the part, and tolerance and surface finish requirements, parts can be formed over a male die (form block), in a female die, or in an expansion die. The side of a part requiring a high surface finish should face the diaphragm, while the side of a part requiring close tolerances should face the tool. Parts with complex shapes and tight radii or made of high strength materials, demanding high pressures, and parts required in large quantities may require tools of zinc or aluminum alloys.

Procedure. The ASEA Quintus fluid cell press has two independently operated press tables. This allows parts to be unloaded and new blanks loaded on tools on one press table while parts are being formed on the other table inside the press. A press table can be loaded with one large single tool half occupying the full size of the table or several smaller tool halves; the number is restricted only by the size of the table.

Once blanks are loaded on the tools, the table is shuttled into the cylindrical press frame to a position where the flexible diaphragm, located in the upper half of the press, covers the entire table area. Oil is then pumped into the cell, causing the diaphragm to expand, which forces the blanks to assume the shapes of the tools. When the parts are formed, the pressure is relieved and the oil is evacuated from the cell allowing the table to be shuttled out from the press so that parts can be unloaded from the tools. The cycle time for a Quintus fluid cell is usually 1 to 3 min, depending on the press size and forming pressure selected.

Rubber-Pad Forming

Fluid Forming

In contrast to conventional two-die forming, which produces local stress concentrations in a workpiece, fluid forming (previously classified as rubber-diaphragm forming) employs a flexible-die technique that inhibits thinning and crack initiation due to the uniformly distributed pressure. In the fluid forming process, a rubber diaphragm serves as both the blankholder and a flexible-die member. Fluid forming differs from the rubber-pad and fluid-cell processes in that the forming pressure can be controlled as a function of the draw depth of the part.

Fluid forming was initially known as the Hydroform process. The process, as originally conceived, is incorporated into the Verson Hydroform press. After a hydraulic pump delivers fluid under pressure into the pressure-dome cavity, the punch containing the die is driven upward into the cavity against the resistance provided by the fluid, and the workpiece is formed.

In the SAAB rubber-diaphragm method, hydraulic fluid being compressed by the press piston alone (no moving die is involved) forces the workpiece to assume the contour of the die. Air vents incorporated into the die facilitate the removal of trapped air and eliminate blisters on the surface of the workpiece. The ASEA Quintus fluid forming press was developed through slight modification of the SAAB process and optimization of press specifications with easily changeable pressure domes.

Another adaption of the fluid forming method is the ASEA Quintus technique used in the ASEA Quintus deep-drawing fluid forming press. Dome pressure and punch draw are both controlled from below the blank by two concentric rams, each of which governs one of these two variables. The units have interchangeable pressure domes.

Fluid forming is intended for punch, cavity, hydroblock, or expansion forming of deep-recessed parts (Fig. 15). Cycle time is 15 to 20 s for most parts.

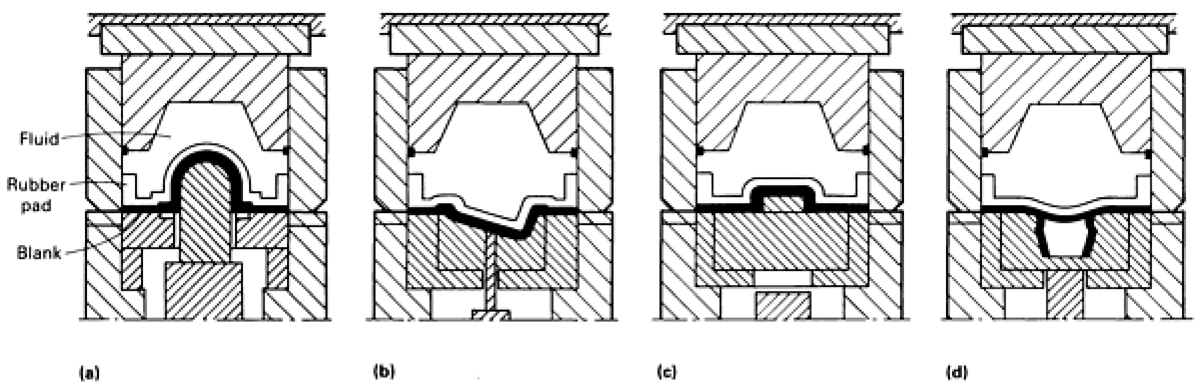

Fig. 15 Four forming techniques that can be used in a fluid forming press. (a) Punch draw. (b) Cavity draw. (c) Hydroblock draw (male-die forming). (d) Expansion draw.

Verson Hydroform Process

This process differs from those previously described in that the die cavity is not completely filled with rubber, but with hydraulic fluid retained by a 64 mm (2½ in.) thick cup-shaped rubber diaphragm. This cavity is termed the pressure dome (Fig. 16). A replaceable wear sheet is cemented to the lower surface of the diaphragm, as shown in Fig. 16. More severe draws can be made by this method than in conventional draw dies because the oil pressure against the diaphragm causes the metal to be held tightly against the sides as well as against the top of the punch.

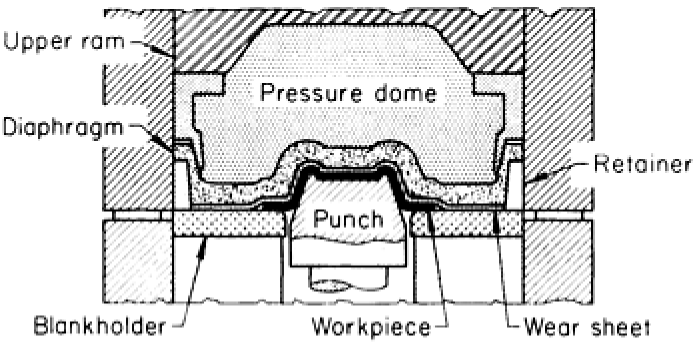

Fig. 16 Fluid-cell forming in a Hydroform press.

Reductions in blank diameter of 60 to 70% are common for a first draw. When redrawing is necessary, reductions can reach 40%. Low-carbon steel, stainless steel, and aluminum in thicknesses from 0.25 to 1.65 mm (0.010 to 0.065 in.) are commonly formed. Parts made of heat-resistant alloys and copper alloys are also formed by this process.

Presses. A special press, called a Hydroform press, is used for this process. A lower hydraulic ram drives the punch upward; the upper ram is basically a positioning device. A hydraulic pump delivers fluid under pressure to the pressure dome. The blankholder is supported by a solid bolster and does not move during the operation.

Dome pressures range from 41 to 103 MPa (6 to 15 ksi), and punch force capacities vary from 3.2 to 19 MN (368 to 2089 tonf). Special guide pins and a platen adaptor convert a standard Hydroform press into a single-action conventional hydraulic press with a force capacity of 6.2 to 40 MN (700 to 4470 tonf). This variation of the process has the punch stationary and the blankholder actuated by the die cushion of a single-action hydraulic press, as shown in Fig. 20.

Maximum blank diameters are 305 to 1020 mm (12 to 40 in.), maximum punch diameters are 254 to 864 mm (10 to 34 in.), and maximum draw depths are 178 to 305 mm (7 to 12 in.). The maximum rating is 1500 cycles per hour. The practical production rate in cycles per hour is usually about two-thirds the machine rating. However, the operation often takes the place of two or three conventional press operations.

Tools. Punches can be made of tool steel, cold-rolled steel, cast iron, zinc alloy, plastic, brass, aluminum, or hardwood. Choice of material depends largely on the work metal to be formed, number of parts to be made, shape of the part, and severity of the draw.

Blankholders are usually made of cast iron or steel and are hardened if necessary. Clearance between punch and blankholder is not critical; it may be 50% or more of the thickness of the metal being drawn.

For short runs, an auxiliary blankholding plate can be placed on a blankholder that is already in place. The auxiliary blankholder plate should not overhang in the punch clearance more than its thickness, and it should not be larger than the blankholder.

Rubber strips are placed on the blank to break the vacuum caused by dome action during drawing. Blankholders can be contoured to match the shape of a preformed blank or to preform the blank as an aid in forming.

Procedure. The blank to be formed is placed on the blankholder. The pressure dome, filled with the hydraulic fluid and covered by the rubber diaphragm, is lowered over the blank, and preliminary pressure is applied through a pump in the hydraulic supply line. The preliminary pressure can range from 14 to 69 MPa (2 to 10 ksi), depending on the part to be formed.

The punch is raised and pushed into the blank from underneath. As the form in the blank rises into the hydraulic chamber, the pressure in the chamber increases sharply, reaching as high as 103 MPa (15 ksi). A pressure control valve keeps the pressure within programmed limits. When parts are formed of thin metal, a vacuum release valve can be built into the punch to aid stripping after forming.

Three cams are programmed to control the operation of the machine. The first controls the height of rise of the punch, the second controls edging or sharpening of the corner radii, and the third returns the punch at the end of the stroke while the blankholder strips the finished part from the punch. The forming of a complex part by the rubber-diaphragm process is described in the following example.

Example 6: Rubber-Diaphragm Forming of a Complex Jet-Engine Part.

Fuel-nozzle swirl cups for high-performance turbojet engines were originally produced by welding six press-formed sections of type 310 stainless steel, AMS 5521 (Fig. 17a). Forming the six sections was difficult, and the finished parts were expensive. The rejection rate was also high.

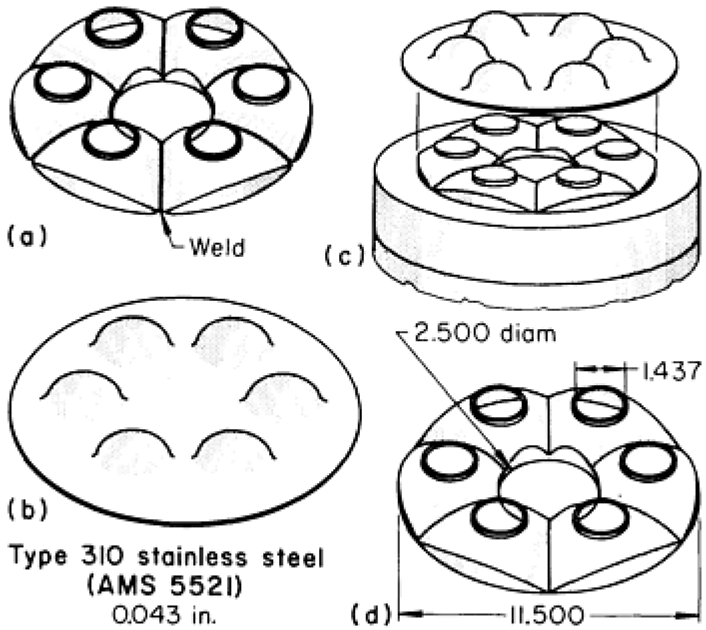

Fig. 17 Original and improved methods of forming a fuel-nozzle swirl cup for a turbojet engine. (a) Part formed by original method; six press-formed sections welded together. (b) Partly drawn blank ready for rubber-diaphragm forming. (c) Punch of six similar wedge-shaped segments doweled into bottom plate, used for rubber-diaphragm forming. (d) Swirl cup as formed by the rubber-diaphragm method and subsequently pierced and trimmed. Dimensions given in inches.

Rubber-diaphragm forming in a Hydroform press was tried. This press formed the part from one blank 1.1 mm (0.043 in.) thick by 324 mm ($12\frac{3}{4}$ in.) in diameter. Less press force was used, and costs were reduced 50%.

Before forming, the blank was rough drawn (Fig. 17b) in a 1330 kN (150 tonf) hydraulic press to a depth of 35.6 mm (1.40 in.), and its thickness was reduced to 0.99 mm (0.039 in.). After degreasing and annealing, the partly formed blank was drawn in a 305 mm (12 in.) Hydroform press, using the punch shown in Fig. 17(c). The blank rested on a blankholder mounted on a subbolster. Diametral clearance between punch and blankholder was a minimum of 50% of the work metal thickness. The production rate was 30 pieces per hour.

After forming, six equally spaced 36.50 mm (1.437 in.) diam holes and a 63.50 mm (2.500 in.) diam center hole were pierced in a 490 kN (55 tonf) mechanical press. The outside diameter was trimmed in a lathe after the part had been pierced, annealed, and restruck. The completed workpiece is shown in Fig. 17(d).

Lubricants. The following example shows the importance of the lubricant and its application when the depth of draw is near the limit for the rubber-diaphragm process.

Example 7: Use of Lubricant to Eliminate Tearing and Wrinkling in Severe Rubber-Diaphragm Drawing.

The stepped cover shown in Fig. 18 represented the limit of forming severity for the rubber-diaphragm equipment that was available. The material was 1.0 mm (0.040 in.) thick cold-rolled drawing-quality 1008 steel. The shell was 102 mm (4 in.) deep and had a step in its outer contour. Attempts to draw the stepped shell in one operation in a Hydroform press were not successful. Subsequently, two Hydroforming operations were developed in which the larger width of the cover was drawn first, and then the narrower portion above the step was produced in a redrawing operation to complete the part.

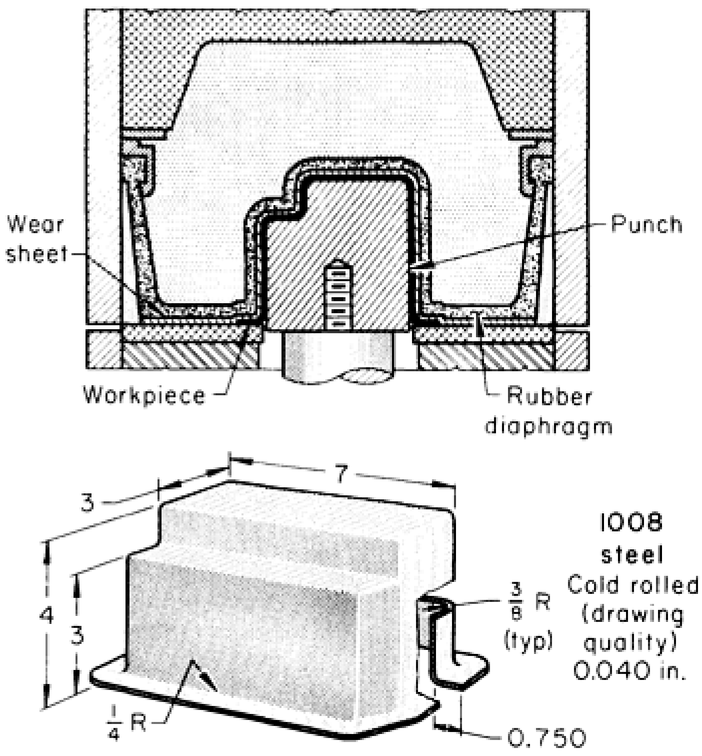

Fig. 18 Drawing of a stepped cover by the fluid-cell process. Dimensions given in inches.

In the first operation, the blankholding pressure had to be carefully adjusted. When the pressure was too low, the metal moved freely and wrinkles appeared at the corners. Too high a blankholding pressure caused tears along the narrow end. Tears and wrinkles damaged the wear sheet and, in extreme cases, the diaphragm itself.

A lubrication program was developed that prevented wrinkling or tearing. After the first draw, the workpiece was cleaned, annealed, and phosphate coated. The phosphate made it possible to use a lighter oil and to apply it more effectively, with heavy applications in some areas and little or none in others. With experience, the operators became expert at judging the location and thickness of the lubricant. Mechanical application of lubricant could not be made selective enough or controlled closely enough for consistent results.

Because the part was nearly impossible to produce by conventional deep-drawing techniques, rubber-diaphragm forming was used. The tools, consisting of two punches and a blankholder, cost considerably less than the several sets of draw dies that would otherwise have been needed, and with the lubricating technique that was developed, there was less danger of tearing or wrinkling than by other processes.

Surface Finish. A major reason for using any rubber-pad process is to preserve the surface finish of the work metal, which would be scuffed or marked by ordinary press-forming tools. In the following example, appearance was an important consideration. The part was to be plated with copper-nickel-chromium. Forming by the rubber-diaphragm method prevented marks that would have been difficult to buff out before plating.

Example 8: Use of a Rubber-Diaphragm Process to Preserve Surface Finish on a Flatiron Shell.

Because a mechanical draw press caused an impact line on the workpiece that was difficult to remove by buffing, production of the flatiron shell shown in Fig. 19 was changed to a rubber-diaphragm process, using a 3.6 MN (400 tonf) Hydroform press. A rubber draw ring of Durometer A 92 hardness helped adjust hold-down pressure so that wrinkles were avoided in the finished product. Two rubber pads were used on the rubber diaphragm. One covered the diaphragm as a reinforcement and protector; the other was a 9.5 mm ($\frac{3}{8}$ in.) thick ring molded to the shell outline. The blank was located in a nest on the blankholder.

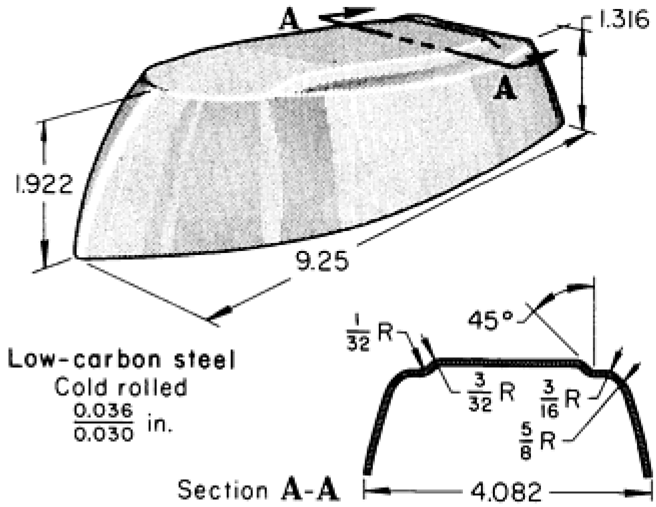

Fig. 19 Flatiron shell that was formed by the fluid-cell process in a Hydroform press to preserve the surface finish. When this shell was drawn in conventional dies, an impact line was caused below the radius that was difficult to remove by buffing. Dimensions given in inches.

Previously, the part had been drawn on a single-action mechanical press of 890 kN (100 tonf) capacity. In this press, the tools had been made of D2 tool steel. The stock was treated with soap and wiped with hydraulic oil near the point of the shell to minimize tearing.

The Hydroform press cycled at 450 strokes per minute. The production-lot size was 50,000 pieces, and yearly production was 850,000 pieces. Life of the rubber pads was as high as 20,000 pieces, and the finish of the part was good enough for subsequent plating with a minimum of buffing.

The sequence of operations was as follows: cut off blank, draw in Hydroform press, trim, pierce, copper plate, buff, nickel-chromium plate. The stock was 0.84 ± 0.08 mm (0.033 ± 0.003 in.) thick cold-rolled low-carbon steel sheet slit to width. Two different qualities of steel were used:

- Aluminum-killed drawing-quality special-surface steel with a commercial finish, dry, maximum hardness HRB 60
- Cold-rolled aluminum-killed steel strip with a No. 2 finish, dry, dead soft, maximum hardness HRB 55

The tolerance on important dimensions was ±0.08 mm (±0.003 in.); on angles, ±½°.

Single-Draw Operation. In the following example, a pressure dome was mounted on the ram of a single-action hydraulic press. The punch was fixed to a shoe mounted on the bolster plate. A die cushion provided the blankholding force. This setup functioned much like a conventional draw die except that the oil-filled pressure dome and rubber diaphragm replaced the draw ring and die cavity.

Example 9: Forming of an Automotive Tail-Lamp Housing in One Drawing Operation in a Rubber-Diaphragm Press.

An automotive tail-lamp housing was drawn in one operation from an aluminum alloy 5457-O blank 1.2 mm (0.048 in.) thick and 311 mm (12¼ in.) in diameter, in a rubber-diaphragm press rated at 69 MPa (10 ksi), as shown in Fig. 20. A water-soluble low-foaming lubricant was used. The production rate was 425 to 450 pieces per hour.

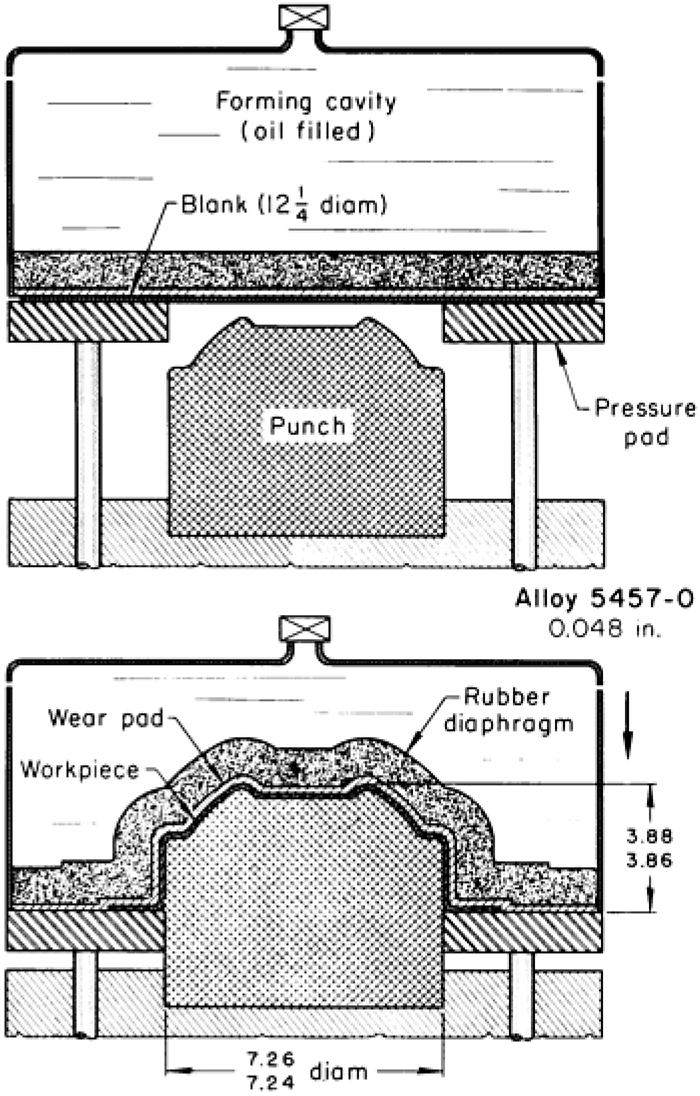

Fig. 20 Forming of an automotive tail-lamp housing in one draw in a fluid forming press. Dimensions given in inches.

To produce this part with conventional tooling, two drawing operations would have been needed to form the sharp radii at the top and bottom of the part. Tooling costs for the rubber-diaphragm press were less than one-third the cost for conventional press tooling.

The blanks were moved from a stack adjacent to the press to an automatic feeder by a pneumatic suction transfer device. A photoelectric cell prevented more than one blank being transferred. The blank passed between lubricating rollers before being fed automatically into the die. In subsequent operations, the housing was trimmed, flanged, and pierced in a mechanical press, using two conventional dies.

SAAB Rubber-Diaphragm Method

For some applications, the male member of a die set is made of rubber, and the female member is made of a hard material. In the Guerin process, shallow draws are made by recessing the form block and using the rubber pad as a punch to form the part (see the section "Shallow Drawing" in this article). The advantage of this method is that the flange is clamped before drawing, thus preventing wrinkling.

In the SAAB rubber-diaphragm method, hydraulic fluid is used behind a comparatively thin rubber pad or diaphragm. A hydraulic piston compresses the fluid against the rubber and forces the blank into the die, as shown in Fig. 21.

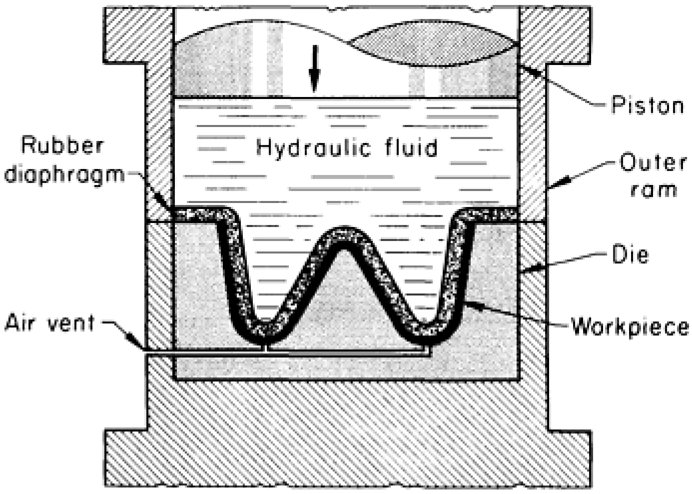

Fig. 21 Principals of SAAB rubber-diaphragm (fluid forming) method. The air vents keep trapped air from causing blisters on the workpiece.

In all rubber-punch forming processes, air vents are provided in the die to allow the air trapped between workpiece and die to escape (Fig. 21). Without air vents, the trapped air would prevent the workpiece from reaching the full contours of the die, and the workpiece would have to be removed after partial forming to release the compressed air and then replaced in the same die to complete the forming.

Bulging Punches

Rubber punches can be used to make tubular parts that must be expanded or beaded somewhere along their lengths. If such parts were made with solid punches, the punches would have to be collapsible so that they could be withdrawn.

Hollow shapes can be bulged into suitable mating dies by applying a vertical force to the punch. The dies must be segmented so that the resulting bulged product can be removed, as shown in the following example.

Example 10: Forming of a Mushroom Shape in a Segmented Bulging Die.

Figure 22 shows the process used in forming a mushroom-shaped frying-pan cover. The workpiece was a rectangular drawn shell of stainless steel, which was placed over a rubber punch of the same shape.

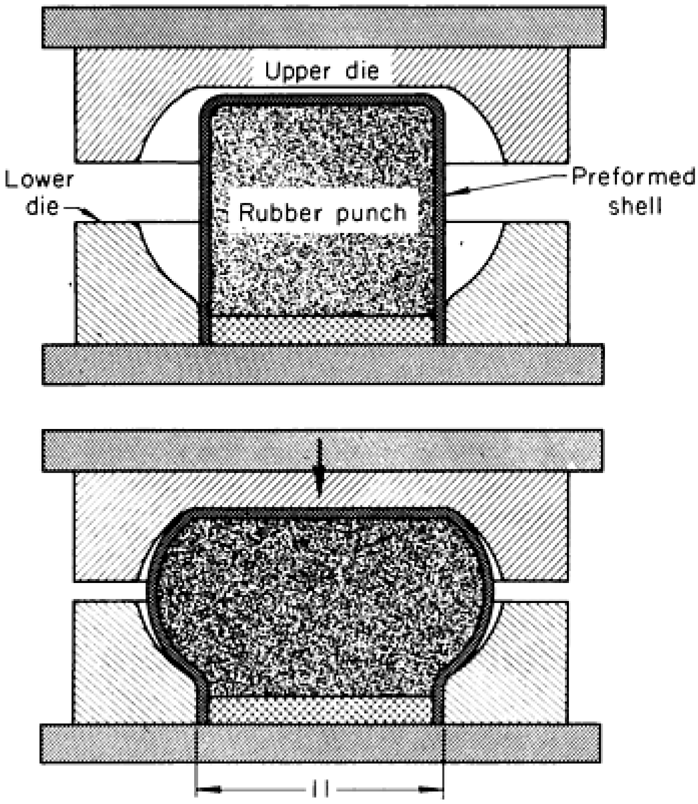

Fig. 22 Bulging of a mushroom shape from a preformed shell in a two-piece die with a rubber punch.

The two dies, which contained between them a cavity of the shape required, were closed until the rubber punch bulged the workpiece. The amount of bulge was determined by the depth of stroke. When the dies were opened, the punch returned to its original shape and was easily extracted from the finished part.

ASEA Quintus Fluid Forming Press

The ASEA Quintus fluid forming press is a vertical press having a circular fluid form unit that contains the rubber diaphragm and pressure medium (Fig. 23). These modular fluid form units serve the same function as the units used in the ASEA Quintus deep-drawing fluid forming press (see the section "ASEA Quintus Deep-Drawing Technique" in this article). The rigid tool half may be a male block, a cavity die, or an expansion die that is situated in a movable tool holder. Blanks are loaded onto the tool holder prior to shuttling the holder into the press for the 10 to 50 s forming cycle required to produce the part.

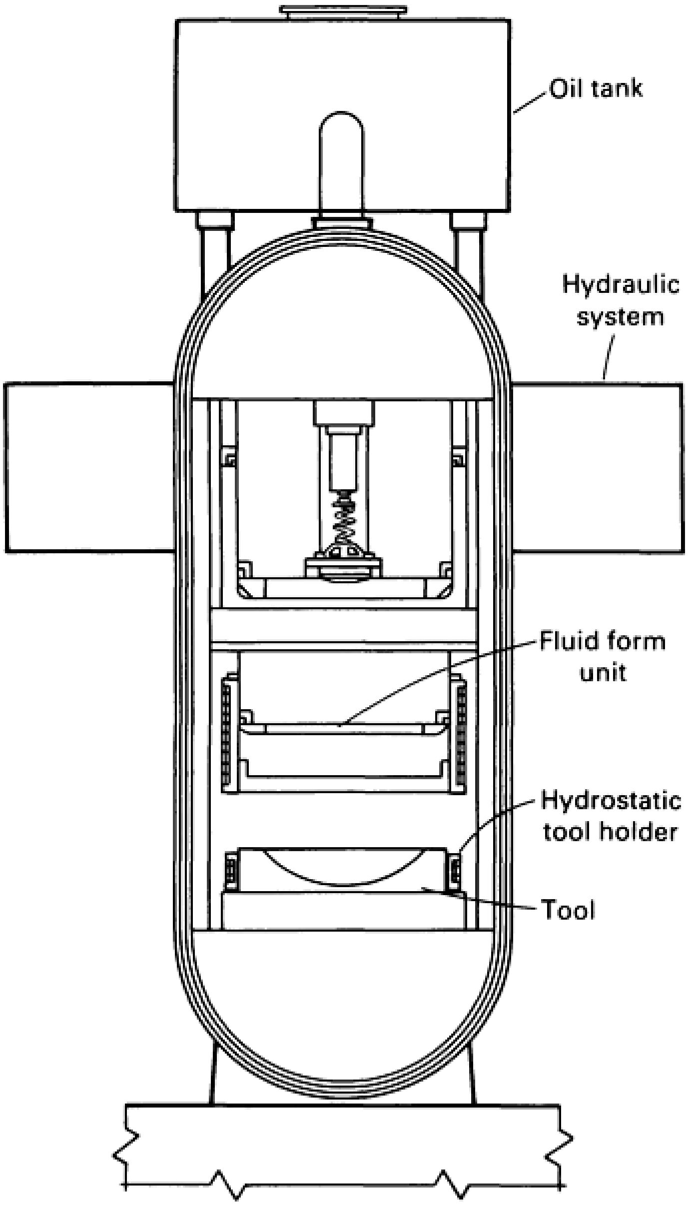

Fig. 23 Schematic of ASEA Quintus fluid forming press showing self-contained fluid form units.

For a 56 MN (6300 tonf) fluid forming press, two fluid form units designed for maximum 315 mm (12.4 in.) draw depth can be used. One unit, with a 63 MPa (9100 psi) forming pressure, has a 1090 mm (43 in.) blank diameter capacity. The other unit, providing a 160 MPa (23.2 ksi) forming pressure, has a 690 mm (27 in.) blank diameter capacity.

ASEA Quintus Deep-Drawing Technique

Fluid forming has been optimized using the ASEA Quintus deep-drawing fluid forming technique, a variation of the SAAB rubber-diaphragm method. The ASEA Quintus fluid forming method incorporates two telescopic rams, an outer ram to control dome pressure, and an inner ram to regulate the length of the punch draw (Fig. 24). Interchangeable domes, which require 20 min to change, allow the user to select a dome of optimal size and to avoid uneconomical use of an oversize dome when manufacturing small parts. Maximum forging pressure can also be increased by installing a smaller dome.

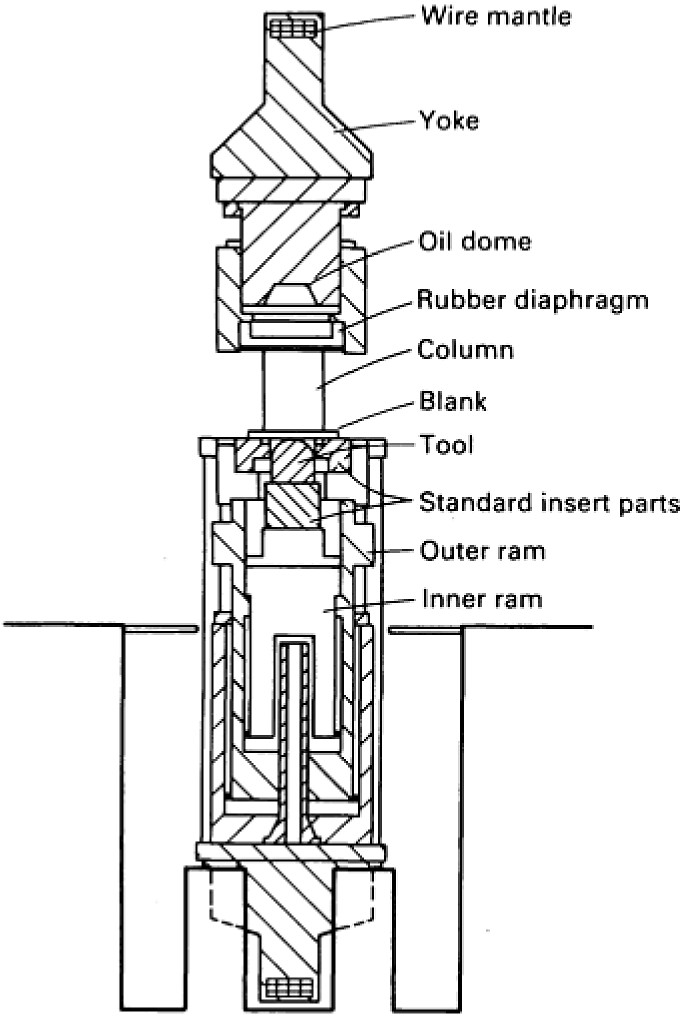

Fig. 24 Schematic of ASEA Quintus deep-drawing press, a fluid forming press with a telescopic ram system.

Each dome is a completely self-contained unit, with rubber diaphragms sealing off the pressure medium. Fluid form units for various pressure levels between 50 and 200 MPa (7.3 and 29 ksi) are available for each press size. Two or three such units should enable the user to make the most cost-effective use of the deep-drawing press. As an example, a set of interchangeable fluid form units for a 27 MN (3000 tonf) press ranges from an 800 mm (31.5 in.) diam unit with a maximum 60 MPa (8.7 ksi) forming pressure to a 450 mm (17.7 in.) diam unit with a maximum 190 MPa (27 ksi) forming pressure. Cycle time ranges from 10 to 60 s, depending on draw depth, part configuration, installed power, and selected pressure.

Complex shapes require accurate press control. As a result of 96 photocells that monitor the continuously varying pressure in the dome, greater accuracy and reliability are attained using a computer program to regulate the position and velocity of the draw depth. A paper cam cut with scissors gives dome pressure versus draw depth. The network of photocells reads the cam and governs an electrohydraulic control valve that controls the oil pressure in the outer cylinder, which is proportional to the dome pressure but much lower. By controlling the low counteracting pressure instead of the dome pressure, increased accuracy and reliability are achieved.

Diameters to 2000 mm (79 in.) can be formed from blanks ranging from 0.1 to 16 mm (0.004 to 0.63 in.) thick. Draw ratios to 3:1 can be produced, making it possible to form a complex part in one operation.

Rubber-Pad Forming

Failures in Rubber-Die Flanging

The rubber-pad forming of flanges can be performed within certain limits. The flange must be wide enough to develop sufficient bending force (Table 2), but not so wide as to exceed the permissible depth of the part. Figure 25 shows some typical flanging failures.

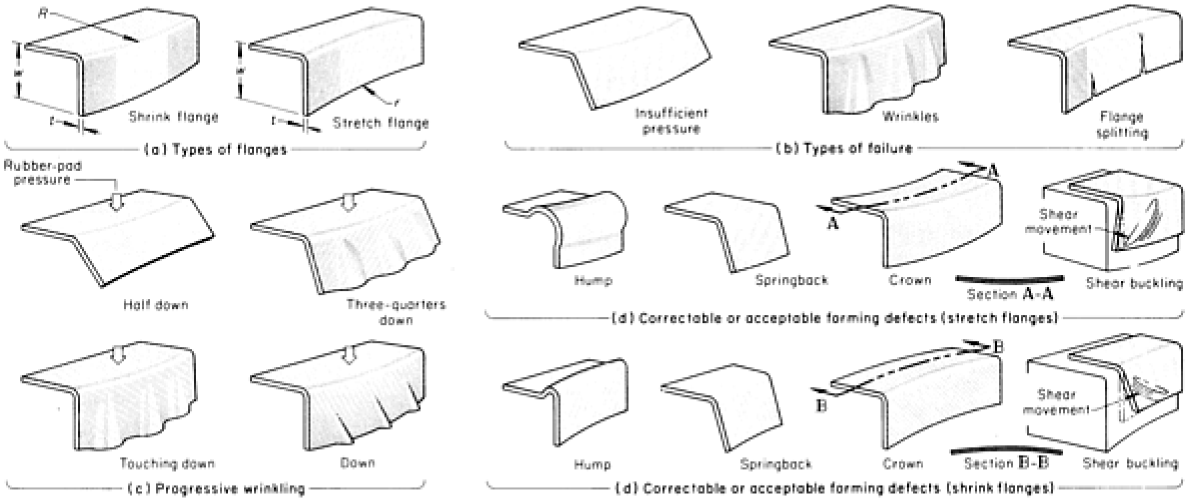

Fig. 25 Principal types of failure in curved flanges made by rubber-die forming.

Three-Roll Forming

Introduction

THREE-ROLL FORMING is a process for forming plate, sheet, bars, beams, angles, or pipe into various shapes by passing the work metal between three properly spaced rolls. This article will discuss sheet and plate, the mill products most often formed by the three-roll process.

Shapes Produced. Figure 1 illustrates some of the shapes commonly produced from flat stock by three-roll forming.

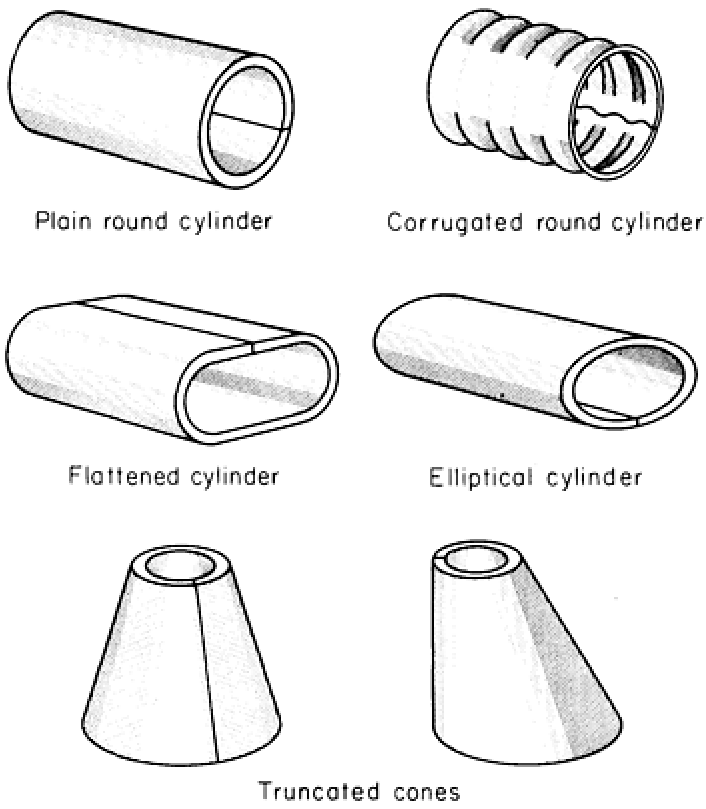

Fig. 1 Typical shapes produced from flat stock by three-roll forming.

The plain round cylinder shown in Fig. 1 is used for pressure tanks, boilers, and related containers, and it represents a large portion of the shapes produced. The corrugated cylinder is produced in quantity for culvert pipe and is formed from flat stock corrugated at the mill. To retain the corrugations in the workpiece, the forming rolls also must be corrugated.

The flattened cylinder (obround) is primarily used for oil-supply tanks for heating systems and transformer cases. The elliptical cylinder is used for tank trucks hauling liquid food products, petroleum products, and chemicals.

Symmetrical and asymmetrical cones are both used in a wide variety of hoppers, bins, vertical storage tanks, concrete mixers, and vessels for chemical and food processing, as well as in piping and ductwork. In addition to the shapes produced for commercial use, three-roll forming is also used to produce various regular and irregular shapes for structural sections of submarines, aircraft, and nuclear reactors.

Metals Formed. Any metal ductile enough to be cold formed by other processes can be formed in a three-roll machine. Steels with a maximum carbon content of 0.25% constitute a major portion of the total tonnage used in three-roll forming. Steel sheet or plate in the 1010 to 1020 category is sometimes used, but most of the steels formed by this process conform to one of the plate specifications: either plain carbon or low-alloy steels, such as ASTM A515 grade 60, A515 grade 70, A516 grade 70, A285, A441, A283, A306, and A36. For the most successful three-roll forming, steels with a minimum elongation of 18% are preferred. Stainless steels, heat-resistant alloys, and aluminum and copper alloys can also be successfully formed by the three-roll process.

Metal thicknesses commonly used range from 1.52 mm (0.0598 in.) sheet (16 gage) to 254 mm (10 in.) plate. In a few applications, 305 mm (12 in.) plate has been successfully formed. The principal factors limiting maximum thickness are the size and power of the rolling machine. Minimum thickness is typically limited only by handling equipment. Any sheet that can be handled without damage can usually be rolled.

It is impractical to roll thicknesses ranging from 1.52 to 254 mm (0.0598 to 10 in.) on the same machine, although any machine can handle a relatively wide range of work metal thicknesses. For example, a machine capable of rolling 9.5 mm ($\frac{3}{8}$ in.) plate (maximum or near maximum) can generally roll sheet as thin as 1.52 mm (0.0598 in.), while a machine with a maximum capability for rolling 1.52 mm (6 in.) plate can successfully roll plate as thin as 13 mm (½ in.)--even less on some machines.

Diameter and Width. The minimum diameter of a workpiece that can be successfully formed in a given machine is governed by the diameter of the top roll on either of the two types of machines used in three-roll forming--pinch type or pyramid type. In general, the smallest cylinder that can be rolled under optimal conditions is 50 mm (2 in.) larger in diameter than the top roll of a pinch-type machine. On a pyramid-type machine, the minimum workpiece diameter is rarely less than 152 mm (6 in.) greater than the top roll. However, more power is required to form sheet or plate into cylinders of minimum diameter than to form cylinders substantially larger than the top roll.

The maximum workpiece diameter that can be rolled is primarily limited by the space available above the machine to accommodate extremely large circles. Thin-gage metal rolled to a large diameter on horizontal rolls becomes less self-supporting as the workpiece diameter increases, and out-of-round cylinders will result if supports are not used. However, by using supports, almost any diameter can be rolled from thin metal. In general, 1.52 mm (0.0598 in.) thick low-carbon steel sheet can be formed into cylinders as large as 1.2 m (48 in.) in diameter without support, while 6.4 mm (¼ in.) thick low-carbon steel can be formed into cylinders as large as 2.1 m (84 in.) in diameter without support.

The width (dimension of the work metal parallel with the axes of the rolls, designated as length in the formed cylinder) of sheet or plate that can be rolled is limited by the size of the equipment; machines with rolls as long as 12.5 m (41 ft) have been built. The width-to-diameter relationship for workpieces that are extremely large in both directions is limited by problems in handling.

Three-Roll Forming

Machines

There are two basic types of three-roll forming machines: the pinch-roll type and the pyramid-roll type. The rolls on most three-roll machines are positioned horizontally; a few vertical machines are used, primarily in shipyards. Vertical machines have one advantage over horizontal machines in forming scaly plate: Loose scale is less likely to become embedded in the work metal. With vertical rolls, however, it is difficult to handle wide sections that require careful support to avoid skewness in rolling. Most vertical machines have short rolls for fast unloading and are used for bending narrow plate, bars, and structural sections.

Conventional pinch-type machines have the roll arrangement shown in Fig. 2. For rolling flat stock up to about 25 mm (1 in.) thick, each roll is of the same diameter. However, on larger machines, the top rolls are sometimes smaller in diameter to maintain approximately the same surface speed on both the inside and outside surfaces of the plate being formed. These heavier machines are also supplied with a slip-friction drive on the front roll to permit slip, because of the differential in surface speed of the rolls. Therefore, as work metal thickness increases, the diameter of the top roll is decreased in relation to the diameter of the lower rolls.

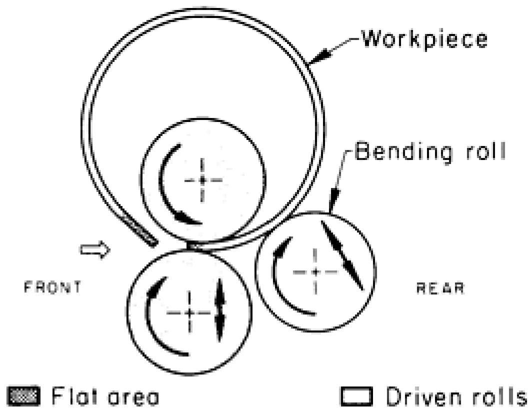

Fig. 2 End view of a cylindrical workpiece being rolled in a conventional pinch-type machine. Note the large flat

area on the leading end and the smaller flat area on the trailing end.

The position of the top roll is fixed, while the lower front roll is adjustable vertically to suit the thickness of the blank. Optimal adjustment of the lower roll is important for gripping the stock and for minimizing the length of the flat areas on the workpiece. The rear, or bending, roll is adjustable angularly (usually 30° off vertical), as shown in Fig. 2. Angular movement of this roll determines the diameter of the cylinder to be formed.

All of the rolls are powered in most pinch-type machines. On some machines, however, only the two front rolls are powered and the bending roll is rotated by friction between the roll and the work metal (Fig. 2). This arrangement is usually satisfactory in forming medium-to-heavy stock to large diameters. However, when forming sheet or plate that is thin or soft (or both) or when the diameter is large, the amount of friction is sometimes insufficient to rotate the bending roll. This condition can result in a marred surface if the work metal is soft or has a bright mill finish (aluminum sheet, for example).

A pinch-type machine can produce a more nearly true cylindrical shape than a pyramid-type machine because the work metal is held more firmly. This results in smaller flat areas on the leading and trailing ends of the workpiece.

As shown in Fig. 2, the work metal is fed to the powered pinch rolls (front), which grip the plate and move it through the machine. Forming begins when the work metal contacts the bending roll (rear) and is forced upward. As the forward motion of the workpiece continues, a cylindrical shape is produced, except for the unformed flat area along the leading end and a small flat area at the trailing end of the workpiece (Fig. 2). The width of the flat area on the trailing end usually ranges from ½*t* to 2*t* (*t*, work metal thickness), depending on the design of the machine.

In most pinch-roll forming, one of two procedures is used to minimize flat areas. The most common method is to preform both ends of the work metal in the machine. This is done by reversing the rotation of the rolls and feeding a short section of the work metal from the rear, thus preforming one end. The work metal is then removed from the machine; the formed section can be fed into the machine from the front, or it can be turned to the opposite unformed end and fed through from the rear of the machine. This procedure eliminates most of the flat areas.

Another method is to preform the leading and trailing ends of the work metal in a press brake, hydraulic press, or joggling press. However, this technique is seldom used, because it is usually more convenient to preform in the pinch-roll machine.

On the other hand, preforming in a press brake or in hydraulic or joggling presses can sometimes save time in the rolling machine, thus increasing the productivity of the machine. Additional advantages of a pinch-roll machine, as compared to a pyramid-roll machine, are:

- When all rolls are power driven, thinner sheets can be rolled, and cylinders can be formed to within about 50 mm (2 in.) of the diameter of the top roll
- A given size of a pinch-type machine can roll a greater range of metal thicknesses because of the method of feed
- Greater dimensional accuracy can be obtained in one pass in a pinch-type machine than in a pyramid-type machine

The principal disadvantage of a pinch-roll machine is its unsuitability for rolling workpieces from angles, channels, and other structural forms.

Shoe-Type Pinch-Roll Machines. One important modification of the conventional three-roll pinch-type machine is the shoe-type machine, which uses the pinch principle and incorporates a forming shoe, as shown in Fig. 3. Because of the relationship of the two front rolls and the forming shoe to the workpiece, the flat area becomes barely discernible compared with the length of flat area obtained when rolling in a conventional machine (without preforming).

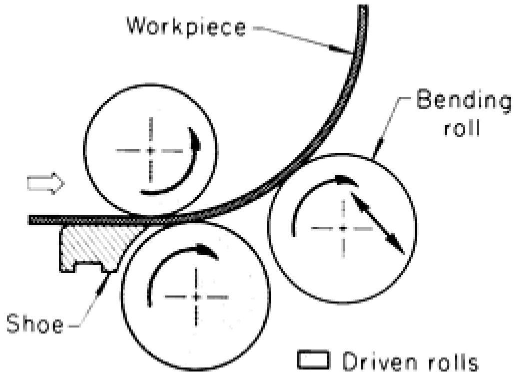

Fig. 3 End view of a cylindrical workpiece being rolled in a shoe-type machine with two powered rolls.

The shoe-type machine is often used to manufacture transformer cases and small tanks, such as jackets for hot-water tanks. This type of machine can be completely automated; therefore, the work metal can be positioned on the table and fed into the machine automatically. During the work cycle, the cylinder is formed and ejected by means of an ejector mechanism and an automatically controlled drop end. Thus, a shoe-type machine is primarily a production machine that is used where large quantities of identical workpieces are to be rolled. For this reason and because of the limitations listed below, shoe-type machines seldom compete directly with conventional pinch-type machines:

- Thickness of the work metal is limited to 12 gage (2.657 mm, or 0. 1046 in.)
- Width of the sheet is limited to 1.83 m (72 in.)
- Shoe-type machines are best adapted to the rolling of round cylinders; the rolling of ovals or obrounds is impractical
- Shoe-type machines are applicable only to cold forming

Within their range of applicability, however, shoe-type machines can produce a rolled cylinder in about half the time required in a conventional machine, primarily because preforming is not required with a shoe-type machine.

Pyramid-Type Machines. Figure 4 illustrates the arrangement of the rolls in a pyramid-type machine. The bottom rolls are of equal diameter, but are about 50% smaller in diameter than the top roll. The bottom rolls are gear-driven and are normally fixed; each roll is supported by two smaller rolls (Fig. 4). The top roll is adjustable vertically to control the diameter of the cylinder formed. The top roll, which rotates freely, depends on friction with the work metal for rotation. Backup rolls are not used on the top roll.

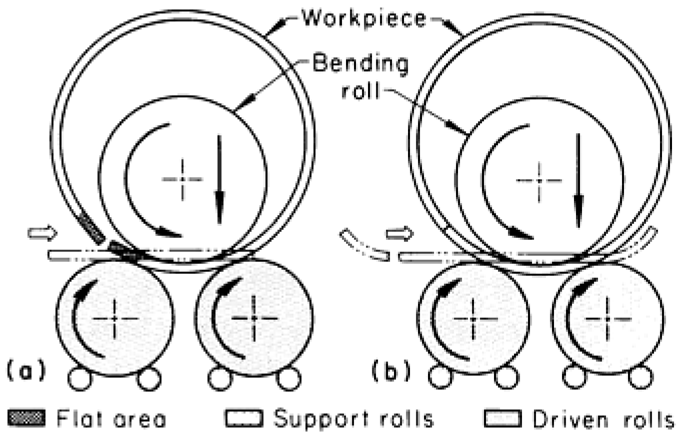

Fig. 4 Arrangement of rolls in a pyramid-type machine. (a) Entrance of flat workpiece and shape of a nearly finished workpiece, including the flat areas on the leading and trailing ends. (b) Similar, except that the

workpiece was prebent to minimize the flat areas on the ends.

As shown in Fig. 4, the work metal is placed on the bottom rolls while the top roll is in a raised position. The top roll is then lowered to contact and bend the work metal a predetermined amount, depending on the diameter of the workpiece to be formed. Machines are usually equipped with a device that indicates the amount of initial bend. Some machines use an ammeter, which shows the amount of current used in forcing the roll downward. However, this device measures force only; variables in the work metal can cause differences in the amount of bend for a given force.

As required bending force increases, machines are designed with rolls of larger diameter, and the distance between centers of the bottom rolls increases. Bending forces are applied midway between the bottom rolls; therefore, less force is needed for a given deflection, but less curvature is produced.

Because the top roll is adjustable, pyramid rolls can be used for forming irregular shapes by bolting dies to the top roll--a technique that is not adaptable to pinch-type machines. In addition, plate, beams, angles, and other structural forms can be straightened with greater ease because the bottom rolls are on the same elevation.

The top roll is an idler; therefore, there are definite limitations on the minimum thickness of work metal that can be rolled (especially when forming large diameters). Adequate stiffness in the work metal is essential to provide enough friction to rotate the top roll. The minimum thickness that can be rolled varies, depending on the specific machine and the work metal composition.

Another disadvantage of the pyramid machine is the large flat areas that remain on both the leading and trailing ends of the work metal. Because the workpiece must remain supported by the bottom rolls at all times, the ends of the work can never get closer to the top roll than the distance between the points of tangency of the workpiece and the rolls. Therefore, it is impossible to eliminate these flat areas by rolling (Fig. 4a).

To minimize flat areas when using pyramid machines, the usual procedure is to preform the ends to the desired radius in a press brake or to roll an oversize blank, then trim the flat ends after. The shell can sometimes be returned to the rolls for truing after the seam has been joined. Occasionally, a narrow shim is placed at the ends to increase the bend radius, but care must be taken to avoid machine overload. The techniques used in forming with pyramid rolls make it more difficult to achieve the accuracy that is obtainable with pinch-type rolls.

Capacity. Three-roll forming machines are rated by the manufacturer according to the maximum thickness and width of low-carbon steel plate the machine can form at room temperature. Values are usually given for single-pass rolling, and allowances are then made for multiple-pass rolling. For example, a machine rated at 19 × 3660 mm (¾ × 144 in.) (thickness and width of plate, respectively) for work metal with a maximum tensile strength of 414 MPa (60 ksi) and capable of rolling plate to a diameter of 2.44 m (96 in.) in a single pass can roll to a final diameter of 584 mm (23 in.) in multiple passes if the top roll is no larger than about 368 mm (14½ in.) in diameter.

If plate thickness is increased to 25 mm (1 in.), the same diameter restrictions would apply, but the allowable plate width would be reduced from 3.66 to 1.42 m (144 to 56 in.) because of the additional power required for the increased thickness of work metal. At this point, another limitation may be encountered because the load imposed on the shorter surface area can become excessive as the plate becomes narrower and thicker. On the other hand, assuming all other factors remain constant, if plate thickness is reduced to 16 mm ($\frac{5}{8}$ in.), the allowable width would revert to full capacity of the machine (3.66 m, or 144 in.), but the rolled diameter could be reduced to 419 mm (16½ in.).

The maximum plate thickness that can be handled by this machine depends on the pinch opening and is rated by the manufacturer of the machine. For example, some machines rated as described above can accommodate work 38 mm (1½ in.) thick, but for forming this thickness in a machine having the indicated capacity, the allowable plate width would be reduced to 533 mm (21 in.) because of the above-mentioned factors. All of the above calculations also take into consideration the limiting factor of roll deflection.

With all other conditions constant, power requirements increase according to the square of metal thickness. Therefore, the power required for forming plate 50 mm (2 in.) thick is four times as great as that required for forming 25 mm (1 in.) thick plate of the same width.

Selection of Machine

Selection between pinch-type and pyramid-type machines depends mainly on the shape of the starting form and of the finished workpiece, the number of formed parts to be produced, accuracy requirements, and the cost. The pinch-type machine produces more accurate workpieces, and it can be loaded and unloaded much faster than the pyramid-type machine. Although both machines can produce shapes other than plain cylinders, the pinch type is capable of rolling a wider range of thicknesses. However, the pyramid-type machine is often preferred for small quantities of varied work, as in a job shop. Because of the wide space that can be obtained between the upper roll and the two lower rolls in a pyramid machine, various types of dies and fixtures can be fastened to the upper roll, thus permitting channels, angles, and various other structural shapes to be rolled or bent, either hot or cold.

Rolls

Rolls used in three-roll forming machines are machined from steel forgings having a carbon content of 0.40 to 0.50% and a hardness of 160 to 210 HB. Plain carbon steel such as 1045 has often been used; when greater strength is needed, rolls are forged from an alloy steel such as 4340. Because the modulus of elasticity is the same for all carbon and low-alloy steels of medium carbon content, roll deflection for a given force will be the same.

Although the hardness range of 160 to 210 HB can be obtained by annealing, rolls with a microstructure obtained by quenching and tempering or by normalizing and tempering are less subject to surface deterioration from spalling. Therefore, the forged rolls are heat treated before being machined.

Roll diameter varies with the length and thickness of plate to be rolled. A typical top roll in a pinch-type machine, rated for forming steel plate up to 64 mm ($2\frac{1}{2}$ in.) thick and 3.66 m (144 in.) wide, would have a minimum diameter of 762 mm (30 in.). Journals for rolls of this diameter are approximately 432 mm (17 in.) in diameter.

Crowning of rolls to compensate for deflection is common practice. The amount of crowning is not necessarily the same for all rolls in a given machine. For example, in some machines, the rolls are not all of the same diameter; under these conditions, a roll that is smaller in diameter requires more crowning than a larger roll because the stress on all rolls is the same. When a machine is used for both light and heavy work, it is usual to crown the rolls for average conditions and then to use strips either at the center of the rolls to compensate for extreme deflection or at the ends to compensate for a lack of deflection (see the section "Roll Deflection" in this article).

Roll Maintenance. The extreme pressures to which rolls are subjected cause them to work harden. Rolls used in continuous production under high pressure sometimes elongate and reduce slightly in diameter. The amount of elongation or reduction in diameter is seldom significant, although the ends of rolls may require trimming after long periods of use.

There is no standard practice for reconditioning rolls. In some plants, rolls that have been subjected to long periods of severe service are trued by removing some or all of the work-hardened layer by turning. When required, the diameter is built up by welding an overlay on the rolls and then finish turning them. On the other hand, some manufacturers recommend that roll surfaces should never be turned. If the surfaces are spalled or otherwise damaged, any protruding metal should be removed by grinding. Although indentations in the rolls are less likely to be harmful, they may mark polished or clad surfaces. When rolling scaly plate, blowing away loose scale with an air lance is helpful in preventing scale from indenting the rolls or the work metal.

Bearings and Lubricants. Bronze has been successfully used for main bearings and is sometimes specified by the user. However, tin-base babbitt is superior to bronze for most applications and is used in most machines. Tin-base bearings are more compatible with the relatively soft steel journals at the pressures and speeds involved, and their ability to absorb particles of scale minimizes the possibility of scoring journals or bearings.

Extreme-pressure lubricants are recommended for the main bearings on all rolls, and a grade containing molybdenum disulfide is especially desirable. Because environmental conditions are likely to vary considerably where three-roll forming is done, the lubricant should have good pumpability over a range of temperatures. Extreme-pressure lubricants are satisfactory for both cold and hot forming.

Three-Roll Forming

Preparation of Blanks

Blanks are usually cut to the desired size before forming. The length of plate (dimension of the work metal perpendicular to the axes of the rolls) required to form a given shape is determined by measuring the mean circumference (or perimeter, if the shape is other than a cylinder), which is the circumference taken at one half the distance between the inside diameter and the outside diameter of the shape to be formed. This method of calculation is the one most generally used in both the cold and hot forming of plate.

Allowance for Shift in Neutral Axis. When greater accuracy is required, the more exact location of the neutral axis is considered when computing the blank, particularly if heavy plate thicknesses are involved. The neutral axis is the boundary between metal in tension and in compression and is usually one-quarter to one-half the thickness of the metal being bent, as measured from the inside of the bend. The exact location of this axis varies to some extent with the bend radius and the mechanical properties of the metal.

During cold forming, the neutral axis shifts inward from the mean by about 26% of the plate thickness. Therefore, for a 457 mm (18 in.) ID cylinder, rolled from 13 mm (½ in.) thick plate, the mean circumference is about 147.6 mm (58.12 in.), and for a 26% shift, the circumference at the neutral axis becomes 145.5 mm (57.30 in.). For a 457 mm (18 in.) ID cylinder of 6.4 mm (¼ in.) thick plate, the mean circumference is 145.6 mm (57.33 in.), and with a 26% shift, it changes to 144.6 mm (56.93 in.); the amount of shift is about one-half that for the 13 mm (½ in.) thick plate. Therefore, the shift of neutral axis is usually disregarded for plate thicknesses less than 13 mm (½ in.) except where greater accuracy is required.

In cold forming, the length of the blank is calculated by using a radius that is determined by subtracting 26% of the plate thickness from the mean radius or by adding 24% to the inside radius. When dimensional requirements are stringent, similar allowances are made for shift of the neutral axis and for thermal expansion in the hot forming of thick plates (75 to 152 mm, or 3 to 6 in.) at 870 °C (1600 °F).

Cutting of blanks can be done by shearing, if shearing equipment is available for the width and thickness of the work metal. Gas cutting is commonly used for preparing blanks that are too thick for shearing. Additional information is available in the articles "Shearing of Plate and Flat Sheet" and "Thermal Cutting" in this Volume.

Edge Preparation. The cut edges of any plate (high-strength steel, in particular) can be a serious problem because of cracking during cold forming, which is cause for rejection of the workpiece. When plate is sheared, the edges are rough and often have surface cracks. Gas cutting usually produces smoother edges, but the edges of gas-cut steel plate will frequently be hardened in cooling from the cutting temperature. Therefore, nucleation sites for cracks are likely to be present from either method of cutting.

The danger from cracking caused by rough edges increases as plate thickness increases and the finished diameter of the cylinder decreases. Because the plate surface that forms the outside diameter of the cylinder is in tension during forming, cracks propagate from edges, which are in tension.

On plate 25 mm (1 in.) or more in thickness, the edges indicated in Fig. 5 should be removed before cold forming. This is not required before hot forming. Usual practice is to employ a chipping hammer and then a portable grinder to smooth the edges. The amount of metal removed is usually negligible, and a slight bevel on the critical edges is sufficient. If a substantial amount of metal is to be removed, allowance must be made for it when calculating the dimensions of the blank.

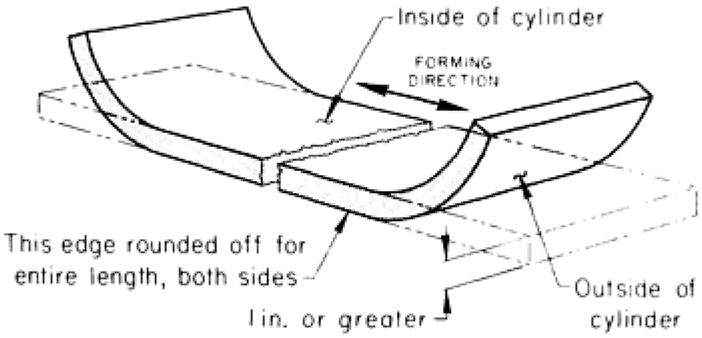

Fig. 5 Sheared or gas-cut blank, showing where metal should be removed from edges before cold forming, to reduce susceptibility to cracking.

Three-Roll Forming

Cold Versus Hot Forming

Because cold forming involves fewer problems and is less costly than hot forming, it is preferred practice to form workpieces at room temperature. In hot forming, dimensional accuracy is more difficult to control, and cost is significantly increased by:

- Heating the blank
- Handling both the blank and the workpiece while the metal is hot
- The necessity for restoring acceptable surfaces by pickling, blast cleaning, or other surface treatment
- The accelerated rate of deterioration of rolls and other equipment because of contact with hot metal

Forming Capacity. When carbon or low-alloy steel is heated, tensile strength decreases and formability increases. Heating the work metal therefore extends the usefulness of a roll-forming machine. For example, a 3 m (10 ft) long pinch-type machine with 495 mm (19½ in.) diam rolls can form a 3.66 m (144 in.) diam cylinder from 64 mm (2½ in.) thick by 622 mm (24½ in.) wide plate at room temperature in one pass (assuming the work metal has tensile strength of 410 MPa, or 60 ksi, at room temperature). With all other conditions remaining constant, by heating the work metal to a temperature high enough to reduce the tensile strength to 70 MPa (10 ksi) or lower, the width of the plate (measured parallel to the roll axes) can be increased to 2.1 m (82 in.) and rolled in one pass, using the same amount of power needed for rolling plate 622 mm (24½ in.) wide at room temperature. To reduce the tensile strength of low-carbon steel and to obtain optimal formability, the usual practice is to heat the steel to 870 °C (1600 °F).

Similarly, the size of machine described above is capable of cold forming a 3.66 m (144 in.) diam cylinder from 44 mm (1¾ in.) thick by 1.5 m (60 in.) wide low-carbon steel plate in one pass. Under the same conditions, except for heating to 870 °C (1600 °F), the thickness of the plate can be increased to 70 mm (2¾ in.).

One method of evaluating the difference in formability between cold and hot rolling is to measure the force required to form a given plate. This is done on pyramid-type rolls by measuring, in terms of amperage, the downward force on the upper roll and the force required to rotate the powered rolls (Fig. 6). The following example demonstrates the difference in current flow, number of passes, and time needed for the cold and hot forming of similar cylinders.

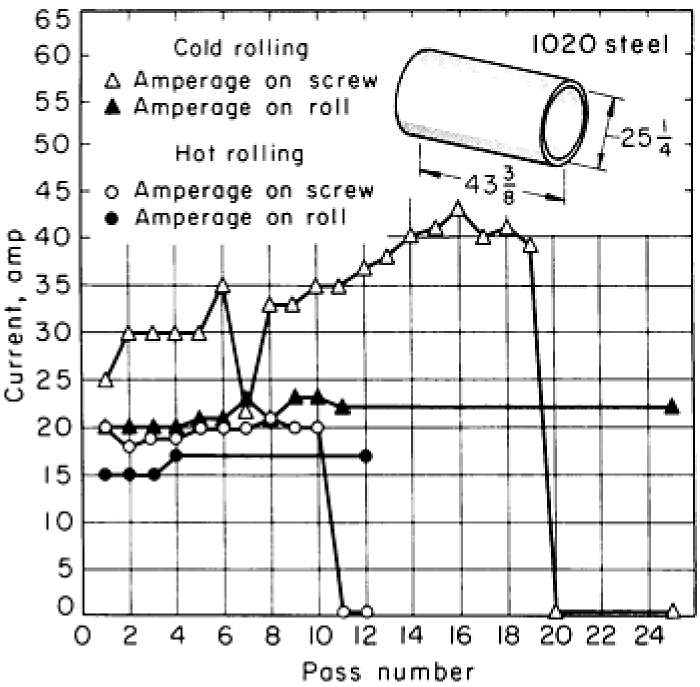

Fig. 6 Comparison of current flow (proportional to force) measured on screw and rolls during cold rolling and during the rolling of 44 mm (1¾ in.) thick plate preheated to 870 °C (1600 °F). Dimensions given in inches.

Example 1: Cold Versus Hot Forming of 44 mm (1¾ in.) Thick Steel Plate.

A pyramid-type machine was used to produce 641 mm (25¼ in.) ID by 1.1 m (43⅜ in.) long cylinders from 1020 steel blanks 44 mm (1¾ in.) thick by 1100 mm (43⅜ in.) wide by 2145 mm (84½ in.) long. When forming was done at room temperature, 25 passes were required with current flow on the upper roll (screw) and power rolls as shown in Fig. 6. Rolling time was 40 min per cylinder. When blanks were heated to 870 °C (1600 °F) and finished at 565 °C (1050 °F), the number of passes was reduced to 12 and rolling time to 11 min per cylinder. Current flow was also reduced, as shown in Fig. 6.

Hot Forming Formability Problems. The technique described in the preceding example for increasing the effective capacity of equipment by hot forming does not apply to all metals, and the amount of decrease in tensile strength varies considerably among carbon and low-alloy steels. For example, heat-resistant alloys, by definition, resist the softening effect of heat, and many of these alloys precipitation harden in the temperature range that would be used for the hot forming of carbon steel (see the article "Forming of Heat-Resistant Alloys" in this Volume). Magnesium and titanium alloys are usually formed at the same elevated temperature used to form the same alloy by other methods (see the articles "Forming of Magnesium Alloys" and "Forming of Titanium and Titanium Alloys" in this Volume). Copper and aluminum alloys are usually formed at room temperature. However, alloys 7075 and 7079, as well as some other precipitation-hardening alloys, must be formed within 24 h after solution treatment. If forming cannot be done within this length of time, the work metal must be stored at -12 °C (-10 °F) to prevent precipitation hardening (see the articles "Forming of Aluminum Alloys" and "Forming of Copper and Copper Alloys" in this Volume).

Maximum Elongation. In many applications with steel, hot forming is mandatory regardless of the capacity of available forming equipment. Common practice is to compute a maximum elongation in the outer surface for cold forming, as determined by:

$$E = \left(\frac{t}{d + t}\right)100 \quad \textbf{(Eq 1)}$$

where E is the percentage of elongation in the outer surface of the cylinder, d is the inside diameter of the cylinder (in inches), and t is the plate thickness (in inches). For example, for a cylinder having an inside diameter of 1.45 m (57 in.) to be formed from 75 mm (3 in.) thick steel plate:

$$E = \left(\frac{3}{57 + 3}\right)100 = 5\% \quad \textbf{(Eq 2)}$$

Elongation of more than 5% (determined by Eq 2) is seldom permitted for cold forming, and the maximum is often 3.5%. If the maximum permissible elongation was 3.5% in the above example, either the minimum cylinder diameter would be near 2.11 m (83 in.) or plate thickness would have to be reduced before cold forming would be permitted. Maximum elongation is established by the user of the formed product, and hot forming is used when specifications cannot be met by cold forming.

Combination Hot and Cold Forming. A combination of hot and cold forming is sometimes advantageous and permits elongation requirements to be met. For example, in forming the 1.45 m (57 in.) diam cylinder described above, one procedure is first to hot form the 75 mm (3 in.) thick plate to a circular segment of about 2.29 m (90 in.), allow the workpiece to cool to room temperature, and then clean and finish form at room temperature. This procedure makes it possible to meet more severe elongation requirements and to retain some of the advantages of cold forming, such as greater accuracy.

Hot-Forming Temperatures for Steel

Carbon or low-alloy steel plate is commonly heated to 870 °C (1600 °F) for hot forming after normalizing at the mill. However, plate in the as-rolled condition is less costly. The as-rolled steel is normalized while it is being heated for forming and cooled during forming. In such an operation, the steel is heated to 900 to 925 °C (1650 to 1700 °F), instead of to 870 °C (1600 °F), before forming.

Finishing temperature is critical for some steels, especially the plain carbon grades, because of the blue-brittle temperature range. It is generally recommended that the finish-rolling temperature should be 565 °C (1050 °F) or higher. If the workpiece cannot be completely formed before it cools to 565 °C (1050 °F), it should be removed from the machine and reheated.

Warm forming is often used when forming requirements are too severe for room temperature and when heating to the conventional hot-forming temperature cannot be permitted because the mechanical properties of the steel would be impaired. A notable example is the forming of quenched-and-tempered grades of high-strength low-alloy steel. Common practice is to heat these steels no higher than the temperatures at which they were tempered and then form at once.

Three-Roll Forming

Power Requirements

The power required to form a given cylinder on three-roll equipment depends on the strength of the work metal, plate thickness, plate width, finished diameter of the cylinder, number of passes used, and temperature (hot or cold forming).

Strength of the work metal, plate thickness, and plate width (measured parallel to the roll axes) determine the diameter of a cylinder that can be formed in a given machine. The curves in Fig. 7, for a 3.1 m (10 ft) long pinch-type roll machine with 483 mm (19½ in.) diam rolls, represent combinations of maximum plate thickness and width that can be rolled at room temperature into cylinders of 3.66 m (144 in.) in diameter or larger in a single pass. The significant influence of the strength of the steel is evident from Fig. 7. For example, 38 mm (1.5 in.) thick low-carbon steel plate of 410 MPa (60 ksi) tensile strength can be rolled into 3.66 m (144 in.) diam cylinders in one pass in widths up to 3.05 m (120 in.) in this machine. Under similar conditions, the width of 38 mm (1.5 in.) thick high-strength low-alloy steel that can be formed to the same cylinder diameter is restricted to about 56 mm (22 in.) (Fig. 7). The machine used was rated at 67 mm ($2\frac{5}{8}$ in.) by 3.05 m (120 in.).

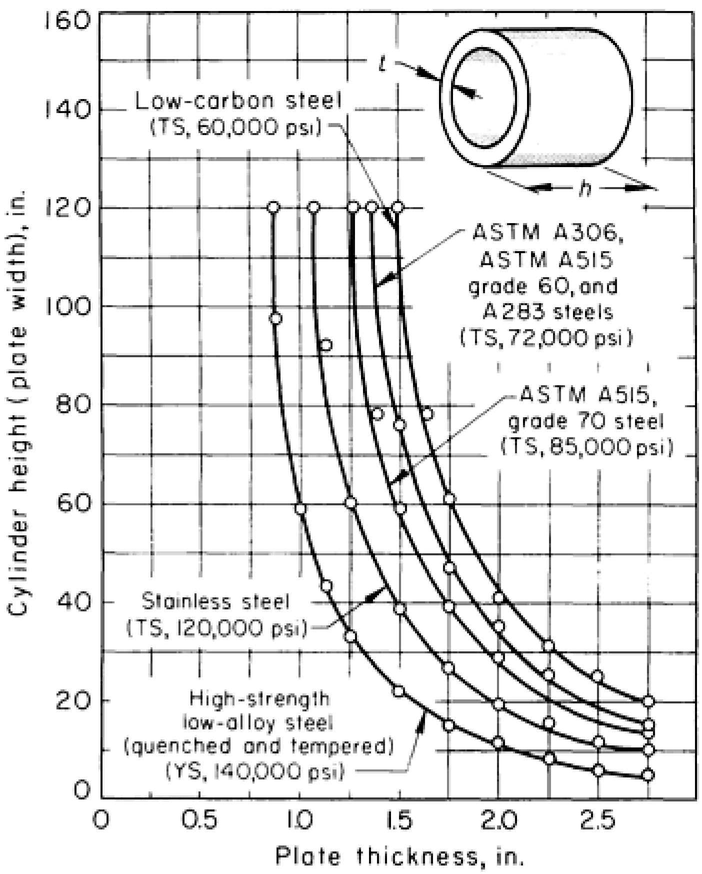

Fig. 7 Interrelationship of cylinder height (*h*), thickness (*t*), and work metal strength for forming in a single pass in a pinch-type roll machine at room temperature.

Work Hardening. Most metals are susceptible to strengthening by cold work (work hardening), although the extent to which metals are affected varies widely among the various compositions. Of the steels commonly processed by three-roll forming, those of low carbon content, such as 1010, are least susceptible to work hardening and seldom present any serious problems. As carbon or alloy content increases, the rate of work hardening increases.

For metals that work harden rapidly, power consumption increases as forming proceeds. Eventually, the machine is overloaded, or the work metal fractures.

Intermediate annealing must be used when work-hardenable metal is severely formed. For steel, full annealing is usually recommended. Process (subcritical) annealing is sometimes used. However, process annealing alternated with cold work is likely to result in excessive grain growth and subsequent poor formability, despite the hardness.

Cylinder Diameter. With other conditions constant, power requirements increase as cylinder diameter decreases when the cylinder is completely formed in one pass. However, the use of two or more passes (up to 12 is not uncommon) permits the rolling of smaller-diameter cylinders without increasing machine size. For example, Fig. 7 shows that 38 mm (1.5 in.) thick by 3.05 m (120 in.) wide plate of low-carbon steel can be formed into a cylinder 3.66 m (144 in.) in diameter in one pass on a given machine. By using 10 or 12 passes, cylinders as small as 65 mm (25½ in.) in diameter have been formed from the maximum thicknesses shown in Fig. 7. For plate thickness of 30 mm ($1\frac{3}{16}$ in.) or less, cylinders as small as 55 mm (21½ in.) in diameter can be formed in multiple passes.

Similarly, for carbon steel having a tensile strength to 590 MPa (85 ksi) and stainless steel to 830 MPa (120 ksi), any of the plate thicknesses shown in Fig. 7 can be rolled to cylinders as small as 70 mm (27½ in.) in diameter. For steels having a tensile strength of about 500 MPa (72 ksi), plate thicknesses of 28 mm ($1\frac{3}{32}$ in.) or less can be rolled to cylinders 56 mm (22 in.) in diameter, using the multiple-pass procedure. The plate thickness limitations for rolling 56 mm (22 in.) diam cylinders then decrease to 26 mm ($1\frac{1}{64}$ in.) (maximum) for steel with a tensile strength of 590 MPa (85 ksi) and to 21 mm ($\frac{13}{16}$ in.) for stainless steel with a tensile strength of about 830 MPa (120 ksi).

Power requirements for quenched-and-tempered high-strength low-alloy steel (970 MPa, or 140 ksi, in Fig. 7) are high, and there is an increased probability of cracking. Suggested limits for maximum plate thickness and minimum cylinder diameter for multiple-pass rolling, regardless of power, are:

Maximum plate thickness		Minimum cylinder diameter	
mm	**in.**	**mm**	in.
25	1	1170	**46**
19	$\frac{3}{4}$	889	**35**
13	$\frac{1}{2}$	826	**32** $\frac{1}{2}$
9.5	$\frac{3}{8}$	775	**30** $\frac{1}{2}$
6.4	$\frac{1}{4}$	**711**	**28**

Temperature. The limitations imposed by steel composition and other factors shown in Fig. 7 are markedly changed when the work metal is heated (see the section "Cold Versus Hot Forming" and Example 1 in this article). However, it is not always possible to use hot forming--for example, for quenched-and-tempered high-strength low-alloy steel (see the section "Warm Forming" in this article).

Three-Roll Forming

Forming Small Cylinders

The cold forming of small cylinders by the three-roll process requires extra care, especially when the diameter of the cylinder to be formed is near that of the rolls. The rolling of cylinders having an inside diameter of less than 50 mm (2 in.) more than the outside diameter of the roll is not generally recommended. However, a skilled operator, using special care, can form cylinders within 38 mm (1½ in.) in diameter in a pinch-type machine.

Forming Large Cylinders

Cylinders that are large in diameter or in length can be formed by the three-roll process. Some special procedures may be required, especially when the sheet is so thin that the cylinder cannot retain a round shape without support. Under these conditions, overhead cranes or temporary braces or both can be used for support.

When flat blanks of the required length are unavailable, two or more sections can be welded together to obtain the required length. The following example describes this practice in the forming of large cylinders.

Example 2: Forming 4.72 m (186 in.) OD Cylinders in a Pinch-Type Machine.

Cylinders 4.72 m (186 in.) in diameter and 2.84 m (112 in.) long were formed from blanks prepared by welding together three sections of copper-clad low-carbon steel. The fabricated blanks were 14.8 m (580¾ in.) long by 2.84 m (112 in.) wide by 14 mm ($\frac{9}{16}$ in.) thick. The cylinders were formed cold on a 19 mm (¾ in.) by 3.7 m (12 ft) pinch-type machine. The major problem in this operation was support because the work was not thick enough to provide natural support. Overhead cranes were used to hold the formed section of the plate during rolling. The ends of the cylinder were tack welded before the workpiece was removed from the machine. Temporary braces were then used to hold the cylinders in a near-round condition while the seam was welded. After welding, outside rounding rings made from 38 × 127 mm (1½ × 5 in.) rectangular steel bars were used to hold the cylinder shape for subsequent attachment to other cylinders. In use, the welded internal parts stiffened the assembly.

Forming Truncated Cones

Pyramid-type machines are generally used in the forming of truncated cones. There are two basic limitations on the shape of conical configurations that can be formed by the three-roll process. First, the smaller diameter (A, Fig. 8) must be large enough to maintain the established workpiece-to-roll relationship on minimum obtainable diameter, and second, the plate must be thick enough to be formed by the holdback method shown in Fig. 8 so that the pressure buildup on the holdback pin does not upset the plate edge or damage the holdback attachment or both.

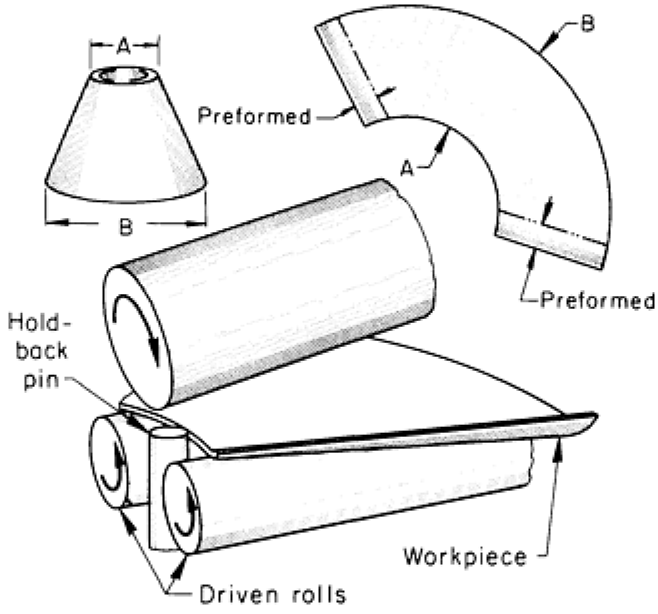

Fig. 8 Rolling a truncated cone in a three-roll pyramid-type machine from a blank with preformed ends.

The size of cone that can be formed depends largely on the pitch, the spacing and length of rolls, and the diameter of the upper roll. As the cone height increases, difficulties in getting the large diameter to follow the small diameter accurately also increase. If the lower roll spacing is too wide, the size of the smaller diameter will be severely limited, because as the work metal passes the holdback pin (Fig. 8), it will curve into the housing that supports the rolls and rolling will be impossible.

Procedure. There are several significant differences between forming conical shapes and forming cylinders by the pyramid-type three-roll process. In rolling cylinders, the blank is rectangular and is rolled in a direction perpendicular to the rolls. In contrast, curved blanks are used for conical shapes, and they are rolled on a curve. In addition, no pin is needed in rolling cylinders, and the top roll is pitched for forming cones but is straight and level when forming cylinders.

Before the developed blank is placed in the pyramid-type three-roll machine for forming a cone, the ends of the blank are preformed in a pinch-type roll from the rear or in a press brake. For forming the cone, the top roll is pitched as shown in Fig. 8. As the rolls drive the blank, its edge drags around the pin, and the various diameters of the cone are formed. The blank is then rolled in multiple passes, dragging around the pin until the ends of the blank are closed. If the pitch of the rolls matches the pitch of the entire length of the cone, a nearly true cone will result.

Truncated cones are sometimes produced by forming two semicircular half-cones and welding them together; the completed workpiece has two longitudinal seams instead of one. In another method, two or more circular tapered sections are formed and welded together. When produced by this method, the finished cone has one longitudinal seam and one or more circumferential seams.

Three-Roll Forming

Forming Bars and Shapes

Pyramid rolls and machines with over-hanging rolls are used to form bars, bar sections, and structural shapes into circles. Shapes that can be processed by this method include rounds, squares, flats (on the edge or on the flat), I-beams, L-shaped structurals, and channels. Hardened roll sections that are adjustable to the thickness or cross section of the shape are used (Fig. 9). Some bars or shapes can be formed with plain, flat rolls, but more often rolls conforming to the shape of the unformed workpiece are required.

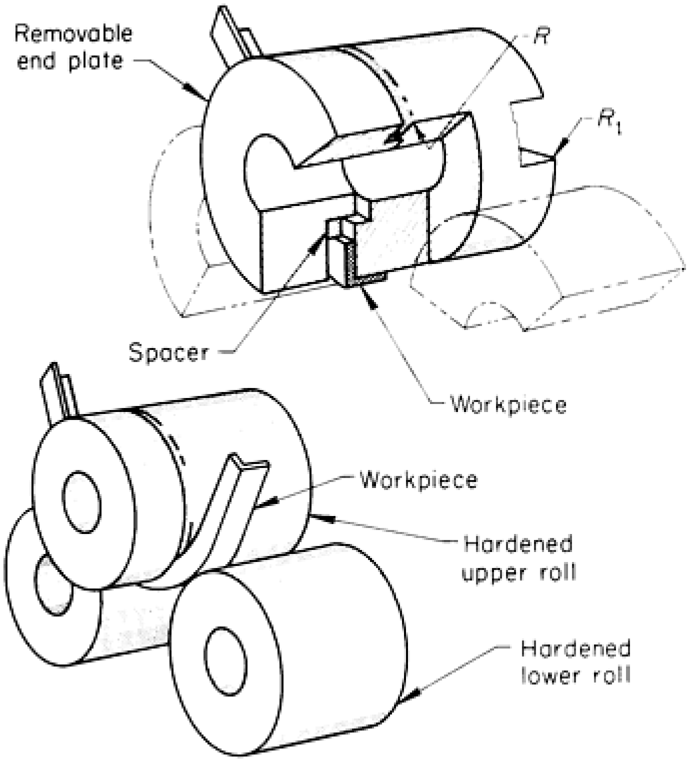

Fig. 9 Roll setup for forming an angle section into a circle. Guide rolls and guide fingers are not required for this application.

The rolls are adjusted to produce the required workpiece diameter in the same manner as in rolling cylinders from sheet or plate. Prebending the ends and rolling the workpiece back and forth are also employed in the three-roll forming of bars and shapes. A significant difference in the rolling of bars and shapes is the frequent use of guide rollers or guide fingers or both, mounted so as to contact the sides of the workpiece and prevent it from twisting during forming.

One of the most difficult shapes to form by the three-roll process is an angle with one leg inside the circle (Fig. 9). When forming this shape, spiraling, twisting, buckling of the inside leg, and reduction of the angle between the two legs are likely to occur. These difficulties can be minimized by using a hardened upper roll having a removable end plate and a spacer that is not more than 0.81 mm ($\frac{1}{32}$ in.) thicker than one leg of the angle (Fig. 9). The radius on the upper roll (R, Fig. 9) must conform to the fillet radius of the angle to be rolled. The other end of this roll (R_1, Fig. 9) can have the same radius or a radius conforming to another angle to be rolled. This end of the upper roll can be used by reversing the roll end for end. In production rolling of the same angle, common practice is to have the same values for R and R_1 (Fig. 9), thus permitting double the roll life by reversing the roll. Guide rollers and fingers (not required for the section shown in Fig. 9) also help to produce accurate circles from bar sections.

Out-of-Roundness

Out-of-roundness, or ovality, of cylinders produced by three-roll forming is caused by one or more of the following variables:

- Varying thickness of the flat blank
- Varying hardness within the blank
- Overforming or underforming of the ends in the preforming operation

- Springback of the work metal
- Temperature of the metal being formed
- Number of passes
- Condition of the equipment
- Operator skill

The most important of the above factors is operator skill; condition of the equipment is also a major factor.

Variations in the mill product (thickness and hardness within a single sheet or plate) are seldom great enough to warrant the extra cost that would be necessary for closer-than-normal control of the work metal. Out-of-roundness and other dimensional variations in the product increase as workpiece diameter increases. Plate thickness above or below the actual crown thickness of the rolls can also cause dimensional variations. For large or small workpieces, much out-of-roundness is caused by variations in preforming the ends, regardless of whether pinch rolls or press brakes are used in preforming.

Springback is overcome by forming to a circle smaller than that required for the finished cylinder. However, the overforming of high-springback material must be done with caution; as the elastic limit is exceeded, metals will take a permanent set and too much overforming can result.

Hot forming may contribute to out-of-roundness because considerable plastic flow can take place when a steel workpiece is heated to 870 °C (1600 °F) or higher. The amount of plastic flow varies as the bending load is applied during forming, and variations are increased by uneven cooling of the work metal. Resulting variations in plate thickness and curvature contribute to out-of-roundness.

Production Example. Without the use of special techniques or secondary operations, there is likely to be considerable variation in out-of-roundness among workpieces that are intended to be identical and are produced under the same conditions. This is demonstrated in the following example.

Example 3: Out-of-Roundness Variations in 44 Cylinders, 432 mm (17 in.) in Diameter.

Cylinders 432 mm (17 in.) in diameter were produced on a pinch-type machine in one pass. Leading edges of the blanks were prebent 15° for a distance of 50 mm (2 in.) with a 102 mm (4 in.) radius. After the cylinders were formed and tack welded, measurements were taken. Out-of-roundness variation in 44 cylinders is plotted in Fig. 10.

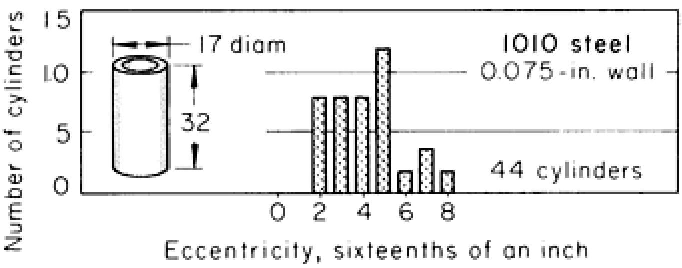

Fig. 10 Out-of-roundness variations in 44 cylinders of the same diameter produced in a pinch-type roll machine. Dimensions given in inches.

The number of passes used to form a given cylinder can have a significant effect on out-of-roundness. In most applications, two or more passes (sometimes as many as 12) will produce cylinders that are more nearly true round than those formed in a single pass.

Methods of Correction. The most effective method for correcting out-of-roundness is to reroll the cylinder carefully before welding. This operation causes a one-third greater load on the machine than the original rolling.

For cylinders having wall thickness no greater than about 9.5 mm ($\frac{3}{8}$ in.), a draw-down type of expander applied after rolling and welding is an effective means of correcting out-of-roundness.

If design permits, beads or flanges can be rolled into the cylinder wall to reinforce it and to help maintain roundness. Oil drums are examples of the effective use of this technique. When dimensional requirements are plus or minus a few thousandths of an inch, stock must be allowed for machine boring the cylinder to the specified diameter.

Three-Roll Forming

Forming Speed

The speed of forming is a critical factor in product quality. Low-carbon steel plate up to 7.9 mm ($\frac{5}{16}$ in.) thick is sometimes rolled at speeds to 18 m/min (60 ft/min). For a speed this high, however, workpiece diameter is necessarily medium to large, because it is impractical to control the machine for rolling small diameters at high speed.

The most commonly used speeds for cold forming (particularly for thick plate) range from 3.7 to 6.1 m/min (12 to 20 ft/min). This range is usually maintained in both cold and hot forming; however, to complete hot forming with a minimum decrease in temperature of the work metal, it is sometimes necessary to increase the speed of the bending roll.

Three-Roll Forming

Roll Deflection

Roll deflection can be calculated by standard formulas, considering the roll as a simple beam supported at both ends. On pyramid rolls, deflection is often minimized by support rollers applied to the lower rolls. These rolls act as backup rolls.

In forming heavy plate, pressures are high and all three rolls are crowned (made larger at the centers than at the ends). Crowning is necessary because the rolls deflect under the bending load; if they were straight, all formed cylinders would bulge somewhat at the center. Because the amount of deflection depends on the bending load, usual practice is to crown the rolls enough to compensate for the average job in the plant. When forming plate thicker than the actual crown deflection, the rolls are shimmed by running strips of thin metal (16, 14, 12, or 10 gage) between the rolls and the inside diameter of the workpiece at the center of the rolls. This shimming compensates for excessive deflection.

When forming metal that is too thin to cause deflection of the rolls, crowning will cause the formed cylinder to be larger in diameter at the ends than in the center. Correction can be made by shimming the ends of the rolls in a manner similar to that described above for shimming the centers.

Three-Roll Forming

Alternative Processes

Three-roll forming is the most practical method of producing large cylinders and truncated cones from heavy plate.

Deep drawing is often the most economical method of producing small cylinders from sheet no thicker than 3.18 mm (0.125 in.). Seamless cylinders or cones can be produced by deep drawing, piercing, and trimming (see the article "Deep Drawing" in this Volume). However, as cylinder size or wall thickness increases, forming by deep drawing becomes impracticable. In some applications, three-roll forming and welding are preferred for producing a hollow shape from stock that is substantially thinner than 3.18 mm (0.125 in.).

Contour Roll Forming. Theoretically, the diameter and length of straight cylinders producible by contour roll forming are almost unlimited. In practice, however, diameter and wall thickness are limited by the size of available equipment. Contour roll forming is rarely used for rolling metal thicker than 6.35 mm (0.250 in.) and is most often used for thicknesses less than 3.18 mm (0.125 in.). Therefore, contour roll forming is impractical for producing large heavy-wall cylinders (see the article "Contour Roll Forming" in this Volume).

Forming two halves (semicircles) between dies in a press and then welding the two half-cylinders is sometimes practical. However, even when presses of sufficient size are available for forming large plate, die cost is likely to be prohibitive. For limited production, a press brake is often used to produce semicircles that can subsequently be joined by welding into cylinders.

Safety

Forming rolls move relatively slowly, but require protection for the operator. The most positive method of protection is to cover the nip point between the feed rolls. One effective guarding device is a solid metal plate covering the nip point between the feed table and the rolls for the full length of the rolls. This plate, with a stud welded to each end, is attached to slotted vertical brackets by nuts and washers so that it is adjustable vertically. The brackets are securely fastened to the feed table.

The height of the feed table can be made adjustable by welding a nut to the lower end of each tubular leg. A long bolt, with a large washer welded to the top of the head, is screwed into the nut to achieve the desired height. A locknut can be used to prevent the bolt from turning because of vibration.

Emergency tripping bars connected to electric cutoff switches or, preferably, to reverse electric switches can be used to stop the rolls. The bars may be at knee level in front of the operator, or directly in front of the bottom feed roll and far enough below the feed point to avoid accidental tripping.

Feeding guides for narrow workpieces can be made of bar stock or angles that are bolted to the feed table. The guides should be slotted for ease of adjustment to various widths of workpieces.

Introduction

CONTOUR ROLL FORMING (also known as roll forming or cold roll forming) is a continuous process for forming metal from sheet, strip, or coiled stock into desired shapes of uniform cross section by feeding the stock through a series of roll stations equipped with contoured rolls (sometimes called roller dies). There are two or more rolls per station. Most contour roll forming is done by working the stock progressively in two or more stations until the finished shape is produced.

Only bending takes place in contour roll forming; the stock thickness is unchanged except for a slight thinning at bend radii. The process is particularly suited to the production of large quantities and long lengths to close tolerances and involves a minimum of handling. Auxiliary operations, such as notching, slotting, punching, embossing, curving, and coiling, can easily be combined with contour roll forming.

Contour roll forming is used in many diverse industries to produce a variety of shapes and products. The process is also used for parts that were previously manufactured by extrusion processes. This use is limited, however, to parts that can be redesigned to have a constant wall thickness. Industries that use roll-formed products include the automotive; building; office furniture; home appliance and home product; medical; railcar; aircraft; and heating, ventilation, and air conditioning (HVAC) industries.

Contour roll forming can be divided into two broad categories: a process using precut lengths of work metal (precut or cut-to-length method), and a process that uses coil stock that is trimmed to size after forming (postcut method).

In precut operations, the work metal is cut to length before entering the forming machine. The precut process usually employs a stacking and feeding system to move blanks into the machine, a contour roll forming machine operating at a fixed speed of about 15 to 75 m/min (50 to 250 ft/min), an exit conveyor, and a stacking system. The precut method is primarily used for low-volume operations and when notching cannot be easily accomplished in a postcut line. Often, the material is run from a coil to a shear or blanking press and then fed mechanically to the contour roll former.

Tooling for the precut method is relatively inexpensive, because cutting requires only a flat shear die or an end notch die. End flare is more pronounced than it is with the postcut method, however, and side roll tooling is required to obtain a good finished shape.

The most efficient, productive, and consistent contour roll forming process is the postcut method. This method requires an uncoiler, a roll-forming machine, a cutoff machine, and a run-out table (see Fig. 1). Postcut contour roll forming can be augmented by various auxiliary operations, such as prenotching, punching, embossing, marking, trimming, welding, curving, coiling, and die forming. These auxiliary operations can be used to eliminate the need for subsequent operations, resulting in production of a finished product.

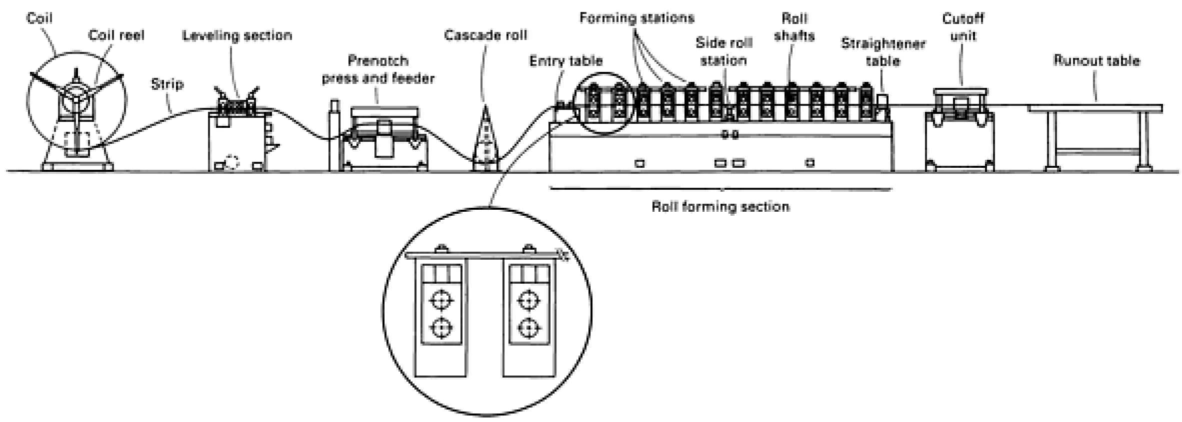

Fig. 1 Setup for contour roll forming of coiled stock (postcut method).

Tooling cost and tooling changeover time are greater for the postcut method than is the case with precut operations, but the increased efficiency of the postcut process balances this limitation.

Contour Roll Forming

Materials

Any material that can withstand bending to the desired radius can be contour roll formed. Thicknesses of 0.13 to 19 mm (0.005 to ¾in.) and material widths of 3.2 to 1830 mm (⅛ to 72 in.) can be used. Length of the formed part is limited only by the length that can be conveniently handled after forming.

In some cases, multiple sections can be formed from a single strip; in other cases, several strips can be simultaneously fed into the machine and combined after forming to produce a composite section. Contour roll forming is almost always performed at room temperature; however, some materials, such as certain titanium alloys, must be formed at elevated temperatures. This is done on specially designed machines.

Influence of Work Metal Composition and Condition. The effect of work metal formability on procedures and results in contour roll forming is generally the same as it is in other forming methods.

Initial yield strength and rate of strain hardening of the work metal affect contour roll forming. One measure for predicting the formability of a work metal is the Olsen cup test (see the article "Formability Testing of Sheet Metals" in this Volume).

Work metals of equal thickness, with differing compositions, initial yield strengths, and rates of strain hardening, could require alterations in the contour rolling operation. Factors to be considered are: power requirements, number of stations, roll material, lubrication, and speed.

In contour roll forming, it is not uncommon to change the work metal but retain the same shape. In such instances, changes may be necessary in equipment and tooling.

When work metal thickness and tooling remain unchanged, it is seldom a problem to change to a more formable work metal. For example, in changing from low-carbon steel to aluminum, major changes would be unlikely. However, it may be necessary to regrind the finish-station rolls to avoid overbending the section; this would usually be determined by a trial run.

When the change is to a metal of higher strength, one or more changes in procedure may be required to achieve desired results. In forming higher-strength metals such as stainless steels, some overforming is usually required to allow for springback. Residual stress in highly cold-worked metal often causes straightening problems, particularly when forming asymmetrical shapes. A common remedy is to add roll stations to decrease the amount of forming in a given station.

In most instances, difficulty in maintaining size and angle tolerance increases as the yield strength of the work metal increases. Optimum rolling speed decreases as yield strength or hardness increases. For example, in changing from carbon steel to stainless, speed is usually decreased 10 to 25%, mainly to prevent rolls from galling when there is an appreciable amount of roll sweep. One method of combating roll galling without greatly reducing speed is to use EP (extreme-pressure) additives in the lubricant; for extreme conditions, pigmented drawing compounds can be added to the lubricant. The main disadvantage of special lubricants is the difficulty and expense involved in removing them from finished workpieces.

Aluminum bronze rolls are often an advantage in shaping the difficult-to-form metals because they resist galling; however, bronze rolls are softer and wear faster than do tool steel rolls. Rolls made from D2 tool steel, hardened and chromium plated, are usually best for contour roll forming of high-strength metals (see the section "Roll Materials" in this article).

Process Variables

In contour roll forming, material is progressively formed as it passes from one station to another. The variable parameters in a roll forming operation include power requirement, forming speed, and type of lubricant. These parameters are determined by width, thickness, and type of material; complexity of the cross section to be formed; coating (if any) on the material; and accuracy required.

The power required by a roll forming machine depends on the torque loss through the drive gearing and the friction between the material and the rolls as the material is being formed. The particular alloy and its thickness must be taken into consideration when looking at the effect of material on power requirements. Generally, contour roll forming machines have motors ranging from 10 to 50 hp on small machines and from 50 to 125 hp on larger machines.

Forming Speed. Speeds used in contour roll forming can range from 0.5 to 245 m/min (1.5 to 800 ft/min), although this speed range represents unusual extremes. Speeds between 25 and 30 m/min (80 and 100 ft/min) are most widely used. One or more of the following can influence optimum forming speed:

- Composition of the work metal
- Yield strength or hardness of the work metal
- Thickness of the work metal

- Severity of the forming operation
- Cutting of finished shapes to length
- Number of roll stations
- Required auxiliary operations
- Use of lubricant (coolant)

Lower speeds in the range indicated above (near 0.5 m/min, or 1½ ft/min) are required for contour roll forming titanium into a relatively complex shape. At the other extreme, a speed of 245 m/min (800 ft/min) has been used in production operations in which conditions were nearly ideal, that is, for contour rolling low yield strength metal, such as aluminum or annealed low-carbon steel, in thicknesses less than 0.91 mm (0.0359 in.), in an operation having mild forming severity and requiring cutoff into relatively long lengths (about 25 m, or 80 ft). To use such high speeds effectively, even though forming is not severe, more stations are usually required, to minimize the amount of forming in any one station. High forming speed usually precludes auxiliary operations, such as punching, notching, or welding, and requires a flood of lubricant at each station.

The first four factors listed above are closely related and influence permissible forming speed. In addition, one or more of the last four factors may dictate a lower speed regardless of the otherwise permissible speed.

Lubricants prevent metal pickup by the rolls (thus improving finish on the work metal and prolonging roll life) and also prevent overheating of rolls and work metal. When rolls become overheated, their life is shortened. If work metal is overheated, it may warp and require straightening. When lubricants can be tolerated, rolling efficiency is usually increased by their use.

Soluble oils (in a 1-to-12 mixture with water) are the most commonly used lubricants. They are usually applied by a pumping action from a self-contained sump in the machine base through a manifold having flexible tubes and nozzles that direct the fluid to the required locations. Gutters are arranged around the top of the machine to catch the fluid and return it to the sump.

Other lubricants have been used satisfactorily for specific applications. In addition to lubricating and cooling, however, a lubricant must be nontoxic, noncorrosive to the metal being formed (as well as to rolls and other machine components), and removable by available shop cleaning facilities. For instance, some silicone-base fluids are excellent lubricants for roll forming, but they are extremely difficult to remove from metal surfaces. This poses problems in obtaining satisfactory plating or adherence of organic coatings or adhesives. Extreme-pressure (EP) lubricants are sometimes used in severe roll forming.

For some applications, no lubricant is permitted (for example, for the forming of painted or otherwise coated metals or for the forming of complex shapes that would entrap lubricants). The result could be a reduction of rolling speed or lower-quality finish, or both. However, in some instances, even though flooding with lubricant cannot be tolerated, other means can be used to supply some lubricant to the rolls. One method is to mount cellulose sponges in constant contact with the rolls, and to keep them wetted with lubricant by hand or by drip applicators.

Despite the fact that lubrication is helpful and often necessary in contour rolling, application and subsequent removal of lubricants are significant cost items. When roll forming steel, however, the selection of hot-rolled, pickled, and oiled grades of work metal has often eliminated the need for an additional lubricant. More information on the role of lubrication and the types of lubricants used in sheet forming is available in the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume.

Contour Roll Forming

Machines

The contour roll forming machine most commonly used has a number of individual units, each of which is actually a dual-spindle roll forming machine, mounted on a suitable baseplate to make a multiple-unit machine. The flexibility of this construction permits the user to purchase enough units for immediate needs only. The purchase of additional length of baseplate on the machine allows the addition of units at any time for future needs. Some of these machines are provided with machined ends on the baseplates, making it possible to couple several machines together, in tandem, to provide additional units as required.

Screws for making vertical adjustments of the top rolls are designed with dials and scales to provide micrometer adjustment and a means of recording the position of the top shaft for each roll pass and each shape being formed. Shaft diameter on most machines ranges from 25 to 102 mm (1 to 4 in.).

Several types of roll forming machines or roll formers are used. They can be classified according to spindle support, station configuration, and drive system.

Spindle Support. Roll forming machines can be classified according to the method by which the spindles are supported in the unit. Generally, two types exist: inboard or overhung spindle machines and outboard machines.

Inboard-type machines (Fig. 2 top) have spindle shafts supported on one end that are 25 to 38 mm (1 to 1½ in.) in diameter and up to 102 mm (4 in.) in length. They are used for forming light-gage moldings, weather strips, and other simple shapes. Material thickness is limited to about 1 mm (0.040 in.), and the top roll shaft is generally geared directly to the bottom shaft. This direct-mesh gearing permits only a small amount of roll redressing (no more than the thickness of the material being formed) on the top and bottom rolls. Tooling changeover is faster on this machine than on the outboard type of machine.

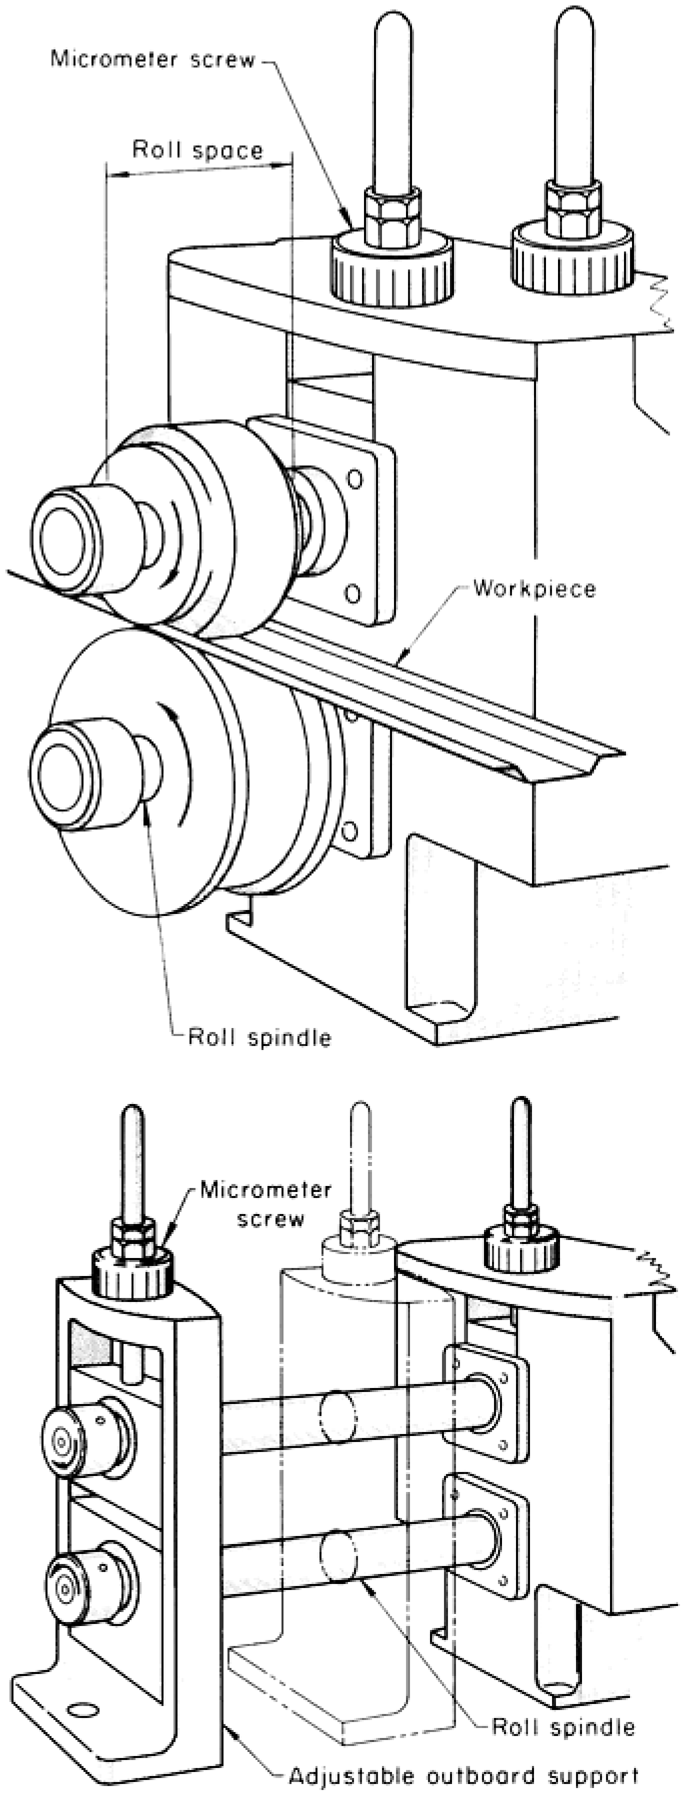

Fig. 2 Two basic machine concepts for contour roll forming. (top) Inboard-type machine. (bottom) Outboard-

type machine.

Outboard machines (Fig. 2 bottom) have housings supporting both ends of the spindle shafts. The outboard housing is generally adjustable along the spindles, permitting shortening of the distance between the supports to accommodate the roll forming of small shapes of heavy-gage material. This adjustment also permits the machine to be used as an inboard type of machine when desired. Outboard machines can be readily designed to accommodate any width of material by making the spindle lengths suit the material width and then mounting the individual units and spindles on a baseplate of suitable width. This type of machine is built with spindle sizes ranging from 38 to 102 mm (1½ to 4 in.) diam and with width capacities up to 1830 mm (72 in.).

Generally, for roll forming material more than 5 mm ($\frac{3}{16}$ in.) thick, machines are constructed so that both top and bottom shafts can be removed by lifting them vertically from the housings after the housing caps have been removed. This permits rolls to be mounted on the shafts away from the machine, an important consideration when heavy rolls are being handled. This type of machine is built in spindle sizes ranging from 50 to 380 mm (2 to 15 in.) in diameter.

Station Configuration. As was previously mentioned, a typical contour roll forming machine consists of several individual forming units mounted on a common baseplate. The manner in which the forming units are mounted determines to a great extent the type of shapes that are formed on the machine.

Single-duty machines are built and designed for a one-purpose profile or for one particular set of roll tooling, and are not normally designed for convenient roll changing. This machine is generally used for long production runs, and its cost is low in comparison to the other styles.

Conventional (standard) machines are more versatile than single-duty machines because the outboard supports are easily removed. This facilitates roll changes, making conventional machines suitable for a variety of production requirements.

To change the tooling, the top and bottom spindle lock nuts are removed and the out-board housing is pulled off the spindles. The tooling can then be removed and replaced with the desired profile.

Side-by-side machines (Fig. 3) are designed for multiple-profiled tooling and provide the flexibility of having more than one set of roll tooling mounted on the spindle shaft at the same time. Generally, this type of machine is limited to two sets of rolls at a given time, but there can be up to three or four sets of rolls when small profiles are being run in production. Changeover from one production profile to another is accomplished by shifting the machine bed to the desired profile. The main advantages of the side-by-side configuration are low initial investments, fast tooling change, and reduced floor space requirement. Roll wear, however, can create problems because one set cannot be reground without regrinding the others at the same time. Adjusting for material variations can also be a problem.

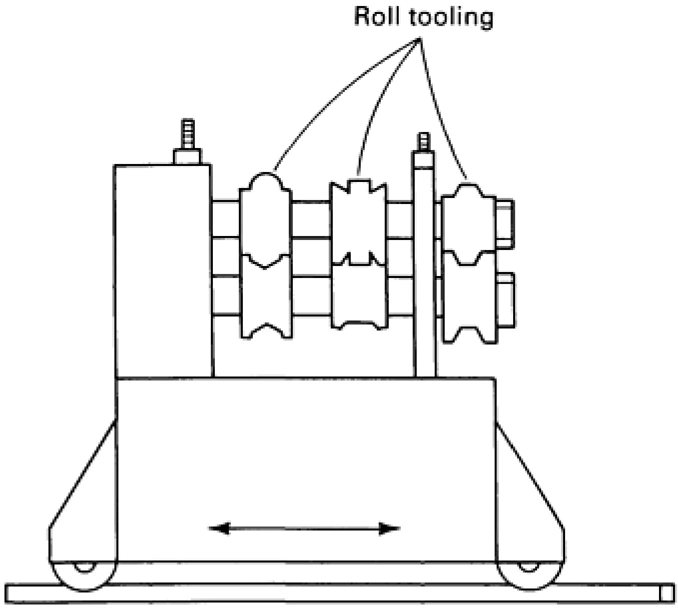

Fig. 3 A side-by-side contour roll forming machine, which allows forming of several different profiles on the same machine.

The double-high machine configuration consists of one set of roll tooling mounted on its own roll shafts and housings at one level on the bed frame, and a second complete set of roll tooling and housings mounted at a different level on the same frame. This particular type of machine is used in the metal building industry for forming building panels up to 1520 mm (60 in.) wide.

The rafted machine configuration resembles the single-duty and conventional configurations, because each configuration has housings and spindle shafts with one particular set of roll tooling mounted on it. However, the rafted configuration has several roll-forming units mounted on rafts or subplates that are removable from the roll-former base. During tool changeover, the individual rafts are removed from the base, and the replacement rafts with the roll-forming units and tooling are installed. On a typical 16-stand roll-forming machine, there are four sets of rafts containing four forming units each.

Double-head machines are designed and constructed with two separate sets of housings and roll shafts mounted so that they face one another. Each housing is mounted on an adjustable plate mechanism to allow the housing to be shifted for a change in overall width while at the same time maintaining the same profile for the edge formation.

This type of machine is very popular in the shelving industry, in which large, flat panels are rolled on a production basis and the panel widths change regularly. A disadvantage of this type of machine is that it does not lend itself to forming the center of the panel. Two of these machines, connected by an automatic transfer mechanism, are used to form the four edges of a shelf; the first machine forms the two long edges, and the second machine forms the two end configurations.

Drive Systems. The five basic methods used to drive roll forming units are chain drive, spur gear drive, worm gear drive, square gearing, and universal drive.

A chain drive consists of a sprocket attached to the individual roll forming unit and connected to the main drive by means of a roller chain. This is accomplished using a continuous roller chain, with one long chain driving each unit, or a shorter chain connected to each individual unit. This drive system is inexpensive and allows flexibility in the construction of the machine.

A spur gear drive consists of a continuous train of spur gears mounted at the rear end of each spindle shaft. Idler gears are positioned between each unit to transfer the drive equally to all the units.

A worm gear drive is very similar to the spur gear drive. However, instead of using the idler gear to transfer the drive to each unit, an individual worm gear box is mounted on the bottom spindle of each unit. The worm gear boxes are coupled in line, which permits the machine designer to spread out the horizontal centers of each roll forming station without being concerned about properly meshing the gear train to the idler gear.

Square gearing also incorporates both spur gears and a worm gear. This type of gearing permits a vertical adjustment of the upper spindle and allows use of a wide range of roll diameters.

Universal drive eliminates the need for any spur gearing or roller chain and sprocket drives. It consists of a series of worm-driven gear boxes with top and bottom outputs that transfer the power source to the individual shafts through a double-jointed universal coupling. On certain applications, only the bottom spindle is driven. This drive system is generally used with rafted-style machines to permit quick tool changeover. Simplicity of design and minimal maintenance are two important advantages of this drive system.

Machine Selection. Several factors must be taken into consideration when selecting a machine to be used in a roll forming operation. These include load capacity, section size and shape, and roll changeover.

Load Capacity. The type and thickness of the material being formed determine to a large extent the load capacity that a given forming machine is required to produce. If material type and thickness change, it is best to select a machine that can provide the additional capacity.

In forming material up to 1.5 mm (0.060 in.) thick, a machine with 38 mm (1½ in.) diam spindles should be used as long as the part is not too wide. A machine with 50 mm (2 in.) diam spindles can be used for forming material thicknesses up to 2 mm (0.080 in.). As the material thickness increases, the diameter of the spindles must also increase to provide strength to create the pressure required to do the forming. Center distances must be increased as the size of the part shape and the movement of material between forming stations increases. These distances are usually determined by the machine builder.

Section Size and Shape. Wide roll-formed sections require wide roll spaces. To support the pressure of the rolls, the spindle shafts must be large enough in diameter to prevent shaft deflection during forming. The distance between the centerline of the bottom spindle and the machine bed determines the maximum roll diameter and hence the maximum section depth.

The more complex the shape of the section being formed, the greater the number of passes (pairs of rolls) required to roll form the section. It is best to select a machine that provides the flexibility of adding or subtracting pairs of rolls in accordance with the part design.

Roll changeover can be costly and time consuming, because material variations may require different roll pressure settings. When several part configurations must be run on one machine, it is best to select a machine that permits the tooling to be changed quickly. If only two or three profiles are run, the side-by-side and the double-high machines are possible selections; the changeover can be performed quickly without losing valuable production time. Another machine to consider is the rafted machine.

Contour Roll Forming

Auxiliary Equipment

In addition to the machines that do the roll forming, several other pieces of equipment are usually required for production operation. Stock for roll forming is usually received in coils; thus, an electric hoist on an overhead track is needed to lift coils from skids and transfer them to a cradle or reel (another piece of auxiliary equipment). Also equipment for welding the end of an expended coil to the lead of the next one, an entrance guide, intermediate guides, a straightening device, and cutoff equipment may be needed.

Stock reels should be equipped with an expandable arbor to fit the inside diameter of the coil, and with a friction drag. Stock reels incorporating these features are commercially available in a wide range of coil capacities (see the article "Presses and Auxiliary Equipment for Forming of Sheet Metal" in this Volume).

The friction drag is necessary to prevent the coil stock from overrunning onto the floor in the event of a sudden stoppage of the roll forming equipment. In the simplest type of motor-driven stock reel, a dancer arm and roll ride the stock in a loop-detector arrangement, which starts and stops the motor as required, supplying stock at the average rate used by the roll former. Stock speed is matched approximately by adjusting a variable-pitch sheave to prevent too-frequent stopping and starting of the alternating current drive motor. This type of control on the stock reel provides acceptable results for most applications. More elaborate controls can be used, such as a direct current motor drive with feedback control to match stock speed with machine speed. Elaborate controls are expensive and should not be considered unless they are needed to meet special workpiece requirements.

Stock reels are available with a swivel base and two arbors. A coil may be positioned on one arbor while the first coil is being used, thus reducing change time. This arrangement is advantageous when coils are relatively small and production requirements are high, because time consumed in changing coils can become a substantial portion of the total production time.

Welding Equipment. Thread-up time can be eliminated by manually welding the end of each expended coil to the leading end of the next one. For stock thickness of 1.6 mm ($\frac{1}{16}$ in.) or more, a semiautomatic welder can be placed in the line. Regardless of the welding method used, any appreciable flash must be removed before the welded joint reaches the first roll station. Provision can be made to remove flash by installing a grinder similar to a band saw blade grinder. More information on combined roll forming and welding operations is available in the section "Tube and Pipe Rolling" in this article.

Entrance guides positioned in front of the first forming station ensure correct alignment of the work metal entering the starting rolls. This is particularly desirable when the part being formed is asymmetrical in the first station because the stock could climb or shift to one side without guides. The simplest form of entrance guide consists of a flat plate with a channel milled to the proper width and depth to accept the strip at its maximum tolerance, plus a simple, removable lid to hold the stock in place. The mounting for this guide should permit adjustment vertically and laterally.

When wide variations in stock width are encountered, a self-centering, parallel-rule entrance guide is preferred. This guide is constructed like a navigator's parallel rule, with the crossbars pivoted and mounted at their centers with a spring, causing the side bars or rules to close on the stock under spring load.

Stock drags are occasionally used to place a slight tension on the stock and to cause it to feed more uniformly through the first few stations. The simplest form consists of two pieces of hardwood. The stock is clamped between the wooden members, which butt against the entrance guide, thus providing enough friction to keep the stock under tension. The amount of tension can be regulated by the clamping force on the wooden members.

Guides between roll stations facilitate entrance of the partly formed stock into the next station. In theory, if rolls are properly designed, guides between stations are unnecessary, because each set of rolls should accept the cross section from the preceding set of rolls. In practice, however, because of such factors as cost, lead time, and availability of space or equipment, the number of roll stations is often fewer than the ideal number; this necessitates more forming in each station than is consistent with the best practice. Therefore, the use of guides between stations helps to compensate for this lack of additional stations, and to minimize springback.

Generally, guides between stations are only required to contact the critical points of the work metal, not the entire contour. Regardless of their shape, guides should be designed with removable top portions to facilitate threading.

Various metals may be used for guides, depending on the end-use of the workpiece. For the areas contacting the moving workpiece, hardened steel (usually, case-hardened low-carbon steel) is preferred from the standpoint of guide life. However, when workpiece finish is critical and hardened steel guides are likely to scratch the surface, bronze or aluminum guides are used. For some work, hard chromium plating of guides minimizes damage to workpiece surfaces and still provides acceptable guide life. Guides can be replated when the plating becomes worn.

Straightening Equipment. Usually it is necessary to straighten the workpiece after it leaves the final roll station. This is done by standard straightening guides attached to the machine beyond the last set of rolls, or by special devices designed for individual applications.

Straightening guides are usually adjustable vertically and laterally; the most versatile types can be swiveled in either elevation or azimuth and can also be rotated about an axis. Most straighteners employed for contour roll forming are either of the roll type or the shoe type.

A roll straightener consists of multiple rolls (individually adjustable) arranged to contact the stock in selected areas. A shoe straightener consists of one or more shoes, usually made of bronze, properly fitted to the contour and adjustable in at least one direction that will crimp the stock to correct for sweep or twist.

There are also applications in which a sweep (curve) is deliberate and desired. A sweep guide is similar to a straightening guide, and a straightening guide often can be adjusted to give the required sweep in a constant radius. For more detailed information on straightening equipment, see the articles "Straightening of Bars, Shapes, and Long Parts" and "Straightening of Tubing" in this Volume.

Cutoff Equipment. Because most contour rolled products are made from coil stock, a system of cutting the formed shapes to length must be provided. There are several types and sizes of flying-shear cutoff machines.

The sliding-die cutoff machine is most commonly used. The action of this machine is similar to that of a punch press, although construction of the machine differs. The flywheel and clutch are placed below the bed, with the ram posts passing through the bed. Gibs are provided in the bed and ram to accept a gibbed die and a punch holder that permits linear movement of the die to match work metal speed during the cutoff cycle.

Tooling

Tooling used in roll forming includes the forming rolls and the dies for punching and cutting off the material. Tube mills require some additional tooling to weld, size, and straighten the tubes as they are produced on the machine; the needed tooling is discussed in the section "Tube and Pipe Rolling" in this article.

Forming Rolls

The rolls are the tools that do the actual forming of the material as it moves through the roll forming machine. Several factors must be considered when designing the rolls to form a particular part. These include the number of required passes, the material width, the "flower" design, the roll design parameters, and the roll material. Flower is the name given to the progressive section contours, starting with the flat material and ending with the desired section profile.

Number of Passes. The roll forming of material into a desired final shape is a progressive operation in which small amounts of forming are performed at each pass or pair of rolls. The amount of change of shape or contour in each pass must be restricted so that the required bends can be formed without elongating the material. Too few passes can cause distortion and loss of tolerances; too many passes increase the initial tooling cost.

Generally, the number of passes depends upon the properties of the material and the complexity of the shape. Other areas to consider are part width, horizontal center distance between the individual stations, and part tolerances. The number of passes must be increased as the tolerances of the shape become tighter.

Material. Material thickness, hardness, and composition all affect the number of passes required to achieve a desired shape. As the thickness of the metal increases, the number of passes required to form the material increases. Steel that has a high yield strength should be overformed approximately 2° and then brought back to finish size on the final pass. Overforming compensates for springback that is encountered when materials having high yield strengths are formed. Material that is coated or that has a polished surface generally requires more passes than does uncoated material. Precut material may also require more passes so that the rolls can pick up the leading end of each section.

Shape complexity is determined by the number of bends and the total number of degrees that the formed part must be bent. It is also influenced by the symmetry of the part design. The forming angle method is a rule of thumb which roll designers use to determine the approximate number of passes.

On simple shapes, a forming angle of 1 to 2° is recommended. This forming angle is based on the amount of bending performed for every inch of distance between station centers (horizontal center distances). The minimum forming length for a single bend is determined by multiplying the height of the desired section by the cotangent of the forming angle. This length is then divided by the distance between station centers on a given machine, to determine the approximate number of passes. For multiple bends, the number of passes must be determined for each bend and then, after the formation of bends have been combined where possible, the approximate number of passes can be determined.

Horizontal Center Distance. If the machine on which the section must be run is predetermined, the specifications and limitations of the machine will have a bearing on the number of passes required. The distance between stations (horizontal center distance) may dictate more stations if that distance is too short. The total distance from flat material to finished section is more critical than the number of stations, because undue stresses are created by forming too fast.

Strip Width. The width of strip required to produce a given shape is determined by making a large-scale layout, dividing it into its component straight and curved segments, and totaling the developed width along the neutral axis. The outside profile and the neutral axis of each curved segment can usually be treated as circular arcs. Also, for bends having an inside radius of up to about twice the stock thickness in low-carbon steel, the neutral plane or axis is located approximately one-third of the distance from the inside surface to the outside surface at the bend.

Developed width, sometimes termed bend allowance, is the amount of material required to form a curved section of a particular shape properly. The two methods for calculating developed width described in this section use general equations and can be employed for all shapes. The equations given are applicable when low-carbon steel is formed; for less-formable materials, values should be increased.

Method One. Using this method, developed width w is calculated as follows:

$$w = r\frac{\alpha}{57.3} \quad \textbf{(Eq 1)}$$

If the inside bend radius is less than two times the material thickness, then:

$$r = r_i + 0.4t \quad \textbf{(Eq 2)}$$

where w is in millimeters (inches), r is the bend radius in millimeters (inches), α is the angle (in degrees) through which the material is bent, r_i is the inside bend radius in millimeters (inches), and t is the metal thickness in millimeters (inches).

If the inside bend radius is greater than $2t$, then:

$$r = r_i + 0.5t \quad \textbf{(Eq 3)}$$

If the material is bent through a 90° zero radius or a 180° zero radius, w is $\frac{1}{3}t$ or $\frac{2}{3}t$, respectively.

Method Two. Another method used to determine developed width for a roll-formed part is with the empirical equation:

$$w = (t \times p + r_i)0.01745\alpha \quad \textbf{(Eq 4)}$$

where w is in millimeters (inches), p is a bend factor based on the ratio of inside bend radius to material thickness expressed as a percentage, and the other quantities are as previously described.

The bend factor p is obtained by first dividing the inside bend radius by the material thickness. After this ratio is obtained p may be determined using either the nomograph shown in Fig. 4 or the following calculations: For a ratio less than one:

$$p = r_A \times 0.04 + 0.3 \quad \textbf{(Eq 5)}$$

For a ratio greater than one or equal to one:

$$p = (r_A - 1.0)0.6 + 0.34 \qquad \textbf{(Eq 6)}$$

where r_A is the inside bend radius divided by the material thickness, r_i/t. If p is calculated to be greater than 45%, the value is 0.45.

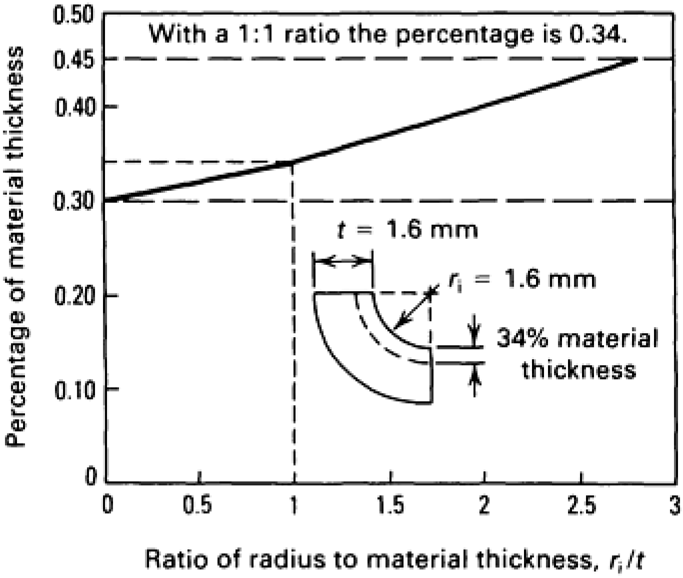

Fig. 4 Nomograph used to determine percentage of material thickness required when calculating bend allowance.

Flower Design. The development of the flower--the station-by-station overlay of progressive section contours, starting with the flat strip width before forming and ending with the final desired section profile--is the first step in the design of tooling for contour roll forming. The intermediate profiles between flat material and finished profile are graduated at a rate that enables the section to be completed in the fewest number of stations of passes without compromising general roll forming parameters. The flower graphically shows the number of passes required to roll form the given profile (Fig. 5).

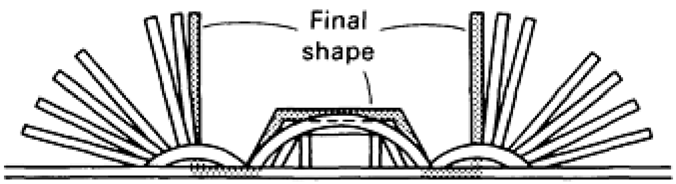

Fig. 5 Development of a flower for design of roll forming rolls. See text for details.

The two prime considerations in designing the flower are: a smooth flow of material from first to last pass and maximum control over fixed dimensions while roll forming. Other factors to be considered include forming position (a section is usually formed in an upward position), vertical reference line with respect to the number and severity of bends, and drive line (the optimal placement in the rolls for equal top and bottom surface speeds).

Roll Design Parameters. After the flower is completed to the satisfaction of the designer, rolls may be drawn around each overlay. For small sections, the roll material should contact the section material as much as possible. It is possible, however, to go too far and overdesign rolls, thereby creating too much roll contact, which can be detrimental. Each roll pass must be examined not only by itself but as part of the total job to determine where to make contact with the section material, where to exaggerate pressures or dimensions, where to clear out rolls so that material flows without restriction from one pass to another, and how to accept the section material from the previous configuration.

Rolls are usually made progressively larger in diameter from one pass to the next to permit the surface speed of each succeeding station to increase. The diameter increase is called step-up. The speed differential between passes creates a tension in the section material and eliminates the possibility of an overfeed between passes. Overfeed is created by an excessive amount of work being done in a single pass, which stretches the section material. Normal step-up is approximately 0.8 mm ($\frac{1}{32}$ in.) per pass on diameter, but it varies depending upon the gage of the section and the particular amount of forming being done in those passes.

Rolls may be solid or split (segmented) depending on the complexity of the section. Simple rolls are usually of a one-piece design, but as complexity of the workpiece increases, the use of split rolls should be considered. There are seldom any marked disadvantages in using split rolls, and one or more of the following advantages can often be gained:

- Turning, grinding, or other machining operations are usually easier to perform on the separate sections of split rolls than on one-piece rolls having a complex contour
- Sections of split rolls are less susceptible to cracking in heat treatment than are single complex rolls
- Handling problems are simplified, particularly for large roll sections
- Because sections of rolls subject to excessive wear or breakage can be replaced separately, split rolls can be more economical than one-piece rolls
- Split rolls permit the use of different roll materials, as needed, for areas of high and low wear
- Split rolls allow flexibility in making different widths of the same section by the use of spacers or additional roll sections
- Split rolls allow for minor adjustments that cannot be made with one-piece rolls

Figure 6 illustrates some of the above advantages of split rolls. In Fig. 6(a), the upper roll is composed of five separate sections. In addition to being easier to manufacture, split rolls of this type can accommodate minor adjustments (by shims or similar means) after the initial trial and before the first production run.

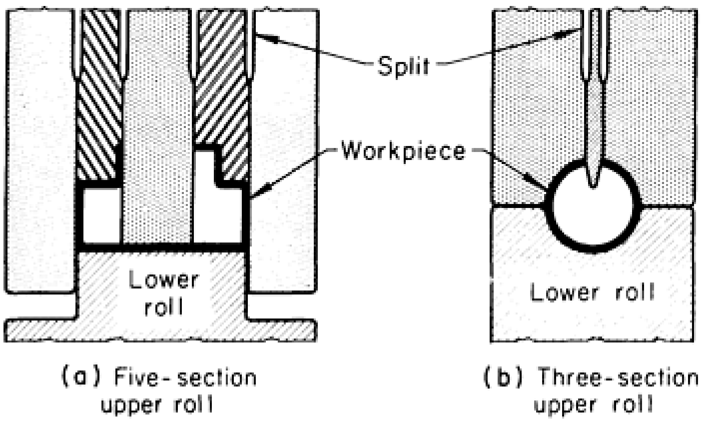

Fig. 6 Two types of split rolls used in contour roll forming. (a) Upper roll constructed in five sections allows for minor adjustments. (b) Three-section upper roll allows replacement of center section.

Figure 6(b) shows an upper forming roll made up of three sections--a narrow center section flanked by two wider sections. In use, the center section is subjected to a higher rate of wear than are the adjacent flanking sections. The center section of this forming roll can be replaced without changing the flanking sections, or can be made from a more wear-resistant metal.

Roll Materials. The materials that are most commonly used for contour rolls are:

- Low-carbon steel, turned and polished but not hardened
- Gray iron (such as class 30), turned and polished but not hardened
- Low-alloy tool steel (such as O1 or L6), hardened to 60 to 63 HRC and sometimes chromium plated
- High-carbon high-chromium tool steel (such as D2), hardened to 60 to 63 HRC and sometimes chromium plated
- Bronze (usually aluminum bronze)

The quantity of parts to be rolled is usually the major factor in choosing the most appropriate roll material, although other factors, as noted below, also affect selection to some extent, and one or more of them may become definitive in particular applications.

Short-Run Production. For rolling small quantities of a specific shape, or when repeat orders are not expected, rolls made of either low-carbon steel or gray iron are commonly used. When the work metal is soft and corner radii are generous, low-carbon steel or gray iron rolls can be used for medium- or high-production runs because rolls are easily made from these materials and are not expensive.

Medium-Run Production. As the size of the production run increases, rolls made of hardened, ground, polished tool steel, such as O1 or L6, are usually more economical and are widely used. Not only are these materials relatively inexpensive, they machine more easily than more highly alloyed tool steels and they can be heat treated by simple procedures. Rolls made of these steels can be plated with up to 25 μm (1 mil) of chromium to reduce galling or scratching of the work metal, or to extend tool life between grinds by decreasing roll wear or minimizing corrosion or pitting.

Long-Run Production. For long production runs (>5 million ft) or continuous high production, it is usually more economical to make rolls from one of the high-carbon high-chromium tool steels, such as D2. These highly alloyed grades cost nearly twice as much as O1, are more difficult to machine and grind, and require more complex heat treatments, but because of their longer life between regrinds, are usually more economical for long runs.

Factors Other Than Quantity. Three other conditions, under any one of which rolls made of steel such as D2 are often preferred (quantity becoming a secondary consideration), are: excessively hard work metal (low formability), excessively sharp radii or other severe forming conditions, and work metal surfaces that are abrasive (such as unpickled hot-rolled steel) and cause excessive roll wear. Rolls made of highly alloyed tool steel may also be plated with chromium for the reasons mentioned in the section "Medium-Run Production" above.

Special Finish Requirements. In many applications, such as the rolling of light-gage stainless steel, aluminum alloys, or coated stock, preservation of surface finish is of primary concern. With these work metals, softer rolls are used to avoid damaging the work metal surface, even though there may be a substantial reduction in roll life.

As workpiece surface finish requirements become more rigorous, softer rolls are required. Rolls made of bronze are often used. In some applications, the plating of hardened steel rolls is sufficient to prevent the marring of work metal surface finish.

Contour Roll Forming

Tube and Pipe Rolling

Welded-seam pipe and tube are contour roll formed by three methods: edge forming, center forming, and true-radius forming. Edge and center forming (Fig. 7a and b) require complete sets of rolls for each size of tube, because the stations that precede welding have the final radii in the roll contours. In true-radius forming (Fig. 7c), the breakdown rolls can be used for a range of sizes, which reduces tooling cost and setup time.

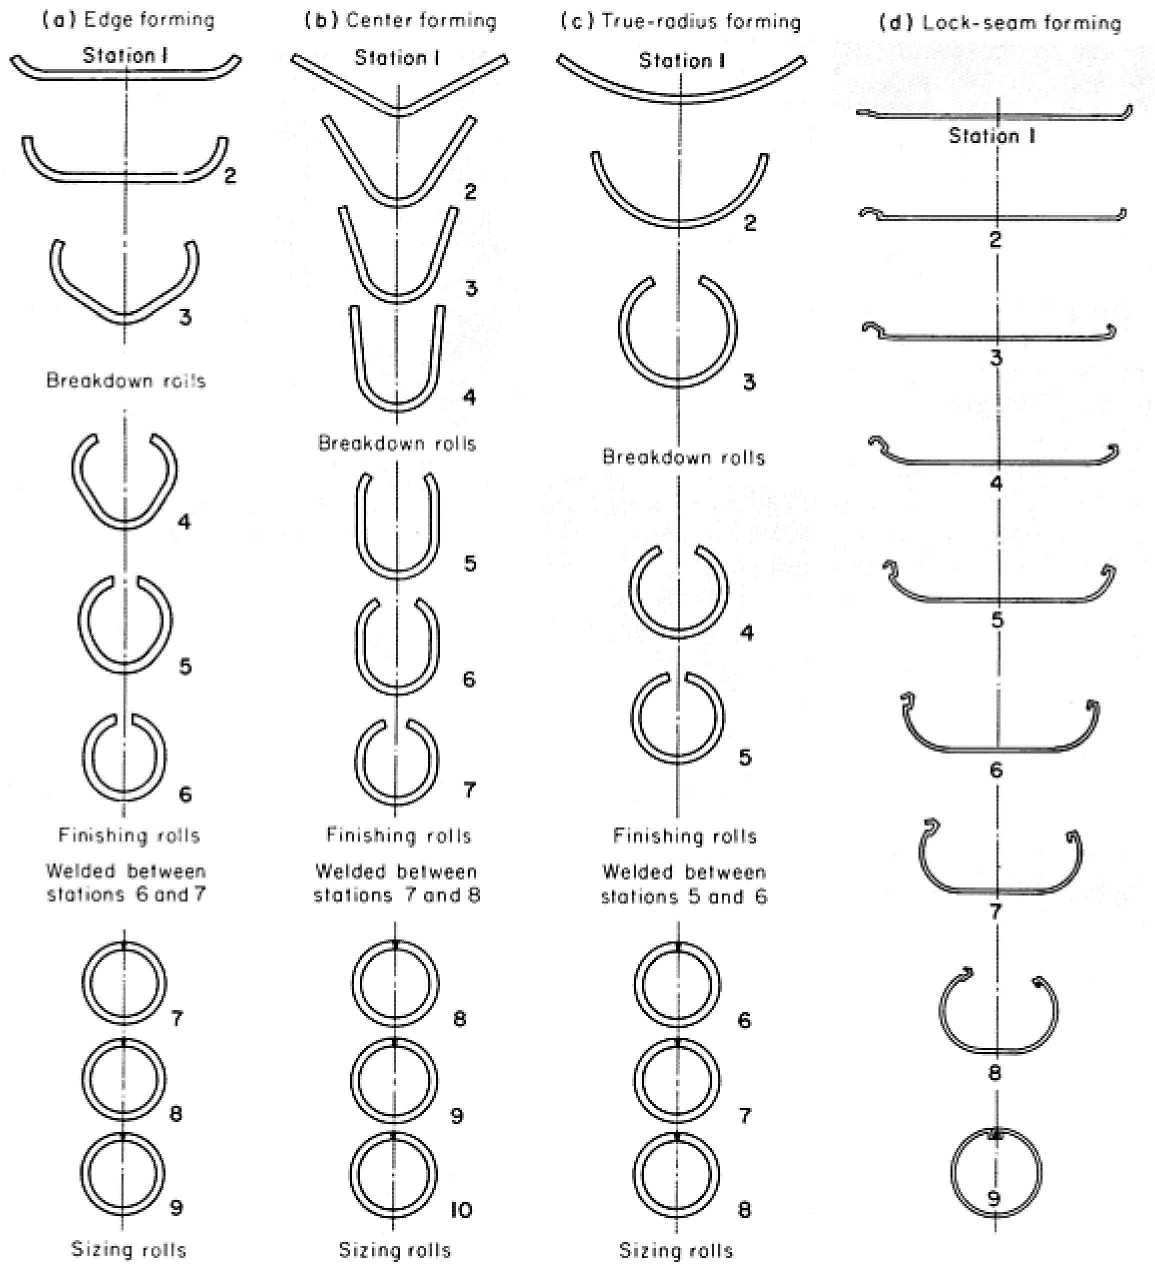

Fig. 7 Typical sequences for forming round pipes and tubes. (a to c) With a butt-welded longitudinal seam. (d) With a lock-seam joint.

For all three methods of producing welded tubing, the forming rolls are termed as breakdown and finishing rolls. Breakdown is usually accomplished in the first three or four roll stations, as indicated in Fig. 7.

Optimum distance between the edges of the stock in the final finishing station (stations 6, 7, and 5 in Fig. 7a, b, and c, respectively) is affected by the method of welding and tube size. For resistance welding, however, the following relations of tube size to distance are typical:

Tube diameter	Distance

mm	in.	mm	in.
9.5	$\frac{3}{8}$	1.57	**0.062**
25	1	3.15	**0.124**
51	2	4.37	**0.172**
102	**4**	**6.35**	**0.250**

Machine size is determined by material thickness and tubing size. Large pipe sometimes requires a machine having spindles 305 to 355 mm (12 to 14 in.) in diameter.

Speed of production is controlled by thickness and type of work metal. Aluminum can be formed and welded as fast as 75 m/min (250 ft/min), whereas titanium tubing is produced at a rate of only 455 mm/min (18 in./min). The welding operation is often the main limitation on the speed at which tubing can be produced by roll forming.

Soluble oils are the most practical lubricant for forming tube, and should be used to prevent galling. A mixture of 25 to 40 parts water to 1 part oil is commonly used.

Long roll life can be expected in producing round tubing. Three to four million feet between regrinds is considered normal.

Lock-seam tube (Fig. 7d) has two edges folded over to form a lock. Production of lock-seam tubing is restricted to relatively thin material (usually less than 0.91 mm, or 0.0359 in.) because heavier stock is too difficult to lock. The lock-seam method is used extensively for thicknesses that are impractical for welding because they are too thin. Maximum thickness is also restricted by tube diameter. As a general rule, stock thickness should not be greater than 3% of the tube diameter. For instance, 0.76 mm (0.030 in.) is about the maximum thickness of strip that should be used to produce 25 mm (1 in.) OD tubing.

Minimum width of the lock should be five times the material thickness. The lock-seam method is also applicable to square tubing.

The various stages of lock-seam forming are shown in Fig. 7(d). Idlers are used between stations 4 to 8. Between stations 8 and 9, a lock housing unit that is equivalent to two stations is used. Both side rolls and vertical rolls are used in the locking stand, the main purpose of which is to lock the two edges of work metal in the groove. A mandrel is placed inside the tube to help form the small lock. This mandrel is in the locking stand and extends beyond station 9. In the last station, two small rolls ride opposite each other on the mandrel, pushing the work metal to form a tight lock between the top and bottom rolls in station 9. It is necessary to have close control over the stock thickness, because a 0.025 mm (0.001 in.) difference in thickness will result in a difference of about 0.13 mm (0.005 in.) in the outside diameter of the tube.

Roll Design for Tube Rolling

A number of designs and methods are used for forming strip into a tubular shape suitable for welding, with many factors involved in choosing the proper roll design for producing a particular tube.

Figure 8 illustrates one of the most commonly used designs for rolls used for forming the tube before welding. The rolls are designed with a single forming radius in each roll pass. This radius decreases progressively in each roll pass until the final pass. The radius of the final roll pass is slightly larger than the finished tube size to permit the insertion of a thin fin in the top roll to act as a guide for the two edges of the material. Generally, for the last two or three roll passes, there are fin rolls in the top rolls to guide the two edges of the strip, prevent twisting of the tube and ensure accurate positioning of the seam entering the welder. Idler rolls mounted on vertical spindles between the driven-roll passes are positioned to prevent excessive rubbing and scuffing of the side of the tube as it passes through the succeeding driven-roll pass. The number of driven-roll passes can vary, increasing as the tube diameter increases, but five driven passes are considered a minimum.

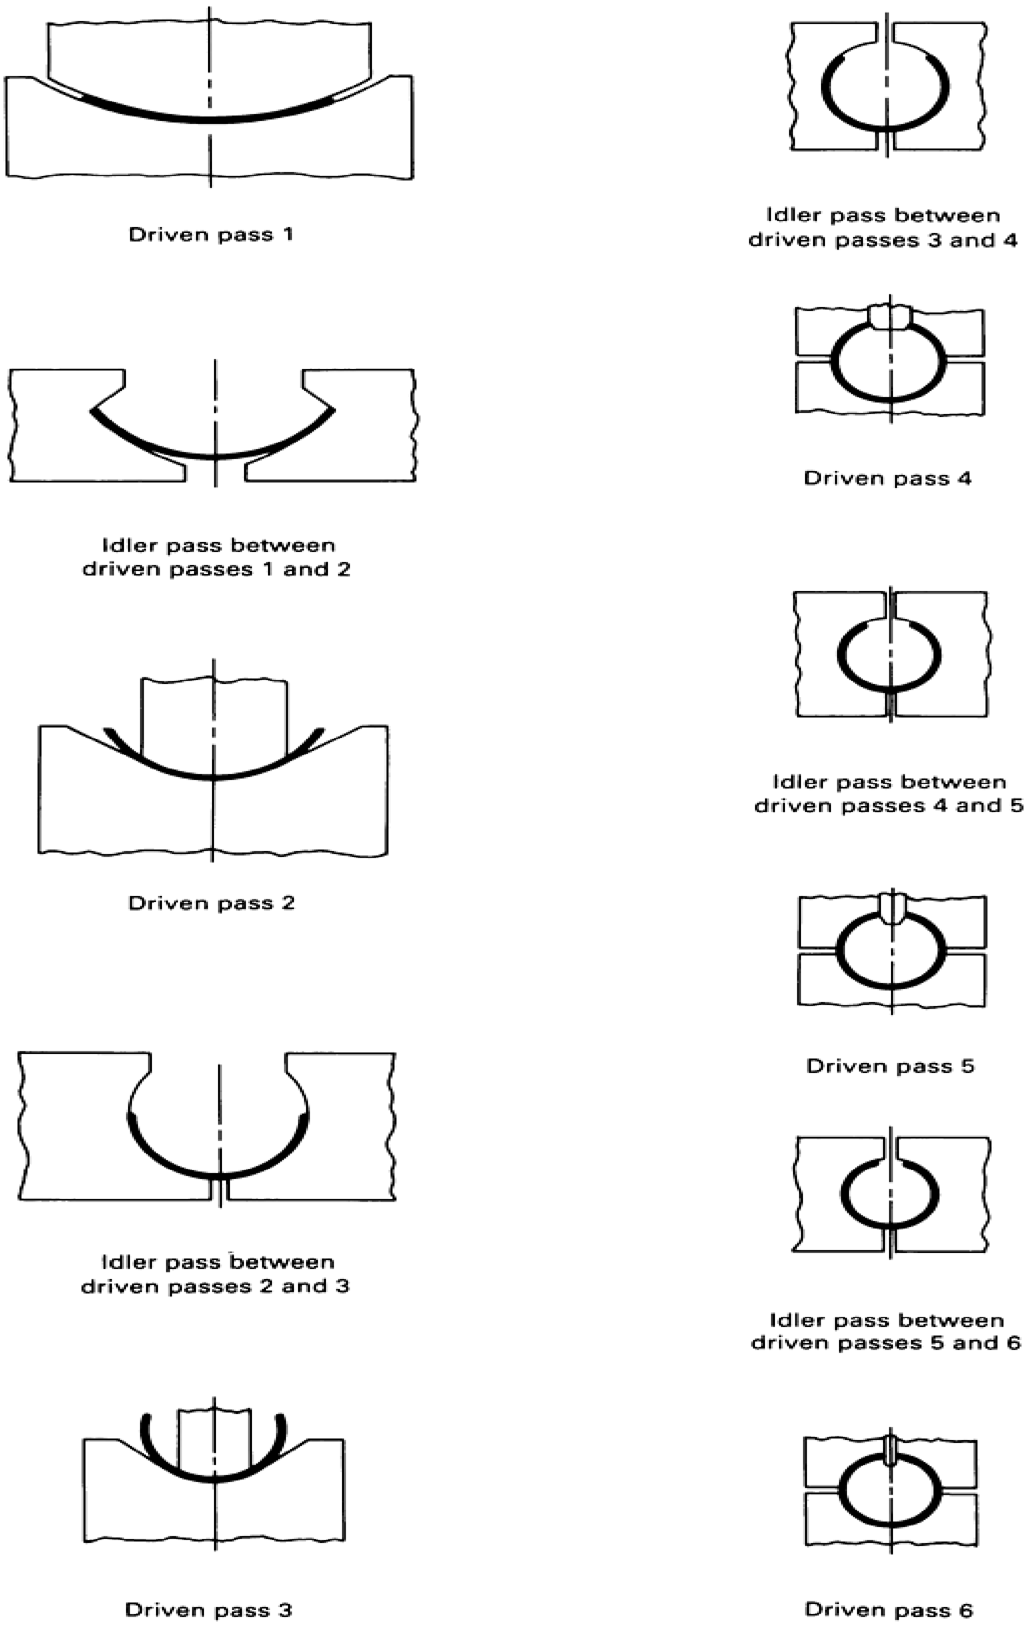

Fig. 8 Typical sequences for roll forming tubing from strip material.

For forming tube with either a very thin wall or a very thick wall (<3% of the outside diameter of the tube, or >10% of the outside diameter of the tube), a modification of the design shown in Fig. 8 is used. This modification is obtained by forming the portion of the strip adjacent to the edges to the finished radius of the tube in the first forming pass, instead of depending on the fin passes to finish form at the edges. This finished form at the edges of the strip helps to prevent buckles and waviness at the edges of the strip as it passes through the forming rolls when very thin material is being formed, and it helps to avoid the necessity of extreme pressures at the fin rolls when extra heavy-gage material is being formed. Figure 9 illustrates the first four sets of rolls used in this method of tube forming. The remaining rolls are similar to those shown in Fig. 8.

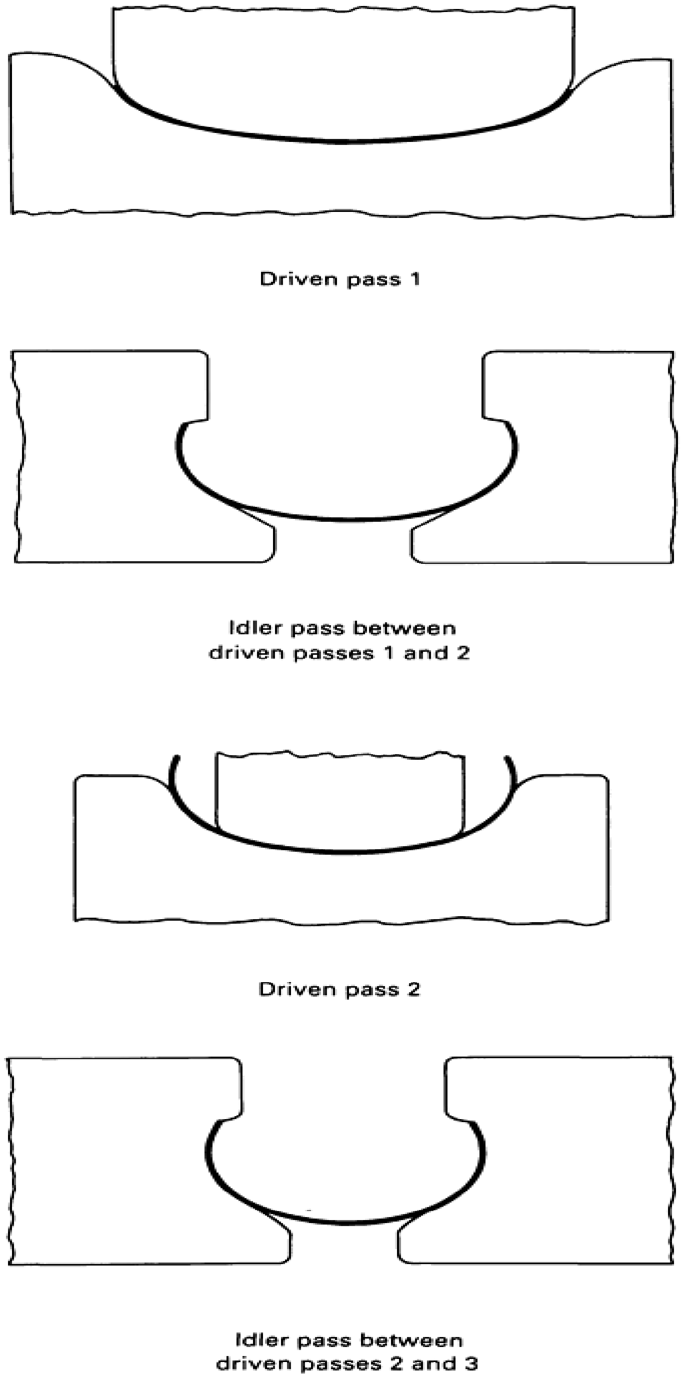

Fig. 9 First group of rolls for forming tubing from thin strip material from the edges inward.

In forming material of high tensile strength when springback of the metal is a factor, a third method of forming is sometimes used. In this design a part of the strip is formed to the finished tube radius in each roll pass, progressing from the two edges toward the middle until the fin passes are reached. The forming radius on the rolls is less than the finished radius of the tube to compensate for the springback of the material.

Welding

Seam welding of pipe and tubing is generally performed using either low-frequency rotary-electrode welding or high-frequency welding; laser welding is beginning to be used (see the section "Laser Welding" below). High-frequency resistance welding and high-frequency induction welding for tube diameters less than 25 mm (1 in.) Fig. 10 has become more predominant in recent years in the production of welded tubing (see the article "High Frequency Welding" in *Welding, Brazing, and Soldering*, Volume 6 of the *ASM Handbook*). With rotary-electrode welding, the maximum wall thickness that is economically feasible is 4.5 mm (0.180 in.). Using high-frequency welders, wall thicknesses as thick as 19 mm (0.75 in.) and as thin as 0.13 mm (0.005 in.) are obtainable. After the welding operation, the piece is usually sized and then straightened before being cut to length.

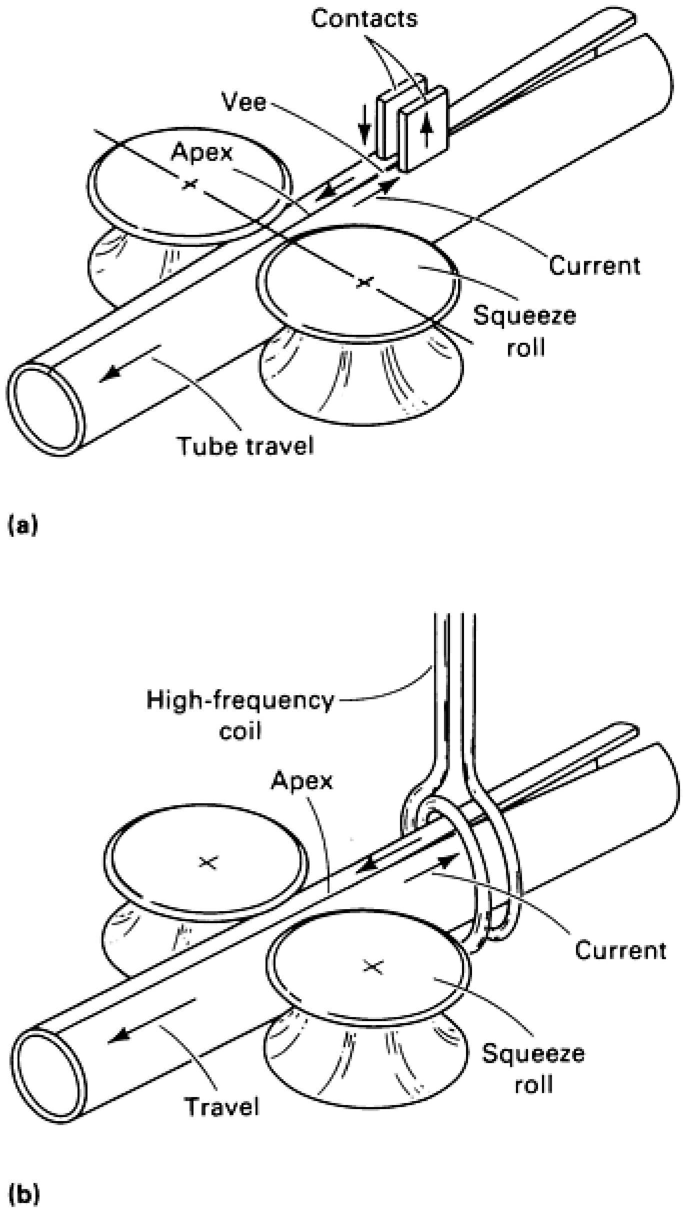

Fig. 10 Two methods of high-frequency welding of longitudinal seams in tubing. (a) Sliding contacts introduce current to the tube edges. (b) Multiturn induction coil induces current to the tube edges.

Laser Welding. Powerful carbon dioxide (CO_2) lasers also have been used to make longitudinal welds in contour roll formed stainless steel tube. In this process autogenous (no filler metal) welds were made in type 304 and type 430 stainless steel tubes using a 5 kW CO_2 laser at a speed of 5 m/min (16.5 ft/min). Tubes had a wall thickness of 1.5 mm (0.060 in.) and a diameter of 48.5 mm (1.91 in.). Laser welding resulted in joints that were tougher and more ductile than joints made by other welding processes.

Sizing and Straightening. Tube and pipe are welded to an outside diameter slightly larger than the finished diameter. The sizing rolls can then produce round, accurately dimensioned, straight, finished tube. A typical set of sizing and straightening rolls consists of three driven-roll passes, vertically mounted idler rolls between each driven pass, and finally a set of idle cluster rolls that are adjustable both vertically and horizontally for final straightening of the tube. The roll radius for each driven roll successively decreases to size the tube down to its proper diameter.

Reshaping of Round Tubing

Several cross sections that can be feasibly produced by reshaping round tubing are shown in Fig. 11. Reshaping can be done either continuously in sequence with the production of round tubing or in a separate operation.

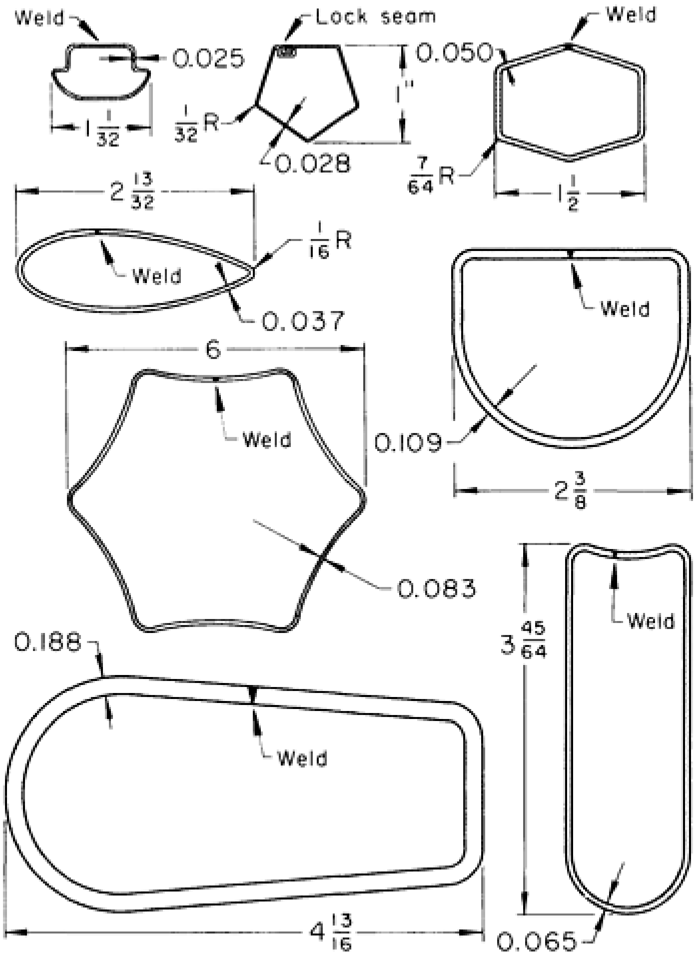

Fig. 11 Cross sections showing typical contours that can be produced by reshaping welded or lock-seam round tubing. In addition to these contours, square, triangular, and rectangular shapes can be formed from round tubing in one or more roll stations. Dimensions given in inches.

On square and rectangular tubing, the flatness of the sides will vary with work metal thickness and hardness. On light gages and in the harder tempers, springback results in a crown effect on the sides. This condition can be corrected by overforming in the final station. In forming rectangles, the longer sides may become convex, and the short sides may become concave. Flatness can be controlled to a minor extent by roll adjustments in the finish station, but a major correction must be made by using concave or convex contours in final Turk's-head rolls.

Rolling speeds used in reshaping tubing of light-gage metal are often equal to those used in producing the basic round tube. For reshaping heavier-gage tubing (for example, over 0.89 mm, or 0.035 in.), speed should be reduced by as much as 25% of that used for forming the round tube, depending mainly on the capacity of the equipment.

Tooling requirements for reshaping round tubing vary with the gage, size, and complexity of the final shape. It is often possible to form simple squares from thin-gage round tubing in one roll station and one Turk's-head station. However, as stock thickness or complexity of shape, or both, increase, more stations are required.

Contour Roll Forming

Tolerances

Cross-sectional tolerances on part dimensions are a result of variations in material width and thickness, physical properties of the material, quality of the tooling, conditions of the machine, and operator skill. Dimensional cross-sectional tolerances of ±0.25 to ±0.78 mm (0.010 to 0.030 in.) and angular tolerances of ±1° are common. Tolerances are slightly greater when wide building panels and deep sections are being formed. If a closer tolerance is required, material with a controlled-thickness tolerance of ±0.05 mm (0.002 in.) should be used.

Length tolerances are dependent on material thickness, part length, line speed, equipment quality and condition, and type of measuring and cutoff system used. For thin material (0.38 to 0.64 mm, or 0.015 to 0.025 in. thick), tolerances of ±0.51 to ±2.36 mm (0.020 to 0.093 in.) are obtainable. For material more than 0.64 mm (0.025 in.) thick, tolerances of ±0.38 to ±1.52 mm (0.015 to 0.060 in.) are obtainable. The minimum tolerances are based on part lengths up to 915 mm (36 in.), and the maximum tolerances are based on lengths up to 3.66 m (12 ft). Tolerances would generally be greater on parts longer than those specified.

In roll forming, it is generally advisable to order the material to be formed with somewhat tighter than commercial quality tolerances. If this is done, a great many dimensional problems can be eliminated. Failure to consider material quality results in needless problems and frustrations.

Straightness

In addition to cross-sectional, angular, and length tolerances, another tolerance to consider is the straightness of the material and the formed section. Some of the parameters that determine straightness include camber, curve or sweep, bow, and twist. The terms camber, curve, and bow are often used synonymously when describing straightness. The horizontal and vertical planes of the formed part are determined by the position in which the part is formed.

Camber (Fig. 12a) is the deviation of a side edge from a straight line. Measured prior to roll forming, the maximum allowable camber is 3.2 mm/m ($\frac{3}{8}$ in. in 10 ft.). Excessive camber contributes to curve, bow, and twist in the finished part.

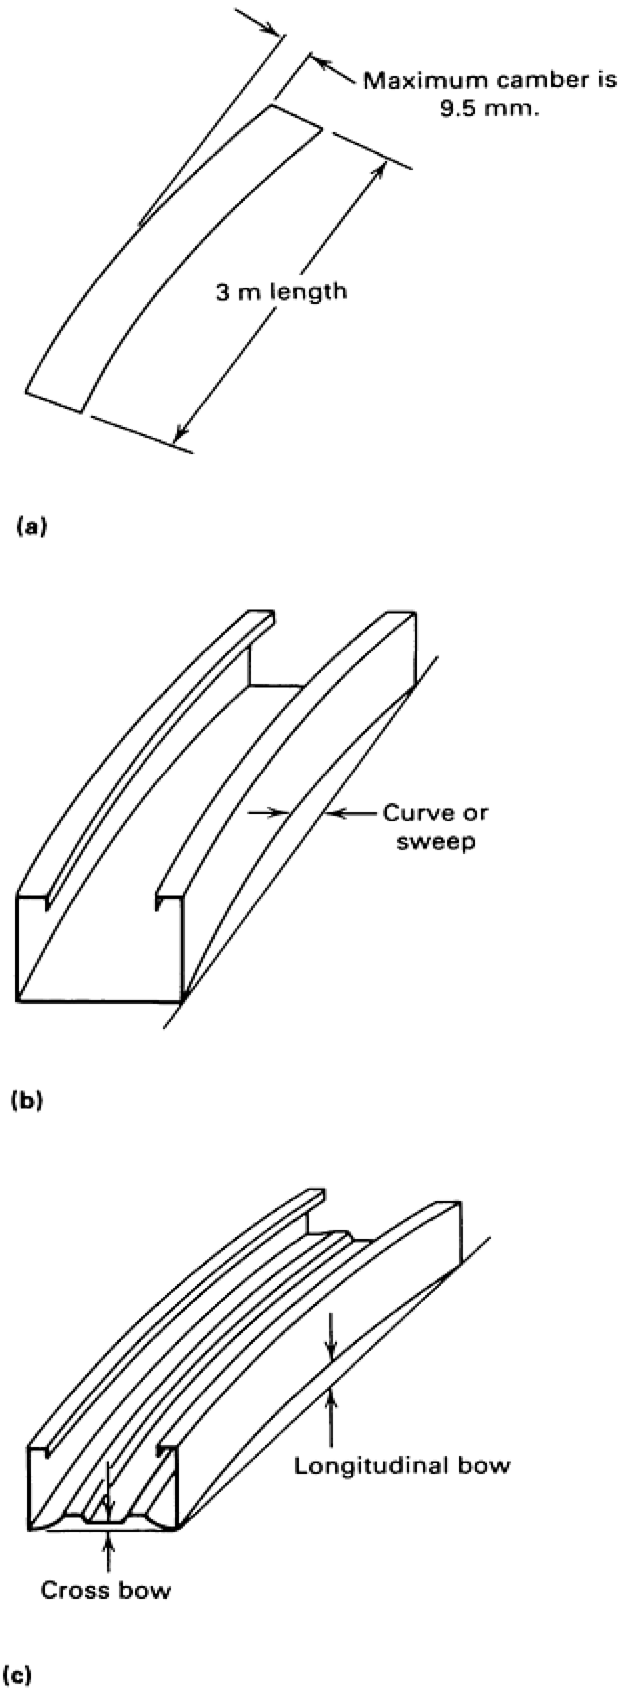

Fig. 12 Straightness parameters for roll formed parts. (a) Camber. (b) Curve or sweep. (c) Bow. See text for details.

Curve or sweep (Fig. 12b) is the deviation from a straight line in the horizontal plane measured after the part has formed. The curve in a formed part can be held to within ±1 mm/m (±1⁄8 in. in 10 ft). Curve or sweep can result from incorrect horizontal roll alignment and uneven forming pressure in a pair of rolls.

Bow (Fig. 12c) is the deviation from a straight line in the vertical plane and can be either cross bow or longitudinal bow. Bow results from uneven vertical gaps on symmetrical sections and from uneven forming areas on unsymmetrical sections. Generally, bow can be held to within ±1 mm/m (±1⁄8 in. in 10 ft).

Twist in a formed part resembles a corkscrew effect and often results from excessive forming pressure. Twist is generally held to less than 5° in 3 m (10 ft).

Quality and Accuracy

Two factors that can affect the quality and accuracy of a roll-formed section are springback and end flare.

Springback is a distortion that becomes evident after the straining of the part has been discontinued. The amount of springback varies with different metal properties such as yield and elastic modulus. Springback can be compensated for in the tool design by overforming. Overforming forms the material past its expected final shape.

End flare is the distortion that appears at the ends of a roll-formed part. The internal stresses incurred in roll forming are much more complex than in other types of bending. These stresses are usually higher in the edges of the material being formed and are released when the part is cut off.

Control of End Flare. End flare occurs to some degree in nearly all roll-formed shapes. It can extend back from the end as little as 50 or 75 mm (2 or 3 in.) or as much as 305 mm (12 in.). End flare can range from a few thousandths of an inch (this small amount is usually ignored) to 12.7 mm (½ in.) or more. The possibilities for flare can pose difficult problems. Both ends may flare outward, or one end may flare outward and the other inward. Excessive flare is caused by hard work metal, workpiece shape, too few roll stations, unsuitable roll design, or a combination of all of these.

There are several means of keeping end flare within acceptable limits. Replacing a hard work metal with one that is more formable will lessen, but not always eliminate, end flare. Minor changes in shape or design of the workpiece are often feasible and should be considered when end flare is a problem. It is much better to recognize the possibility of excessive flare before designing the rolls than to attempt correction after the rolls are made. The best way to minimize end flare is to provide enough roll stations to prevent the sides or edges of the work metal strip from elongating.

Surface Finish

Contour roll forming seldom improves the initial finish of the work metal. One exception is the roll forming of unpickled hot-finished steel, from which much scale is removed. It is usually possible to preserve the existing finish on unformed areas of the work metal. Sheet and strip ranging from unpickled hot-rolled steel to highly polished stainless steel are contour roll formed with a minimum of damage to the surface finish. In addition, work metals having almost every known type of coating are contour roll formed in high production with no damage to the coatings.

This does not mean that no damage to the work metal will occur if the specific applications are not carefully considered in planning the processing technique. In addition to normal precautionary measures, such as keeping the work metal clean before rolling and maintaining the equipment properly, one or more of the following must be considered and possibly adjusted when minimum damage to the surface finish is a primary requirement:

- Roll design or number of rolls in a given station
- Number of stations
- Roll material and finish
- Lubricant
- Rolling speed

As severity of forming increases, the possibility of damage to the work metal surface increases and may require alteration of the rolls within a station. For example, in forming deep channels, the shape can be produced using top and bottom rolls.

Side rolls can be added to improve dimensional tolerance. When maintenance of surface finish is a problem, the use of side rolls is helpful, because it minimizes roll sweep, which is inevitable when the shape is produced solely by top and bottom rolls. Excessive roll sweep is likely to damage both the work metal and the rolls.

Although sliding friction caused by roll sweep may damage surface finish, there is even greater likelihood of damage from excessive forming pressure in a given roll station. Therefore, as severity of forming increases, the possibility of damage to the work metal finish can be lessened by adding stations, thus decreasing the amount of forming done by a given set of rolls and reducing forming pressures.

Roll material and roll finish also contribute to the surface finish obtained in contour roll forming. Chromium-plated steel rolls or aluminum bronze rolls are best for preserving work metal finish.

Lubrication is preferred in contour roll forming and has a significant effect on work metal finish. When lubricants cannot be tolerated, as in the roll forming of coated metals, more attention must be given to roll design, additional stations, roll materials, and possibly lower rolling speeds than would be used if copious amounts of lubricant were permitted.

Each metal presents a different problem in maintaining surface finish.

Hot-rolled unpickled steel seldom offers any problem in maintaining surface finish. Rolling removes much of the scale and usually improves the finish, provided a flood of lubricant is used to flush away the scale. Otherwise, this scale will be trapped between work metal and rolls, resulting in damage to both surfaces. Rolls made from abrasion-resistant tool steel such as D2 are especially recommended for roll forming of hot-rolled unpickled steel.

Cold-finished carbon steel, aluminum, and brass are usually rolled with a minimum of damage to work metal finish. One or more of the conditions listed above may require special attention, depending mainly on severity of forming. A flood of lubricant is desirable in roll forming cold-finished metals.

Highly polished stainless steel or aluminum can also be contour roll formed without damage to surfaces. However, each step of the procedure becomes more critical than is the case with roll forming lower-quality finishes. Greater attention must be given to roll design, fitting, and maintenance. Chromium-plated rolls are usually preferred when work metal finishes are critical. Maximum cleanliness in all phases of the operation (including the use of freshly cleaned work metal) is mandatory for achieving desired results. Special lubricants are preferred for roll forming stainless steel and may be essential when forming is severe and quality of finish is critical.

Galvanized Steel. Success in roll forming hot dip galvanized steel depends mainly on the quality of the zinc coating, maintenance of the rolls, and lubrication. Inferior galvanizing or severe bends, or both, cause the coating to loosen and stick to the rolls. Wipers that contact the working surfaces of the rolls will aid in preventing surface damage. Chromium-plated rolls are also helpful in minimizing damage to galvanized work metal.

Precoated metals (vinyl and other organic coatings) must be rolled without lubricant and sometimes pose problems, although by paying careful attention to the conditions listed above, precoated metals can be contour roll formed without damage to the coating surface. One of the most common applications is the forming of aluminum siding for buildings. Complete preservation of finish depends mainly on severity of forming. Sometimes it is necessary to increase radii if the particular operation is to be successful.

Embossed metals are also roll formed without lubricants. Shapes are designed to avoid excessive forming pressure, and bend radii not less than twice the metal thickness are used to prevent distortion of the embossing. Forming of aluminum eaves troughs is an example of this operation.

Use of Computers

Computers are becoming an important aid in the design of roll-forming tooling. Consistency, accuracy, and speed enable the designer to determine the optimum design for each roll pass in less time than is required when the calculations are performed by hand. The capability to display the profile of the part enables the designer to see how the material flows through each pass. This profile enables the designer to determine whether too much work is being performed at a particular pass.

The numerical information compiled by the computer can be employed in numerically controlled machining operations to ensure that rolls are accurately produced. The computer also aids in the setup of the rolls on the machine by specifying the size and locations of the required shims and spacers. All this information and data can be stored for future use and reproduced whenever necessary.

To design the rolls, information about the roll forming machine, the cross section of the final shape, and the initial forming sequence are entered in the computer program. The computer numerically defines the coordinates of each corner and displays on the computer terminal the profile of the part at each pass as well as various perspectives of the flower diagram. Input changes can be made to vary the material flow through the roll forming machine so that optimum flow is achieved. Computer output includes flower diagrams, drawings of the cross-sectional shape, drawings of the rolls, and tabular data defining the material and rolls. A computer can also produce the tapes used in the manufacturing of the rolls on numerically controlled machines.

Explosive Forming

Revised by A.E. Doherty, Explosive Fabricators, Inc.

Introduction

EXPLOSIVE FORMING changes the shape of a metal blank or preform by the instantaneous high pressure that results from the detonation of an explosive. This article is concerned only with the explosives generally termed high explosives, and not with so-called low explosives.

Metal tubing up to 1.4 m (54 in.) in diameter in lengths up to 4.6 m (15 ft) have been formed using the explosive forming process. Diameters of 1.4 m (54 in.) or less can have lengths of up to 9.1 m (30 ft).

Typical domes constructed of 6- to 12-piece gore sections fabricated from explosively formed metal can measure up to 6.1 m (20 ft) in diameter. Russian engineers have used the process to fabricate gore sections for a 12 m (40 ft) diam dome.

Systems used for explosive-forming operations are generally classified as either confined or unconfined. This article will primarily deal with unconfined systems.

Confined systems (Fig. 1) use a die, in two or more pieces, that completely encloses the workpiece. The closed system has distinct advantages for the forming of thin stock to close tolerances, and it has been used for the close-tolerance sizing of thin-wall tubing. However, confined systems are generally used only for the forming of comparatively small workpieces because economic feasibility decreases as the size of the workpiece increases.

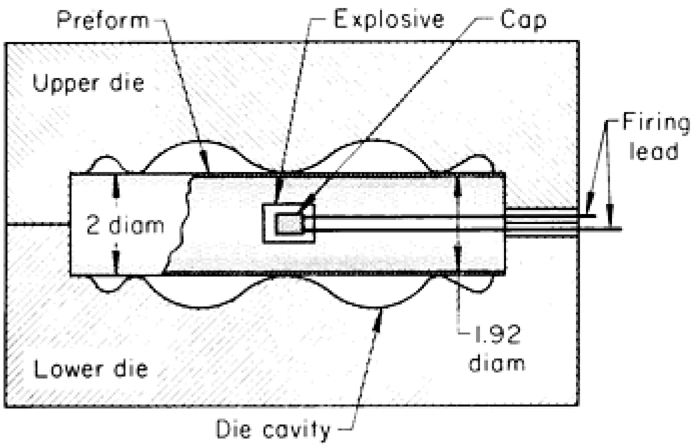

Fig. 1 Confined system for explosive forming. Dimensions given in inches.

Unconfined Systems. In an unconfined system (Fig. 2), the shock wave from the explosive charge takes the place of the punch in conventional forming. A single-element die is used with a blank held over it, and the explosive charge is suspended over the blank at a predetermined distance (the standoff distance). The complete assembly can be immersed in a tank of water, as shown in Fig. 2, or a plastic bag filled with water can be placed over the blank.

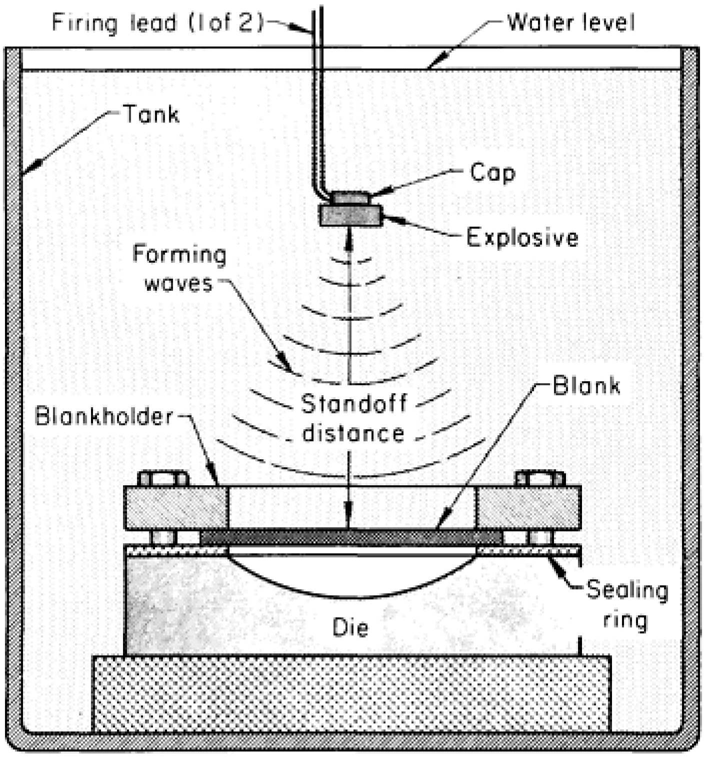

Fig. 2 Unconfined system for explosive forming.

The unconfined system is inherently inefficient, because only a small part of the total energy released by the explosion is effective as forming energy. The medium in which the explosion occurs plays an important role in determining the efficiency of the system. Efficiency increases with the density of the medium. Therefore, most explosive forming of large pieces is done in a medium more dense than air. Water is the most commonly used medium for ambient-temperature explosive forming. Molten aluminum has been used as the medium in explosive forming at elevated temperature.

Under normal operating conditions, it is best to detonate the explosive charge as far below the surface of the water as possible. This reduces the amount of water that is thrown by the explosion, and it reduces the amount of energy lost by venting to the atmosphere the gas bubble that results from the detonated charge. However, there is a depth for a given size of charge below which additional efficiency will not occur.

The amount of energy or peak pressure delivered can be calculated from standard formulas. A cylindrical charge (or point charge) is generally located near the centerline of the part and at a standoff distance that is related to the span of the workpiece over the die cavity. For large parts, it is generally impractical to use a point charge. For example, in forming large hemispheres or end closures for rocket motors, Primacord--either shaped in a large loop and located close to the outer periphery of the part or strung in a net form (using a fish net as a suspension device)--is ordinarily used instead of a point charge. Primacord is a cordlike detonating fuse that consists of a filament of explosive material covered by a protective water-repellent coating.

The variations in energy level delivered from various shapes of charge are small when the charge is fired in a water medium if standoff distance is 305 mm (12 in.) or more. When charges are placed close to a blank (within 25 to 50 mm, or 1 to 2 in.), energy transfer mechanisms from the explosive to the workpiece change. Figure 3 shows an example of these effects.

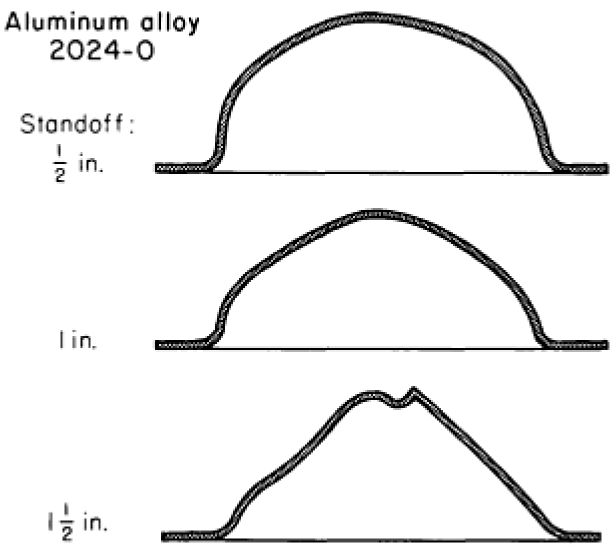

Fig. 3 Cross sections of explosive-formed workpieces showing the effect of slight changes in standoff distance at close range.

Explosive Forming

Revised by A.E. Doherty, Explosive Fabricators, Inc.

Equipment

The primary equipment for explosive forming in an unconfined system consists of a water tank, a crane, a vacuum pump, and a detonator control (firing) box.

The water tank must withstand the repeated impacts of the explosive shock without rupturing. Many tanks are designed to be large enough so that the shocks reaching the walls from centrally placed charges are considerably reduced. Figure 4 shows the stress in a tank wall as a function of the radius of the tank for a 0.5 kg (1 lb) charge of TNT and a constant wall thickness of 25 mm (1 in.). These data show that an increase in the diameter of the tank from 1.2 to 12 m (4 to 40 ft) lowers the stress level in the tank wall by only about 26%--from 11.4 to 8.45 MPa (1650 to 1225 psi). At the same time, the weight of tank-wall material increase tenfold.

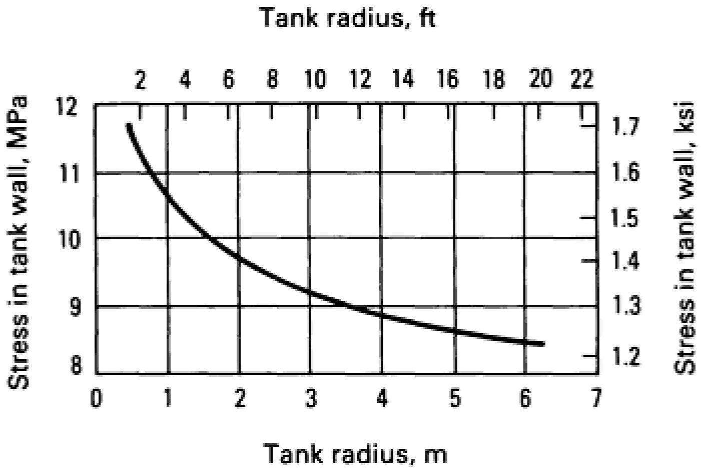

Fig. 4 Effect of tank radius on stress produced in a 25 mm (1 in.) thick tank wall by the detonation of 0.45 kg (1 lb) TNT at the tank center.

One of the best approaches to the reduction of tank-wall thickness is to moderate the pressure of the shock wave before it strikes the tank wall. Figure 5(a) shows the use of inflated rubber tubing for the reduction of stress in the tank walls. The rubber tubing acts as a cushion; in one application, it provided an 83% reduction in stress. A considerable amount of tubing would be needed to use this technique in a large tank, and it would be difficult to maintain the position of the tubing and to prevent damage to the tubing during explosions. The use of an air-bubble curtain as shown in Fig. 5(b) appears to be one of the best solutions for low-cost water tank construction. To be effective, a uniform and closely spaced curtain of bubbles must be maintained along the walls of the water tank. The bubble curtain is controlled by the size and spacing of holes in the air line at the base of the tank and by the air flow and pressure maintained in the line. A maximum charge size of 0.5 kg (1.1 lb) of TNT has been fired in a 2.4 m (8 ft) diam tank having 12.5 mm (½ in.) thick steel wall, 25 mm (1 in.) thick steel bottom, and a curtain of air bubbles with no visible signs of damage to the tank wall when the bubble curtain was operating.

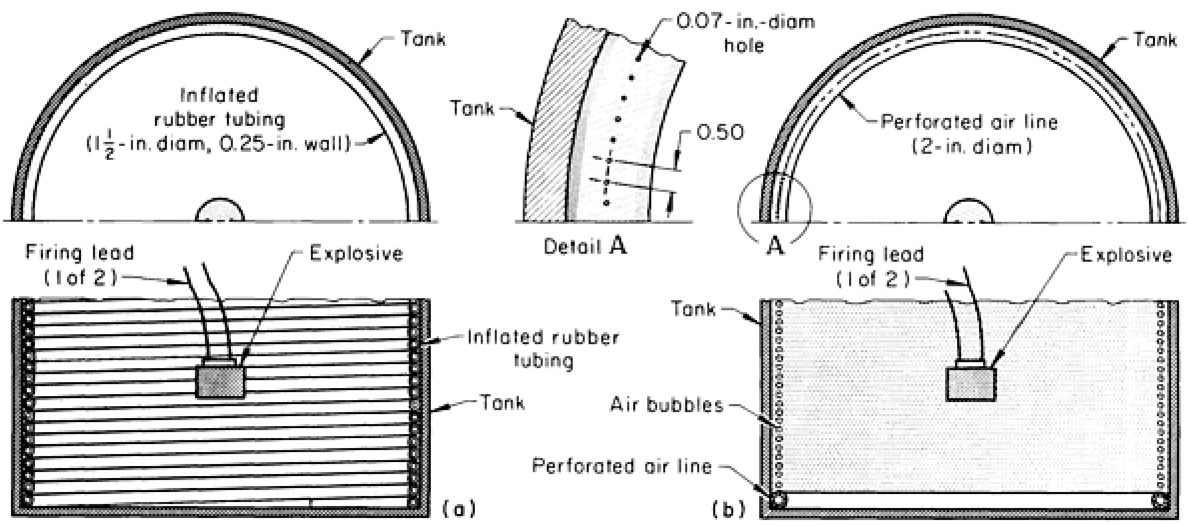

Fig. 5 Use of inflated rubber tubing (a) and an air-bubble curtain (b) for reducing the stress in the tank walls induced by explosion. Dimensions given in inches.

The base of the tank must withstand at least as much impact as the tank walls. It is advantageous to place the tank in solid rock, where possible. A heavy base of reinforced concrete can be used if it is covered by a heavy steel plate to distribute stress in the concrete evenly, preventing localized high stresses. Shock-absorbing material can be placed between the concrete and the steel baseplate; a sheet of rubber will provide some stress reduction. The use of a closely coiled, inflated rubber hose between the baseplate and the base of the tank is also effective in reducing stress; stress in the base can be reduced by as much as 80% with this technique. The hose should be inflated with only enough air to support the baseplate and the water head above it; overinflation will increase stress-wave transmission and may result in damage to the hose.

Difficulties in sealing the tank base to the tank wall must also be overcome. In some metal tanks, the joint has been welded, but not with complete success. Seals of resilient plastic have provided satisfactory results, and they are easy to repair if a leak develops.

A crane is usually needed to move material around the facility, as well as in and out of the water tank. Ideally, the crane should be air operated to avoid having electric power lines within the firing area. The required capacity of the crane depends on the size and weight of the dies to be handled. A jib crane is one of the best systems for handling large dies. One of the largest portable dies used in an explosive-forming operation weighed 9500 kg (21,000 lb).

A vacuum pump will probably be needed for most explosive-forming operations when parts are formed under water. If the firing area is to be maintained with a minimum of electric lines, an entire pump operating on water pressure will work satisfactorily. A mechanical pump driven by an electric motor can be used; the vacuum lines are brought into the firing area from a remote pumping site. An electrically driven mechanical pump is preferred because it has a considerably greater capacity than a venturi pump and is more economical to operate. A pump that will not be affected or damaged by water intake is the best type. These are sometimes called liquid ring pumps. If a conventional vane-type mechanical pump is used, it is important to eliminate any possibility of water entering the pump. In a high-production facility, where the application of a vacuum might be unacceptably time consuming, a storage tank in the vacuum line will greatly assist the operation. If it is deemed necessary to operate an electrically driven vacuum pump in the firing area, it should have shielded wiring and a sealed motor.

Detonation Circuit. Under ideal conditions, the firing box for the electric blasting caps is the only electric device that should be permitted in the area where explosives are handled. A firing box should be constructed on the fail-safe principle so that any malfunction will immediately cause the circuit to be disarmed. The following characteristics are desirable in the design of a firing box for use in explosive-forming applications:

- The device should be operable only with a key that is carried by the individual setting the charges
- When the device is not armed with the key, this fact should be visually discernible from the work area
- The lead wires to the cap should always be shorted when the circuit is not armed
- When the circuit is armed with the key, both a visual and an audible warning of its armed condition should be activated automatically
- A method of checking the continuity of the blasting circuit should be an integral part of the firing box

A schematic wiring diagram for a detonator that meets these requirements is shown in Fig. 6.

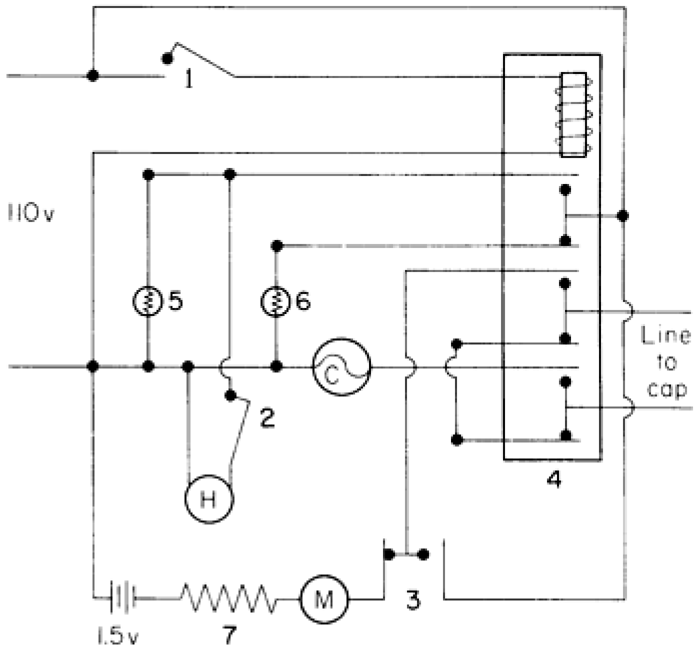

Fig. 6 Wiring diagrams for a safe detonator for explosive forming. 1, key switch (single pole, single throw); 2, horn switch (single pole, single throw; momentary-off operation); 3, continuity and firing switch (single pole, double throw); 4, relay (triple pole, double throw); 5, "armed" warning light; 6, "safe" warning light; 7, 10,000 Ωresistor. C, 5 A circuit breaker; H, horn; M, microammeter.

The current for firing the blasting caps can come from a 6 V battery or directly from a 110 V line. If a 110 V line is used, it is advisable to use a circuit breaker to protect the lines if a short occurs during firing.

Figure 6 shows the circuit for a firing box in the unarmed condition, the condition being demonstrated by current flowing through the uppermost of the three poles in the relay (4) to the "safe" warning light (6). Switch 1 is actuated by a key carried by the responsible person. It operates the relay. The upper pole disconnects the "safe" warning light and connects the "armed" warning light (5) and the horn (H). The two other poles shift to disconnect the short circuit of the line to the caps and connect its two leads to the firing circuit. Switch 3 is the detonating switch. Before it is thrown, the firing circuit is completed through the battery and the microammeter for a continuity check of the circuit. When switch 3 is thrown, the 110 V line is connected to the firing circuit and the cap detonates. Thus, the conditions listed above are met.

Explosive substances used in the explosive process have detonation velocities ranging from 1400 to 8380 m/s (4600 to 27,500 ft/s). Additional properties of selected explosives used in explosive forming are listed in Table 1. The conversion from solid explosive to gaseous products takes fractions of a second and creates temperatures of 3000 to 5500 °C (5432 to 9900 °F) and pressures of 6.9 to 28 GPa (1000 to 4000 ksi) (Ref 2).

Auxiliary Equipment. During the operation of an explosive-forming facility, debris will probably collect on the surface of the water or be distributed throughout the water tank. Skimming equipment, such as that used for swimming pools, serves well for the removal of material floating on the surface. Material distributed throughout the water must be removed by filtration. However, any explosive material collected in the water tank will be pumped through the filtration lines and possibly into the pump, where it may collect and later cause an accident.

In locations where water is plentiful, the tanks are emptied by gravity and refilled frequently; in other areas, the same water must be reused. The dumping of tank water into sewer lines should be avoided because any explosive suspended in the water may be trapped by an obstacle in the sewer and accumulate into a concentration that could cause a serious accident. When an incomplete detonation of the explosive material is detected, attempts should be made to recover as much of the undetonated explosive as possible for later destruction. The filter material should be handled as explosive material when it is emptied.

The amount of explosive stored within the facility should always be kept to a minimum and preferably should not exceed the supply necessary for one day's operation. For the temporary storage of explosives within the facility, small storage containers can be made from discarded refrigerators. The caps should be stored in one and the explosives in another. The main storage of explosives for the operation should be at some distance from the facility. Local ordinances regarding explosive storage and storage containers should always be checked.

Explosive Forming

Revised by A.E. Doherty, Explosive Fabricators, Inc.

Die Systems and Materials

Basic differences between tooling for explosive forming and for conventional forming arise from the type of loading that the die material must withstand. In explosive forming, high-impact loads transmit shock waves through the metal that cause unusual stress patterns within the die material; therefore, corners should be eliminated where possible. Shock loading causes the die to fracture along lines from the corners, rather than through the thinnest section as in static fracture. Figure 7 shows the modes of fracture for conditions of static and dynamic (shock) loading.

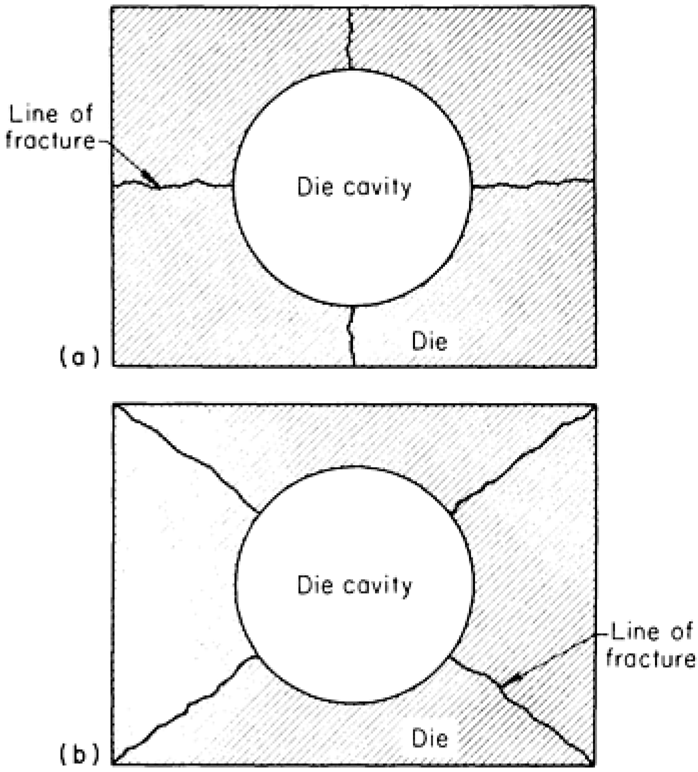

Fig. 7 Modes of fracture of a rectangular die under static (a) and dynamic (b) loading.

Evacuating Ports and Seals. In most explosive forming, a vacuum is applied between the blank and the die cavity. If possible, some method of sealing should be made an integral part of the die. In many applications, the use of rubber projecting about 1.6 mm ($\frac{1}{16}$ in.) above the die surface has provided the necessary seal. Because explosive forming causes the metal to pick up detail from the die, the vacuum port in the die should be kept small and should be located in a part of the die where its impression can be removed from the workpiece in a subsequent trimming operation. If this is not possible, the vent hole should be located so that the dimple that is formed will not be objectionable.

Blankholder Design. A blankholder is generally necessary to prevent wrinkling of the metal as the blank is drawn into the die. The size of the blankholder and the clamping pressure needed depend on the type of metal being formed. With a soft metal, such as annealed aluminum, very little blankholder pressure is needed; hard metals, such as stainless steel, need high pressures to prevent wrinkling.

Bolts or heavy-duty C-clamps are often used to clamp the blankholder to the die. Hydraulic clamping jacks are usually efficient in the forming of materials such as aluminum that do not need high clamping forces for the blankholder.

In applications in which the parts to be made are concentric and the forming is to be done in air, it may be possible to eliminate the blankholder. A taper-wall die has been used for forming cones, where the blank is situated on a taper leading into the die. This technique can provide savings when above-ground operations are used.

Die Design Calculations. Typical design calculations for cylindrical dies are as follows (Ref 2). To determine the explosive load, the properties of the material to be formed are used. It is first necessary to determine the yield pressure:

$$P_y = \frac{2 \cdot YS \cdot t_m}{D}$$

where P_y, is the yield pressure, YS is the yield strength, t_m is the material thickness, and D is the diameter. Next, the equivalent static pressure is found:

$$P_{ex} = KP_y$$

where P_{ex} is the equivalent static pressure to size explosively, K is the forming factor (average K value is 3 to 20, depending on the complexity of the part being formed), and P_y is the yield pressure.

To find the die wall thickness, the design stress is first determined:

$$\sigma_t = \frac{YS}{X}$$

where σ_t is the design stress, YS is the yield strength, and X is the safety factor (X value is 4 to 6). Then, using Lame's formula:

$$R = r\left[\frac{\sigma_t + P_{ex}}{\sigma_t - P_{ex}}\right]^{1/2}$$

where R is the outside radius of the die, r is the final part radius, σ_t is the design stress, and P_{ex} is the equivalent static pressure to size explosively. Therefore:

$$W_t = R - r$$

where W_t is the die wall thickness, R is outside radius of the die, and r is the final radius of the workpiece. The die wall thickness calculated by the above equations can be further reduced by the use of stiffening ribs (Fig. 8).

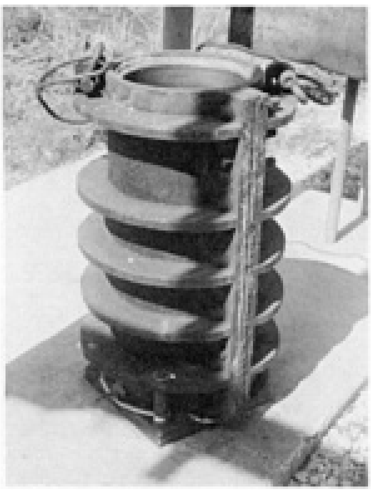

Fig. 8 Explosive forming die with stiffening ribs that was used to size more than 1500 stainless steel tanks. Source: Ref 3.

Materials for Solid Dies. Solid dies made from heat-treated alloy steel maintain contour, surface finish, and dimensional accuracy for a relatively long time. To avoid brittle fracture under overloads, a maximum hardness of 50 HRC is desirable.

Where the need for long life and good surface finish does not justify the cost of alloy steel dies, low-carbon steels such as 1010 or 1020 may be good alternatives. In practice, a light coat of lubricating oil over the steel die surface after each forming operation will provide sufficient protection from rusting. In addition, steel dies should be dried and coated with oil at the end of each day's operation. A castable alloy containing about 95% Zn and small amounts of aluminum and manganese has been widely used when the production quantity does not exceed 100 pieces.

Reinforced concrete has been considered for the construction of dies large enough to exceed the machining capabilities of all-metal dies. The ease of producing large concrete dies is a primary advantage. Disadvantages include the low tensile strength of concrete.

Plaster has been used for one-shot dies. Because the rate of loading is very fast, the shape of the brittle die material is transferred to the metal surface before the die crumbles. Better results are produced if a plaster die is contained in a metal case so that the plaster is loaded in compression to the greatest extent possible. The case should be cylindrical to minimize stress concentration.

Materials for Composite Dies. Glass cloth/epoxy resin laminates backed with either concrete or a sand, gravel, and epoxy mix are used. This system is usually contained in a low-carbon steel container, such as A36 pipe, for cylindrical systems. Where heavy loading is encountered, the life of a plastic laminate is about 25 pieces before it begins to crack and must be replaced. Because replacement cost is low, this is not a serious disadvantage.

Concrete has been used for the die working face when only one shot is needed. Ice dies have been successfully used on domes as large as 3.05 m (120 in.) in diameter.

The use of plastic laminates in zinc alloy dies of complex shapes will provide a considerable savings in die sinking time. The body of the zinc alloy die is cast roughly to shape, and a plastic laminate made from a plaster matrix is then seated in the die by backfilling with a resilient plastic. Dies have also been made from laminate plates and conventionally formed thick-wall shells.

Explosive Forming

Revised by A.E. Doherty, Explosive Fabricators, Inc.

Transmission Mediums

Most of the early work in explosive forming was done in air, which provided very high peak pressures for very short periods--usually a few microseconds. Consequently, the total impulse available for forming was less than that in a liquid medium, which provides slightly greater confinement of the charge and higher efficiency in terms of total impulse. The size of charge needed for forming a given part in water is approximately 80% smaller than that needed if the art were formed in air.

Liquids. Water is one of the best media for explosive forming because it is readily available in most locations, inexpensive to use, and produces excellent results. The energy absorbed by a medium is a direct function of its density; therefore, considerably more energy might be lost by waves transmitted through a liquid than through air. This loss of energy, however, is more than compensated for by the additional confinement of the explosive charge and the lengthening of the pulse due to the trapped energy. The net result is an increase in total impulse available in a liquid over that transmitted in a gas for the same charge size and standoff distance. When a charge is confined in a liquid medium and the charge is far enough from the surface of the water, several pulses can be obtained as a result of the overexpansion and overcompression of the gas bubble from the explosive charge. The greater confinement of the explosive by the water evens out the pulse distribution and maintains a positive pressure for a period of milliseconds. Figure 9 shows pressure differences between water and air media, at various standoff distances, using a 1.8 kg (4 lb) charge of TNT.

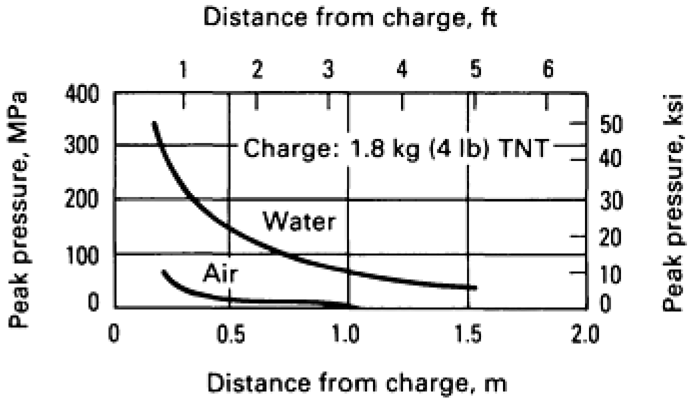

Fig. 9 Peak pressure versus standoff distance for explosive charges fired in air and water.

Other liquids, such as oil, have been successfully used as transmission media. Depending on their densities, they perform in the same general manner as water, but water is usually preferred because of easier handling. Higher-density liquids, such as mercury, are too expensive for general use.

Solid media, in the form of rubber sheets, cast plastics, or even metals, are sometimes used in explosive forming. Plastics and rubber improve the formability of some metals. The use of a plastic transmission medium has proved especially helpful in the close-tolerance sizing of tubing details.

Solid media afford some protection to the surface of the part being formed. Sometimes, in liquid media or in air, small slivers of metal projected from the blasting cap or from wire or other material used to attach the charge may strike the surface of the blank and cause scrap. Difficulty is also sometimes encountered because of slight irregularities in the shape of the explosive charge, which cause the formation of jets. The jet effect is smaller under water and is normally troublesome only at very small standoff distances. Perhaps one of the most beneficial characteristics of a solid medium is the uniform distribution of pressure over the surface of the part being formed.

The explosive forming of heated metals demands the use of some inexpensive medium that will maintain its characteristics at relatively high temperature and will not transmit much heat to the explosive charge. Several materials, including sand and small glass beads, have been used for this purpose. If sand is used, some buffer material should be placed over the blank to prevent the sand from embedding in the work metal or marking the surface.

Revised by A.E. Doherty, Explosive Fabricators, Inc.

Shock-Wave Transmission

Shock waves travel through a medium at the speed of sound. When a minimum of energy loss is desired at an interface between two different media, they should be selected to have a close acoustical impedance match. The acoustical impedance is a function of the density of the medium; therefore, as a first approximation, matching the densities of the media helps to increase the efficiency of the system.

Figure 10 shows the effect on the depth of draw of placing an intermediate medium, such as a sheet of rubber, over a blank. The increase in rubber thickness lowers the maximum depth of draw a given explosive charge will produce, but it may increase the overall depth of draw the piece will tolerate because of the improved distribution of forming stresses on the work metal. The use of a solid intermediate medium allows more material to draw from under the blankholder without wrinkling and without fracturing the cup at the apex.

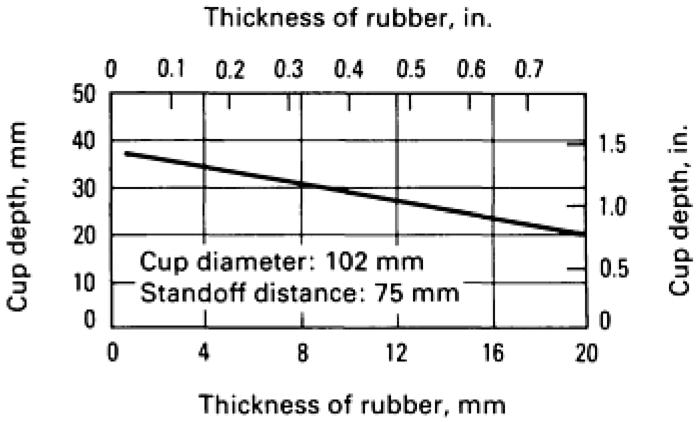

Fig. 10 Effect of thickness of rubber pad placed on blank on depth of draw of a 1.63 mm (0.064 in.) thick PH 15-7 Mo stainless steel cup in explosive forming with 1520 mm (60 in.) of 100 grain Primacord.

The same reasoning is applicable to the impedance between the explosive charge and the medium in which it is detonated. By obtaining a reasonable impedance match between the explosive and the medium, only weak reflections occur at the surface of the medium container. If the container walls are shaped properly, the reflections can be used to reinforce the shock wave that strikes the workpiece. They can also be directed to areas of the workpiece that need greater amounts of energy for forming.

Explosive Forming

Revised by A.E. Doherty, Explosive Fabricators, Inc.

Forming of Sheet

Explosive forming has been most extensively used to produce parts from sheet metal. For concentric shapes, the tooling and charge placement are relatively simple, and only minimal experience is needed to produce acceptable parts. Nonconcentric shapes, however, such as beaded panels, electrode forms, and other asymmetrical shapes, involve techniques using uneven force distributions, shock-wave reflectors, and shaped charges.

Tooling Considerations. For concentric parts, fairly simple techniques such as casting or turning can be used for the production of tools. The more complex dies used for nonconcentric parts necessitate hand finishing or profile milling. Special features can be incorporated into dies to control metal deformation and to minimize buckling.

In simple drawing operations, buckling is prevented by the pressure applied to a blankholder. With concentric parts, an equal blankholder pressure is applied around the circumference; with nonconcentric parts, variations in blankholder pressure are needed to accommodate variations in depth of draw. Pressures can be estimated for concentric shapes, but a trial-and-error system must be used to establish the pressure patterns for nonconcentric shapes. In such systems, the blankholder pressure for the minimum depth of draw should be 2 to 4% more than for areas of maximum draw. Control of metal movement during forming can also be accomplished by using a bead around the die to induce more friction between the blank and die. Another method is to notch the blank perimeter to reduce compression forces. This method is much less flexible, particularly when a trial-and-error approach is used in the initial forming. The forming of thin sheet metals can be assisted by sandwiching the blank between two low-carbon sheets to increase the cross section.

Tolerances as close as ±0.025 mm (±0.001 in.) have been met on small parts by explosive forming. However, working tolerances are generally ±0.25 mm (±0.010 in.). Variations are directly related to the amount of pressure applied in the forming operation. The use of plastic or rubber fillers over parts also has considerable bearing on the variations in workpieces. Because filler materials decrease the total pressure imposed on the part but maintain the pressure for a longer period of time, the increase in total impulse improves conformation to the die and minimizes springback. There are few applications in which explosive forming in steel dies cannot equal or better the dimensional stability of conventional forming.

Placement of Explosive Charges. Explosive-forming operations usually require that the charges be at some standoff distance from the parts to be formed; a contact charge supplies a peak pressure so high that the blank may be ruptured. Positioning of the explosive charges can be performed by a number of techniques, provided the following conditions are met:

- The method of positioning should be substantial enough that immersion in a water tank for firing will not displace the charge
- The rigging for the charge should not break into flying projectiles that might damage the workpiece

To meet these requirements, various types of rigging have been used. For large parts, small-gage wire is used and is generally retrieved with the die. For smaller parts, masking tape is normally preferred for locating the charge because it is easy to handle. Permanent steel rigging can also be used if the charge is separated from the rigging by at least 50 mm (2 in.). Cardboard tubes work well for separating the charge from the rigging if the tube is not immersed in the water longer than 5 min before the charge is fired. For longer immersion times, the tube should be sprayed with a plastic coating.

It is often possible to obtain the same results with different types of charges. For example, tank ends can be formed with cylindrical and spherical charges or with an equal weight of Primacord wrapped on a cardboard tube. Similar results are obtained if the diameter of the Primacord does not exceed twice the diameter of the solid cylindrical charge. Consequently, when the supply of one type of explosive has been depleted, it is often possible to substitute another type that is on hand.

Special shapes of explosive charge are generally needed for the forming of nonconcentric shapes. The development of a special charge is difficult, and the shape is usually made by trial-and-error tests. Energy transmission to the part can also be varied through the use of a rubber blanket covering surface areas that need the least forming. The most prevalent technique involves the use of several charges to work the metal into the die in steps.

Shock-wave reflectors are suitable for producing parts that need a deeper draw in one particular region. However, these reflectors become very complicated if there is more than one such region in a part.

Economics of Explosive Sheet Forming. Simple shapes that are readily formed by conventional methods should not be considered for explosive forming; no economic advantage will be realized. More complex shapes, as well as metals with special properties (such as the work-hardening stainless steels), lend themselves to explosive forming. Size must also be taken into account; explosive forming can produce extremely large items that would be impractical to form by conventional methods.

Cost comparisons for fabricating parts by both explosive and conventional forming methods require sufficient quantities to establish cost information. The number of pieces to be produced affects the relative economy. Although explosive forming is often applicable only to short production runs, as many as 20,000 pieces have been produced competitively by explosive forming.

Explosive Forming

Revised by A.E. Doherty, Explosive Fabricators, Inc.

Forming of Plate

The explosive forming of metal plate has been practical because presses large enough to form heavy plate are generally not available. Economic advantages are realized when a forming operation, prior to the machining of thick parts, can reduce the subsequent machining time and the weight of raw material required. Explosives have been used to pierce holes in heavy shapes. This operation requires the use of a wave guide, with appropriately positioned and sized holes, over the workpiece.

Tooling Considerations. To support the higher loads required for the explosive forming of metal plate, the tooling must be of heavier construction than that used in sheet forming. Plates are usually not formed to close tolerances, particularly because they are often machined in a subsequent operation. Forming is generally done in free-forming dies such as the one shown in Fig. 11.

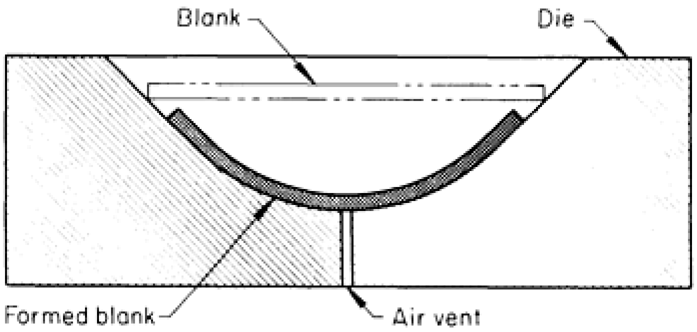

Fig. 11 Tapered-entrance die used for the explosive forming of plate without a blankholder.

Tolerances that can be met in explosive-formed plate materials are the same as those usually applied in the explosive forming of sheet metal, that is ±0.25 mm (±0.010 in.). Considerably greater tolerances than this are usually allowed on parts that are to be subsequently machined. With free-formed plate materials, variations as great as ±6.35 mm (±0.250 in.) have been considered acceptable.

Placement of explosive charges for plate forming is similar to that for sheet forming, except for the scaled-up size of the tooling, workpiece, and explosive charges. Because water is the preferred transmission medium in these operations, the operations must be performed in large water tanks, or if firing is aboveground, a large water bag can be used. In each approach, the explosive energy is transmitted to the workpiece through water.

Because of the relatively simple shapes involved in plate forming, charge shapes and placement are less complex. Centrally located charges and ring charges positioned at the desired standoff distances are usually used.

Forming of Tubes

Explosive forces have been successfully used in tube-forming operations. This process has allowed the formation of many unique tubular shapes by beading and bulging the initial workpieces in selected areas.

Tooling Considerations. To facilitate removal of the completed tubular workpieces, it is necessary to use either split dies or split tapered die inserts, depending on the particular part to be formed. The use of split dies makes evacuation more difficult than with single dies in that rubber seals are necessary between the die halves. The parting line between the die segments will often leave undesirable marks on the formed parts. This marking effect can be lessened by reducing the explosive charge and increasing the number of shots or by increasing the clamping forces on the die halves.

Some control of the amount of bulging can be achieved through the use of end plugs to apply some restraining force to prevent drawing from the ends of the tube. This precaution can be critical in thin-gage tubing, which may wrinkle if the ends of the tube are not restrained.

Shock-wave reflectors can be incorporated into the tooling for explosive forming. They find applications in tooling for nonconcentric shapes or where reentrant angles are desired. With the use of special reflectors, the charge can be placed at one end of the tube, and a reflector can be placed inside the tube to concentrate the shock wave in certain areas. Very large bulges (350% of tube diameter) have been produced with the use of reflectors, intermediate anneals, and step-forming operations. The reflectors can vary considerably in design, ranging from a solid filler with an angled cut (to concentrate the energy on one side of the tube) to exponential shapes for reentrant angles.

Tolerances as small as ±0.025 mm (±0.001 in.) have been held in the forming of small-diameter tubes, but tolerances of the order of ±0.25 mm (±0.010 in.) are more generally accepted. Extremely close tolerances demand the construction of heavy, accurate dies that will withstand repeated heavy loading in the production of the desired parts.

Placement of Explosive Charges. The setup for forming generally requires the use of line charges placed on the centerline of the tube. Alignment of the charge is critical because the tube provides some reflective characteristics to the shock wave, and misalignment can cause higher pressures in the side of the tube closest to the charge. A rigid plastic tube can be used to cover the explosive charge and to keep it in line.

Normally, a die is necessary when a specific contour is wanted. Simple bulges can be formed in heavy-wall tubes without a die, but tolerances cannot be held closely on the diameter or on the contour of the bulge.

Application. The sound-suppressor tubes used on all commercial jet aircraft represent an application that has involved the production of more than 10,000 pieces. The main economic advantage in this application is derived from the close tolerances that can be held, as well as the elimination of brazing and other manual operations normally required for the assembly of conventionally formed tubes.

Explosive Forming

Revised by A.E. Doherty, Explosive Fabricators, Inc.

Forming of Welded Sheet Metal Preforms

Explosive forming has been used in the forming of components from welded preforms. Such preforms are necessary when the initial tube size is larger than that obtainable commercially or when a specialized starting shape is needed. Because subsequent forming operations will be conducted, it is necessary that good-quality ductile welds be made in preform fabrication. Generally, the welds are planished, and the preforms are annealed prior to forming. In addition, when possible, the welds are located in areas where minimal stretching is expected in order to reduce the possibility of weld failure during forming. Figures 12 and 13 show typical aircraft components that were explosively formed from welded sheet metal preforms.

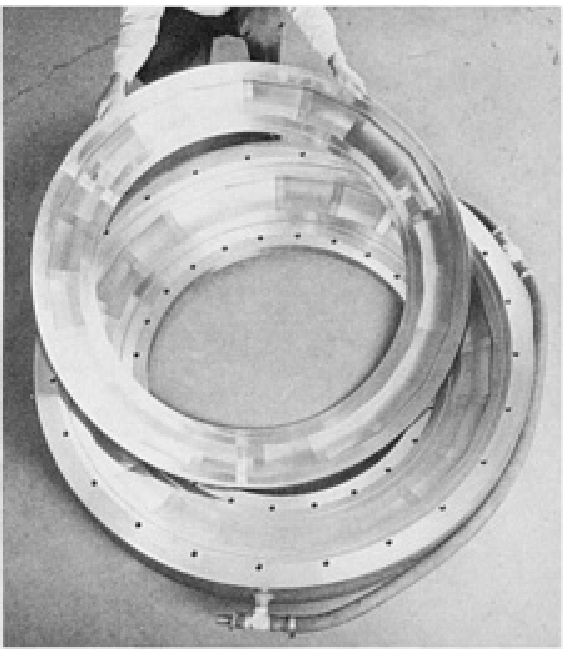

Fig. 12 Aircraft cooling coil that was explosively formed from a welded sheet metal preform. The finished part measures 152 × 457 × 457 mm (6 × 18 × 18 in.) and was fabricated from 1.57 mm (0.062 in.) thick aluminum. Courtesy of Explosive Fabricators, Inc.

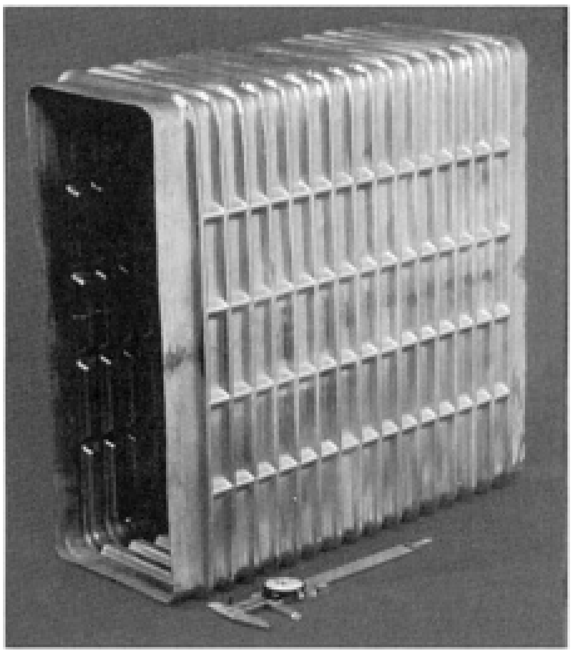

Fig. 13 Jet engine afterburner component, explosively formed from a welded sheet metal preform that has a 914 mm (36 in.) minor diameter and a 1015 mm (40 in.) major diameter. The 0.89 mm (0.035 in.) thick Waspalloy workpiece utilized the 4340 steel die, on which it rests, in its fabrication. Courtesy of Explosive Fabricators, Inc.

Tooling Considerations. The size of part may limit the use of split dies and may limit the process to applications in which natural draft will permit removal of the part from the die. No other special considerations are necessary for tools except for the forming of thin parts that may wrinkle when a vacuum is applied between the preform and the die.

Tolerances for parts that are explosive formed from welded sheet can be held to ±0.25 mm (±0.010 in.), although a more practical tolerance of ±0.81 mm (±0.032 in.) is normally specified. The higher forces that would be necessary to meet closer tolerances would shorten die life and increase die costs for a given production run. Close tolerances also require a higher degree of weld finishing prior to forming.

Placement of Explosive Charges. The type and placement of explosive charges in forming welded sheet assemblies depend on the final shape of the part desired. Line charges positioned at the axis of the assembly are used for long right-cylindrical shapes. With a cone-shaped part, a point charge located near the base of the cone may be preferable. Generally, the same type of explosive system is used in all forming operations regardless of blank construction.

Economics of Forming Welded Assemblies. The economic advantages that may be realized in the explosive forming of welded sheet metal assemblies depend on the complexity of the part design and the number and type of operations needed in conventional fabrication. In addition, the characteristics of the work metal, such as ease of forming, welding, and machining, will influence the comparison. In one case, the explosive forming of a 787 mm (31 in.) long aircraft skin section having 305 and 127 mm (12 and 5 in.) diam ends and made from two aluminum alloys (6061 and 5086) resulted in a savings of 38% per piece over the conventional bulging method, while a savings of only 12% per piece was realized using the conventional shear-spinning method instead of the conventional bulging forming method.

Explosive Forming of Heated Blanks

Refractory metals such as tungsten are explosive formed with better results when the blanks are heated. The arrangement shown in Fig. 14 was used to form a dome from tungsten sheet that was heated to 675 °C (1250 °F). Molten aluminum was used as the transmission medium. The explosive, a 0.012 kg (0.026 lb) charge of composition C-4 plastic demolition explosive (detonation velocity: 8050 m/s, or 26,400 ft/s; supplier: U.S. Government) was protected by an insulated tube to avoid premature explosion. The die was constructed from 4130 steel. A dome 114 mm (4.5 in.) in diameter by 25 mm (1 in.) high was formed within a tolerance of ±0.076 mm (±0.003 in.) in one shot.

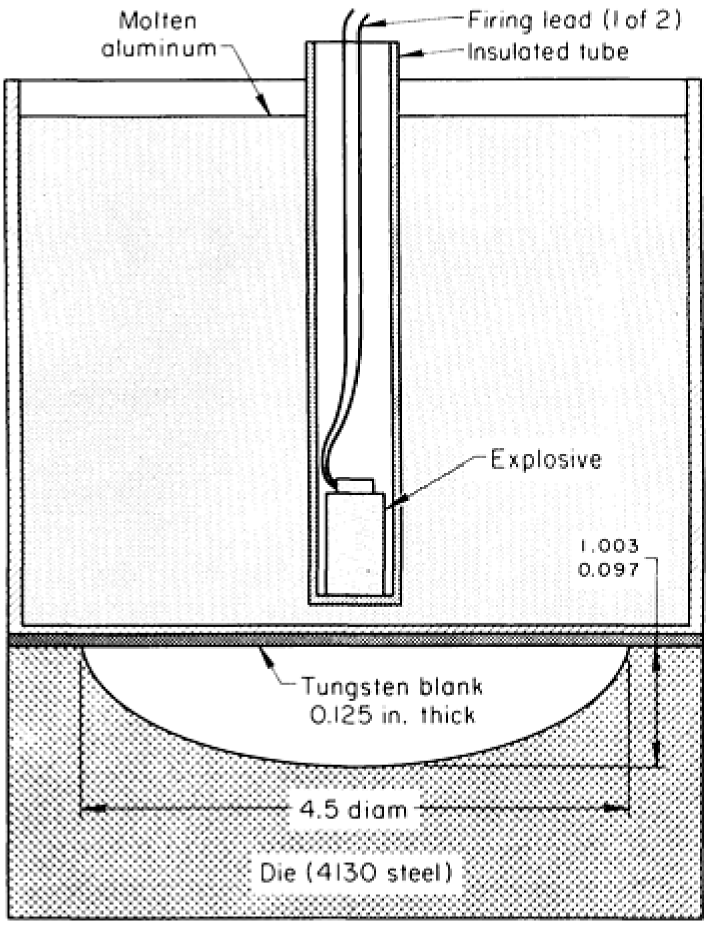

Fig. 14 Use of molten aluminum as a medium in the elevated-temperature explosive forming of tungsten. Dimensions given in inches.

Formability

In normal explosive-forming operations, the major characteristics of the work metal that determine formability are ductility and toughness. It is general practice not to exceed the elongation, as determined by tension testing, in forming a part from the same metal. Toughness criteria cannot be as readily applied, because forming represents biaxial and triaxial stressing, as compared with uniaxial stressing in the tension test. In addition, the design of tooling can influence the apparent formability of a material.

Comparisons of formability of various materials by explosive forming are subject to the particular experimental design under which they are tested. As a result, absolute values of formability are not obtained, but relative behavior for use in other explosive forming operations can be established. A comparison of the formability of some metals, using annealed aluminum alloy 1100 as a basis, is shown in Fig. 15. The apparent formabilities shown can be increased through modified tooling design in other operations. Increasing the forming temperature will also provide obvious forming advantages.

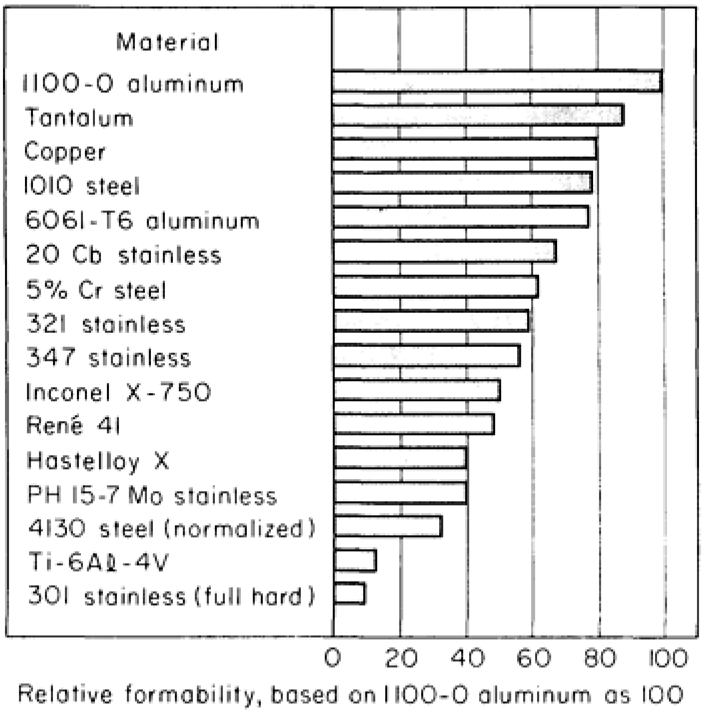

Fig. 15 Formability of various metals by explosive forming relative to that of aluminum alloy 1100-O. The comparison is based on the forming of 0.81 mm (0.032 in.) thick material with explosive at 381 mm (15 in.) standoff distance. All metals were annealed unless otherwise indicated.

Explosive Forming

Revised by A.E. Doherty, Explosive Fabricators, Inc.

Safety

In and around an explosive-forming facility, any fire- or spark-producing equipment must be eliminated. Precautions should include the collection of all matches and lighters from any person entering any building where explosives are present. During operations, only persons absolutely necessary for carrying out the operations should be present.

Misfires during an operation are extremely hazardous and time consuming. Precautions should be taken to ensure that an electrical short circuit does not occur during the immersion of the setup for firing in the water tank. Incorrect placement or improper size of the blasting cap may cause failure of the charge to explode when the cap detonates.

Precautions to be taken if the firing circuit has been energized and the charge does not go off include a check of the continuity of the circuit. If the circuit is good, another attempt should be made to fire the charge. If this fails, the firing circuit should be disconnected from the power source and the power source tested for proper output. If no failure is found in the power source, the lead wires in the firing circuit can be inspected visually from a distance to determine if any shorts have occurred. Under no circumstances should the charge be brought to the surface for examination until 15 min has elapsed from the last time attempts were made to fire the charge. All personnel should leave the area during this waiting period. After the specified time has elapsed, the charge should be brought to the surface and a new cap installed. When defective blasting caps are found, they should be destroyed with any other scrap explosive at the close of operations for each working day.

Electromagnetic Forming

Revised by Michael M. Plum, Maxwell Laboratories, Inc.

Introduction

ELECTROMAGNETIC FORMING (EMF) is an assembly technique that is widely used to both join and shape metals and other materials with precision and rapidity, and without the heat effects and tool marks associated with other techniques. Also known as magnetic pulse forming, the EMF process uses the direct application of a pressure created in an intense, transient magnetic field. Without mechanical contact, a metal workpiece is formed by the passage of a pulse of electric current through a forming coil.

The parameters that determine the applicability of the EMF process are:

- Forming can be accomplished through a nonmetallic coating or container because the magnetic field passes through electrical nonconductors
- Most of the forming takes place after the pressure impulse has ended, in contrast to most metal-forming processes. The metal is rapidly accelerated, gaining a large amount of kinetic energy by moving only a short distance during the impulse. This kinetic energy subsequently does the actual work of forming
- The metals that are most efficiently formed by EMF are those with relatively high electrical conductivity, such as copper, aluminum, low-carbon steel, brass, and molybdenum. Metals with lower conductivity, such as stainless steel, can be formed by using either very high energy or an intermediate, highly conductive "driver"
- The ratio of the masses of pieces used in assembly operations may be much more significant than their relative mechanical strength or elastic properties. Because EMF does not use static forces, relatively light structures can be used to support the dies
- No torque is applied to the workpiece in swaging and expanding operations, in contrast to spinning and rolling. Because the magnetic field behaves much like a compressed gas, it exerts a uniform pressure that is relatively independent of variations in spacing between the workpiece and the forming coil
- No lubricant is required because the contact between the magnetic field and the workpiece is frictionless
- The peak pressure is limited (by the strength of the forming-coil material) to much lower values than are

commonly encountered in shearing, punching, and upsetting operations. However, the pressure that can be applied by the magnetic pulse can be very high compared to the average pressure in mechanical forming
- The process, being purely electromagnetic, is not limited to repetition rate by the mechanical inertia of moving parts. The timing of the magnetic impulse can be synchronized with microsecond precision, and machines can be made to function at repetition rates of hundreds of operations per minute. The strength of the magnetic impulse can be controlled electrically with high precision

The major application of EMF is the single-step assembly of metal parts to each other or to other components, although it is also used to shape metal parts. Within the transportation industry, for example, one automotive producer assembles aluminum driveshafts without welding to save a significant amount of weight in light trucks and vans to meet requirements for reduced energy consumption. Using the EMF process allows the joining of an impact-extruded aluminum yoke to a seamless tube without creating the heat-affected zone associated with welding. Numerous other uses of the EMF process are described in the section "Applications" in this article.

Electromagnetic Forming

Revised by Michael M. Plum, Maxwell Laboratories, Inc.

Process Description

In its simplest form, the EMF process uses a capacitor bank, a forming coil, a field shaper, and an electrically conductive workpiece to create intense magnetic fields that are used to do useful work. This very intense magnetic field, produced by the discharge of a bank of capacitors into a forming coil, lasts only a few microseconds. The resulting eddy currents that are induced in a conductive workpiece that is placed close to the coil then interact with the magnetic field to cause mutual repulsion between the workpiece and the forming coil. The force of this repulsion is sufficient to stress the work metal beyond its yield strength, resulting in a permanent deformation.

Speed of Forming. The conductivity of the workpiece and the eddy currents which interact with the magnetic field of the coil result in a net pressure on the surface of the workpiece. As the workpiece surface moves inward under the influence of this pressure, it absorbs energy from the magnetic field. To apply most of this available energy to forming, and to reduce energy loss due to permeation of the workpiece material (which wastes energy by resistance heating), the forming pulse is kept short. In most forming applications, pulses have a duration of between 10 and 100 μs. The significance of pulse frequency is described in the section "Electrical Principles" in this article.

The basic circuit used for electromagnetic compression forming of a tubular workpiece consists of a forming coil, an energy-storage capacitor, switches, and a power supply of nearly constant current to charge the capacitor, as shown in Fig. 1. Figure 1(a) shows the flux-density pattern of the magnetic field produced by discharging the capacitor through the forming coil in the absence of an electrically conductive workpiece. The evenly spaced flux lines indicate a uniform flux density within the coil. Figure 1(b) shows the change in field pattern that results when the capacitor is discharged through a forming coil in which a tubular workpiece of highly conductive metal has been inserted. The magnetic field does not penetrate the workpiece and is intensified by confinement in the small annular space between the coil and the workpiece (as depicted by more closely spaced flux lines).

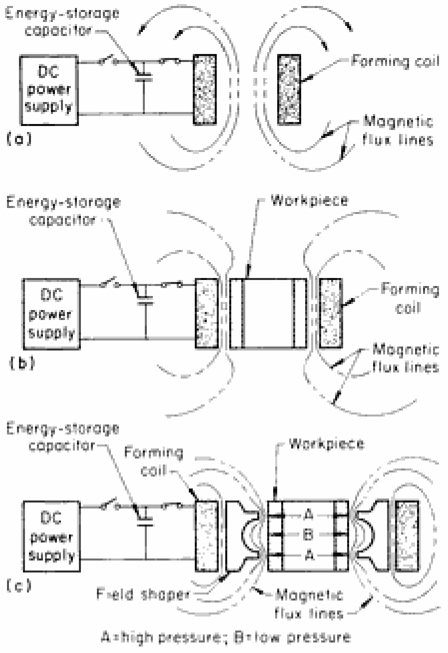

Fig. 1 Basic circuit and magnetic field patterns for electromagnetic compression forming of a tubular workpiece. (a) Field pattern in absence of workpiece. (b) Field pattern with workpiece in forming coil. (c) Field pattern when field shaper is used.

Field shapers, which are massive current-carrying conductors that are inductively coupled to the forming coil, are used to concentrate the magnetic field at the point at which forming is desired. Figure 1(c) illustrates the use of a field shaper to localize the magnetic pressure in certain regions of the workpiece. This technique most efficiently uses stored energy to produce high local forming pressures in desired areas. Field shapers also allow the use of a standard forming coil for a variety of applications. The field shaper, which is simpler to make, can be tailored to the specific part to be formed.

In the following example, a field shaper was used to concentrate the forming force where it was needed, and to limit the force in fragile areas of the workpiece. Thus, the forming pressure along the length of the workpiece was easily controlled.

Example 1: Use of a Field Shaper to Form a Stator Housing.

The housing for the stator assembly of an electric motor was formed in place, as shown in Fig. 2. A steel blank (the workpiece) was compressed onto the stacked laminations and shaped to conform to the supporting mandrel in a single EMF operation. The laminations were bound rigidly in place without the use of rivets or bolts; simultaneously, grooves (for mounting end bell housings) were formed precisely concentric with the inner surface of the laminations.

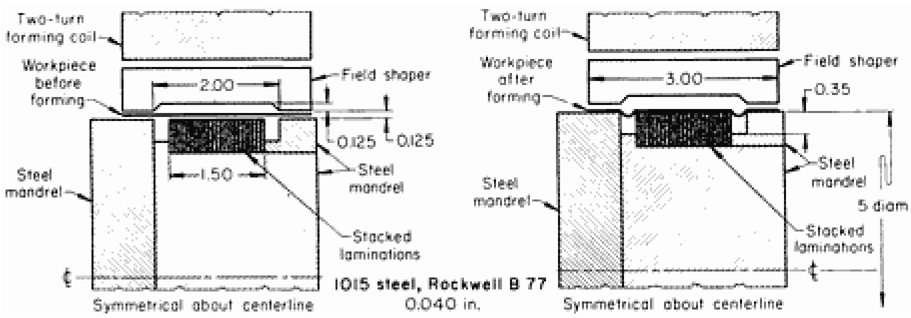

Fig. 2 Setup for EMF of a steel housing around stacked stator laminations, using a field shaper. Dimensions

given in inches.

About 40 kJ (29,500 ft · lbf) of energy was needed, because of the high pressure required for forming the grooves. Because such a high pressure would have deformed the laminations, a field shaper was built into the coil. The pressure along the length of the workpiece in this arrangement varied approximately in inverse proportion to the square of the spacing.

The assembly shown in Fig. 2 was produced with this experimental tooling at a rate of 240 per hour, using manual loading and unloading. The forming was done in a 48 kJ (35,400 ft · lbf) machine.

Forming Methods. Electromagnetic forming can usually be applied to three forming methods: compression, expansion, and contour forming. As shown in Fig. 3(a), a tubular workpiece is compressed by an external coil, usually against a grooved or suitably contoured insert, plug, tube, or fitting inside the workpiece. A tubular workpiece is expanded by an internal coil, as shown in Fig. 3(b), usually against a collar or other component surrounding the workpiece. Flat stock is almost always contour-formed against a die, as indicated in Fig. 3(c).

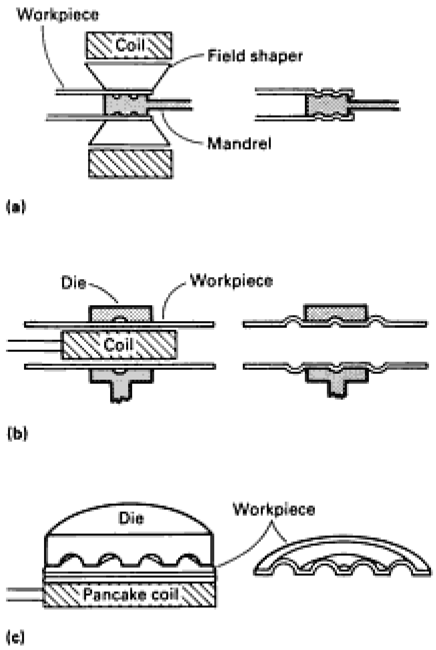

Fig. 3 Three basic methods of EMF. (a) Compression. (b) Expansion. (c) Contour forming.

In special circumstances, such as access problems, it is possible to achieve EMF by attracting metal toward a coil via a special pulse waveform (Ref 1). However, this process is not nearly as efficient as the three forming methods described above.

Workpiece Design. In addition to acting as an electrical conductor, the workpiece must provide a continuous electrical path. The current in a tubular workpiece flows around its circumference. Therefore, if a tubular workpiece were slit through its length, as shown in Fig. 4(a), the resulting interference with the current flow would eliminate the forming forces.

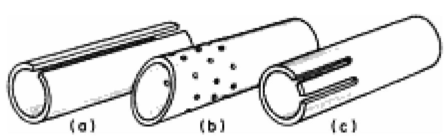

Fig. 4 Design aspects of tubular workpieces that affect applicability of EMF. (a) Full-length slit. (b) Perforations and angular cut. (c) Partial-length slots.

Figure 4(b) shows a tubular workpiece containing perforations as well as a cut at one end that is at an angle with the axis. Such minor irregularities do not seriously interfere with current flow and are acceptable under many conditions. However, deep slots in the end of a tube, such as those shown in Fig. 4(c), interfere with the current flow in such a way as to produce uneven pressure on the workpiece.

Applicability. In compression-forming applications, the pressure requirement is dependent upon the hoop strength of the workpiece. A formula used to determine applicability of the process to a given workpiece:

$$\frac{(YS)(2t)}{OD} = H_y \qquad (H_y)(N) = P_m$$

where *YS* is the yield strength of the material, *t* is the wall thickness of the workpiece, *OD* is the outside diameter, and H_y is the pressure to yield the hoop. Because of factors such as inertia effects, the increase in yield strength that can occur at high strain rates, and the geometry of the part, the magnetic pressure, P_m, required may be a factor, *N,* of two to ten times the pressure required to overcome the static yield strength of the material.

For example, to form a 50 mm (2 in.) OD tube of 6061-T6 aluminum with a wall thickness of 1.3 mm (0.050 in.), the approximate magnetic pressure required is:

$$\frac{(276 \text{ MPa})(2 \cdot 1.3 \text{ mm})}{50 \text{ mm}} = 14 \text{ MPa}$$

or

$$\frac{(40 \text{ ksi})(2 \cdot 0.050 \text{ in.})}{2.0 \text{ in.}} = 2 \text{ ksi}$$

For an *N* of 10, the magnetic pressure required would be 140 MPa (20 ksi). However, the EMF process is capable of applying 340 MPa (50 ksi) in compression when using standard work coils. Therefore, EMF is generally applicable to electrically conductive workpieces that require a magnetic pressure of less than 340 MPa (50 ksi).

Advantages and Limitations

The EMF process offers several advantages over other forming techniques, but has some limitations.

Repeatability. Because EMF is an electrical process, its energy outputs are nearly infinitely adjustable. The electromagnetic pulse can be controlled to the degree that it affords repeatability of current, and therefore pressure, to within one-half of 1% of the output setting. As a result, the forming is very highly repeatable. In fact, once the equipment has been set up for a particular forming operation, the only forming variable is the material. Operation of the equipment requires only a signal to activate the charging and automatic firing of the capacitor bank. That signal can be given by a microprocessor, as in the case of automated systems, or by an operator pressing palm buttons in a manual operation.

Noncontact. Unlike other mechanical processes in which a tool contacts a workpiece, in EMF the magnetic field that applies the pressure requires no lubrication, leaves no tool marks, and therefore requires no cleanup after forming. Materials that have previously been anodized or plated or have had some other surface preparation can therefore be formed without materially affecting the surface conditions.

One exception that does require lubrication is when the workpiece is driven against a mandrel and then removed. Although the workpiece itself is touched only by the magnetic field, the mechanical interface between the workpiece and the mandrel will often require some type of lubricant to facilitate removal of the workpiece.

Springback. In the process of forming, the material is loaded into its plastic region, resulting in permanent deformation, so that the springback often associated with mechanical processes is virtually eliminated. Because there is no mechanical contact, there is no mechanical stress introduced during forming other than work hardening.

Strength. Joints made by the EMF process are typically stronger than the parent material. This result is not unique to EMF. Compression of a tube will normally result in a wall thickening, which adds to the strength of the joint. Because the forming takes place in a matter of a few microseconds, the high strain rate forming does not affect the material properties in an adverse way.

The speed of joining or forming is limited only by the time required to load and unload the workpiece. Equipment has been designed and is operating in full production at rates of three times per second. No apparent limitations exist to achieving rates several times faster.

Ductility Effect. The EMF process allows increased ductility (that is, formability) for certain aluminum alloys because of the lack of mechanical stress and friction normally encountered with mechanical processes. It has also been demonstrated that parts typically requiring interstage annealing in other mechanical forming processes can be formed in one EMF operation.

Tooling for the process is relatively inexpensive. The machine and the work coils can be viewed as general-purpose tooling. Field shapers are used to couple individual workpieces to the coil. In the case of expansion forming, external split dies are used. If evidence of the parting line on the workpiece is aesthetically unacceptable, tolerances at the split of such dies must be very tight. Such dies are often made of nonconductive material to avoid any potential of inducing currents, as in a steel die, thereby causing electrical arcing between the die halves. In contrast to conventional flat forming, only a female die is used when forming sheet stock by the EMF process.

General Limitations. The speed of joining or forming also represents one of the limitations of the process. Because forming takes place in such a short period, the material does not have an opportunity to stretch; therefore, the process does not lend itself to deep drawing of materials. The process is also limited to those materials that are electrically conductive. Materials with an electrical resistivity of 0.15 $\mu\Omega \cdot$ m or less are ideal candidates for the process. Included in this group are such materials as copper, aluminum, brass, and mild steels. More highly resistant materials can be formed using special EMF equipment that operates at frequencies in the range of 20 to 100 kHz. Such equipment tends to be physically larger and more expensive than systems in general use. One example of such equipment was built for a U.S. Department of Energy contractor to weld end closures of nuclear fuel pins.

Pressure Limit. The maximum pressure that can be applied by standard compression coils is approximately 340 MPa (50 ksi). Thus, the process is restricted to relatively thin-wall tube or sheet products, unless special, strong coils are constructed.

Revised by Michael M. Plum, Maxwell Laboratories, Inc.

Production Methods

The EMF technique is suitable for both manual-feed and automated production processes.

Manual-Feed Equipment. With manual feed, the production rate is limited by the speed at which an operator can load and unload parts. To speed up production, insulating fixtures (into which the workpieces are inserted) are typically mounted in the coil or field shaper. For assembly operations, the fixture situates the workpieces in the proper position with respect to one another as well as to the coil or field shaper. Typically, pushing a palm button initiates the charge-and-fire cycle.

A variety of holding or clamping devices are used to secure the workpiece during forming. Production rates of 600 to 1200 assemblies per hour are typical of this type of equipment, shown in Fig. 5.

Fig. 5 Semiautomatic EMF system for assembly of automotive cruise control power units.

Fully Automated Equipment. Special materials-handling equipment is required for those applications whose production rates exceed manual-loading capabilities. High repetition rates can be attained by property matching the characteristics of the power source, the energy-storage unit, the switching components, the forming coil, and the workpiece. A rate of 12,000 operations per hour has been demonstrated in production; faster rates are limited primarily by the capability of the loading equipment.

In one high-speed application, the flame height control orifice of a disposable cigarette lighter is assembled at a rate of three per second. More than a dozen machines installed worldwide produce more than 400 million parts annually. The hollow, caplike aluminum orifice, with a 3.18 mm (0.125 in.) diameter and a 0.89 mm (0.035 in.) wall thickness, is formed on the end of the fuel wick, as shown in Fig. 6. Assemblies are individually fed into the work coil by high-speed handling equipment.

Electromagnetic Forming

Revised by Michael M. Plum, Maxwell Laboratories, Inc.

Applications

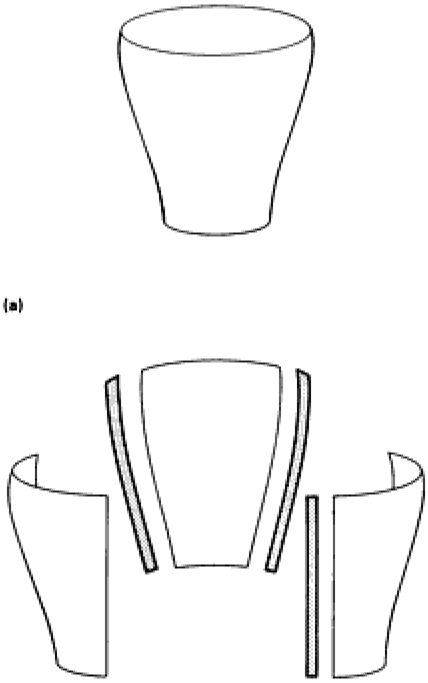
Electromagnetic forming is chiefly used to expand, compress, or form tubular shapes. It is occasionally used to form flat sheet, and it is often used to combine several forming and assembly operations into a single step.

In the automotive industry, EMF is used by all three major U.S. manufacturers and several foreign producers to assemble components such as air conditioner accumulators, high-pressure hoses, shock absorber dust covers, rubber boots on constant velocity (CV) joints, oil cooler heat exchangers, steering wheels, gasoline fill tubes, and accessory motor packages.

Universal joint yokes, drive linkages, cams, gears, and various other linkages or fittings are assembled to drive shafts or torque tubes by EMF. In this type of application, a torque joint, tube, or hollow shaft is compressed onto a fitting inside the tube. Splines, pockets, or knurl configurations can be used in the fittings to provide torque resistance, depending on torque strength requirements, types of materials, and dimensions.

In the manufacture of electrical equipment, EMF is used to join components of high-voltage fuses, insulators, back-shell connectors, and lighting fixtures; heavy-duty electrical connections are made by swaging a terminal sleeve over a conductor cable.

Aircraft applications include engine nacelles (Fig. 7), torque shaft assemblies, control rods and linkages, the forming and assembly of cooling system ducts, and the sizing of tubing. The EMF process is also used in the production of TOW, MLRS, and Viper missiles; helicopter rocket launchers; and in the swaging of preformed rotating bands on ordnance projectiles. In addition, manufacturers of appliances, consumer products, computers, and other products use the technique. In nuclear work, fuel rod sheaths are compressed, fuel pins are welded, and sealing operations are performed in remote, shielded areas.



(a)

(b)

Fig. 7 Aircraft Nacelle Program: EMF (one-piece) versus conventional (multiple-piece) production. (a) EMF production characterized by: one form die, one trim tool, lighter weight, reduced assembly time. Tool cost: 340 h. Production time: 14 h. (b) Conventional production characterized by: six form tools, six trim tools, use of splice plates, additional assembly time. Tool cost: 880 h. Production time: 24 h. Savings for EMF method: 41%.

Axially loaded joints made by EMF are used in some aircraft applications and in actuator rods, where it is important to avoid excess weight. For long life under exposure to high stress and vibration, design of these joints is critical.

These assemblies are made by swaging the end of a tube into circumferential grooves in the second tube or fitting, as shown in Fig. 8. Close tolerances and close fit on the parts to be joined are not necessary. Because a loose slip fit is usually satisfactory, clearance of as much as 9.5 mm (3/8 in.) has been used.

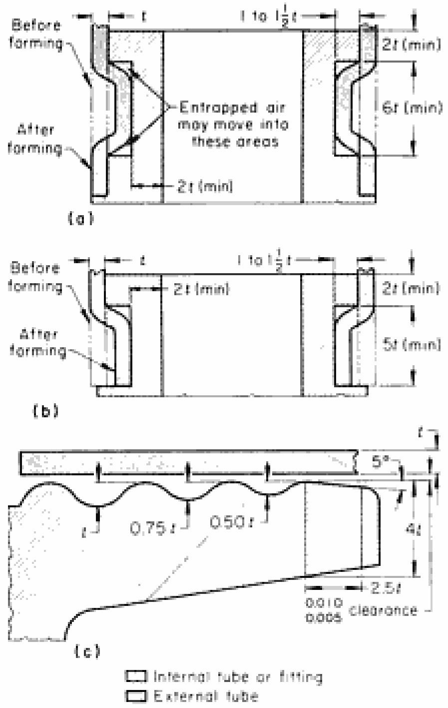


Fig. 8 Three types of axially loaded joints made by EMF. (a) Design for lightly stressed assembly. (b) Alternative design for lightly stressed assembly. (c) Design for highly stressed assembly. Recommended dimensional limits given in inches.

One arrangement that is suitable for joining lightly stressed members is shown in Fig. 8(a). A second arrangement, shown in Fig. 8(b), is equally satisfactory and requires considerably less energy for forming.

The joint contour shown in Fig. 8(c) is recommended for highly stressed, axially loaded assemblies. Three grooves with generous radii are used to avoid stress concentration. The grooves become progressively deeper toward the end of the external tube. Tests indicate a better distribution of stress on all grooves under axial load as a result of the variation in groove depth. Tests also indicate much less tendency for the end fitting to move relative to the tube, up to the yield point of the unformed tube section. This is important to members subjected to repeated reversals of load. Joints are typically made in which the unformed section of tube fails without detectable relative joint movement. When the tube must be highly stressed in service, it is preferable that the fitting (inside part) be of higher yield strength than the tube.

The fitting must be designed with proper cross section or must be adequately supported internally, so that this member does not go through yield; therefore, the difference in springback after forming will contribute to tightness of the joint. It may be desirable to reduce wall thickness of the fitting to ensure deflection and springback, leaving the tube with residual hoop stress.

On large parts with appreciable groove volume, it may be necessary to draw a vacuum on the inside of the tubular component to remove air from the groove area. Otherwise, air can be entrapped and can offer considerable resistance to the high-velocity forming. A simpler way to deal with this problem, when design permits, is to provide extra volume in the form of square corners in the groove, as shown in Fig. 8(a) and 8(b).

Torque joints assembled by EMF are preferred to welded joints in some applications, for at least three reasons: the absence of scale and residual flux; the ease of inspection for quality; and the absence of heat distortion.

The spline joint is best suited for torque joints using tubes with heavy wall thickness. Joints made by driving the tube into pockets machined parallel to the axis of the fitting are used with thin-wall tubes. For low torque requirements, coarse knurling of the fitting before assembling to the tube is satisfactory and economical. The use of specially designed field shapers and coils, as in the example in the following section, enables efficient high-speed production of torque joints.

Automotive Driveshafts. A major high-production application of EMF has been the assembly of aluminum driveshafts (torque tubes) used on minivans, trucks, vans, and recreational vehicles of one U.S. manufacturer. By significantly reducing the mass, a single shaft can replace two-piece units and a center bearing assembly. Electromagnetic forming was chosen because it provided a better torque-carrying capability than did a welded joint of the same diameter. The EMF process creates no heat-affected zone in the aluminum and can be used with alloys not considered to be weldable.

The initial application used a tube of 6063-T832 alloy with a 75 mm (3 in.) inside diameter and a 1.9 mm (0.076 in.) thick wall. The yoke is a multisplined impact extrusion. An additional driver ring is used over the tube and is formed with the tube onto the splines. The 6061-O ring, with a 2.64 mm (0.104 in.) wall, provides additional joint strength and receives the balancing weights (see Fig. 9). By welding weights to the ring, the mechanical integrity of the torque tube is not affected. Tubes are fabricated in various lengths and diameters. All are assembled on semiautomated EMF machines with a maximum capacity of 60 kJ (44,300 ft · lbf).

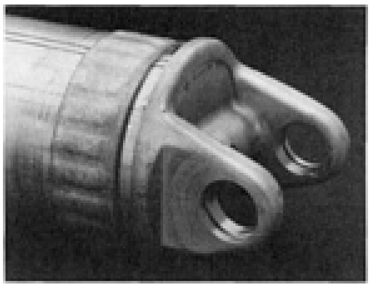

Fig. 9 Aluminum driveshaft assembled by EMF.

Electromagnetic Hammers and Riveters. In addition to contour forming against a die, flat coils are used in two unique aerospace applications: as an electromagnetic hammer and as an electromagnetic riveter. The hammer is used to flatten surfaces on the aluminum skin of the central fuel tank of the space shuttle, while the riveter is used in the assembly of 747 jet aircraft wings.

An electromagnetic hammer exerts momentary high pressure over a small area of a metal workpiece. In contrast to mechanical hammers, it requires no dynamic material contact with the workpiece and consequently produces almost no change in the metal grain structure.

In one version of the hammer, designed for use on an aluminum tank, the currents generate pressures up to 35 MPa (5 ksi), which can deform the aluminum in as short a time as 100 μs. The repulsive force also acts on the coil, causing it to kick back. The coil is therefore mounted in a holder that allows for this motion and makes it possible to reposition the coil simply by sliding it back toward the workpiece. Figure 10 shows a hand-held electromagnetic hammer.

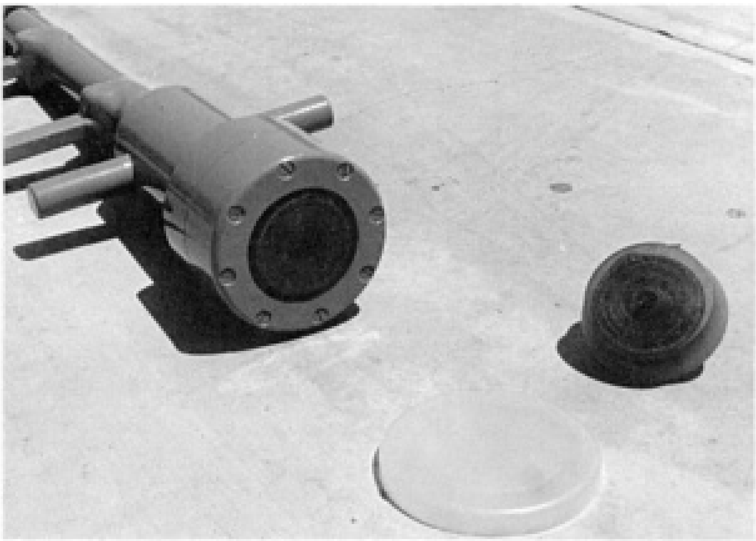

Fig. 10 Hand-held electromagnetic hammer.

In another application, flat coils are used as part of an electromagnetic riveting (EMR) system to drive a mechanical ram to upset rivets. Electromagnetic riveting is a proved method for installing rivets of various materials to precision interference profiles for fluid-tight and fatigue-critical applications. The process makes precision installations without massive, stationary equipment.

The high-velocity single-impact riveting process converts electromagnetic energy into mechanical kinetic energy to drive rivets. The EMR equipment consists of a power supply and two opposed guns with special power transmission cables connecting the guns and the power supply. Compared to large automatic hydraulic riveting machines, the EMR rivet quality is higher; yet the system is substantially lower in initial procurement costs. It features a quieter operation and reduced floor space requirements. Even when compared to conventional hand gun driving, EMR is far superior in quality and cost performance, and noise level is reduced by several orders of magnitude. Standard, available rivets are used in the EMR process, and rivet installations are uniform and repeatable, with an extremely low rejection rate.

The process was initially developed for riveting the 747 aircraft wing panels, which were too large to fit on an automatic hydraulic riveting machine. The process proved so successful that a computer-controlled tool was developed to incorporate EMR into the 767 aircraft wing spar assembly.

The EMR process is considered generally adaptable to any structural design in which fluid-tight, fatigue-critical, or large-diameter fasteners are required. The EMR system has been mounted on a robot for automated assembly of automotive components.

Electromagnetic Welding. The EMF concept has been expanded to encompass impact welding, in addition to forming and mechanical joining. This refinement is referred to as pulsed magnetic (PM) welding and is in use in the manufacture of nuclear fuel pins.

High-frequency high-intensity pulsed magnetic fields are being used to produce fuel pin end closures on cladding of interest to a breeder reactor program. Solid-state welds between the fuel pin cladding and a tapered end plug insert are produced by a pulsed magnetic field that accelerates and collapses the cladding, causing it to exert high-velocity impact on the end plug insert.

The field is produced when capacitively stored energy is switched into a single-turn work coil. The resulting high velocity of the cladding produces an impact bond. The peak magnetic field is in the range of 50 T (500,000 gauss), which translates into pressures in excess of 689 MPa (100 ksi). These pressure loadings accelerate the cladding radially inward. Collapse velocities of 304.8 m/s 1000 ft/s have been measured.

The end plug design is an important parameter in the welding process. The insert is tapered to allow the impact region to self-clean and to relieve itself of the stress waves created by the impact. As the impact point moves along the tapered surface, the high-velocity impact causes plastic deformation at the region of impact. At the high strain rates that occur at impact, the cladding and end plug material behave like high-viscosity fluids. The result is that a small surface layer is ejected. This self-cleaning action results in an atomically clean surface, and welding is accomplished without going to a melt temperature. Bonds have routinely been observed with lengths five to ten times the cladding wall thickness.

Most of the work has been performed on type 316 stainless steel fuel pin cladding that was 20% cold worked with a 5.84 mm (0.230 in.) outside diameter and a 0.38 mm (0.015 in.) wall thickness. Other cladding materials were welded using identical conditions. These included Inconel 706, Nimonic PE 16, and RA 330, which were in the solution-annealed condition.

Combinations of Operations. Some parts that would require a number of separate conventional forming operations can be made in a single operation by EMF. For instance, simple tooling can be devised to combine blanking, piercing, or other cutting operations, and accomplish complex forming in one step. In the example that follows, a simple die was made to pierce two holes in an aluminum alloy tube, expand the tube, and form a 180° flange on one end of the tube, all in one EMF operation.

Example 2: One-Operation Forming and Piercing by EMF.

The tubular part shown at the right in Fig. 11 was produced in one EMF operation by using an expansion coil to form, flange, and pierce a length of tubing against a single-piece die (setup shown at the left and center in Fig. 11). The workpiece was a 100 mm (4 in.) length of aluminum alloy 6061-O tubing with an 83 mm (3¼ in.) outside diameter, 0.89 mm (0.035 in.) thick wall, and a yield strength of 50 MPa (7 ksi).

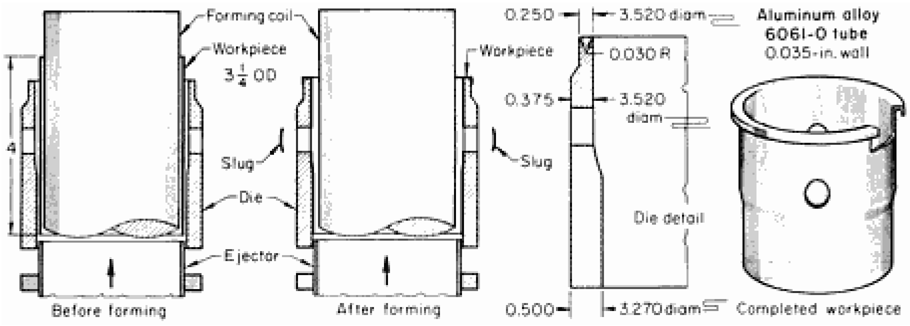

Fig. 11 Forming and piercing a tubular part in one operation. Dimensions given in inches.

The die was turned from 4340 steel tubing with a 12.7 mm (½ in.) thick wall, and two holes were drilled in the die to accomplish the piercing operation. The formed part was removed from the die by means of a simple ejector. The forming equipment had a capacity of 6 kJ (4400 ft · lbf), and cost approximately $18,000. The production rate was 240 pieces per hour, using manual loading and unloading.

Plastics, Composites, Rubber, and Ceramics. The material onto which a workpiece is formed is not a significant factor in the process except that it must be strong enough to withstand the impact of the workpiece. Therefore, assemblies using metal parts formed onto plastics, composites, rubber, and ceramics are common.

Automotive components such as electric fuel pumps, gasoline fill tubes, cruise control power units, and emission control devices use aluminum, usually anodized, over plastics. Wall thicknesses of 0.50 to 1.3 mm (0.020 to 0.050 in.) are assembled over plastics that include Delrin 100, glass-filled polyester, and polycarbonate. Fiberglass, carbon fiber, and other composite materials are joined with aluminum, copper, and brass in applications ranging from high-voltage fuses to drive shafts for trucks.

Banding of rubber boots on shock absorbers, CV joints, and the like was among the earliest applications. Surge arrestors, insulators, and other ceramic devices are assembled by EMF. Its potential application with new types of ceramics has not been fully explored.

Electromagnetic Forming

Revised by Michael M. Plum, Maxwell Laboratories, Inc.

Safety

The potential hazards of EMF operations may be categorized as either mechanical and sonic or electrical hazards.

Mechanical and Sonic Hazards. Electromagnetic forming equipment can cause substantial damage if its forces are misdirected, as would be expected of any equipment that exerts high pressure and delivers energy at a high rate. The magnetic pulse produces pressure perpendicular to the surface exposed to the field. Thus, if a cylindrical workpiece is positioned in such a way as to pass completely through a compression coil, only radial forces will be exerted on it during the forming operation. If, however, such a workpiece were inadvertently inserted only partly through the coil, the force produced by the magnetic pulse on the end could be sufficient to eject the workpiece from the coil at high velocity. In the same way, improperly positioned parts could be ejected from an expansion coil. An appropriate coil shield should be provided to protect personnel. Proper fixturing must be used to ensure that the machine will operate safely.

The sound produced in EMF operations results from the rapid movement of the workpiece compressing the air, and ordinarily is at a moderate level. If, however, the area of the workpiece that is moved in the air is large, and the distance moved is great, additional sound conditioning may be required. Production units are designed to comply with Occupational Safety and Health Administration (OSHA) requirements.

The possibility of an electrical arc in a coil or field shaper is a remote potential source of mechanical or sonic hazard. In the unlikely event of an electrical insulation failure, essentially all of the energy in the capacitor bank may be directed into an arc, generating high-intensity sound and perhaps forcibly ejecting bits of insulation or metal. A shield should be placed between the operator and the work coil to protect personnel. Protection against the sonic hazard depends on the distance between the operator and the coil. Care should be taken to prevent metallic chips from falling onto exposed parts of the field shaper gaps, where they could produce an arc-over. Insulators should be regularly checked for wear and cracks.

Electrical Hazards. Voltages used in typical EMF operations range up to 10 kV, and the capacitor banks can deliver extremely high current. Furthermore, voltages up to 50 kV are used for special applications, such as impact welding. All high-voltage components of the system are completely contained in a well-grounded heavy-gage metal cabinet. Doors and panels are electrically interlocked to avoid unauthorized access to high-voltage components. Maintenance personnel should work on energy-storage circuitry only after shorting the storage capacitors according to manufacturer's instructions. Maintenance personnel should also observe all standard precautions when working with the high-voltage components of the machine.

Pulsed voltages of the type that appear at the coil terminals of EMF equipment are much less dangerous than direct voltage. Normally, pulses of no more than 1000 V appear in any exposed portion of the equipment. The typical 10 kHz pulse appears for less than 1 μs. Nonetheless, precautions should be taken to prevent operators from being directly exposed to such voltages. The workpiece should never be held by hand because the possibility always exists that an arc-over between coil and workpiece could occur.

Coils are encased in metal shells that act as eddy current shields. As a result, the magnetic field is reduced to a very low level at any distance beyond the coil. Although the potential dangers may seem obvious, all personnel should be warned against touching or holding a coil, field shaper, or workpiece during the forming operation.

Electromagnetic Forming

Revised by Michael M. Plum, Maxwell Laboratories, Inc.

Equipment

The basic pieces of equipment in an EMF system are the capacitor bank, the coil, and the field shaper.

Capacitor banks are the energy-storage devices used for EMF. To charge the capacitor bank, alternating current is converted to high-voltage direct current by a suitable power supply or charging circuit. The charging rate must be fast enough to charge the capacitor bank in an interval not less than the desired repetition rate for the pulse discharge. For maximum energy transfer to the coil during the impulse, internal resistance and inductance in the power supply must be kept to a minimum.

Standard commercial EMF machines have capacitor bank energy sources rated from 8 to 200 kJ (5900 to 147,500 ft · lbf). Units with a capacity greater than 16 kJ (11,800 ft · lbf) are designed on a modular basis with increments of 4 kJ (3000 ft · lbf).

Because production rates with manual loading and unloading are generally about 200 to 600 pieces per hour, machines for this type of operation are designed for pulse repetition rates in this range. The faster pulse repetition rate desired for use with automatic work-handling equipment is readily obtained, however, as it is limited only by the characteristics of the charging circuit and the rate at which the components of the system dissipate heat.

Commonly available machines use capacitor banks rated at 8 to 16 kJ (5900 to 11,800 ft · lbf). Each capacitor is switched into a parallel-plate bus (or low-inductance coaxial cable) system through individual molybdenum anode ignitrons specially designed for pulse service. The capacitors are charged through a constant-current rectifier system.

The energy stored in the bank is precisely measured by a voltage-metering circuit. When the preset energy level is reached, the charging cycle is terminated and the switches (ignitrons) are triggered, either automatically or by an outside pulse, to discharge the capacitors into the forming coil. The storage systems are designed to have very low internal inductance, so that maximum energy is transferred to the forming coil during the impulse.

The maintenance of control circuits and charging circuits using solid-state components is comparable to that required in other industrial equipment of moderate to low complexity. The average life of a capacitor at a cycling rate of 600 operations per hour at maximum energy is about 3 million operations. At reduced energy levels, capacitor life is much longer.

Coils and Field Shapers. The three primary factors in the design of coils and field shapers are electrical characteristics, size, and strength. The theory of their design is extremely complex, and material and construction requirements are highly critical, because forming coils must accept the repetitive discharge of large amounts of electrical energy in pulses lasting only 10 to 100 μs and must generate uniform forming pressures as high as 340 MPa (50 ksi).

Using interchangeable field shapers with standard coils in compression operations promotes convenience, versatility, and economy. For long production runs, coils with fixed field shapers provide greater efficiency and durability. A variety of coils of standardized designs are available. Depending on the type and the application, coils can provide from a few hundred thousand to several million operations before repair or replacement is required.

In terms of size, the diameter of the section in the workpiece to be formed determines the diameter of the working surface of the field shaper, or of the coil when a shaper is not used. A clearance of about 1.3 mm (0.050 in.) per side is ordinarily needed for insulation and work insertion and removal. For maximum efficiency, the clearance is kept as small as possible because the effective force varies inversely with the square of the clearance distance.

In respect to strength, coils are usually of multiturn design, with sufficient mass to withstand repeated forming impacts. The coil not only must be strong enough to sustain these repeated thrusts, but also must be massive and rigid enough to minimize its deflection under load.

The problem of building coils to withstand high load is distinctly different in each of the three basic types of coils. Because there are no stringent volume restrictions on compression coils, they can be strong and massive, regardless of the size of the workpiece.

The coil receives support from a metallic coil body (usually of beryllium copper) and an insulating structure (see Fig. 12 and 13), which are needed for safe and efficient handling and for the efficient use of electrical energy.

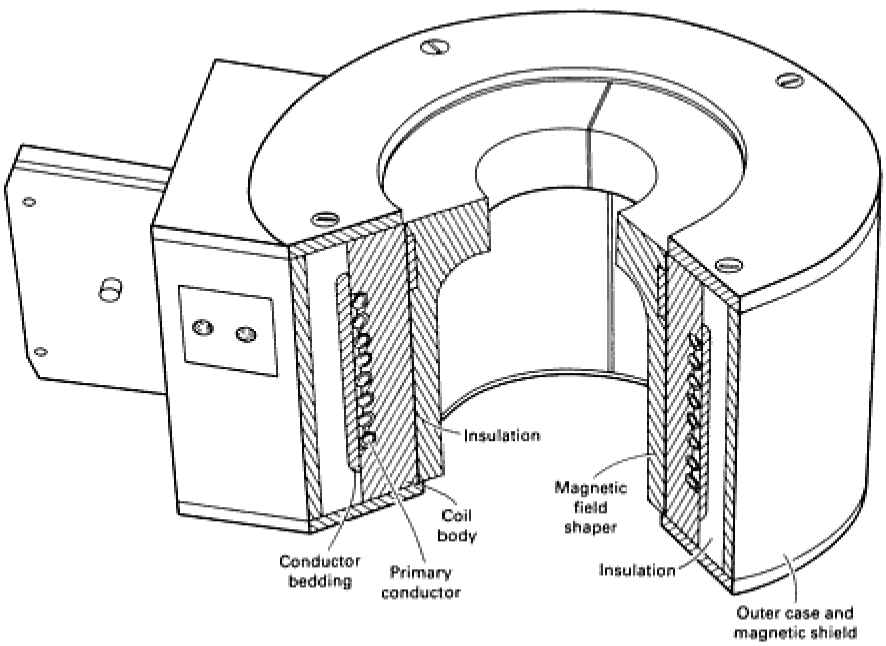

Fig. 12 Sectioned view of magnetic compression coil with removable magnetic field shaper.

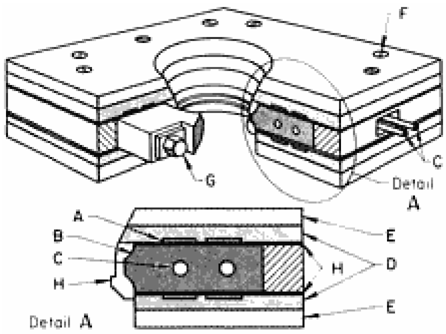

Fig. 13 Heavy duty wafer-type compression forming coil. A, primary conductor; B, beryllium copper field shaper; C, water passage; D, fiberglass insulation; E, steel backup plates; F, press bolt; G, shaper press bolt; H, shaper insulation.

Expansion coils must fit inside the workpiece, and thus the space to provide a strong structure is restricted. In small-diameter coils, shown in Fig. 3(b), the conductors must be relatively small in cross section to allow space for the return flux, and the conductors must be supported by an insulating mandrel. The force that can be exerted by these coils is ultimately limited by the strength of the mandrel. Production coils are typically 50 mm (2 in.) in diameter or greater.

Some flat spiral coils, shown in Fig. 3(c), also depend on the strength of an insulating backing to give the conductors support, so that the peak force they can exert depends mainly on the strength of the support. Other contour-forming coils have been made with massive construction; these have the same load limitations as do compression coils.

General-Purpose Compression Coil. Figure 12 shows a type of compression coil designed for ruggedness and versatility in applications on tubular parts up to 230 mm (9 in.) in diameter. Standard coils have inside diameters of 100, 150, or 250 mm (4, 6, or 10 in.) and have interchangeable field shapers of beryllium copper, each designed for a specific workpiece.

The flux concentration at the inner wall of the field shaper causes it to heat faster than the rest of the assembly. It is cooled by convection or by forced air circulation. In high-speed coils, the field shaper is sometimes water cooled. Heat generated in the coil body and primary conductor is removed by water circulating in the copper tubing of the primary conductor.

Heavy-Duty Compression Coils. Even stronger, more efficient construction is found in a heavy-duty single-turn coil and in the wafer-type coil shown in Fig. 13, for which the forming pressure is limited only by the properties of the shaper material. Wafer coils are used in energy ratings up to 60 kJ (44,300 ft · lbf) and pressure ratings up to 340 MPa (50 ksi).

Expansion Coil. Light-duty expansion coils, for use at pressures up to about 50 MPa (7 ksi), consist of solenoid coils of beryllium copper tubing wound on fiberglass forms. They are commonly up to 250 mm (10 in.) in active length and 100 mm (4 in.) in diameter, and are usually designed for the forming of specific workpieces. Coils that are 0.60 m (2 ft) long or more than 2 m (6 ft) in diameter have been built and applied successfully in the aerospace industry.

In the following example, a deep contour was formed in a hoop-shaped part by impact against a ring die, using an expansion coil.

Example 3: Electromagnetic Forming of a Grooved Hoop-Shaped Part.

As shown in Fig. 14, a grooved hoop-shaped part was formed by expanding a welded blank of 0.75 mm (0.030 in.) thick steel into a ring die, without using a field shaper. The weld bead was ground smooth before forming. Because of the high velocity of the blank when it struck the die, it conformed accurately to the die contour. About 40 kJ (3000 ft · lbf) of energy was used. The 4340 ring die (Fig. 14) was made by rolling, welding on lugs, bolting into a hoop shape, and then turning the inside contour in a lathe. Because the die was not subjected to static pressure, there was no need for the sturdy construction that would have been necessary had other forming methods been used. Using the EMF technique, it was merely necessary that the die be many times more massive than the workpiece.

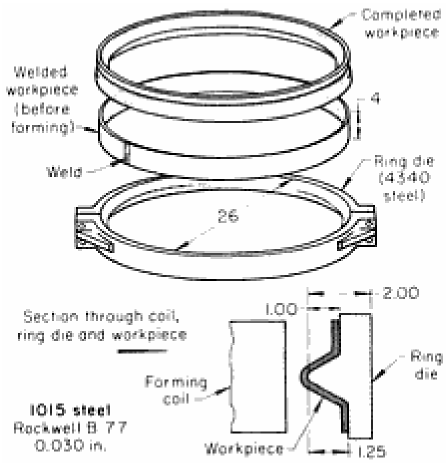

Fig. 14 Grooved hoop-shaped part. Dimensions given in inches.

Flat Spiral Coil. For contour forming of flat blanks, flat spiral coils apply essentially uniform pressure over a circular flat area, except for a small area in the center. It is difficult to achieve durability at peak pressures above 35 MPa (5 ksi) in such coils. The design of a flat spiral coil depends greatly on the requirements of the application. The electromagnetic forming of a contoured part from flat stock, using a flat spiral coil, is described in the example that follows.

Example 4: Electromagnetic Contour Forming of an Orifice From a Flat Blank.

The fluid flow constrictor shown in Fig. 15 was formed by the use of a flat coil in a setup like that shown in Fig. 3(c). The annealed 1010 steel blank, a flat annular disk with a 200 mm (8 in.) diameter, was laid on the coil under the die. The magnetic field generated pressure against the disk, driving it against the die.

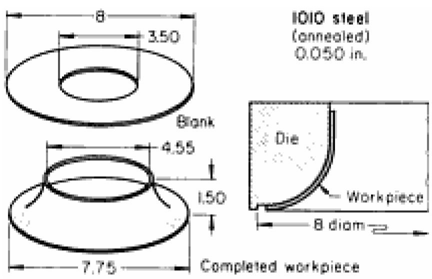

Fig. 15 Contoured part made from a flat blank by EMF. Dimensions given in inches.

The forming equipment had a rating of 12 kJ (8900 ft · lbf). An output of 10 kJ (7400 ft · lbf) was used in forming the orifice. The production rate was 240 pieces per hour. Because of its use as a flow constrictor, the 115 mm (4.55 in.) orifice diameter was accurately held. It was maintained without any trimming after forming. In cross section, the formed part had an exponentially curved contour.

Electromagnetic Forming

Electrical Principles

Because of the short duration of the magnetic impulse in EMF, the pressure must be high enough to impart sufficient kinetic energy to the workpiece during the pulse to do the desired forming. Any resistance to the motion of the workpiece during the impulse reduces the amount of useful forming energy transferred. Accordingly, for high efficiency, the peak pressure should be several times that necessary to exceed the static yield strength of the workpiece and to overcome any other constraints for the duration of the impulse.

Pressure Waveform. Electrically, a forming coil is an inductor, along with a small amount of series resistance. When an energy storage capacitor is discharged through such a coil, the discharge is a momentary oscillating current. The frequency of this oscillation is often called the ringing frequency by electrical engineers. This oscillating current has a damped sine waveform. The frequency is inversely proportional to the square root of the product of the capacitance of the storage bank and the inductance of the coil. The rate of decrease of the amplitude of the pulse is proportional to the resistance of the coil circuit. The pressure produced by the coil is proportional to the square of this current; thus, the pressure pulse is essentially positive and approximates a damped sine square form, as illustrated in Fig. 16.

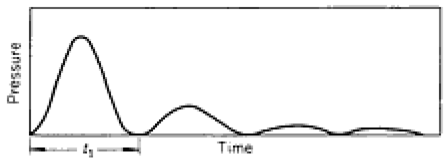

Fig. 16 Typical pressure waveform in EMF.

Virtually all of the forming energy is provided by the first wave; succeeding waves transmit less energy to the workpiece because of their lower energy content and because of the progressively widening gap between coil and workpiece as forming takes place. The portion of the energy of the electrical discharge that is not transferred to the workpiece as kinetic, or deformation, energy appears as resistance heating.

An energy discharge, or pulse, can be characterized by its peak pressure, which is that of the first wave, and by the duration of the first wave (Fig. 16). The time between successive waves changes slightly as the workpiece moves (changing the inductance of the coil) and as heating changes the resistance of the electrical circuit. However, these effects are ordinarily negligible.

Peak pressure is approximately related to other process variables. It is:

- Directly proportional to the energy of the electrical impulse from the capacitor bank
- Inversely proportional to the resistivity of workpiece and coil
- Inversely proportional to the total of the volume of the workpiece and the field shaper penetrated by the electromagnetic field (skin effect) and the volume between the coil and workpiece surfaces

The effect of workpiece size and electrical resistivity on peak pressure is discussed in the section "Typical Energy Relations" below. Wave duration for the first wave in a pressure pulse in the idealized situation is inversely proportional to the ringing frequency of the system:

$$t_1 = \left(\frac{1}{(2f)}\right)$$

Also, to a close approximation:

$$t_1 = k\left(\frac{Cd\ s}{l}\right)^{1/2}$$

where k is a proportionality constant, C is the capacitance of the energy storage bank, d is the diameter of the workpiece (for the surface adjacent to the coil), l is the working length of the workpiece (width of coil), and s is the thickness of the flux pattern between coil and workpiece (including skin depth of workpiece and field shaper). Thus, the wave duration increases with increasing capacitance of energy bank, diameter of workpiece nearest the coil, and spacing between coil and workpiece, but decreases with increasing length of workpiece. The skin depth in workpiece and field shaper increases with the increasing wave duration.

Revised by Michael M. Plum, Maxwell Laboratories, Inc.

Typical Energy Relations

The actual energy relations in the forming of aluminum alloy 6061-O, with a resistivity of 0.038 μΩ· m, and low-carbon steel, with a resistivity of 0.12 μΩ· m, are shown in Fig. 17. The data were obtained using a 12 kJ (8900 ft · lbf) machine operating at rated capacity with a standard wafer-type compression coil of the type shown in Fig. 13. In the forming operations described, the initial gap between field shaper and workpiece was 1.5 mm (0.060 in.).

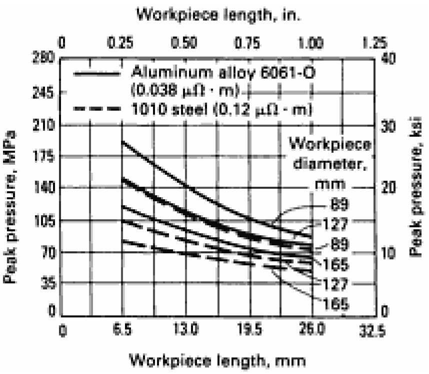

Fig. 17 Effect of workpiece dimensions and electrical resistivity on peak pressure.

The variation of peak forming pressure with workpiece length is shown for tubular workpieces 89 to 165 mm (3½ to 6½ in.) in diameter with a wall thickness greater than 0.75 mm (0.030 in.).

The effects of workpiece dimensions and resistivity on peak forming pressure or pulse height were qualitatively as predicted in the section "Electrical Principles" in this article. The pressure for a workpiece length of 25 mm (1 in.) was about half of that for a length of 6.4 mm (¼ in.); the pressure for a workpiece diameter of 165 mm (6½ in.) was about two-thirds of that for a diameter of 89 mm (3½ in.). Peak pressure was higher for work metal of lower resistivity: 20 to 50% higher for the 6061-O than for the low-carbon steel, with the percentage difference being greater for workpieces of larger diameter and shorter length.

Because the pressure is directly proportional to the energy, Fig. 17 is valid for other energy levels as well. Thus, if the 12 kJ (8900 ft · lbf) equipment produces a pressure of 95 MPa (14 ksi) on a workpiece 125 mm (5 in.) in diameter and 15 mm (0.6 in.) long, it will produce 70 MPa (10.5 ksi) if operated at a 9 kJ (6600 ft · lbf) level, or 50 MPa (7 ksi) at a 6 kJ (4400 ft · lbf) level.

The same relations apply for other combinations of coil and storage bank, as well as for other types of coils. Qualitatively they are similar; quantitatively they depend on the actual dimensions, design of the coil, and capacitance of the storage bank.

Although the length and diameter of the workpiece have a substantial effect on the peak forming pressure, they have only a slight effect on the length of the pressure pulse, which is about 50 to 60 μs. The reason is that coils of the type shown in Fig. 13, to which Fig. 17 refers, are designed to have a limited range of inductance regardless of the workpiece contours.

Drop Hammer Forming

Introduction

DROP HAMMER FORMING is a process for producing shapes by the progressive deformation of sheet metal in matched dies under the repetitive blows of a gravity-drop hammer or a power-drop hammer. The configurations most commonly formed by the process include shallow, smoothly contoured double-curvature parts; shallow-beaded parts; and parts with irregular and comparatively deep recesses. Small quantities of cup-shaped and box-shaped parts, curved sections, and contoured flanged parts are also formed.

Advantages and Limitations. The main advantages of drop hammer forming are:

- Low cost for limited production
- Relatively low tooling costs
- Dies that can be cast from low-melting alloys and that are relatively simple to make
- Short delivery time of product because of simplicity of toolmaking
- The possibility of combining coining with forming

These advantages must be weighed against the following limitations:

- Probability of forming wrinkles
- Need for skilled, specially trained operators
- Restriction to relatively shallow parts with generous radii
- Restriction to relatively thin sheet (about 0.61 to 1.63 mm, or 0.024 to 0.064 in.; thicker sheet can be formed only if the parts are shallow and have generous radii)

Drop hammer forming is not a precision forming method; tolerances of less than 0.8 to 1.6 mm ($\frac{1}{32}$ to $\frac{1}{16}$ in.) are not practical. Nevertheless, the process is often used for sheet metal parts, such as aircraft components, that undergo frequent design changes or for which there is a short run expectancy.

Hammers for Forming

Gravity-drop hammers and power-drop hammers are comparable to a single-action press. However, they can be used to perform the work of a press equipped with double-action dies through the use of rubber pads, beads in the die surfaces, draw rings, and other auxiliary equipment.

Because they can be controlled more accurately and because their blows can be varied in intensity and speed, power-drop hammers, particularly the air-actuated types, have virtually replaced gravity-drop hammers. A typical air-drop hammer, equipped for drop hammer forming, is shown in Fig. 1.

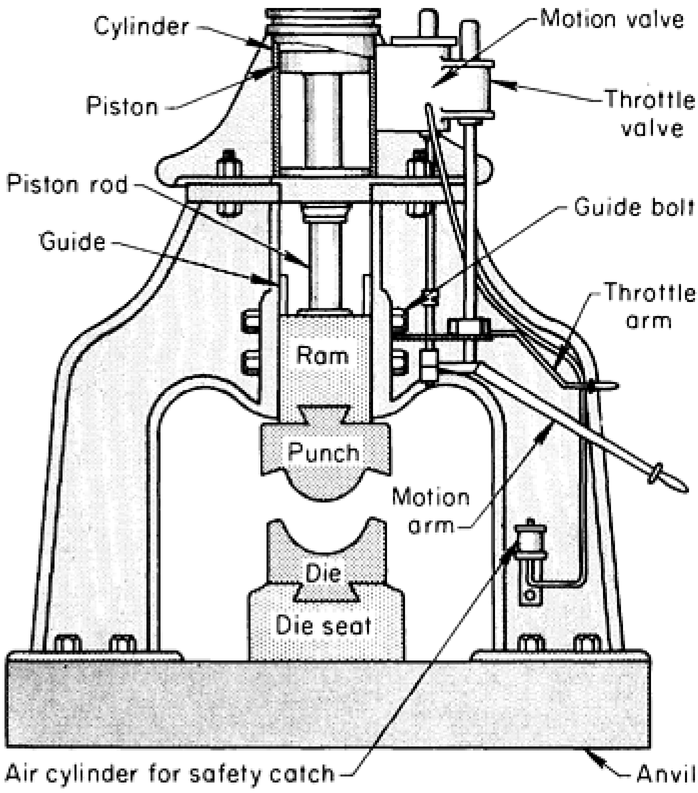

Fig. 1 Schematic of an air-actuated power-drop hammer equipped for drop hammer forming.

Power-drop hammers are rated from 4.5 to 155 kN (10M to 35,000 lbf), representing energies from 15 to 575 U (11,000 to 425,000 ft · lb). Air-drop hammers range in size (ram area) from 762 by 610 mm (30 by 24 in.) to 3.05 by 3.05 m (120 by 120 in.) with impact energies ranging from 8.9 to 134 kJ (6600 to 99,000 ft · lbf). Ram dimensions and other pertinent details concerning these hammers can be found in the article "Hammers and Presses for Forging" in this Volume.

Planishing hammers are used to supplement drop hammer forming. These are fast-operating air-driven or motor-driven machines that are generally used for low-production operations to form dual-curvature surfaces. They are also used to planish welds and to smooth out wrinkles or other imperfections in drawn or drop hammer formed parts.

Tooling

In general, a tool set consists of a die that conforms to the outside shape of the desired part and a punch that conforms to the inside contour (Fig. 1).

Tool Materials. Dies are cast from zinc alloy (Zn-4Al-3.5Cu-0.04Mg), aluminum alloy, beryllium copper, ductile iron, or steel. The wide use of zinc alloy as a die material stems from the ease of casting it close to the final shape desired. Its low melting point (380.5 °C, or 717 °F) is also advantageous. All dies, regardless of die material, are polished.

Punches are usually made of lead or a low-melting alloy, although zinc or a reinforced plastic can also be used. The sharpness of the contours to be formed, the production quantity, and the desired accuracy primarily govern the choice of punch material. Lead has the advantage of not having to be cast accurately to shape, because it deforms to assume the shape of the die during the first forming trial with a blank.

Rubber Padding. In some drop hammer forming, both a working (roughing) punch and a coining (finishing) punch are used. When the working punch becomes excessively worn, it is replaced by the coining punch, and a new coining punch is prepared. Another method of achieving the same results with one punch is to use 3.2 to 25 mm ($\frac{1}{8}$ to 1 in.) thick rubber pads. Rubber that is suitable for this purpose should have a hardness of Durometer A 60 to 90. In some cases, soft semi-cured rubber is used. (More information on Durometer hardness testing is available in the article "Miscellaneous Hardness Tests" in *Mechanical Testing*, Volume 8 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.) In the positioning of pads for a particular part (Fig. 2), the maximum thickness of rubber is situated where the greatest amount of pressure is to be applied in the initial forming. As forming progresses, the thickness of the rubber is reduced by removing one or more of the pads after each impact.

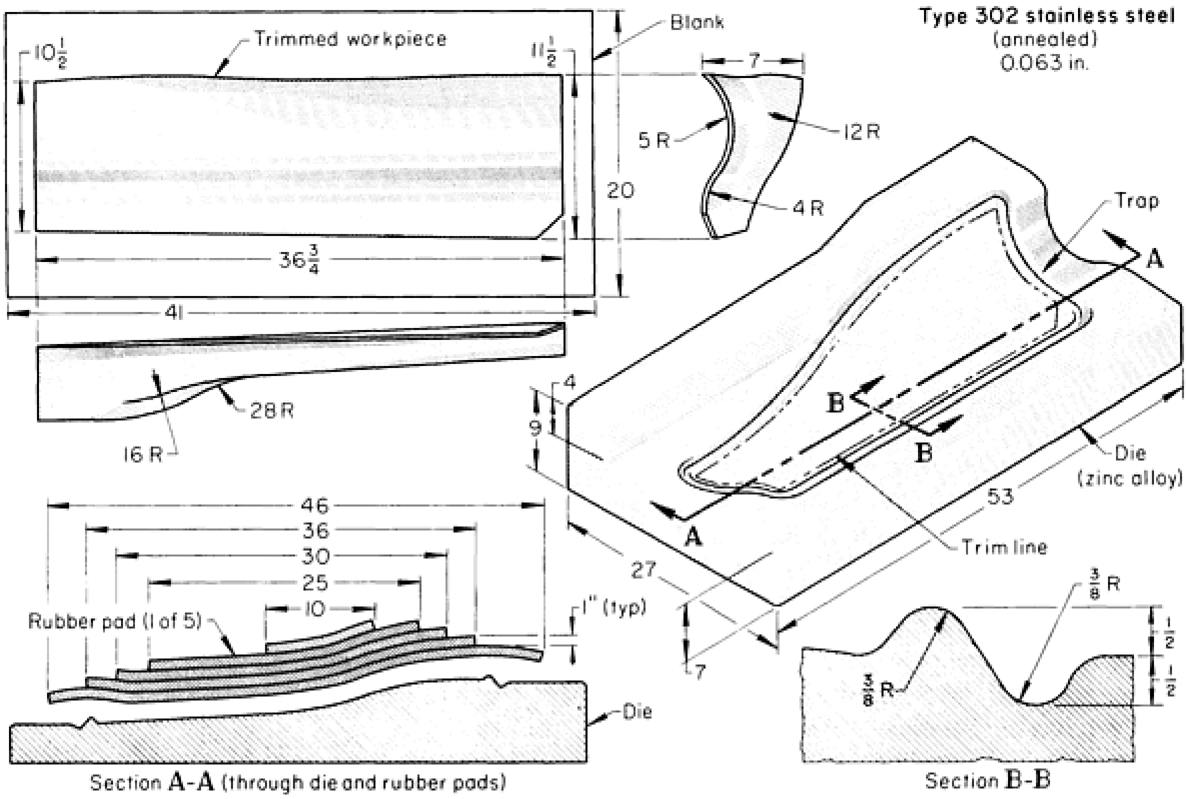

Fig. 2 Smoothly contoured stainless steel part that was hammer formed in a die with a peripheral trap for hold-

down. Dimensions given in inches.

Trapped Rubber Forming. Drop hammer forming using trapped rubber dies is a process derived from the Guerin process, which is today synonymous with the term "rubber-pad" forming (see the article "Rubber-Pad Forming" in this Volume). Both the Guerin and Marform (which is a refinement of the Guerin process) processes use hydraulic pressure instead of a drop hammer as the forming force. The trapped-rubber process using a drop hammer is used extensively by the aerospace and aircraft industries to fabricate sheet metal parts such as instrument panels, tank sections, air frames, stabilizer tips, air ducts, and doors made of aluminum alloys, titanium alloys, and stainless steels.

The drop hammer used in the trapped-rubber process offers several advantages over the hydraulic press used in the Guerin and Marform processes:

- Develops greater force (up to 44 MN or 5000 tonf) per unit of applied energy in shorter time and at less cost
- Minimizes springback as a result of dynamic application of force
- Reduces tendency of material to wrinkle due to better material flow
- Reduces amount of hand finishing required due to dynamic application of pressure

---

Lubricants

Lubricants are used in drop hammer forming to facilitate deformation by reducing friction and minimizing galling and sticking, and to preserve or improve surface finish. Selection of a lubricant depends primarily on the type of work metal, the forming temperature, the severity of forming, and the subsequent processing. Recommendations for lubricants used with steels and with aluminum, magnesium, and titanium alloys are given in the sections of this article that deal with the processing of those metals.

Blank Preparation

The blanks for drop hammer forming are generally rectangular and are prepared by shearing. The blank should be large enough to yield a part with a flange 50 to 75 mm (2 to 3 in.) wide in order to facilitate drawing of the metal during forming. When multistage forming is used, the part can be trimmed to provide a flange not less than 13 mm (½ in.) wide for the final forming stage.

Sheared edges are generally satisfactory for drop hammer forming, because the wide flange permits some cracking in the flange area without harming the part. The blank should be deburred to avoid possible damage to the tooling.

Drop Hammer Coining

Tableware, coins, and a variety of decorative items produced in copper alloys, stainless steel, sterling silver, and other metals are commonly coined by the drop hammer process. Processing details and production examples of drop hammer coining are given in the article "Coining" in this Volume.

Multistage Forming

With the drop hammer process, complicated parts can be formed by means of a single die and punch. However, when a large quantity of a particular part is required, it is common practice to adopt a multistage forming technique, employing several sets of dies and punches. The forming operation in any one stage is less severe than if the part were formed in a single operation. Metals that work harden appreciably are usually annealed after each operation, unless a suitable die sequence eliminates the need for annealing.

Unless contact of the work metal with lead is undesirable, the number of stage dies can be kept at a minimum by using lead pads to reduce the depth of the die cavity. Lead can be poured into the die, or lead sheet can be laid in the bottom of the recess, to the desired height; the lead is then formed to contour by a heavy blow of the punch. After the part has been preformed with the padded die, the pad is removed, and the part is then formed to the full depth of the die.

Control of Buckling

Forming a deeply recessed part in thin sheet by any conventional method usually requires a high hold-down force in order to prevent buckling. In drop hammer forming, the hold-down action is restricted to the end of the stroke. Therefore, buckles are free to form during most of the stroke. The hold-down pressure takes effect when the punch contacts the top of the wrinkles formed in the flange and rapidly increases until the die is bottomed. The wrinkles can be removed only at the end of the stroke and only if they are not too deep.

Multistage Processing. To avoid the formation of wrinkles that are too deep to be removed in the late stages of the stroke, the forming process is divided into several forming stages. The wrinkles formed in each stage are slight and can be eliminated at the end of the stroke or, if necessary, by manual hammering. To provide adequate hold-down action at the end of each operation, it is common practice to use stage dies with surfaces that extend slightly beyond the trim line and to use punches equipped with suitable beads or traps.

Hold-Down for Deep Parts. To form deep parts, a series of plywood or metal hold-down rings can be used; one ring is removed after each blow. These rings usually vary in thickness from 6.4 to 25 mm (¼ to 1 in.). The desired metal flow can be approached during the early stages of forming by using a blank that is considerably larger than that required to form the part. The excess metal is trimmed off after several blows. The stiffness of the oversize blank prevents draw-in and therefore induces stretching, which counteracts the tendency toward buckling. The die for a part with a deep recess must be designed with a horizontal surface to accommodate beading.

Processing of Steels

Carbon and low-alloy steels containing less than 0.30% C are the most easily formed by the drop hammer process. Higher carbon content decreases formability and promotes cracking. Although lead additions do not adversely affect the formability of steel, the sulfur additions that are characteristic of resulfurized free-machining steels promote susceptibility to cracking.

All carbon and low-alloy steels require full annealing for satisfactory drop hammer forming.

Stainless steels that are extensively formed by the drop hammer process include AISI types 302, 304, 305, 321, and 347. For severe drop hammer forming, grades containing not less than 10% Ni (and preferably about 12%) should be selected in order to minimize cracking. All stainless steels are drop hammer formed in the fully annealed (solution treated) condition.

Sheet Thickness. The drop hammer forming of steel sheet (particularly stainless steel sheet) less than 0.46 mm (0.018 in.) thick is impractical, because of wrinkling and the difficulties encountered in attempting to planish the wrinkles. The most common range of steel sheet thickness for drop-hammer formed parts is 0.61 to 1.6 mm (0.024 to 0.063 in.). Thicknesses up to 1.98 mm (0.078 in.) have been hammer formed.

Tool Materials. Cast zinc alloy is the most widely used die material for the drop hammer forming of carbon, low alloy, and stainless steels. Alloy cast iron dies are substituted when a large quantity of parts is required. Inserts of an air-hardening tool steel can be used in order to increase the life of dies with sharp fillets and corners.

Punches are made of either zinc alloy or cast iron, and are ground to size. A zinc alloy punch, cast directly into the die, can be used for shallow parts, but it may be undersize (because of shrinkage upon cooling) if the part contains large cavities. Lead punches are also extensively used, although they are easily distorted when used to form steels. Punch life can be considerably increased by facing the punch with an untrimmed finish-formed steel part.

Lubricants. When zinc alloy dies and zinc alloy or lead punches are employed, many steel parts can be formed without a lubricant. Harder tool materials or more severe forming may require the use of a light lubricant, such as SAE 10 or SAE 30 mineral oil.

Precautions for Stainless Steels. Stainless steels, especially the austenitic grades, work harden more than the carbon and low-alloy steels that are suitable for hammer forming. In the cold forming of stainless steel, it is necessary to stretch the metal, rather than allow it to draw into the die. Stretching prevents the formation of wrinkles that are difficult to eliminate. By means of stretching, quarter-hard and even half-hard types 301 and 302 can be drop hammer formed, although only to a very limited extent. Part configuration must be simple and of only moderate depth; otherwise, wrinkles (in a shallow part) or distortion (in a complex shape) will occur. Although it is preferable that the part be made in a single die with a single blow, some commercial quarter-hard parts have required as many as three or four blows for successful forming.

When moderately complex parts are formed in a drop hammer in several stages, it is advisable to consider intermediate annealing in order to offset the effects of work hardening. It is not necessary to pickle after each annealing treatment (provided scaling is not too heavy), except before the finish-forming operation and after the final annealing treatment. If the part is formed in zinc alloy dies, any adhering zinc particles must be removed by pickling or by treatment in a fused salt bath (caustic soda) before annealing treatments (both intermediate and final). This requirement is most important for parts that are to be welded or that will be exposed to elevated-temperature service. Failure to remove the zinc may result in cracking.

Springback. Carbon and alloy steel parts, and especially stainless steel parts, having large radii and smooth contours are more difficult to maintain in desired shape than parts with relatively sharp radii, because of the greater springback under these conditions. Common practice is to compensate for this springback from the desired contour by trial and error. If this method is not successful, the part must be distorted elastically upon assembly, that is, sprung into the final shape.

Parts with reverse contours (saddleback parts) are extremely difficult to form without excessive wrinkling.

Limits in Deep Recessing. When deeply recessed parts are to be formed in a drop hammer, the recesses are limited in both depth and contour. With a single die, a cup-shaped or dome-shaped part can be formed to a limiting depth of 60 to 70% of that obtainable by means of double-action dies. Square and rectangular steel boxes (even shallow ones) require a minimum corner radius of 6.4 mm (¼ in.) or five times the metal thickness, whichever is larger. For deeper boxes, progressively larger corner radii are necessary, and these minimum radii apply to boxes of any width.

Processing of Aluminum Alloys

The drop hammer forming of aluminum alloys is most suitable for limited production runs that do not warrant expensive tooling. The process is often used for parts, such as aircraft components, that undergo frequent design changes. Some forming applications also involve coining and embossing. The article "Forming of Aluminum Alloys" in this Volume contains more information on the forming of aluminum alloy sheet.

Work Metal. Annealed tempers of all aluminum alloys are the most suitable for hammer forming. Intermediate work-hardened tempers of the nonheat-treatable alloys are often used for channel shapes and shallow embossed panels.

Heat-treatable alloys are often partly formed in the annealed condition. The part is then solution heat treated, quenched, restruck to size, and artificially aged. Restriking is also necessary to remove distortion caused by quenching. Drop hammer forming can be done on freshly quenched alloys immediately after quenching, or it can be done later if the alloys are refrigerated to prevent aging.

Sheet Thickness. Under comparable conditions, with the same equipment and with the same thickness of sheet, aluminum wrinkles more easily than steel under a drop hammer. To obtain results comparable to those obtained with steel, aluminum alloy sheet should be at least 40% thicker than the steel, or preferably in the approximate thickness range of 0.86 to 3.18 mm (0.034 to 0.125 in.).

Equipment and Tool Materials. Aluminum alloys are drop hammer formed in gravity-drop, power-drop, and planishing hammers. Dies are cast from aluminum, zinc alloy, iron, or steel. Dies for high production are usually cast in iron or steel. All dies are polished. Most punches are made of lead or a low-melting alloy, although zinc alloy or reinforced plastic can also be used. The softer punch materials have the advantage of deforming readily to assume the shape of the die during forming trials. When planishing hammers are used, the preferred tool material is hardened, polished tool steel.

Forming Characteristics. Annealed aluminum alloys are readily formed under the drop hammer. Simple components can often be produced by a single blow. Deep shapes require extreme care in blank development and die design. Blankholders are not used; therefore, wrinkles are difficult to avoid, especially when thin sheet is being formed.

Processing of Magnesium Alloys

The drop hammer forming of magnesium alloys is performed on preheated sheet in heated dies. This procedure is suited to the production of formed parts having shallow depths and asymmetrical shapes and to parts for which special springback control is required.

Work Metal. Magnesium sheet alloys in the annealed condition are preferred for drop hammer forming. The ideal sheet thickness for forming is 3.2 mm (1/8 in.) and the part should be designed so as to be formable in six stages or fewer. For sheet thinner than 3.2 mm (1/8 in.), ten stages or fewer are recommended.

Equipment and Tool Materials. Both gravity-drop and power-drop hammers are suitable for the forming of magnesium alloys. Zinc alloy is the preferred punch and die material, although lead punches are sometimes used for production runs of not more than 50 pieces. When lead comes in contact with magnesium sheet, there is danger of lead pickup, which can cause corrosion of the sheet. Although lead pickup may occur at room temperature, it is more likely to occur at the elevated temperatures at which magnesium alloys are formed. Therefore, if lead pickup cannot be tolerated or if the production run exceeds 50 pieces, either zinc alloy or cast iron can be substituted for lead.

Lubricants. Vegetable-lecithin oils provide good lubrication at temperatures to 260 °C (500 °F). Suspensions of colloidal graphite may have to be used if temperatures are to exceed 260 °C (500 °F). However, these suspensions are more difficult to remove when parts are cleaned after forming.

Preheating. Magnesium alloy parts are usually formed at temperatures of 230 to 260 °C (450 to 500 °F), depending on the alloy (see the article "Forming of Magnesium Alloys" in this Volume). Heating times are 5 min per stage for sheet up to about 1.29 mm (0.051 in.) thick, and up to 9 min per stage for thicker sheet (up to 3.2 mm, or 0.125 in.).

The oven used to heat the parts between stages should be situated near the drop hammer; the decrease in temperature during transfer from the oven to the hammer will range from 17 to 25 °C (30 to 45 °F) in 5 s. The dies can be heated by placing them in an oven located near the hammer, and they can then be kept at temperature with ring burners or torches during the forming of the part.

Small dies can be anchored to an electrically heated cast iron platen installed on the hammer bed, but this method is impractical for large dies. The punch and die can also be heated by electric elements or by a heat-transfer fluid. The working temperatures should not exceed those recommended.

Rubber pads can be used in the initial forming operation. At 230 °C (450 °F), the reduction obtainable with rubber staging is approximately 10%. Special types of rubber are available for forming at temperatures to 315 °C (600 °F). The rubber pads are removed before the final blow is delivered to set the material.

Springback. One advantage of the elevated temperatures used in the drop hammer forming of magnesium is the marked reduction or total elimination of springback, provided the maximum practical temperatures are always employed. The rate of the deformation is important in drop hammer forming and must be carefully controlled upon severe drawing or when material in the hard (H24) temper is being formed. The rate of deformation can be controlled by the operator, although not to close limits. Parts that require relatively severe forming can be started by allowing the punch to descend slowly into the die and by using subsequent strikes to set the material.

Dimensional Tolerances. Tolerances of ±0.76 mm (±0.03 in.) have been held in the production of magnesium parts. When close tolerances are important, press forming is usually the preferred method for the forming of magnesium parts.

Drop Hammer Forming

Processing of Titanium Alloys

Various titanium sheet alloys have been formed by the drop hammer process, including Ti-13V-11Cr-3Al, Ti-8Al-1Mo-1V, Ti-6Al-4V, and Ti-5Al-2.5Sn. In general, the alloys containing aluminum as the principal alloying element are the most difficult to form. The minimum thickness of titanium sheet for hammer-formed parts is about 0.64 mm (0.025 in.).

Tool Materials. Contact between titanium and low-melting tool materials, such as zinc alloy or lead, should be avoided--particularly when the titanium is formed at elevated temperature or must be heat treated after forming. When these tool materials are used, contact with the workpiece can be avoided by capping the punch and die with sheet steel, stainless steel, or a nickel-base alloy. The choice of capping material depends on the tool life desired. The longest tool life is obtained by capping with nickel alloy sheet such as Alloy 600 (UNS N06600) in thicknesses of 0.64 to 0.81 mm (0.025 to 0.032 in.).

In general, steel and ductile iron dies are used when the tooling must be heated above 205 °C (400 °F). Preheating of both the work metal and the tooling is not uncommon.

Rubber Pads. High-temperature rubber pads are used both in preforming operations before the final strike and as electrical insulators to prevent current loss to the tooling when the work metal blank is heated by the electrical-resistance method.

Lubricants used in the drop hammer forming of titanium should be nonchlorinated. Extreme-pressure oils and both pigmented and nonpigmented drawing compounds are used in most operations.

Preheating Tools and Blanks. Difficult titanium parts are formed at elevated temperature (see the article "Forming of Titanium and Titanium Alloys" in this Volume for recommendations and precautions). Thermal expansion of the blank and the tooling must be considered. If the tooling is not preheated, the amount it expands will depend on the length of time it is in contact with the blank. The allowance for thermal expansion used in the design of tooling for titanium is 0.006 mm/mm (0.006 in./in.) for a forming temperature of 540 °C (1000 °F). The allowance for expansion of circular or elliptical parts should be made radially, not peripherally. When hot sizing is to follow forming, the drop-hammer tooling is usually made to net dimensions without consideration of thermal expansion.

Formability Versus Temperature. Variation of the drop-hammer formability index for two titanium alloys with temperature is given in Fig. 3. It is evident from the curves that significant increases in formability can be achieved at temperatures above 540 °C (1000 °F).

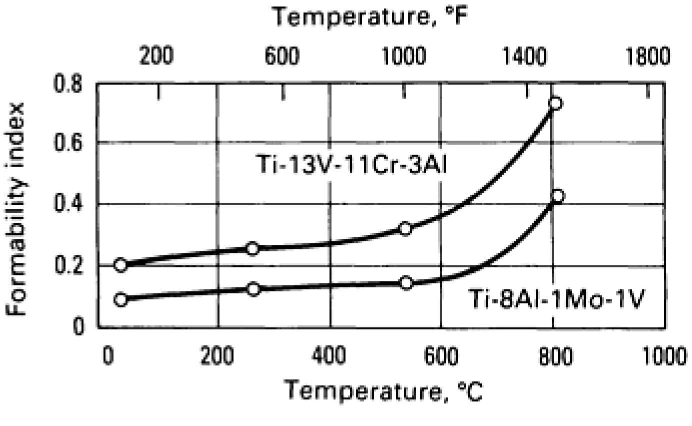

Fig. 3 Effect of forming temperature on the drop hammer formability of two titanium alloys.

Drop Hammer Forming Limits

The severity of permissible deformation in drop hammer forming is limited both by geometrical considerations and by the properties of the work metal. The forming limits can be predicted by considering parts of interest as variations of beaded panels. For parts characterized in this way, the critical geometrical factors are the bead radius *r*, the spacing between beads *s*, and the thickness of the work metal *t* (Fig. 4).

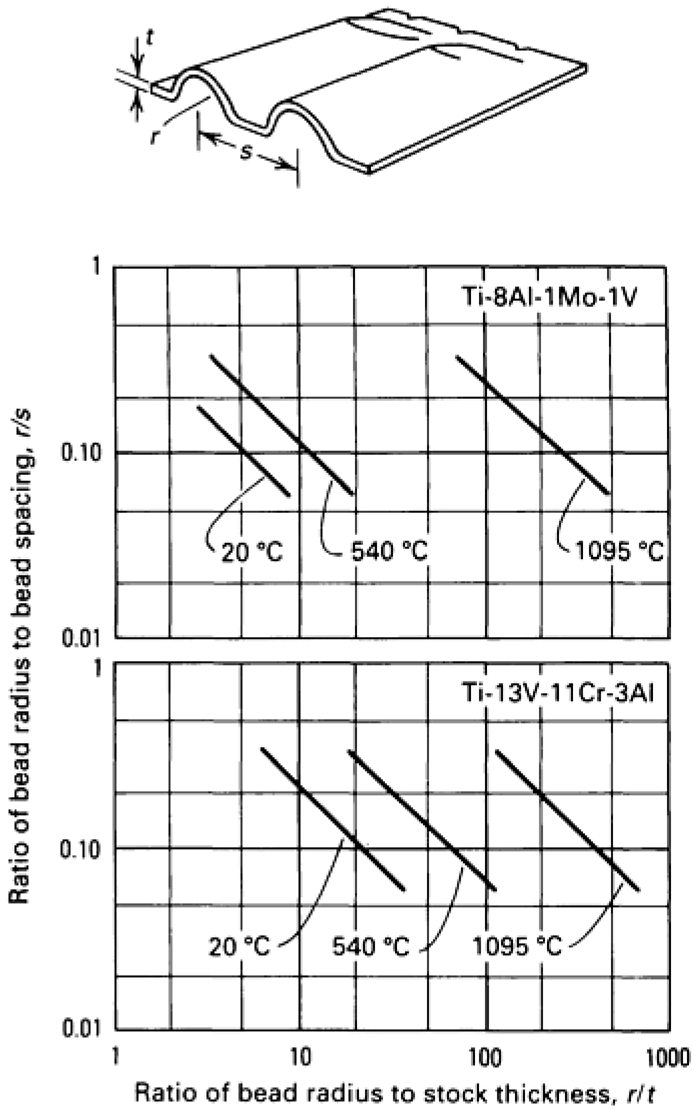

Fig. 4 Formability limits of beaded titanium alloy panels at room temperature and at elevated temperature.

Two of the forming limits depend entirely on dimensional relations and are the same for all materials; the ratio of the bead radius *r* to bead spacing must lie between 0.35 and 0.06. The lower formability limit is controlled by the necessity of producing uniform stretching and avoiding excessive springback. If the *r*/*s* ratio is too small, there will be greater localized stretching at the nose of the punch.

Within the limits set for all materials by the r/s ratio, success or failure in forming beaded panels depends on the ratio of the bead radius to the sheet thickness (r/t) and on the ductility of the work metal. The part will split if the necessary amount of stretching exceeds the ductility available in the material. The splitting limit can be predicted from elongation in a 12.7-mm (0.5-in.) gage length in tension tests at the temperature of interest.

Formability limits for two titanium alloys are plotted in Fig. 4. Both charts show the marked improvements in formability resulting from the better elongation values at elevated temperature.

Introduction

BARS are bent by four basic methods: draw bending, compression bending, roll bending, and stretch bending.

Draw Bending

The workpiece is clamped to a rotating form and drawn by the form against a pressure die (Fig. 1). The pressure die can be either fixed or movable along its longitudinal axis. A fixed pressure die must be able to withstand abrasion caused by the sliding of the work metal over its surface. A movable pressure die, because it moves forward with the workpiece as it is bent, is less subject to such abrasion. It provides better guidance and more uniform restraint of the work material. On power bending machines, draw bending is used more than any other bending method.

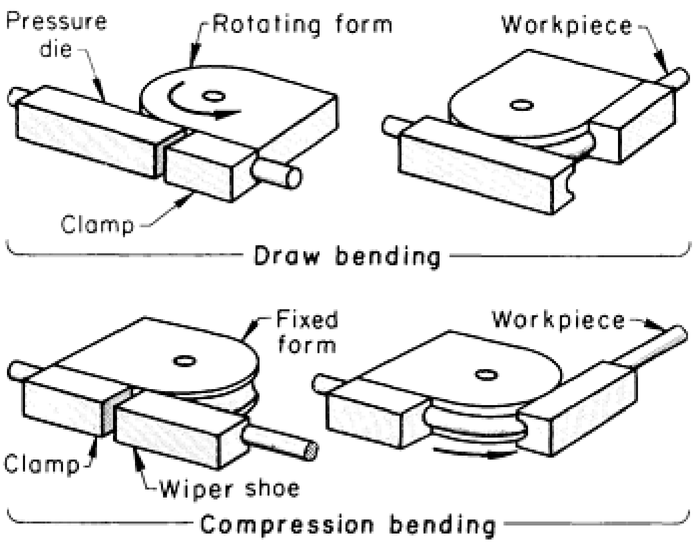

Fig. 1 Essential components and mechanics of draw bending and compression bending of bars and bar sections.

Compression Bending

The workpiece is clamped to a fixed form, and a wiper shoe revolves around the form to bend the workpiece (Fig. 1). Compression bending is most useful in bending rolled and extruded shapes. A bend can be made close to another bend in the workpiece without the need for the compound dies required in draw bending. Although compression bending does not control the flow of metal as well as draw bending, it is widely used in bending presses and in rotary bending machines.

Roll Bending

Three or more parallel rolls are used. In one arrangement using three rolls, the axes of the two bottom rolls are fixed in a horizontal plane. The top roll (bending roll) is lowered toward the plane of the bottom rolls to make the bend (Fig. 2). The three rolls are power driven; the top roll is moved up or down by a hydraulic cylinder. (Other three-roll arrangements are covered in the article "Three-Roll Forming" in this Volume.

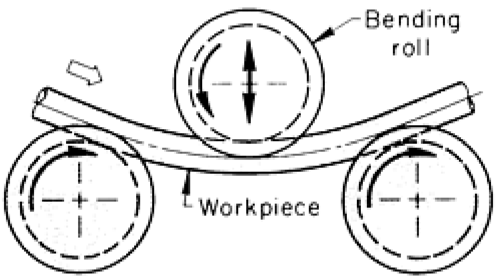

Fig. 2 Operating essentials in one method of three-roll bending.

A roll arrangement for four-roll bending is shown in Fig. 3. The bar enters between the two powered rolls on the left. The lower bending roll is then adjusted in two directions according to the thickness of the bar and the desired angle of bend.

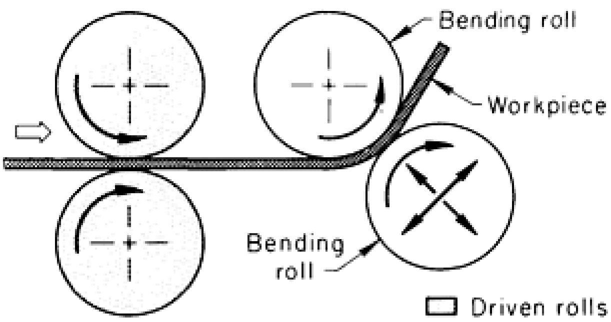

Fig. 3 Operating essentials in four-roll bending.

Rings, arcs of any length, and helical coils are easily fabricated in a roll bender. The bend radius usually must be at least six times the bar diameter or the section thickness in the direction of the bend. To limit distortion in the roll bending of asymmetrical sections, a double section can be made and split in two after bending. Rings are sometimes made by roll bending coils and cutting them into rings for welding.

Roll bending is impractical for making more than one bend in a bar. It is difficult to control springback in a roll bender, and it may take several passes through the rolls to make the needed bend. Therefore, this method of making bends is slower than other methods. Another disadvantage of roll bending is that a short section of each end of the bar is left straight. For three-roll bending, the ends can be preformed in a press before bending, or the straight parts can be trimmed off. The following example describes a production application of three-roll bending.

Example 1: Three-Roll Bending of a Structural Section.

A 7.6 kW (10 hp) three-roll bender was used to bend a steel angle 75 × 75 × 9.5 mm (3 × 3 × $\frac{3}{8}$ in.) into a circular reinforcing flange 1520 mm (60 in.) in diameter. The angle was of hot-rolled ASTM A107 steel. The top roll of the bender was a plain cylinder; each of the two bottom rolls consisted of two cylindrical sections held apart by a spacer to provide a recess for the edge-bent flange. The operations were performed in the following sequence:

- Cut angle to developed length plus 254 mm (10 in.)
- Set rolls to bend correct radius; roll 360°
- Cut off ends of the rolled bar
- Weld the bar into a ring
- Grind the weld flush
- Roll the ring in the three-roll bender to make it a true circle

---

Stretch Bending

Large irregular curves are obtained using stretch bending. The workpiece is gripped at the end, stretched, and bent as it is stretched around a form. Usually, less springback occurs when the work is bent while it is stretched. The gripped ends are customarily trimmed off. This method can accomplish in one operation what would otherwise take several operations. The result is a possible savings in time and labor, even though stretch bending is a slow process. The tools, form blocks, or dies for stretch bending are simpler in design and less costly than conventional press tooling. Stretch bending of bars is described in more detail in the article "Stretch Forming" in this Volume.

Bending Machines

The machines used for the bending of bars include the following: devices and fixtures for manual bending, press brakes, conventional mechanical and hydraulic presses, horizontal bending machines, rotary benders, and bending presses. Shapers have also been used to perform specific bending operations.

Manual Bending. Hand-powered machines or fixtures are used in many shops for making bends that do not require much energy to form. This equipment is supplied with ratchets, levers, or gears to give the operator mechanical advantage. Different types of fixtures are used for manual draw bending, stretch bending, or compression bending. Roll bending is seldom done by hand. The tools used in manual bending are the same as those used on some power bending machines. The maximum sizes of low-carbon steel bars that can be manually cold bent are given in Table 1.

Table 1 Maximum sizes of low-carbon steel bars for manual bending

Shape	Size mm (in.)
Rounds	25 mm (1) (diam)
Squares	19 mm ($\frac{3}{4}$) (per side)
Flats bent on flat	9.5 × 102 ($\frac{3}{8}$ × 4)
Flats bent on edge	6.4 × 25 ($\frac{1}{4}$ × 1)
Angles	4.8 × 25 × 25 ($\frac{3}{16}$ × 1 × 1)
Channels	4.8 × 13 × 25 ($\frac{3}{16}$ × $\frac{1}{2}$ × 1)

Press brakes are used for all types of bending, especially in small-lot production (25 to 500 pieces), when standard tooling or low-cost special tooling can be used. Often, the punch is not bottomed in the die; but the stroke is controlled, and the bar is bent "in air" (Fig. 4). With this technique, various bend angles can be made with the same die (see also the article "Press-Brake Forming" in this Volume).

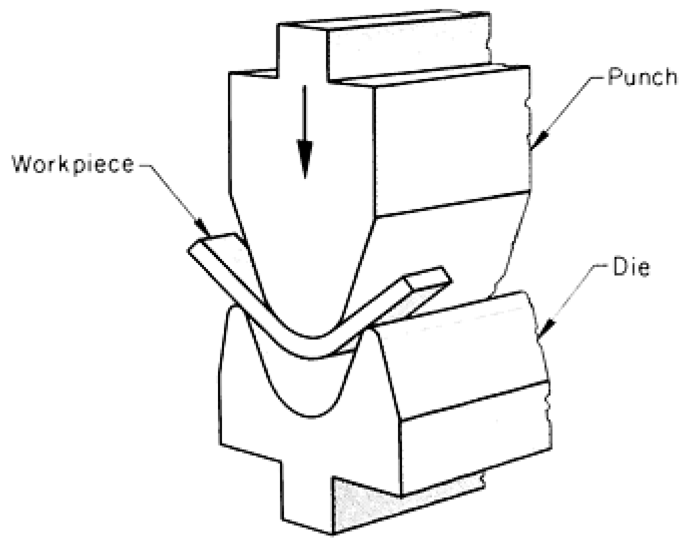

Fig. 4 Air bending of a bar in a press brake.

Mechanical presses are generally used only for mass production, because only large production lots can justify the cost of tooling, which is more than that for most standard bending tools. Figure 5 shows a round bar being bent into a U-bolt in a press. The bar is first cut to length and pointed at both ends (preliminary to a later threading operation). The bar is then loaded into the press and held in a grooved die that bends the bar into a U in one stroke. In the setup shown in Fig. 5, more than one workpiece can be bent at a time. The following example describes an application of a mechanical press in bending bars.

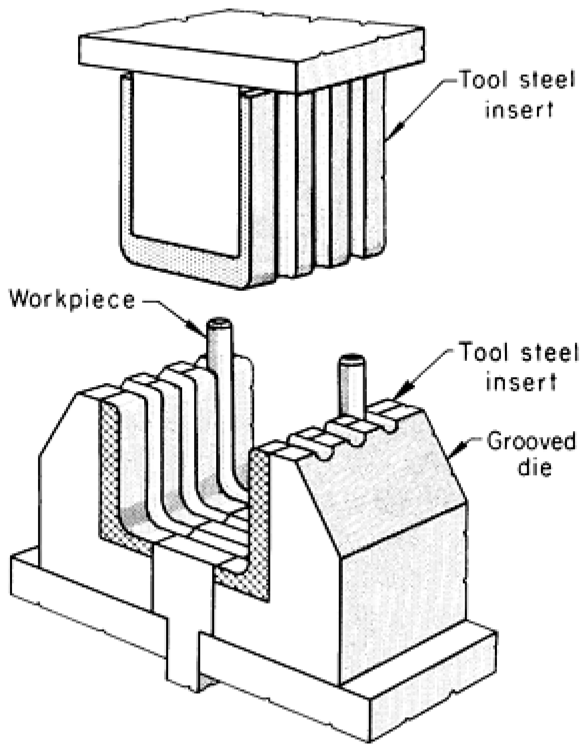

Fig. 5 Use of a grooved die in a mechanical press for bending a round bar into a U-bolt in one stroke.

Example 2: Bending a Welded Assembly in a Mechanical Press.

The wheel spider shown in Fig. 6 had three 254 mm (10 in.) long spokes of 9.52 mm (0.375 in.) diam low-carbon steel. The spider was assembled by welding the three spokes to a 13 mm ($\frac{1}{2}$ in.) thick steel hub. The assembly was loaded into a 670 kN (75 tonf) mechanical press, a double bend (joggle) was made in the spokes, and the short straight surface between the two bends was flattened to 6.4 mm ($\frac{1}{4}$ in.) thick. The wheel rim was then welded to the spokes as shown in Fig. 6(d). Next, the assembly was loaded into another press, in which the legs were sheared flush with the outer edge of the rim and a 3.2 mm ($\frac{1}{8}$ in.) diam hole was pierced in the flattened area of each spoke. The production rate was 25 per minute.

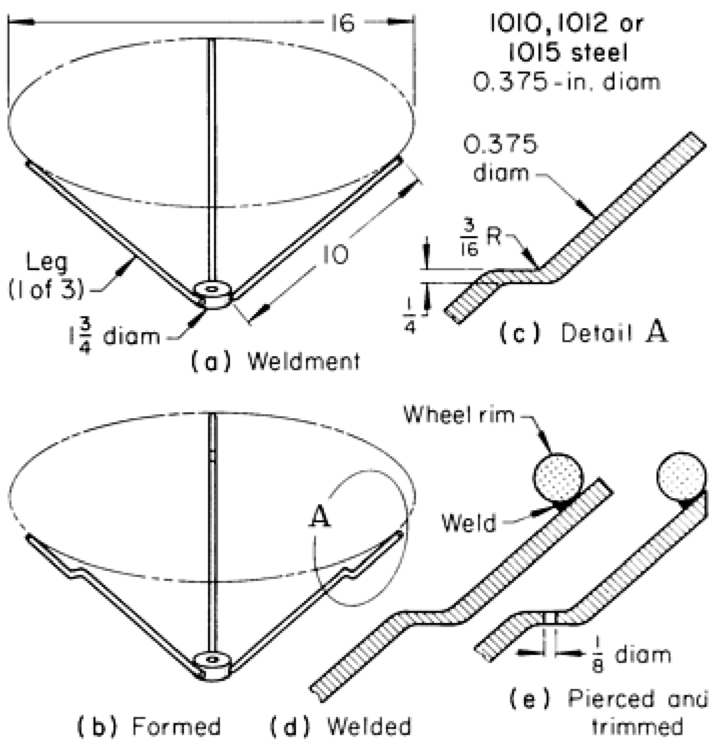

Fig. 6 Welded bar assembly that was formed by bending in a mechanical press. Dimensions given in inches.

Hydraulic presses are often used to bend bars in much the same manner as mechanical presses. Although hydraulic presses are usually slower than mechanical presses, they have the advantage of exerting full force over a long stroke. Therefore, deep bends can often be made on a hydraulic press much smaller than the mechanical press that would be required. In the following example, a hydraulic press needed so little head room that a closed shape could be bent over it.

Example 3: Bending a Double-Bar Structure in a Hydraulic Press.

A double-bar structure was constructed of two 11 mm ($\frac{7}{16}$ in.) diam bars that were connected by welded cross members to form a ladderlike structure. A rectangular shape was formed by making four 90° bends having 16 mm ($\frac{5}{8}$ in.) inside radii. The two bars (sides of the ladderlike structure) were bent simultaneously, using a punch that forced the bars between rollers. By using a small (27 kN, or 3 tonf) vertical hydraulic press, the four bends could be made consecutively, allowing the workpiece to encircle the press ram as bending was completed. The overhead clearance would not have been available with a mechanical press. This technique permitted the fabrication of 360 double bends (90 frames) per hour.

Horizontal bending machines for bending bars consist of a horizontal bed with a powered crosshead that is driven along the bed through connecting rods, crankshaft, clutch, and gear train. Dies are mounted on the bed, and forward motion of the crosshead pushes the bar through the die. The long stroke and generous die space make this machine useful for a variety of cold- and hot-bending operations, although speeds are lower than those for mechanical presses of similar capacity. Horizontal benders are available in capacities from 89 to 2700 kN (10 to over 300 tonf).

Rotary benders, either vertical or horizontal, are used for the draw, compression, or stretch bending of bars. Such machines consist of a rotary table in either a horizontal or vertical position on which the form block or die is mounted (Fig. 1). Suitable hydraulic or mechanical clamping, tensioning, or compressing devices are provided to hold the workpiece while the die rotates to the required position, or while the workpiece is bent about the central forming die. Some machines can make bends by two, or all three, methods.

Bending presses are most widely used for bending tubing (see the article "Bending and Forming of Tubing" in this Volume). However, bending presses are occasionally used for bending bars, as in the following example.

Example 4: Making a Double Crank in a Bending Press.

Double cranks such as the one shown in Fig. 7 were made in a bending press from round bars 7.9 or 9.5 mm ($\frac{5}{16}$ or $\frac{3}{8}$ in.) in diameter. The bars were cut to length and fed into the press to flatten the ends and pierce the holes. The two sharp bends were made one at a time in the same press with a V-die. A bearing bracket was assembled on the crank, followed by a double-staking operation in the same press. The greatest demand on the press was in the end-flattening operation, which required a press capacity of 8900 to 13,300 kN (100 to 150 tonf).

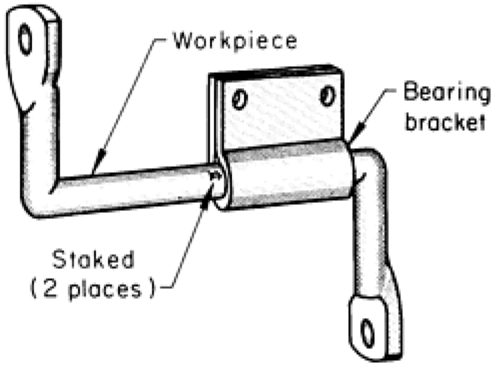

Fig. 7 Double crank produced in a bending press.

Shapers can be tooled for bending operations. One method is to have the fixed die, or anvil, held on the knee of the shaper and the punch mounted on the ram (Fig. 8). The shaper must make one stroke only. The stroke can be adjusted to allow for springback in the workpiece; therefore, the workpiece can be bent to fairly close limits.

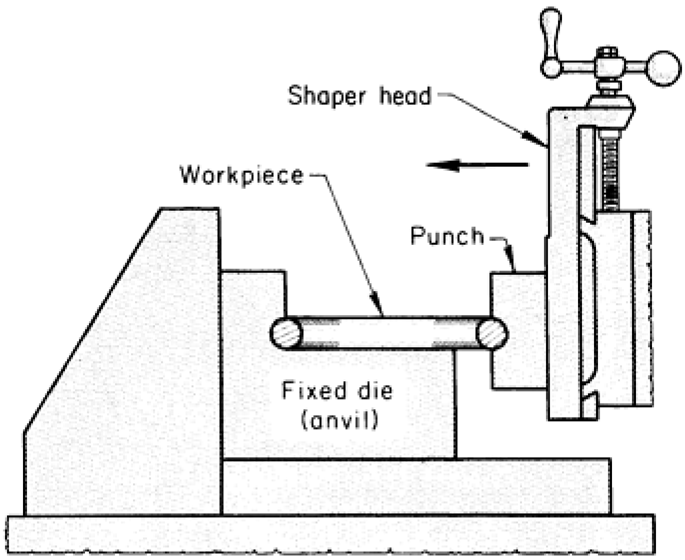

Fig. 8 Use of a shaper for correction of springback in U-bolts, J-bolts, or rings.

The setup shown in Fig. 8 is used to correct for springback in formed parts such as J-bolts, U-bolts, and rings. A V-punch and die mounted in the shaper can make bends of various kinds.

A shaper can also be provided with a rack and pinion to produce rotary motion for bending (Fig. 9). Bend radius can be varied by the use of center pins of different diameters. A typical use of a shaper in the bending of bars is described in the following example.

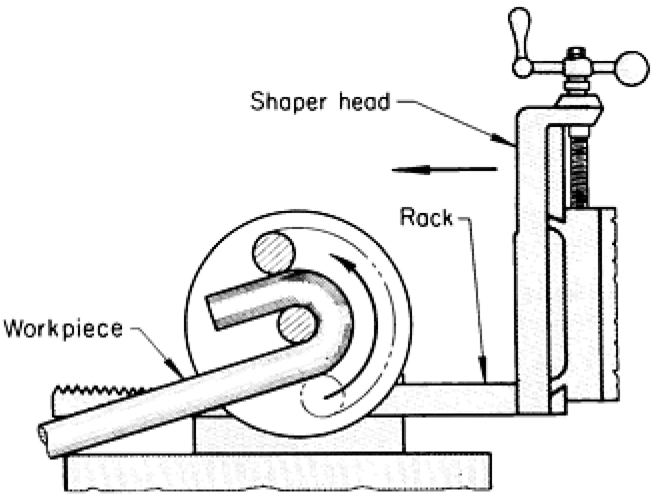

Fig. 9 Bending with rotary motion in a shaper.

Example 5: Shaper Versus Press for the Bending of J-bolts.

Originally, J-bolts were press bent cold in a die from sheared lengths of 13 mm ($\frac{1}{2}$ in.) diam hot-rolled merchant bars of 1025 steel. The press made the J-bolts by bending the bar into a half circle with one long arm. Because the unbalanced support caused variations in bending, some of the parts were unacceptable.

The job was put on a shaper. For this operation, the stock was sheared to double lengths, which the shaper bent into a circular loop with two long arms (the ends). The looped bar was then sheared in half. The cost of tooling for the shaper was much less than that for the press.

A rack-and-pinion-actuated fixture similar to that shown in Fig. 9 was used to bend the bar into a circular loop. The bar stock was placed in the fixture at a slight angle to allow one leg to pass the other during forming. After the bar was cut in two, the J-bolt was finished in a setup such as that shown in Fig. 8.

Tools

Tools for draw and compression bending are shown in Fig. 1. The form used in both processes is shaped to the contour of the bend. It is usually grooved to fit the work. Often, the form is part of a right cylinder whose straight portion (frequently, an insert) provides the surface against which the work is clamped. Hydraulic or mechanical pressure holds the clamp against the workpiece. Annular grooves or roughened surfaces grip the bar or bar section.

To allow for springback, the bend radius is made smaller on the form than is required for the workpiece. The form is also designed for a greater angle of bend than is needed. These two adjustments permit overbending the piece to allow for springback. Such adjustments are made by trial and error. The form is tested and corrections are made before it is heat treated.

The finish on the form (rotating or fixed) should be just good enough to avoid marring the workpiece. For most bar bending, a machined finish is sufficient. For decorative stainless steel and polished aluminum, grinding or polishing of the form surfaces may be needed. However, the clamping area should not be ground or polished unless necessary. The smoother the finish in the clamping area, the greater the danger that the workpiece will slip through the clamp. The pressure die and wiper shoe require a good finish (usually ground) because the work metal must slide along them.

When air bending bars in a press brake, simple V-blocks will suffice for the female dies. The opening of the V-blocks should be eight times stock thickness for standard sections, and ten times stock thickness for heavy sections. The upper die (punch) is shaped to the inside radius of the bend, and the angle of bend is controlled by the length of stroke. The same die set can be used for making various bends, as well as for various stock thicknesses, by adjusting the stroke.

Press brakes can use rubber pads for tooling on bends that need support (see the article "Press-Brake Forming" in this Volume). Completely shaped dies for bottoming can also be used in a press brake, as shown in Fig. 10.

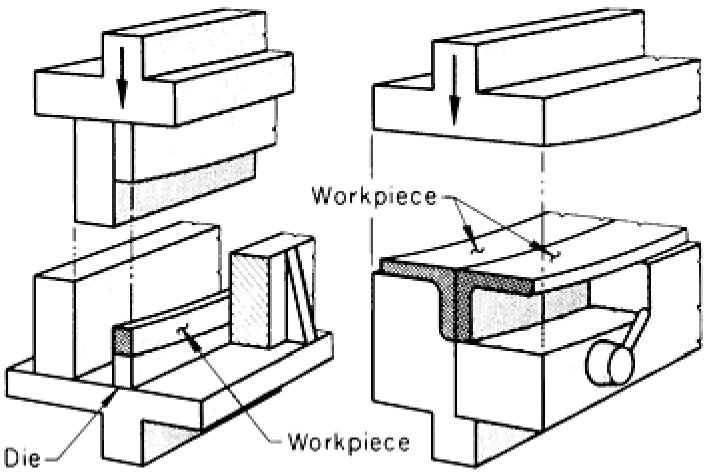

Fig. 10 Die setups in a press brake for edge bending a bar (left) and for bending two structural angles (right).

Most dies used in conventional mechanical or hydraulic presses are completely shaped bottoming dies, which makes them more expensive than tooling for other bending machines. Tooling for bending presses is specially designed to fit the needs of the machine and the work to be done. Dies for bending presses are simple to construct and relatively inexpensive. Tools for stretch bending are covered in the article "Stretch Forming" in this Volume.

Die Materials. Dies are usually made of hardened steel for the production of thousands of pieces per month. Tool steel is used for small one-piece dies. Larger dies are made of low-carbon steel and then carburized and hardened. Clamping inserts are made separately.

For moderate production of a few hundred pieces per month, unhardened carbon steel is often used. If only a few parts are needed, wood or an aluminum alloy may be strong enough for dies.

For bottoming dies in presses, hardened tool steel is always used. For cold bending, A2 tool steel hardened to 58 to 62 HRC is most often selected. A hot-work tool steel, such as H11, hardened to 45 to 50 HRC is usually the choice for hot bending.

Bend Allowance

The stock consumed in a bend (that is, overall length of a bend) can be computed from the radius of curvature at the neutral axis and from the angle of the bend. A formula often used for this computation is:

$$W = 0.01745\ \alpha(r + \delta)$$

where W is the bend allowance, α is the angle of bend (in degrees), r is the radius of bend to inner stock surface, and δ is the distance from the inner surface to the neutral layer (a commonly used approximation when this figure is not known is one-third to one-half stock thickness). The constant 0.01745 is a conversion factor changing degrees to radians.

When bar stock for a workpiece whose ends are within, or very near, the bend area is cut square to the neutral axis, the ends, after forming, will not be square to the neutral axis. The basic reason for this is the difference in circumference of the outer and the inner surfaces of the bend. Additional deviation from squareness can be expected because all of the material toward the outside of the bend from the neutral axis has undergone a tensile load and the material inside this line has been under compressive load. Unless compensation can be made for these variations, the ends of the formed part must be trimmed if they are to be square to the axis. However, when end details, locating surfaces, and other considerations necessitate such action, it is still possible to cut the blanks to size in such a way that trimming after forming is eliminated.

Lubrication

Successful bending depends to a large extent on the type of lubricant used. No one lubricant works equally well on all materials. Selection of a lubricant varies among different shops. Typical lubricants for bending specific metals are listed in Table 2.

Table 2 Typical lubricants for bending various metals

Work metal	Lubricant
Low-carbon steel	**Water-soluble, vegetable-oil base drawing oil**[a]
Stainless steel and other high-alloy iron-base alloys	**Mineral-oil-base drawing oil**[a]
Aluminum alloys and copper alloys	**Mineral oil**
Brass (severe bends)	**Soap solution**[b]
Hot bending of carbon, alloy, and stainless steels	**Molybdenum disulfide**

(a) Available as proprietary material.

(b) Creamy mixture of laundry soap and water

Overlubrication, in either quantity or type of lubricant, must be avoided. Not only is excessive lubrication likely to cause wrinkling, but the cost of removal must be considered. It is never good practice to use a pigmented compound if successful results can be obtained with an unpigmented compound, because pigmented compounds are more difficult to remove.

Wiper dies are lubricated with a very small quantity of high-grade drawing lubricant. It is important not to overlubricate pressure dies and wiper shoes.

Bending and Forming of Tubing

Introduction

THE PRINCIPLES for bending tubing are much the same as those for bending bars (see the article "Bending of Bars and Bar Sections" in this Volume). Two important additional features in the bending of tubes are that internal support is often needed and that support is sometimes needed on the inner side of a tube bend.

The wall thickness of the tubing affects the distribution of tensile and compressive stresses in bending. A thick-wall tube will usually bend more readily to a small radius than a thin-wall tube. Table 1 lists the minimum practical inside radii for the cold draw bending of round steel or copper tubing, with and without various supports against flattening and wrinkling.

Table 1 Minimum practical inside radii for the cold draw bending of annealed steel or copper round tubing to 180°

Radii can be slightly less for a 90° bend, but must be slightly larger for 360°.

Tubing outside diameter	Minimum practical inside radius		
	Grooved bending tools		Cylindrical bending block without mandrel; ratio, <30[a] (poor conditions)
	With mandrel; ratio, <15[a] (best conditions)	**With mandrel or filler; ratio, <50[a]**

(a) Ratio of outside diameter to wall thickness of tubing

Selection of Bending Method

The four most common methods of bending tubing are basically the same as those used in the bending of bars: compression bending, stretch bending, draw bending, and roll bending. The method selected for a particular application depends on the equipment available, the number of parts required, the size and wall thickness of the tubing, the work metal, the bend radius, the number of bends in the workpiece, the accuracy required, and the amount of flattening that can be tolerated.

Hand Versus Power Bending. The bending methods and tooling used in hand bending are the same as those for power bending. Steel tubing as large as 38.1 mm (1.50 in.) in outside diameter with a 1.65 mm (0.065 in.) wall thickness can be bent by hand, but the process is slow and repeatability is questionable. Some hand benders use an adjustable friction device, a kind of sliding brake, to prevent sliding of the tubing. The friction prevents wrinkles and other defects in bending. The following two examples illustrate several of the factors that must be taken into consideration in selecting either hand bending or power bending to fabricate tubing.

Example 1: Hand Bending of a U-Shaped Furniture Part Having Two 90° Bends.

Bending equipment was needed to produce a U-shaped furniture part with two 90° bends from 19 mm ($\frac{3}{4}$ in.) outside diameter 1010 steel welded tubing with a 1.25 mm (0.049 in.) wall thickness. The two bends were made to a 50 mm (2 in.) radius as measured on the tube centerline. A small amount of flattening was tolerated. Production rate was 500 pieces per month.

Because no great accuracy was needed and because the production volume did not warrant more than a minimum investment, a bending fixture for compression bending by hand was selected, along with tooling to allow for both bends to be made in one setup. If production volume had been larger, a power-driven bender or a bending press might have been selected.

Example 2: Power Bending of Machine Tool Hydraulic Lines.

In the production of hydraulic lines for machine tools, from 9.5 mm and 13 mm ($\frac{3}{8}$ and $\frac{1}{2}$ in.) OD steel tubing and from 6.4 mm ($\frac{1}{4}$ in.) OD copper tubing, hand bending required 6400 manhours per year for 44,000 bends. A change to power bending reduced the man-hours needed to 450.

Tools

Tools used for the bending of tubes are similar to those for the bending of bars (see the article "Bending of Bars and Bar Sections" in this Volume). One important difference is that tools for tubes need carefully shaped guide grooves to support the side-walls and to preserve the cross section during the bend.

Form blocks, or bending dies, resemble those described in the article "Bending of Bars and Bar Sections" in this Volume. They either rotate or are fixed, depending on the arrangement of the machine in which they are used. One end of the tube is clamped at the end of the groove in the form block, and the tube is bent by being forced around the block and into the groove. For round tubes, the depth of the groove in the form block should be one-half the outside diameter of the tube to provide sufficient sidewall support.

The block becomes the template for holding the shape of the bend. Form blocks can be made of wood, plastic, or hardboard; if they are to be used for an extensive production run, they can be made of tool steel and hardened.

Clamping blocks hold the end of the tube to the form block and maintain the holding force necessary to make the bending action effective. Although the groove in the clamping block should be well formed, the finish should not be so fine that the tube will slip. Ordinarily, the as-machined finish is adequate, but sometimes ridges or serrations are machined into the clamp to increase the holding force. Rosin can be applied to the tube to prevent it from slipping in the clamp.

If the clamped area is to be part of the finished piece, care must be taken to prevent scratches or mars. If the clamping groove has to be ground or polished to provide a good surface, the portion of the tube to be clamped will have to be longer to distribute the higher clamping force better. When the clamping length is short, the end of the tube is sometimes plugged to prevent it from deforming from high clamping forces. Table 2 lists typical clamping lengths for bending steel tubing.

Table 2 Typical clamping lengths for bending steel tubing

Radius of bend centerline	**Wall thickness of tube, mm (in.)**	Typical length clamped
1 × OD	<0.89 (0.035)	**4-5 × OD**
	0.89-1.65 (0.035-0.065)	**3-4 × OD**
	>1.65 (0.065)	**2-3 × OD**
2 × OD	<0.89 (0.035)	**3-4 × OD**
	0.89-1.65 (0.035-0.065)	**2-3 × OD**
	>1.65 (0.065)	**$1\frac{1}{2}$-$2\frac{1}{2}$ × OD**
3 × OD	<1.65 (0.065)	**2-3 × OD**

Pressure dies are used in the draw bending of tubing to press the workpiece into the groove in the form block and to support the outer half of the tube. The most commonly used pressure die is as long as the developed length of the bend plus some allowance for holding, and it does not slide over the tube but travels with it as it moves toward the bend area (see the article "Bending of Bars and Bar Sections" in this Volume). In one face, it has a groove with a depth that is slightly less than one-half the outside diameter of the tube.

A stationary pressure die or even a roller can be used on noncritical work. Either unit has a tube-forming groove machined in its face. Most stationary pressure dies are made of low-carbon steel, which can be case hardened to resist wear. Tool steel such as O1, A2, or D2, hardened to 55 to 60 HRC, or aluminum bronze is commonly used for sliding dies.

In compression bending equipment, where the tube is clamped to a nonrotating form block, a wiper shoe replaces the pressure die. Its relationship to the workpiece is similar to that of the stationary die described above in that the wiper shoe slides over the workpiece. However, instead of being fixed, the wiper shoe revolves around the stationary form block, progressively pressing the tube into the form block groove. For most applications, the length of the wiper shoe is from three to five times the outside diameter of the tube. The wiper shoe is made of tool steel and hardened to 55 to 60 HRC, or of a bearing bronze.

Wiper dies are stationary straight-groove dies (not to be confused with the wiper shoes described above) that are sometimes needed in draw bending to support the tube on the side opposite the pressure die as the tube is about to be drawn into the contour of the form block. Metal that will form the inside of the bend undergoes severe compression that is transmitted back toward the as yet unbent end of the tube, where it could cause wrinkles if not for the support of the wiper die.

The wiper die has a groove that is machined and ground to conform to the tube being bent and to fit the groove and lips of the form block, ending in a featheredge pointing toward the tangent point of the bend and extending to within 3.2 to 13 mm ($\frac{1}{8}$ to $\frac{1}{2}$ in.) of the tangent point. Although it is difficult to maintain this distance without deflection, it must be done meticulously if the wiper die is to prevent compression wrinkles. Wiper dies are machined from 52100 (or L2 tool steel) for low-carbon steel tubing or from aluminum bronze for stainless steel tubing. Wiper dies are never hardened.

Mandrels, which are described in detail in the following section of this article, are of three general types--rigid, flexible, and articulated--and are made to support the inside of the tube during bending. Rigid mandrels fit the interior of the tube, and are sometimes shaped to conform to the start of the bend. However, because they are rigid, they support the entire circumference of the tube only as far as the point of bending and not beyond the tangent of the bend. Plug mandrels and formed mandrels are included in this category.

Flexible mandrels bend with the tube. They are generally built up of shims or laminae. This type of mandrel is sometimes used with square tubes and box sections where only a few bends are needed. Inserting and removing flexible mandrels is usually difficult. Articulated mandrels include ball mandrels (discussed below) and various other shaped mandrels that are used in much the same way as ball mandrels.

Loose fillers such as sand and various low-melting alloys also serve as mandrels for low-production applications.

Dies used in press-type bending machines are similar to those described in the article "Bending of Bars and Bar Sections" in this Volume. Dies, including wing dies for bending presses, may have grooves for one to six tubes to be bent in one press stroke.

Formed rolls are used in the roll bending of tubes. Grooves corresponding to the outer surfaces of the tubes to be bent are cut or ground into the outer surfaces of the rolls so that they fit the surface of the tube as it is bent. A more complete description of the rolls used in roll bending is available in the article "Three-Roll Forming" in this Volume.

Bending Tubing With a Mandrel

Mandrels are sometimes used in bending to prevent collapse of the tubing or uncontrolled flattening in the bend. A mandrel cannot correct failure in bending after the failure has begun, nor can it remove wrinkles.

Figure 1 shows five types of mandrels used in the bending of tubing. The plug mandrel and the formed mandrel are rigid, but the three other types shown are flexible or jointed to reach farther into the bend.

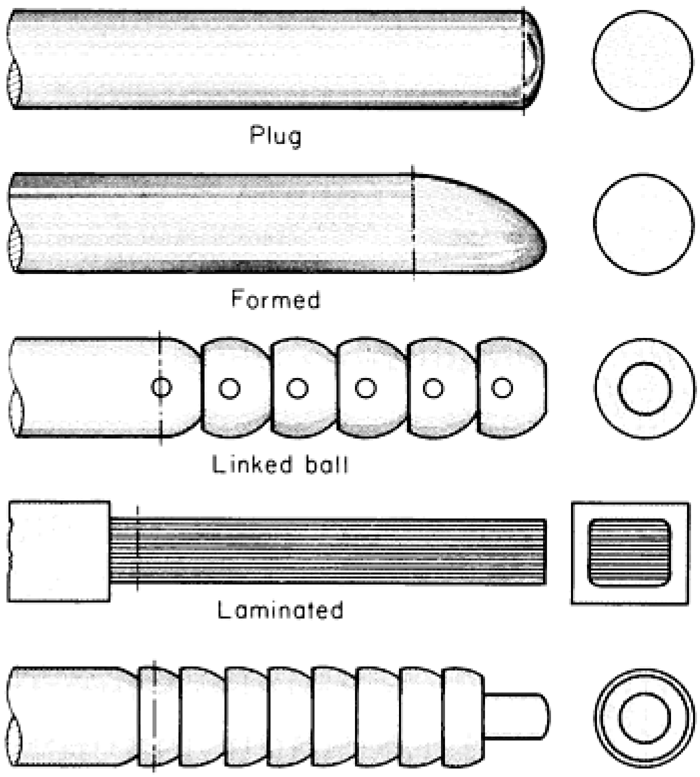

Fig. 1 Five types of mandrels used in the bending of tubing. Broken vertical lines are points at which bends should be tangential to mandrel centerlines.

The largest diameter of the rigid portion of the mandrel should reach a short distance into the bend; the distance that it extends past the tangent straight portion depends on the type of mandrel and the size of the tube and is usually established by trial. If the mandrel extends too far, it can cause a bulge in the bend. Conversely, if the mandrel does not extend far enough, wrinkles may form, or the outer tube surface may flatten in the bend area.

The need for a mandrel depends on the tube and bend ratios. The tube ratio is D/t, where D is the outside diameter and t is the wall thickness. The bend ratio is R/D, where R is the radius of bend measured to the centerline.

Table 3 can be used to determine whether or not a mandrel is needed for bending steel tubing. Figure 2 shows the usual conditions that require the use of a mandrel and what type of a mandrel is needed.

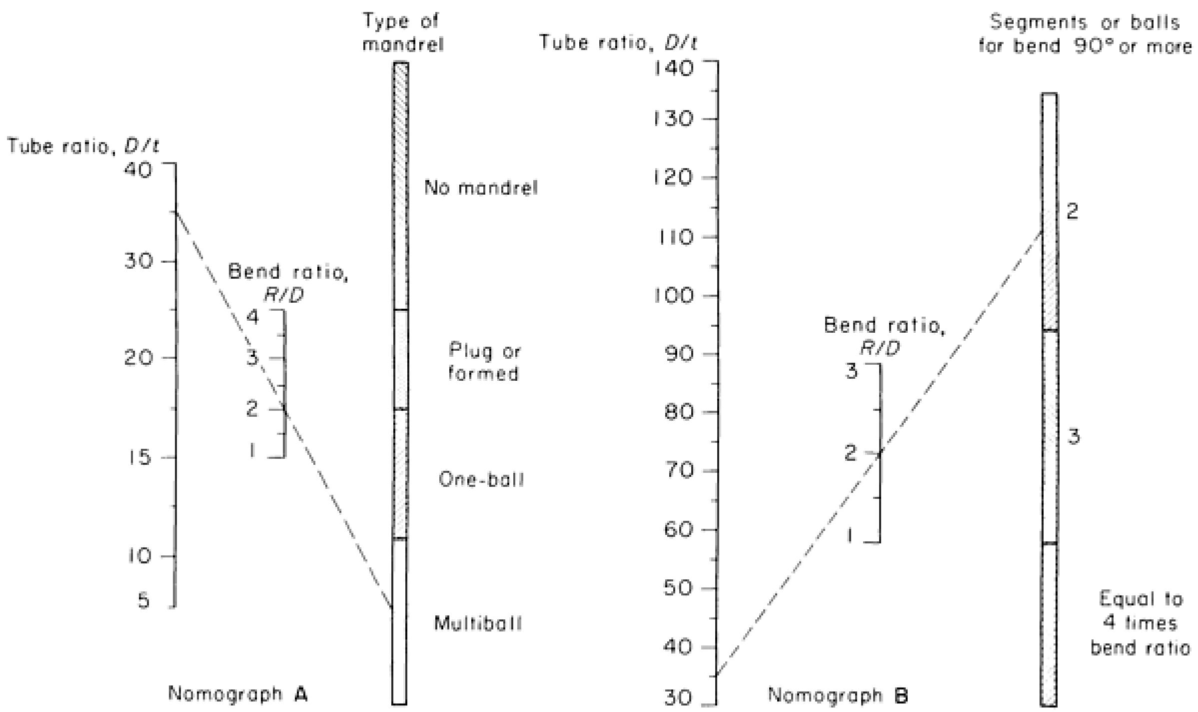

Fig. 2 Nomographs for determining when a mandrel is needed and the correct type to use. See text for explanation.

The nomographs given in Fig. 2 are used in two steps to determine if and when a mandrel is required and which specific type will suffice. In nomograph A, the first step is to find the tube ratio and the bend ratio in the left-hand and center scales and to lay a straightedge across them. The zone on the right-hand scale where the straightedge falls shows whether or not a mandrel is required, and which type. Bends for which D/t is more than 40 always require a multiball mandrel.

If a multiball mandrel is indicated, step two requires the user to refer to nomograph B in Fig. 2. As before, the tube ratio and the bend ratio are located in the left-hand and center scales and a straightedge is laid across them. The number of balls needed in the multiball mandrel will be indicated on the right-hand scale.

Plug and formed mandrels are fixed, and the tube is drawn over the tip of the mandrel in forming. This action work hardens the tube so that it resists flattening during bending. Clearance between the mandrel and the inside of the tube should not be more than 20% of the wall thickness. If the mandrel is too tight, the tube is likely to fail in the bend. Mandrels are necessary in tubes other than round in order to avoid distortion of the cross section. The use of plug and formed mandrels is shown in the following two examples.

Example 3: Use of a Plug Mandrel in Bending Welded Low-Carbon Steel Pipe.

A short length of 19 mm ($\frac{3}{4}$ in.) pipe (26.67 mm, or 1.050 in., OD by 2.87 mm, or 0.113 in., wall) of welded low-carbon steel was bent 90° to a 50 mm (2 in.) radius. Despite the thick wall, the small bend radius made it necessary to use a plug mandrel to support the pipe against flattening. Other tools used were a form block, a clamp, and a pressure die.

The bending machine was a power-driven rotary draw bender rated for a maximum of 25 mm (1 in.) extra-strong seamless low-carbon steel pipe (33.40 mm, or 1.315 in., OD by 4.55 mm, or 0.179 in., wall). The bends were made at the rate of 300 per hour.

Example 4: Bending Oval Tubing With a Formed Mandrel.

Oval tubing measuring 25 × 111 mm (1 × 4$\frac{3}{8}$ in.) in outside dimensions and with a wall thickness of 1.65 mm (0.065 in.) was bent on edge to make a U-shape with two 90° bends at 229 mm (9 in.) radius. The tubing was welded hot-rolled low-carbon steel. Wrinkles, shear marks, or other visible defects were not permitted.

The bends were made in a draw bender rated for 89 mm (3$\frac{1}{2}$ in.) OD by 2.10 mm (0.083 in.) wall thickness steel tubing with 276 MPa (40 ksi) yield strength. This piece, bent with a formed mandrel, form block, clamp, and pressure die, demanded the full rated torque of the machine. The mandrel was lubricated. The bends were made at a rate of 250 per hour.

Ball mandrels with one or more balls are used for many bends. During bending, the metal is stretched tightly over the mandrel, making withdrawal difficult. Withdrawal mechanisms are needed. In thin-wall tubing of softer metals, as the mandrel is withdrawn it sizes the bend somewhat, smoothing the stretched metal and correcting the shape of the cross section.

The bodies and balls of one-ball mandrels used on most tubing are commonly made of carburized low-carbon steel, hardened, ground, and polished. For the bending of stainless steels, they are made of polished aluminum bronze.

One-ball mandrels used in the bending of tubes up to 32 mm (1$\frac{1}{4}$ in.) in outside diameter generally have a body that is undersize 0.13 to 0.18 mm (0.005 to 0.007 in.), with a ball 0.25 to 0.36 mm (0.010 to 0.014 in.) smaller than the inside diameter of the tube. Square or shaped tubes require a mandrel that fits closer. If the bends are in one plane, the body and the ball of the mandrel can be grooved to clear weld flash or seams. More commonly, a mandrel is made undersize to clear the obstruction. When the workpiece must be bent in several planes, it can be reinserted with the seam in the groove, but it is usually better to specify tubing with a controlled weld flash.

Ball mandrels are often made with several balls, as shown in Fig. 1. The balls or segments are always smaller than the body, and they can be jointed by links and pins, ball joints, or steel cable. A linked or jointed mandrel is usually stronger than a comparable mandrel joined by steel cable. The linked mandrel bends in only one plane and is easier to load than one that is less rigid. The ball-jointed mandrel is also in wide use, and it has the advantage of having rotating balls to equalize wear. Ball-jointed ball mandrels are made in many sizes--down to one for tubes as small as 5.64 mm (0.222 in.) in inside diameter. Ball-jointed and steel cable ball mandrels cannot be grooved to clear weld flash and seams, because the mandrel segments rotate.

Many multiball mandrels make bends with a centerline radius that equals the outside diameter of the tubing. Ball mandrels can be used on bends that are not possible with formed mandrels.

Example 5: Multiball Versus Formed Mandrel in Forming a U-Shaped Bend.

A U-shape was produced by making two 90° bends in 32 mm ($1\frac{1}{4}$ in.) OD welded tubing of low-carbon steel in 1.24 and 1.65 mm (0.049 and 0.065 in.) wall thicknesses. The bend radius for both types of tube was 60 mm ($2\frac{3}{8}$ in.). Wrinkles, shear marks, or other visible defects were not permitted.

For the 1.65 mm (0.065 in.) wall thickness tubing, the bend was made with a formed mandrel, which adequately supported tubing of this wall thickness. However, a formed mandrel could not be used for the 1.24 mm (0.049 in.) wall thickness tubing. For the thinner-wall tubing, the D/t ratio was so large that it was necessary to use a well-lubricated three-ball mandrel and wiper die. The ball mandrel was required to support the outer wall in the bend area, and the wiper die was required to prevent wrinkling caused by compression in the inner wall of the bend.

The machine used was a draw bender rated for steel tubing with 89 mm ($3\frac{1}{2}$ in.) OD, 2.10 mm (0.083 in.) wall, and 276 MPa (40 ksi) yield strength.

If the formed mandrel had been used in bending the 1.24 mm (0.049 in.) wall tube, the tube would have deformed excessively from inadequate support. A formed mandrel would have to be advanced farther into the bend area than is normally done. This would cause a hump and greater thinning of the tube wall where the outside of the bend was stretched over the end of the mandrel. When wall thickness is less than approximately 1.24 mm (0.049 in.), this technique should not be used, because there is not enough metal to take the stretch without breaking.

Clearances for mandrels vary from 0 (to produce some bends the mandrel is forced into thin-wall tubing) to 2.41 mm (0.095 in.) or more. The clearance needed depends on stock material, wall thickness, bend radius, and quality of the bend. The better the bend, the more closely the mandrel must fit.

Mandrels are even more necessary in bending nonround tubing than in bending round tubing (see Example 4). Segmented mandrels must be used in almost all bending of square, hexagonal, and octagonal tubing. The number of segments that are needed in the mandrel usually depends on the wall thickness of the tubing.

Chromium plating extends the life of some mandrels, and the plating can be renewed for further use. Platings should not be more than 0.008 to 0.013 mm (0.0003 to 0.0005 in.) thick because thicker platings may flake off. Plated mandrels should be stripped and replated when the plating is worn through at any point. Polished mandrels usually work best, but ground or machined surfaces are satisfactory when slight marking on the inside of the tube is acceptable.

The bending of a fragile thin-wall tube may require the careful use of a multiball mandrel and a wiper die. If the bend is changed to a larger radius or if a stronger or thicker-wall tube is substituted, the mandrel can be changed to a less complicated one, and the wiper die may not be needed. A plug or form mandrel can sometimes be used instead of a multiball mandrel, even when the bend is made to the minimum practical radius.

Dimensional Accuracy. Regardless of other conditions, when accuracy is important, the use of a mandrel is mandatory. The following example describes an application that illustrates the degree of accuracy that can be achieved by using a mandrel.

Example 6: Use of a Plug Mandrel to Hold Close Tolerance on Four Bends.

The tube shown in Fig. 3 was used in a return-line manifold of a high-pressure hydraulic system on a large tractor. The radius of each of the four bends was required to be within ±1°. Overall length was required to be within ±0.38 mm (±0.015 in.).

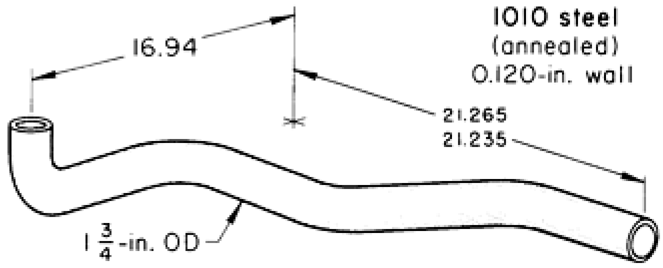

Fig. 3 Manifold tube that was bent to an accuracy of ±1° on each of four bends. Dimensions given in inches.

To achieve this degree of accuracy, a considerable amount of tool adjustment was required during each setup. From two to six tubes were bent before acceptable tubes were produced. To produce a lot of 40 tubes, 2$\frac{1}{2}$ man-hours were required, including setup.

Bending was done in a powered draw bender, using a round-end plug mandrel. The mandrel had a drilled hole to deliver a constant flow of lubricant inside the tube during bending. The lubricant was a mixture of lard oil and low-viscosity mineral oil.

Mandrel Materials. Most mandrels are made of tool steel (W1, O1, A2, and F1 are typical selections) and hardened to 55 to 60 HRC.

Bending Tubing Without a Mandrel

It is less expensive to bend tubing without a mandrel. Trial bending is generally necessary to determine which bends can be made. Tubing with thick walls is more likely to be bendable without a mandrel than thin-wall tubing. Bends with large radii are more likely to be formable without a mandrel than those with small radii. Slight bends are more feasible than acute bends. Wide tolerances on permissible flattening make a bend easier to form without a mandrel. Springback is greater without a mandrel, but it can be compensated for by overbending or lessened by increasing force on the pressure die.

Machines

The machines used in the bending of tubes are essentially the same as those used in the bending of bars (see the article "Bending of Bars and Bar Sections" in this Volume). In general, bending machines fall into three categories: rotary benders (stretch, compression, and draw bending), press benders (stretch and compression bending), and roll benders.

Powered rotary benders are commonly used to bend tubing as large as 203 mm (8 in.) in outside diameter. At least one machine can bend tubing as large as 305 mm (12 in.) OD with a 6.4 mm ($\frac{1}{4}$ in.) wall, and a few special power benders can bend 457 mm (18 in.) pipe.

Boilermakers normally use power benders that can bend 75 mm (3 in.) OD steel tubing with 13 mm ($\frac{1}{2}$ in.) wall to a centerline radius as small as 75 mm (3 in.). The following example describes the use of rotary benders.

Example 7: Bending Steel Tubing for Automobile Seat Frames.

Steel tubing with 25 mm (1 in.) OD and 1.24 mm (0.049 in.) wall was bent 90° to make the frame for automobile seats. The inside of the bend was collapsed into a dimple for clearance, but most of the column strength was maintained by holding the shape of the outside of the bend. This was done in part by collapsing the inner wall of the tube over a convex punch instead of a conventional groove. The centerline radius of the 90° bend was 16 mm ($\frac{5}{8}$ in.). The bends were made two at a time in a fast rotary bender.

Bending presses are hydraulic machines that are made especially for bending both bars and tubes, but most often for tubes. The ram of a bending press can be stopped at any point in the stroke. Wing dies and a cushioning device help to wrap the work around the ram die, as shown in Fig. 4. When the ram moves down, it causes the wing dies to pivot by a camming action and to wrap the workpiece around the ram die. The wing dies wipe the work to control the flow of metal; a compression bend is made on each side of the ram die, without wrinkles or distortion.

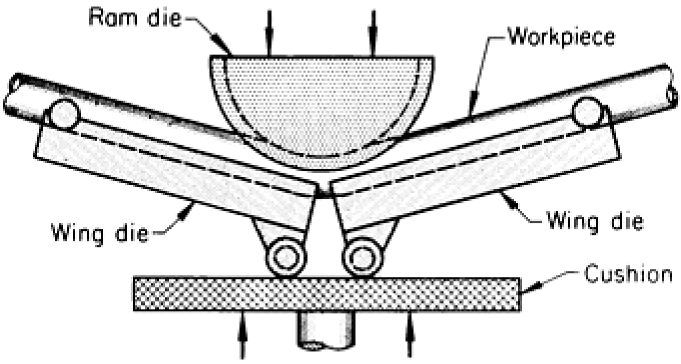

Fig. 4 Essential components and mechanics of a bending press.

A bending press can usually make bends much faster than machines that are not made especially for bending. The open design of the press makes possible the bending of complex shapes in one setup. Single bends can be made sequentially, or the press can make several bends simultaneously. Bends can be made to various angles and in various planes. The tube or bar is usually passed through the press in one direction, and the press makes a sequence of bends automatically. The work is held against stops to locate each bend.

When several bends are made in one or more workpieces at each stroke of the press, all bends are in the same plane. Different angles and bend radii can also be made in the same workpiece, and the angles and spacing of bends can be adjusted. One disadvantage of the bending press is that it causes a slight reduction in the thickness of the workpiece at the bend.

Automatic bending presses are used for production bending. Capacities are 26 to 360 kN (3 to 40 tonf) for bends that generally do not exceed 165°. Bends in the same plane should be separated by a distance equal to twice the outside diameter of the tube. Bends in different planes should be separated by a distance equal to at least three times the outside diameter of the tube. If the bent portion is to be joined with another bend into an accurate circle, the length of the straight legs on each end of the bend should be at least twice the outside diameter of the tube. Bends can be made beyond these limits, but at greater cost. Bends are usually made in dies that are slightly tight on the tubes to prevent flattening and wrinkling. Exhaust pipes for automobiles, with bends in various planes, are made in automatic bending presses, as in the following example.

Example 8: Forming Automobile Exhaust Pipes From 1010 Steel Welded Tubing.

Figure 5 shows an exhaust pipe 2.1 m (82 in.) long with bends to bypass the obstructions on the underside of a vehicle. These pipes were made of hot-rolled or cold-rolled 1010 steel welded tubing with 44 mm ($1\frac{3}{4}$ in.) OD and 1.52 mm (0.060 in.) wall. Hardness was 63 to 78 HRB.

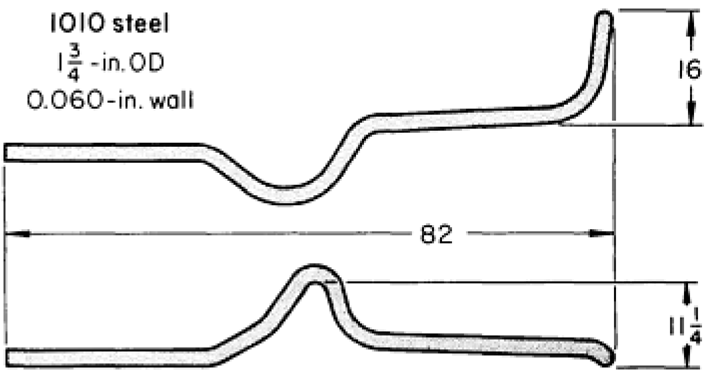

Fig. 5 Automobile exhaust pipe produced in an automatic hydraulic bending press. Dimensions given in inches.

Bending was done in an automatic 180 kN (20 tonf) hydraulic bending press, using a punch with a 127 mm (5 in.) centerline radius in the groove and two wing-die shoes. Locating fixtures and a checking fixture (off the press) were also used.

The press made different angles of bend by using turret-mounted stops to control the stroke. The location of the bend was set by backstops at the right side of the press. Counting the plane of the first bend as 0°, the radial position (roll of the tube) for the plane of each bend in turn was located by stops along a bar on the left of the machine. In loading the tubes for the first bend, it was important to keep all weld seams in the same place so that all tubes would bend alike.

The tube was nested in the wing-die shoes for the first bend, and the work was then moved by hand for each of the other bends. All the bends were standard. Tolerances were:

Angles of bend	**±0° 15'**
Angles of tube ends (all planes)	**±0° 30'**
Maximum depth of depressions and wrinkles	**3.05 mm (0.12 in.)**
Linear dimensions	**±1.52 mm (±0.06 in.)**

All the bends were made cold. The punch was set to clear the work by 13 mm ($\frac{1}{2}$ in.) for loading, and the total machine time to make five bends was 0.1305 min. Production was 130 pieces per hour on a 10,000-piece order.

Roll benders for bending tubes are similar to those used for bending bars, as described in the article "Bending of Bars and Bar Sections" in this Volume, but tolerances are more critical on the rolls and spacing. Roll benders are discussed in the article "Three-Roll Forming" in this Volume. The contour of the rolls must match that of the tube to minimize wrinkling or flattening. Tubes of sizes up to 203 mm (8 in.) OD by 6.10 mm (0.240 in.) wall can be bent into arcs, circles, or helixes. Rings are easily made on three-roll benders. Helix coiling is described in the following example.

Example 9: Coiling a Helix of Round Steel Tubing in a Three-Roll Bender.

Steel tubing of 50 mm (2 in.) OD and 6.10 mm (0.240 in.) wall was coiled in a three-roll bender into a helix 610 mm (24 in.) in mean diameter with 64 mm ($2\frac{1}{2}$ in.) pitch and 20 turns, as shown in Fig. 6. The tubing, 38.4 m (126 ft) long, was made by welding together random lengths 3.0 to 7.3 m (10 to 24 ft) long. The welds were then ground flush. The form rolls were contoured to fit the 50 mm (2 in.) outside diameter of the tubing. The tubing was started into the rolls so that it coiled without stop until the helix was completed. If the coiling had been stopped, the diameter of the helix might not have been constant. After coiling, the helix was removed and trimmed to length.

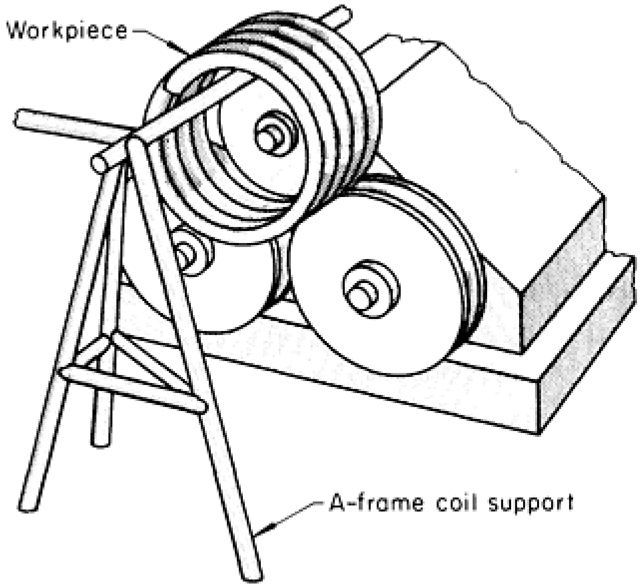

Fig. 6 Coiling a helix from round steel tubing by three-roll bending.

Hot Bending

Most of the bends described so far in this article have been made by cold bending (workpiece at room temperature). There are obvious advantages to cold bending:

- Heating equipment is not needed
- The benefits of previous heat treatment are not destroyed
- Subsequent cleaning or descaling is less likely to be needed
- Workpiece finish is better
- Thermal distortion is avoided

On the other hand, cold bending demands more energy than hot bending for the same bend. There is more springback after a cold bend and more residual stress in the tube. Bends cannot be made to as small a radius cold as they can hot.

Tubes are bent hot to make bends of small radius, adjacent bends with little or no straight tube between them, bends in material with little cold ductility, bends that take too much power to bend cold, and bends in fragile assemblies where the force of cold bending might cause damage. Temperatures and procedures in the hot bending of carbon, low-alloy, medium-alloy, and stainless steel tubes are summarized in Table 4. The disadvantages of bending tubes hot include high cost, slow production, and poor finish on bends.

Table 4 Temperatures and procedures for hot bending of steel tubes

Steel	**Temperature, °C (°F)**	Procedures
Carbon steels		
ASTM A106, A178, A192, A210	980-1095 (1800-2000) or <730-(1350)	**Do not heat beyond 1095 °C (2000 °F) and do not bend between 730 and 870 °C (1350 and 1600 °F)[(a)].**

Low-alloy steels		
ASTM A209, A213 (gr T11 and T22), A335 (gr P2)	980-1095 (1800-2000) or <730-(1350)	**Do not heat beyond 1095 °C (2000 °F) and do not bend between 730 and 870 °C (1350 and 1600 °F)[(a)].**
Alloy steels		
ASTM A213 (gr T5 and T9)	980-1095 (1800-2000)	**Do not heat beyond 1095 °C (2000 °F) and do not bend between 730 and 870 °C (1350 and 1600 °F)[(a)]. Heat treat after bending 730-745 °C (1350-1375 °F).**
Stainless steels		
Types 304, 310, 321	>1150 (2100)	**After bending, heat treat to 1095-1120 °C (2000-2050 °F). Furnace cool to 315 °C (600 °F); air cool[(b)].**
Type 446	**>1150 (2100)**	**Do not bend at less than 870 °C (1600 °F). Heat treat at 790-870 °C (1450-1600 °F); water quench.**

(a) Ductility is sometimes low in this range; therefore, the range should be avoided for hot bending.

(b) This treatment has proved best for maximum strength in service at elevated temperature.

Tubes of carbon steel and most alloy steels can be bent to a much smaller radius by hot bending than by cold bending. A bend radius of 0.7 to 1.5 times the outside diameter of the tube can usually be made by hot bending. The wall thickness of the tube affects this range. The tube wall must not be so thin that it will distort or thin excessively in the outer wall. If the tube ratio (outside diameter divided by wall thickness) is more than 10, the tube probably needs internal support in bending, unless there is some upsetting of the tube that thickens the wall.

Figure 7 shows the tube relations that can usually be successfully bent hot in a die but without a mandrel, and Fig. 8 shows the tube relations that can usually be successfully bent hot with a mandrel or filler. Figure 7 applies to tubes 38 to 75 mm (1.5 to 3 in.) in diameter; Fig. 8 is for tubes of all diameters.

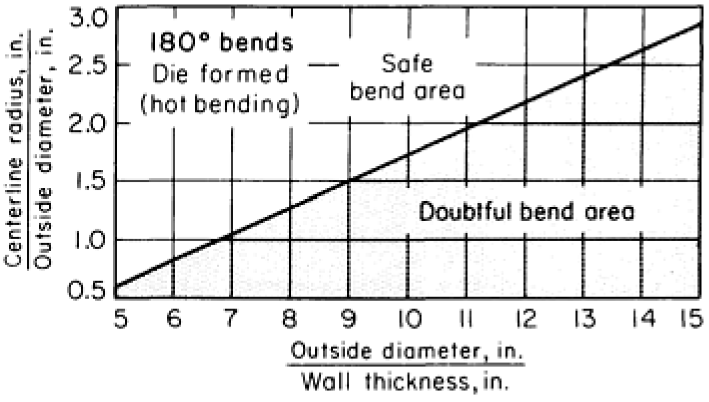

Fig. 7 Chart for determining conditions for the successful hot bending of tubes 38 to 75 mm (1.5 to 3 in.) in

diameter without the use of mandrel.

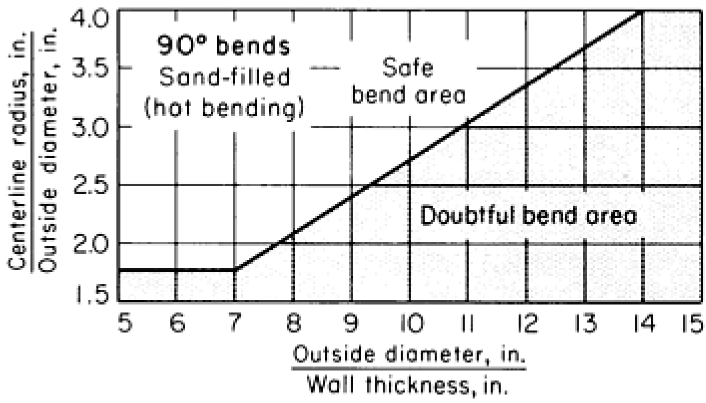

Fig. 8 Chart for determining conditions for the successful hot bending of tubes of all diameters with the use of a mandrel or filler.

If a mandrel is not practical for internal support of the tube, the tube can be packed with dry sand. First, a plate is welded to one end of the tube to block the end. The tube is filled with sand and is tamped or vibrated to make sure the sand is packed tight. Another plate is welded to the open end, the tube is heated, and the bend is made. Finally, the plates are cut off and the sand is emptied out. Various specialized techniques for bending tubes hot are described in Examples 10, 11, and 12.

Example 10: Five-Step Bending of a Tube.

Return bends for the coils of a boiler were made by bending 50 mm (2 in.) outside diameter carbon steel tube 180° on a 38 mm ($1\frac{1}{2}$ in.) centerline radius. The tube had a 6.60 mm (0.260 in.) wall. The sequence of operations was:

- Bend 180° on 114 mm ($4\frac{1}{2}$ in.) centerline radius in a conventional rotary bender
- Heat the bend area to 980 to 1095 °C (1800 to 2000 °F) in a furnace
- Reshape the bend to 50 mm (2 in.) radius in a bending press
- Close legs to 75 mm (3 in.) between centers in a vertical press
- Restrike in the vertical press to make bend radius 38 mm ($1\frac{1}{2}$ in.)

The last three operations listed above were performed in rapid sequence so that all bends were made before the tube cooled below 870 °C (1600 °F). Production rate was 30 pieces per hour.

Thinning of the outer wall can sometimes be controlled better in hot bending by heating only the part of the workpiece that will be the inner wall of the bend. This reduces its compressive strength so that the bend causes very little stretch of the outer wall. This method makes good bends with centerline radii of 1.3 to 1.5 times the outside diameter of the tube with the usual tooling in a rotary bender.

Boiler tubes are bent by heating one side for one-third of the way around the tube. The heated portion becomes the inside of the bend, and because it yields more easily in compression, thinning of the outer wall is limited. The tubes are bent to a U-shape in a bending machine. The U can then be reheated on the inside as before, and the bend can be squeezed in a press in one or more steps to make a narrower U, as in the following example.

Example 11: Localized Heating for a Compression Bend.

Return bends were made for use in the economizer of a boiler. The tube was made of carbon steel, 50 mm (2 in.) OD by 7.21 mm (0.284 in.) wall. The operations were:

- Heat the tube to 705 to 730 °C (1300 to 1350 °F) in a special burner that heated the bottom 120° of the tube for a 457 mm (18 in.) length where the bend was to be made (Fig. 9)
- Bend the tube in a rotary bender 180° to 190 mm ($7\frac{1}{2}$ in.) between centers with the heated portion on the inside of the bend
- Squeeze the tube between dies in a hydraulic press to 152 mm (6 in.) between centers
- Squeeze, as in the third step, to 121 mm ($4\frac{3}{4}$ in.) between centers
- Squeeze, as in the third step, to 89 mm ($3\frac{1}{2}$ in.) between centers
- Reheat the entire surface of the bend for 203 mm (8 in.) on each side
- Size in a die
- Squeeze, as in the third step, to 64 mm ($2\frac{1}{2}$ in.) between centers
- Normalize

The production rate, with three men working, was 20 bends per hour.

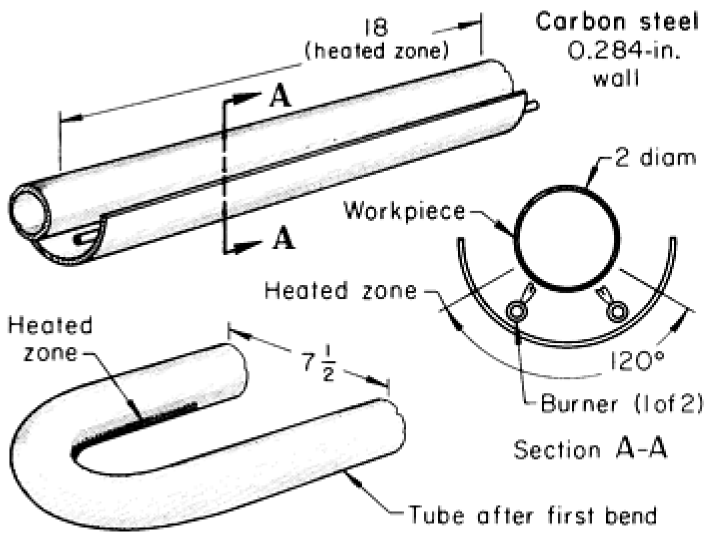

Fig. 9 Compression bend produced in tubing, and special burner used for localized heating of the workpiece before bending. Dimensions given in inches.

Dry Sand as Filler. Large tubes are commonly bent hot while they are filled with dry sand. The bending is done on a bending table made of cast iron plates. The plates have a continuous pattern of cored holes. A bending form for the desired radius is bolted to the bending table. Steel pins or stops can be placed in the holes in the table to keep the work in line. A clamshell furnace in sections is the usual source of heat. Winches, jacks, and hoists supply the bending force. A typical application is described in the following example.

Example 12: Hot Bending a Large Tube on a Cast Iron Bending Table.

A 180° bend with a 381 mm (15 in.) radius was made near the center of a 4.6 m (15 ft) length of steel tube, 184 mm ($7\frac{1}{4}$ in.) OD by 25 mm (1 in.) wall. A plate was welded to one end of the tube to close it. The tube was dropped, closed-end down, into a pit and was filled with sand. The tube was vibrated and tamped to make sure the sand was well compacted, and the open end was closed with another welded-on plate.

The bending table was set up for the bend. The proper form block was bolted to the table, and lines tangential to the bend were laid out for proper location of stop pins (Fig. 10).

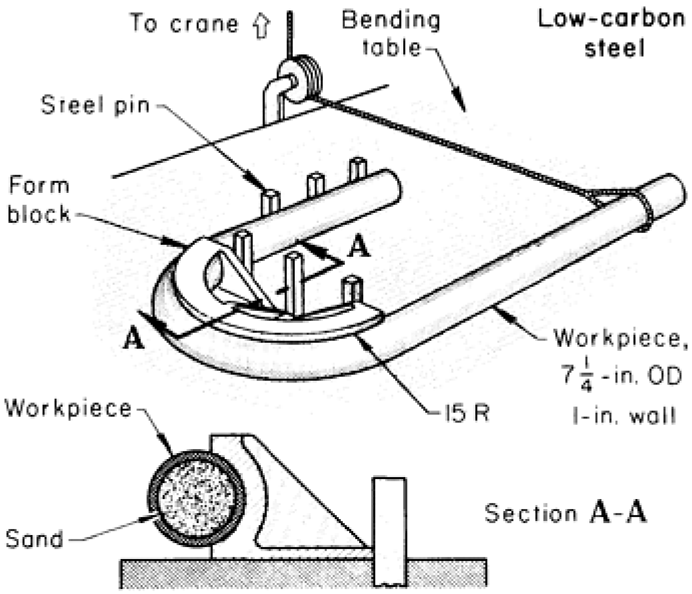

Fig. 10 Final position in the hot bending of a large sand-filled tube.

The tube was heated to 980 to 1095 °C (1800 to 2000 °F) in a clamshell furnace and set on the bending table. One end was clamped down to the table. The other end was pulled by a cable, which, guided by a series of strategically located pulleys fastened to the table, bent the tube incrementally around the form block to the final position shown in Fig. 10.

When the bend passed inspection, the ends of the tube were cut off and the sand was poured out. The entire process, including preparation and handling, took 45 min.

Hot Versus Cold Bending. The selection of hot or cold bending can depend on available equipment, the cost of new equipment, labor costs, the urgency of the job order, and the size of the production lot.

Tube Stock

Tubes are classed as seamless, welded, lock-seam, butt-seam, and jacketed.

Steel tubing is available both seamed and seamless. Seamed tubing with internal flash demands special consideration when a mandrel is to be used in bending (see the section "Bending Tubing With a Mandrel" in this article).

Lock-seam tubing can be bent if the seams are tight. A test is to twist a 914 mm (3 ft) long section of tubing in the hands; any grating or slipping indicates a seam too loose to make good bends.

Butt-seam tubing is similar to welded tubing but with no weld at the joint; it is seldom used. To make good bends, it must be accurate in dimensions, have no scale, and be bent with the seam in the plane of the bend. A mandrel must always be used. It is more economical to use welded tubing.

Stainless steel jacketed tubing is made by roll forming a sheet of stainless steel onto a butt-seam tube of low-carbon steel. The stainless steel jacket is rolled into a lock seam in the open seam of the inner tubing. For best bending, the stainless steel jacket should be at least 0.51 mm (0.020 in.) thick, and the two layers should be rolled tightly together. Tools for bending such jacketed tubing cost more than tools for bending plain tubing; an aluminum bronze wiper die, a hardened steel mandrel, and unusually high pressure on all tools are required, and all of these add to the cost of the tooling. In addition, the seam must be in the plane of the bend, either inside or outside.

Galvanized steel tubing can be bent to a radius as small as four times the outside diameter. For tube to be bent to smaller radii, galvanizing should be done after bending, because the galvanized coating is likely to flake if galvanized stock is used.

Aluminum-coated tubing (hot dipped) can be bent by essentially the same techniques used for uncoated tubing of the same diameter and wall thickness, using slightly higher clamping pressures to avoid slipping. Additional information is available in the article "Press Forming of Coated Steel" in this Volume.

Seamless tubing should be free of scale or rust. Wall thickness, concentricity, and hardness vary in seamless steel tubing. These variations are likely to cause variable springback, wrinkles, and excessive flattening. Common pipe in all sizes and thicknesses is easily bent if it is clean and free of rust or scale, inside and out.

Stainless steel tubing can be bent to a greater angle, at a given radius, than low-carbon steel. Austenitic types in the 300 series are most commonly bent because they are strong and ductile. Tubing in a stabilized condition at a temper no higher than quarter hard will make good bends with low scrap rates. Both welded and seamless tubing are available. Thin-wall tubes should have the exact diameter and wall thickness specified. Annealing is usually recommended after bending operations.

Copper alloy tubing is usually extruded. It is easily bent in the annealed condition, and it has little springback. Copper and some brasses may not need to be annealed. Copper-nickel alloys, however, are more difficult to bend and have greater springback.

When copper alloys are annealed, as most of them are, oxides should be removed by pickling before the tube is bent to protect the tooling. Oxides increase friction and wear in bending.

Aluminum alloy tubing, like copper alloy tubing, is usually extruded, or extruded and drawn. Soft aluminum may tear or collapse upon bending. The oxide coating that forms on exposed surfaces of aluminum alloys is abrasive to tooling. Lubrication prolongs tool life.

Anodized aluminum and decorated aluminum can usually be bent without damaging the finish. Aluminum pipe is bent by hand to a radius usually not less than four times the outside diameter. The bending of aluminum tubing is discussed in the article "Forming of Aluminum Alloys" in this Volume.

Bending Thin-Wall Tubes

The techniques used to bend thin-wall tubes are the same as those used to bend standard tube and pipe, but they are more carefully applied. A tube can be classified as thin wall if the ratio of outside diameter to wall thickness (*D*/*t*) is greater than 30 to 1. The wall thickness, if not related to the tube diameter, is a meaningless measure. For example, a tube wall 0.51 mm (0.020 in.) thick would be a standard wall thickness for a tube 3.2 mm ($\frac{1}{8}$ in.) in outside diameter, but for a 152 mm (6 in.) tube it would be a very thin wall. The centerline radii given in Table 5 for bending tubing of various *D*/*t* ratios with a ball mandrel and a wiper die are conservative and are often exceeded.

Table 5 Average practical centerline radii for bending thin-wall steel tubing with a ball mandrel and wiper die

(a) No wiper die required

Machines used to bend thin-wall tubing have a greater capacity than necessary so that they will be stable and rigid. Their bending action must be smooth and steady. Run-out on machine spindles should not exceed 0.013 mm (0.0005 in.). Mandrel rods must be heavy enough so that they do not stretch or buckle when the slip-fitting mandrel is inserted into the tubing.

Auxiliary equipment includes:

- A means for pressurizing the tubes with air or hydraulic oil (hydrostatic mandrel) to keep them from necking after they are drawn past the last mandrel ball
- Hydraulic feed on pressure dies to hold tubes in compression

- Mandrel oscillators that move the mandrel back and forth to keep the tubes from necking down

The amplitude of mandrel oscillation can be adjusted from 3.2 to 25 mm ($\frac{1}{8}$ to 1 in.); frequency, from 1 to 500 cpm.

Tools for bending thin-wall tubes must be more accurately made than those for standard tubes. The form block or bending die should have a run-out at the bottom of the groove of not more than 0.025 mm (0.001 in.). The depth of the groove should equal 55% of the outside diameter of the tube. The width of the groove should equal the outside diameter of the tube plus 10% of the wall thickness. The width of the clamping groove on the bending die should equal the outside diameter of the tube minus 10% of the wall thickness. The length of the clamping groove should be five to six times the outside diameter of the tube unless special clamping provisions such as flaring or clamping cleats are included. The clamp and the bending die can be keyed or doweled for perfect alignment. Clamping plugs are sometimes used; these should either be slip fitted in the tube or expandable.

The pressure die should have a groove wider than the tube outside diameter by an amount equal to 15% of the wall thickness. The width should not vary from end to end by more than 0.013 mm (0.0005 in.). Variation in the groove will cause a pinching or relieving effect. If all tools are properly adjusted, only light pressure is needed on the pressure die, which can be adjusted against a solid bar with the same diameter as the outside diameter of the tube.

The wiper die has a groove whose width is equal to the outside diameter of the tube plus 10% of the wall thickness. The groove should be highly polished and have a thin coat of light oil. Too much or too heavy oil will cause wrinkles. The groove must be a full half-circle in cross section to support the entire inner half of the tube. The groove must also fit closely to the form die for at least 15° back of the point of bend so that it cannot be forced away by the pressure buildup of the compressed inner wall of the bend. Failure to maintain the position of the wiper die can cause wrinkles.

Multiball mandrels are generally used with thin-wall tubes. They have a clearance no greater than 10% of the wall thickness of the tube. The mandrel must be positioned very carefully so that the full diameter of the body is just at the start of the bend (first ball of cable or ball-socket mandrels at the bend tangent). A template should be used to set the mandrel. If auxiliary oil or air pressure in the tube is not used, there must be enough balls to reach completely around the bend.

Interlock tooling is sometimes used for bending thin-wall tubes. The clamp is keyed to the form block, the wiper die is locked to the pressure die, and the pressure die is locked into alignment with the form block. Interlock tooling was specifically developed for automatic bending; but it has some advantages for general bending. The tools will not crush or mark the work, and setup time and scrap can be reduced.

Material should be especially uniform in thin-wall tubing that is to be bent and should all be from the same source--preferably the same heat. Because tooling dimensions are held closely, close-tolerance tubing is recommended despite its added cost.

Production Example. Thin-wall tubing is frequently bent to elbows that have a centerline radius equal to the diameter, and it is not uncommon for the diameter to be as much as 90 times greater than the wall thickness--for example, a 152 mm (6 in.) diam tube with a 1.65 mm (0.065 in.) thick wall. Many such elbows are used in vacuum-line service, an application in which no wrinkles are permitted. They are commonly made from 1020 steel tubing in the as-received condition. Bends are made with ball mandrels, wiper dies, and an oil-base lubricant. Some manufacturers of elbows use chromium-plated tools to minimize tool wear.

It is often difficult to prevent thin-wall tubing from slipping during bending. Methods used to provide adequate clamping are described in the following example.

Example 13: Procedures to Prevent Slipping of Tubes During Bending.

The tube shown in Fig. 11 was used in a high-pressure hydraulic circuit of an earthmover. Five bends, ranging from approximately 20 to 86°, were made in a powered compression bender. All bends were made on a 152 mm (6 in.) centerline radius.

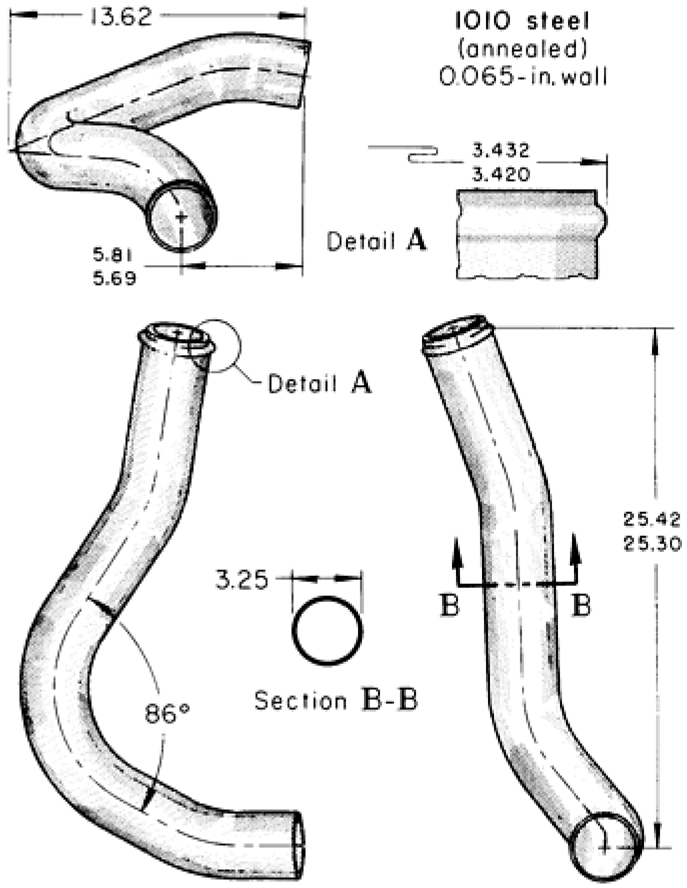

Fig. 11 Component of a hydraulic system that required five bends. Dimensions given in inches.

The 86° bend posed a problem because only 127 mm (5 in.) of tube was available for clamping; adjacent bends were in other planes. Surfaces of the clamps were rough, but the tube slipped during bending, causing unacceptable bends. The first approach was to line the clamps with emery cloth, but this did not add enough friction to prevent slipping. A second approach was to increase the force on the clamp. Until a hydraulic cylinder could be installed to provide this force, a factory lift truck was used. Acceptable bends were produced by increasing the force on the pressure die.

The tubing had a phosphate coating. A three-ball mandrel with an oil hole provided a constant supply of lubricant (a mixture of lard oil and mineral oil) to the inside of the tube. Tools were of W1 or W2 tool steel, hardened.

Lubrication for Tube Bending

Where a mandrel is used, both the mandrel and the interior of the tube are heavily coated with a thick lubricant. Pigmented lubricants are useful for adding body between the mandrel and the tube. Thick lubricants are sometimes heated to 120 °C (250 °F) and sprayed onto the inner surface of the tube. An oil hole in a mandrel can be used to lubricate the inside of a tube during bending (Example 13).

The wiper die, on the other hand, needs only a very light lubricant, applied sparingly, if at all. Nothing must interfere with the close fit between wiper die and tube, which prevents compression wrinkles.

Not all metals react to lubricants in the same way. In general, mineral oils are always acceptable, as are organic fats. Certain sulfur and chlorine additives can stain or corrode stainless steel or copper and should be used with caution. For aluminum, special additives have been developed for use with light or medium mineral oil; the same formulations work well on copper and brass.

Tube Spinning

Revised by Jack D. Stewart, Sr., Stewart Enterprises, Inc.

Introduction

TUBE SPINNING is a rotary-point method of extruding metal much like cone spinning, except that the sine law (see the article "Spinning" in this Volume) does not apply. Because the half angle of a cylinder is zero, tube spinning follows a purely volumetric rule, depending on the practical limits of deformation that the metal can stand without intermediate annealing. Tube spinning is also limited by the smallest percentage reduction in thickness that will ensure complete flow of the metal. This minimum reduction is usually 15 to 25%, depending on the metal and on the thickness of the original tube.

Applicability. Spinning is one method of reducing the wall thickness of tubular shapes and increasing their strength, particularly for aircraft and aerospace applications. Producing specific shapes from tubing is a major function of tube spinning. For example, one or more flanges can be spun at selected areas on a tube, often at a savings in labor and material costs when compared with other processes such as machining. Tube spinning has also been used because ring forgings having the desired relationship between wall thickness and length were not available.

All ductile work metals are suitable for tube spinning; the practical ranges of compositions and strengths are approximately the same as for the power spinning of cones. Metals as hard as 35 HRC have been successfully spun. Most tube spinning is accomplished without heating the workpiece.

The amount of wall reduction that can be accomplished without intermediate annealing is given for a number of metals in Table 2 in the article "Spinning" in this Volume. The amount of permissible reduction is often greater for the spinning of tubes than for the spinning of cones or hemispheres, particularly in the case of backward spinning.

The range of tube sizes that can be spun depends primarily on the available equipment. Tubelike preforms that have an inside diameter in a range from 4.75 mm to 3 m (0.187 to 120 in.) have been successfully spun. Wall thicknesses of the starting tubes are often as great as 25.4 mm (1.0 in.) for steel and 31.8 mm (1.25 in.) for aluminum and under ideal circumstances have exceeded 41.3 mm ($1\frac{5}{8}$ in.) for steel and 63.5 mm ($2\frac{1}{2}$ in.) for aluminum.

The minimum size of tube that can be spun is more likely to be a limiting factor than the maximum size, because of machine characteristics. For example, a large machine is not well suited to spinning small tubing, because it has insufficient spindle speed. The relationship between spindle speed and tube size should be such that a minimum of 120 m/min (400 sfm) can be obtained. Very small (<9.5 mm, or 0.38 in., diam) tubes are usually spun on machines that hold the tube stationary while the tool rings rotate around it.

Preform Requirements. Preform is the name commonly applied to a tube or a tubular shape before it is spun. A preform may be a straight, symmetrical tube, or it may have been changed in shape by the addition of an internal flange for clamping. Tubular shapes used for spinning include forged or centrifugally cast tubes (both of which are completely machined before spinning), welded tubing, seamless tubing, and extruded tubing.

For spinning, the inside diameter should vary no more than ±0.051 mm (±0.002 in.) on tubes up to 76 mm (3 in.) in inside diameter or no more than ±0.152 mm (±0.006 in.) on tubes with inside diameters of 75 to 510 mm (3 to 20 in.). Tolerances of +0.5, -0 mm (+0.020, -0 in.) are typical for tubes 635 mm to 1.27 m (25 to 50 in.) in diameter; tolerances of +0.75, -0 mm (+0.030, -0 in.) are used for larger sizes. The roundness and wall thickness of the preform will also affect tolerance. A 41.3-mm ($1\frac{5}{8}$-in.) wall thickness, 3-m (120-in.) preform will usually have at least 1.7 mm (0.067 in.), and frequently 4.75 mm (0.187 in.), of positive tolerance to permit loading.

The wall thickness of the preform should be within ±0.075 mm (±0.003 in.) unless the preform is machined all over in which case wall thickness should be within ±0.025 mm (±0.001 in.). Ovality should be within 0.05 mm (0.002 in.) for small-diameter preforms within 0.30 mm (0.012 in.) for large diameters.

Tube Spinning

Revised by Jack D. Stewart, Sr., Stewart Enterprises, Inc.

Methods of Tube Spinning

Two distinctly different techniques are used for tube spinning; namely, backward and forward. They are so termed because of the directional relationships between metal flow and tool travel. In both methods, the workpiece is fixed in one position at one end, and the remaining length is free to slide along the mandrel.

Backward Spinning. In backward spinning, the workpiece is held against a fixture on the headstock, the roller advances toward the fixed end of the workpiece, and the work metal flows in the opposite direction (Fig. 1a). Two advantages of backward spinning over forward spinning are:

- The preform is simpler for backward spinning because it slides over the mandrel and does not require an internal flange for clamping
- The roller traverses only 50% of the length of the finished tube in making a 50% reduction of the tube wall, and only 25% of the final length for a 75% reduction

The latter advantage not only increases production but also allows workpieces to be spun that are beyond the normal capacity of the machine. For example, a machine having only a 1.27-m (50-in.) length of stroke can produce a workpiece 2.54 m (100 in.) long using a 50% reduction. Backward tube spinning is also unique in that the majority force distribution is compressive. Consequently, metals with relatively low ductility can sometimes be backward spun to significant reductions.

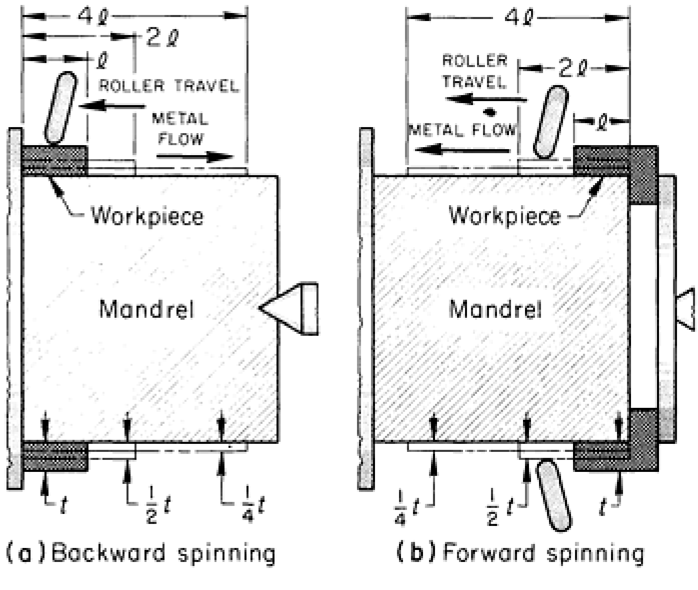

Fig. 1 Metal flow and roller travel in backward and forward tube spinning.

The major disadvantage of backward tube spinning is that the first portion of the spun tube must travel the greatest distance and is therefore the most susceptible to distortion (Fig. 2). This disadvantage is seldom critical when spinning tubes of constant wall thickness. However, when the preform has weld sculptures of substantially greater thickness than the tube wall (as in solid fuel rocket cases), distortion can be a problem. For example, in backward spinning of the tube shown in Fig. 2, one side became an inch longer than the other, even though the preform was essentially perfect and the mandrel was accurate within 0.038 mm (0.0015 in.) total indicator reading.

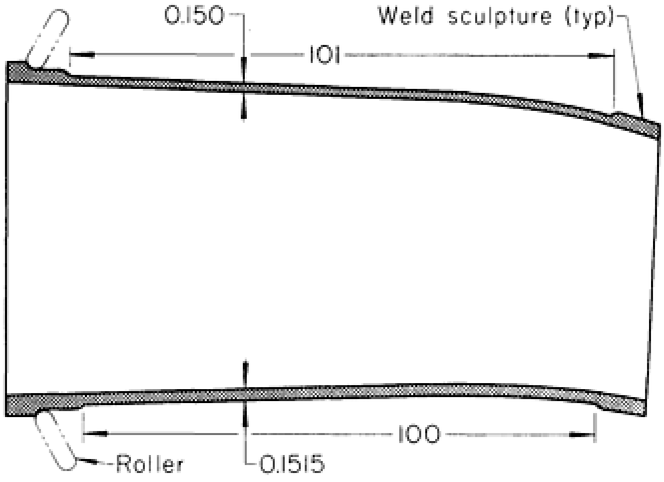

Fig. 2 Example of distortion in backward tube spinning. See text for explanation. Dimensions given in inches.

Forward Spinning. In forward spinning, the roller moves away from the fixed end of the workpiece, and the work metal flows in the same direction as the roller, usually toward the headstock (Fig. 1b). The main advantage in forward spinning as compared to backward spinning is that forward spinning will overcome the problem of distortion (Fig. 2). In forward spinning, closer control of length is possible because as metal is formed under the rollers it is not required to move again, and any variation caused by the variable wall thickness of the preform is continually pushed ahead of the rollers, eventually becoming trim metal beyond the finished length.

The disadvantages of forward spinning are that:

- Some arrangement such as the one illustrated in Fig. 1(b) must be made for clamping the preform to the mandrel at the tailstock end
- Production is slower in forward spinning because the roller must traverse the finished length of the workpiece

Tube Spinning

Revised by Jack D. Stewart, Sr., Stewart Enterprises, Inc.

Machines for Tube Spinning

Machines used for tube spinning are usually the same as those used for the power spinning of cones or other shapes. The few special features required for tube spinning are normally specified and can be supplied on all power spinning machines. A power spinning machine will have the same size capacity for tube spinning as for cone spinning. A 1.9 × 2.5-m (75 × 100-in.) machine has the capacity to spin a tube 1.9 m (75 in.) in diameter 2.5 m (100 in.) long. Machines available have the capacity to spin tubes ranging in size from 457 mm (18 in.) in diameter to 3.8 m (150 in.) long. The length dimension applies to the travel of the roller, or tool carriage, so that by using backward tube spinning it is possible to produce a workpiece much longer than is indicated by the size of the machine. The maximum size of the workpiece that can be produced using the backward technique is limited by two considerations:

- The amount of reduction that can be taken on the final spinning operation (a 50% reduction would result in a tube twice as long). The machine force capacity and work metal characteristics will determine the possible reduction
- The clearance provided for workpiece removal. A machine with a capacity of 1.27 m (50 in.) usually

has enough tailstock motion so that a workpiece 1.27 m (50 in.) long can be removed from a mandrel 1.27 m (50 in.) long. Many machines have been built with greater-than-standard tailstock clearance so that backward tube spinning can be used to the greatest advantage

The capacity in terms of force for spinning cones is seldom specified for tube spinning. A machine with the force capability for spinning a 25-mm (1-in.) thick plate into a cone through a 50% reduction in one operation does not have the capability of reducing a tube with a 25-mm (1-in.) thick wall 50% in one pass. Therefore, most tube spinning is done in smaller reductions per pass.

Cone spinning is a shearing-type operation, while tube spinning is similar to extrusion, which requires higher compressive forces. This has been determined by sectioning blanks, scribing the surfaces in block patterns, silver brazing them together, spinning them (both shear and tube), and resectioning to expose the scribed surfaces. In the shear-spun parts, the material is displaced along a shear plane, the square blocks resembling parallelograms; in the tube-spun parts, the squares are elongated in the direction of the axis of the tube, but are compressed in the radial direction.

Most tube spinning is done on machines with two opposed rollers. This practice minimizes the deflection caused by spinning with one roller when the length-to-diameter ratio of the mandrel and workpiece is large. Even on machines employing opposed rollers, when the length-to-diameter ratio is excessively large, deflection of the mandrel is often a problem because the mandrel and workpiece are pushed off center. To counteract this problem, machines have been built with more than two rollers. When three or more rollers are used, they have the same centering effect as a steady rest.

Most modern tube-spinning machines are numerically controlled by computers. For spinning straight tubes, mechanical stops can be used to limit the travel of the cross-slide unit and thus control the diameter of the workpiece. Numerically controlled machines, however, are rarely run against such stops; computer control offers greater flexibility and the advantage of compensating for deflection and taper. At least one very large machine has been retrofitted with laser detectors to compensate for column deflection automatically. Accuracy with this system is in the range of ±0.038-mm (0.0015-in.) wall thickness over more than 2.54 m (100 in.) in length at a nominal 2.54-mm (0.100-in.) wall thickness.

Revised by Jack D. Stewart, Sr., Stewart Enterprises, Inc.

Tools for Tube Spinning

The tools required for tube spinning are a mandrel, rollers (two are usually required), a puller ring (for removing the workpiece from the mandrel), a drive ring (which can also be used as a puller ring), and a control system (such as computer numerical control or a tracer system).

Mandrels. Many mandrels for tube spinning are made solid. However, as size increases and weight becomes excessive, the usual practice is to hollow them out; this is done by coring if the mandrels are made from castings or by boring if they are made from forgings or bars. Mandrels are sometimes fabricated from several machined components.

Mandrel wear is a major problem because of the severe service to which mandrels are subjected. Wear increases as the strength of the work metal increases or as the wall thickness of the workpiece decreases. The only means of minimizing mandrel wear or deterioration is to make the mandrels from extremely wear-resistant metals.

Alloy cast iron (usually hardened to about 58 HRC) is often used as a mandrel material for limited-production spinning. In many cases, alloy cast iron (sometimes used as-cast) has given acceptable results even for medium-production spinning, provided the work metal is easy to spin and the wall of the as-spun workpiece is not too thin. Conversely, when the application is more severe, alloy cast iron mandrels have been known to fail by spalling and pitting after spinning only a few pieces.

Mandrels made of steels such as 4150 and 52100 hardened to about 60 HRC have proved successful for many spinning applications, particularly when severity, as determined by work metal and wall thickness, is considerably less than maximum. In some applications, it has been desirable to sacrifice some wear resistance to gain toughness in the mandrel. Under these conditions, a hot-work tool steel such as H12 hardened to 52 to 55 HRC has been used. Tool steels such as D2 or D4 hardened to approximately 60 to 62 HRC have proved best for mandrels when service is rigorous, particularly for high-production spinning.

Regardless of what mandrel material is used, best practice calls for a light polishing of the mandrel after every 10 to 20 workpieces. This is done to remove any metal pickup and therefore prevent scratches on the inside diameter of the workpiece.

Rollers used for tube spinning are subjected to rigorous service. Typical tube-spinning rollers (tool rings) are shown in Fig. 3. A surface finish of 0.25 μm (10 μin.) or better is preferred. Most of the rollers used for tube spinning are made from D2 or D4 tool steel hardened to HRC 60 or slightly higher; M4 tool steel at 62 HRC has also given satisfactory service. Rollers of M42 tool steel heat treated to 64 to 65 HRC and quadruple tempered have demonstrated excellent wear resistance. Rollers made in accordance with this practice have been known to last for 4000 to 5000 h when spinning hot rolled tubes of 1020 to 1025 steel.

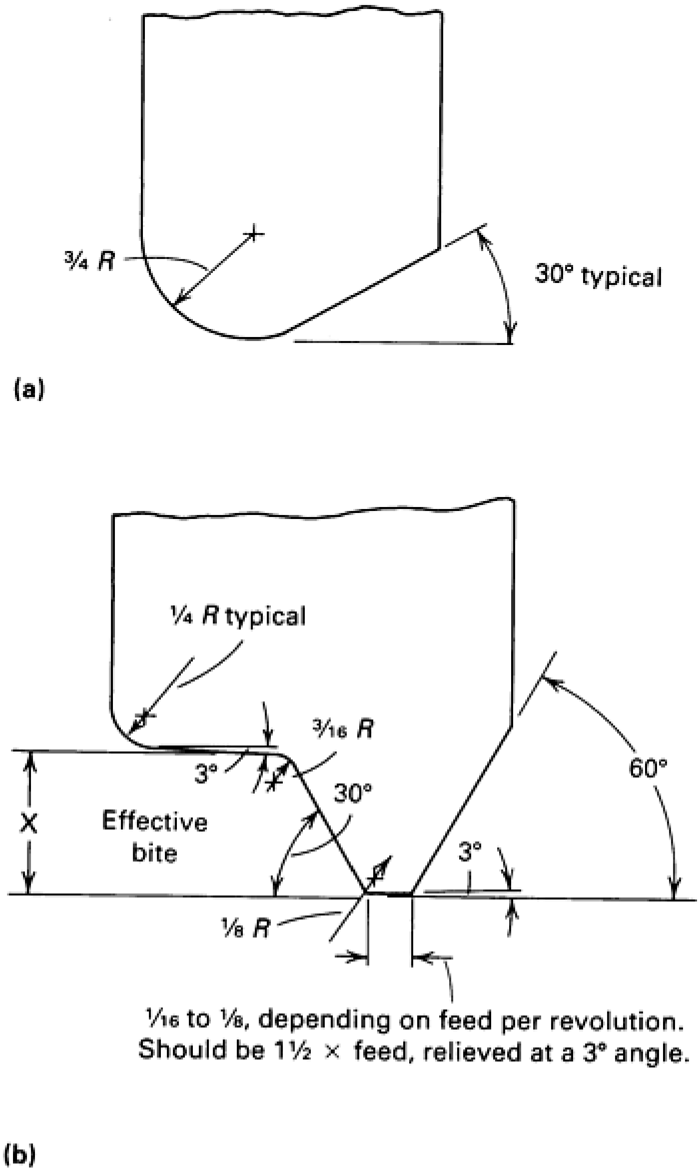

Fig. 3 Typical tool rings (rollers) used in tube spinning. (a) Pure radius tool ring. Common radii range from 9.5 to 25 mm ($\frac{3}{8}$ to 1 in.); sets are usually prepared in 6.4 mm ($\frac{1}{4}$ in.) increments. (b) Typical tube-spinning tool ring designed to operate properly at bite X only. The ring must be changed for each different reduction desired. Dimensions given in inches.

Staggered rollers have been successfully used for the forward spinning of workpieces such as missile cases. The two rollers shown in Fig. 4 are staggered radially so that each takes a portion of the total bite. When this practice is employed, the lead roller takes approximately 30% of the total bite, and the second roller takes the remainder. The only disadvantage is that more power is required because more metal is moved per unit of time.

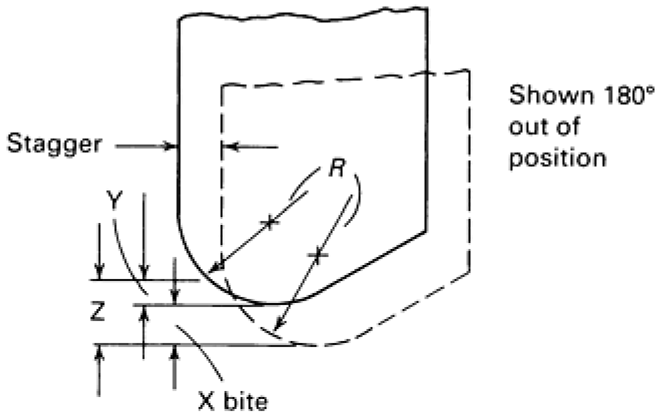

Fig. 4 Typical use of two staggered pure radius tool rings (rollers) for tube spinning. The lead tool ring is normally set for a bite Y that is approximately 30% of the total bite Z.

Auxiliary tools for tube spinning, such as stock pullers and drive rings, are usually made from a low-carbon steel such as 1020.

Tube Spinning

Revised by Jack D. Stewart, Sr., Stewart Enterprises, Inc.

Tube Wall Thickness Limitations

Limitations on the wall thickness of the preform that is practical for tube spinning are influenced by the formability characteristics of the work metal and available power. Depending on the characteristics of the work metal, the minimum reduction for the first pass is approximately 15%, but for many metals, it is greater than 15%. Because the reduction must always be a percentage of wall thickness, power consumption increases with wall thickness.

Metals that can usually be spun satisfactorily using a wall reduction of 15% on the first pass include low- and medium-carbon steels, alloy steels (including high-strength steels such as D-6ac), and all of the low-carbon stainless steels. With the largest standard machine currently available, the maximum starting wall thickness for the above metals is about 28.6 mm (1.125 in.). Under certain circumstances, however, a larger starting wall thickness may be acceptable. For example, a 3 m (10 ft) diam Inconel ring with a starting wall thickness of 41.3 mm ($1\frac{5}{8}$ in.) has been produced by spinning. The main reason such a starting wall thickness could be used is the large diameter of the preform; there is a relationship between preform starting wall thickness and diameter. Larger diameters permit thicker walls up to the machine power limits.

Successful spinning of the softer metals, such as the aluminum alloys, requires a higher percentage of reduction per pass (30% minimum) to prevent the formation of a large burr at the leading edges of the rollers. However, less force is required to spin aluminum. Therefore, for spinning aluminum alloys 2014 and 2024, using the largest available machine, the wall thickness of the preform can still be as great as 28.6 mm (1.125 in.), even though the percentage reduction is greater than for higher-strength metals.

To spin extremely soft metals such as 3003 aluminum, percentage reduction per pass must be increased. For spinning this grade of aluminum or other metals at a similar hardness, about 12.7 mm (0.500 in.) is the maximum wall thickness of the preform. Spinning of thicker-wall preforms of soft metals has been accomplished, but subsequent machining operations were required to produce acceptable surfaces.

Minimum Wall Thickness. The minimum thickness of preform wall that can be successfully spun is not clearly established, although small preforms with walls as thin as 1.0 mm (0.040 in.) have been spun. Spinning of extremely thin-wall preforms is infrequent.

Dimensional accuracy of the wall after spinning is not appreciably affected by preform thickness, provided total reduction between process anneals is no greater than 80%.

Tube Spinning

Revised by Jack D. Stewart, Sr., Stewart Enterprises, Inc.

Effect of Machine Variables in Tube Spinning

The two basic machine variables that affect workpiece accuracy are feed per revolution and machine deflection.

Feed per revolution is of concern during the development phase of a tube-spinning operation because it directly affects finished wall thickness, surface finish, and workpiece diameter. Increased feed per revolution will produce a workpiece having greater wall thickness, smaller inside diameter (inside diameter lighter to the mandrel), and rougher surface finish.

Because feed per revolution and roller radius or bite are interrelated, the effect of changes in feed per revolution can be modified by changes in the dimensions of the roller. An increase in roller radius produces thicker walls, larger inside diameters, and finer surface finishes on spun parts. Therefore, except for the effect on wall thickness, an increase in roller-to-workpiece contact area through the use of increased roller radius has the same effect as a decrease in feed per revolution. Similarly, increasing feed from 0.76 to 1.27 mm/rev (0.030 to 0.050 ipr) and increasing roller radius from 6.35 to 12.7 mm (0.250 to 0.500 in.) may cause an increase in wall thickness, but will have little or no effect on inside diameter and surface finish. To maintain uniform wall thickness, the distance between the roller and the mandrel must be decreased to compensate for the increased roller deflection that results from increases in feed per revolution or from increased area of roller contact (larger radius).

Machine deflection varies among different machines and must be determined by experimentation for each different setup. To some extent, deflection can be established for a particular size of machine. For example, it has been determined that a 1.07 × 1.27 m (42 × 50 in.) movable-slide machine will have approximately 0.64 mm (0.025 in.) of deflection when reducing D-6ac steel from a wall thickness of 2.92 to 1.78 mm (0.115 to 0.070 in.). However, roller shape, roller setting, and feed per revolution can cause a variation in deflection ranging from 0.25 to 1.27 mm (0.010 to 0.050 in.). Whether or not rollers are staggered (Fig. 4) has a marked effect on the magnitude of machine deflection.

Further variation in deflection among makes and models of machines can result from slight variations in the mechanical condition of slides, roller-synchronizing systems, hydraulic circuits, or gear trains. These variables primarily affect the uniformity of feed per revolution; if uniformity is not maintained during spinning the result will be a workpiece with varying wall thickness.

Deflection must be compensated for. One technique for controlling workpiece diameter involves adjusting the feed per revolution.

Machine variables cause the most difficulty in unit or low production. Once settings have been established for the spinning of a given workpiece on a specific machine, it remains only to adjust for any changes in roller shape, roller wear, or feed rate. If these adjustments are made, machine variables will not appreciably affect workpiece accuracy during production runs.

Finish of Tube-Spun Parts

Roller radius, composition and condition of work metal, feed per revolution, and lubricants affect the surface finish of tube-spun workpieces.

Roller Radius. Standard rollers for tube spinning can be modified for a specific application to produce workpiece finishes as good as 1 to 2 μm (40 to 80 μin.). Optimum results are usually obtained by modifications in lead angle, relief angle, and width of flat, depending on the work metal and the reduction per pass. When surface finish is of secondary importance, the standard type of roller is preferred because the contact area is low, thus minimizing horse-power requirements. The main disadvantage of standard rollers is that any given shape is restricted to a narrow range of bite; when there is a marked difference in reduction per pass and finish is highly important, it may be necessary to change rollers between passes.

In most tube spinning, optimal surface finish is obtained by using large-radius rollers staggered and offset as shown in Fig. 4. A surface finish of 0.5 to 1 μm (20 to 40 μin.) is common when using this type of tooling. Compared to standard rollers, the large-radius rollers are also better adapted to producing consistent surface finishes where there is substantial variation in percentage of reduction per pass. However, power demand is greater for large-radius rollers than for standard rollers.

Work Metal Variables. Composition and condition of the work metal affect the surface finish obtained in tube spinning. Some work metals are extremely susceptible to burring and tearing. For example, 6061-O aluminum alloy can be reduced only a small amount in one pass because of its susceptibility to burring. However, when this alloy is solution treated and aged, good surface finish can be obtained using reductions of 25 to 30% per pass. For optimal surface finish on some work metals (notably cast preforms of stainless or maraging steels), a common technique is to make one relatively heavy spinning pass (for example, 30%) and then take a light machining cut to remove burrs and tears prior to additional spinning passes. Thick walls in conjunction with very small preform diameters, regardless of other conditions, are likely to result in unacceptable surface finish.

Feed per revolution has a marked effect on surface finish in tube spinning. For an otherwise established set of conditions, surface finish becomes rougher as feed rate is increased. In most tube spinning, dimensional accuracy is more important than finish and must be given primary consideration in establishing rates of feed.

Lubricants. The effect of lubrication on surface finish is less important than might be expected, although efficient lubrication is recommended for obtaining an optimal finish. During tube spinning, the most reliable indication of lubricant efficiency is obtained by observing the lubricant pattern on the mandrel after workpiece removal. A thin, even film is ideal. Dry spots indicate poor application, or breakdown during forming. Such conditions will result in scratches in the workpiece inside diameter and excessive deterioration of the mandrel. Lubricants and coolants for all power spinning are discussed in the article "Spinning" in this Volume.

Tube Spinning

Speeds and Feeds for Tube Spinning

The technique for controlling speed is less complex for tube spinning than for cone spinning because in tube spinning there is no substantial change in diameter during a spinning cycle. In tube spinning, best results are obtained by using speeds considerably higher than would be used for most metal-cutting operations. Speeds used in practice vary widely and depend greatly on the capabilities of the machine; 120 m/min (400 sfm) is about the minimum speed for best results in any tube-spinning operation, and speeds much higher than 120 m/min (400 sfm) are usually preferred. The minimum speed of 120 m/min (400 sfm) often limits the minimum size of the tube that can be spun because of limitations of spindle speed. Speeds of 180 to 360 m/min (600 to 1200 sfm) are most common, mainly because this range is more compatible with spindle speeds for the size of the work being spun.

Maximum speed is not critical for tube spinning until adequate coolant cannot reach the roller contact points and the workpiece overheats. Similarly, there is no close correlation between work metal composition and spinning speed.

Feeds for tube spinning may be expressed either as millimeters (inches) per revolution or as millimeters (inches) per minute. Feeds used in practice cover a range as great as 38 to 380 mm/min (1.5 to 15 ipm). In terms of millimeters per revolution, feeds vary from approximately 0.076 to 0.20 mm/rev (0.003 to 0.080 in./rev). However, most tube spinning is done at the lower rates of feed.

A higher feed rate usually results in a coarser finish on the workpiece. Feeds are often adjusted as required to obtain a specified dimension.

Tube Spinning

Effects of Tube Spinning on Work Metal Properties

Tube spinning cold works the metal and has a marked effect on its properties; the magnitude of change depends on the percentage reduction and the susceptibility of the metal to work hardening. Table 1 shows how percentage reduction affects the tensile strength, yield strength, and elongation of 1015 steel tube.

Table 1 Effect of increasing reduction in wall thickness on mechanical properties of 1015 steel tube

Preform was 184 mm ($7\frac{1}{4}$ in.) in outside diameter by 12.7 mm ($\frac{1}{2}$ in.) in wall thickness.

Wall thickness		Total reduction, %	Tensile strength		Yield strength		Elongation, %, in 50 mm (2 in.)
mm	in.		MPa	ksi	MPa	ksi	
12.73	0.501	0	386	56	229	33.2	**34.5**
10.46	0.412	17.5	541	78.5	476	69.4	**13.5**
8.33	0.328	35	572	83	525	76.2	**12.5**
4.90	0.193	61	598	86.8	542	78.6	**11**

The change in strength and ductility for several metals after various percentages of reduction of wall thickness is given in Table 2; the influence of composition is evident. For example, 4130 steel during a wall reduction of 80% increased 72% in tensile strength and decreased 71% in ductility (measured by elongation). Type 304 stainless steel subjected to the same wall reduction increased 202% in tensile strength and decreased 88% in elongation.

Table 2 Mechanical properties of various alloys before and after power spinning

Alloy	Reduction in wall thickness, %	Tensile strength, MPa (ksi)		Yield strength, MPa (ksi)		Elongation in 50 mm (2 in.), %	
		Before	**After**	**Before**	**After**	**Before**	After
1010 to 1020 steel, hot rolled	50	386 (56)	600 (87)	228 (33)	541 (79)	34.5	**11**
1020 steel, cold rolled	65	421 (61)	758 (110)	310 (45)	621 (90)	30	**9**
1045 steel	70	518 (75)	793 (115)	351 (51)	703 (102)	30	**8**
Alloy steel (Fe-0.44C-1.49Si-1.98Cr-0.48Mo)	91	758 (110)	1910 (277)	534 (77.5)	1600 (232)	19.3	**9**
4130 steel	80	560 (81)	965 (140)	360 (52)	721 (104.5)	28	**8**
Type 304 stainless steel	80	593 (86)	1792 (260)	233 (34)	1172 (170)	65.6	**8**

Tube Spinning

Revised by Jack D. Stewart, Sr., Stewart Enterprises, Inc.

Tube Spinnability

The spinnability of a metal is the maximum reduction it can withstand before failure during spinning. A test setup for determining tube spinnability by forward spinning is shown in Fig. 5. The roller path was set at an angle, ϕ, of 2 to 4° such that the wall thickness of the tube was gradually reduced from t_0 to t_f, where the tube failed. Typical sections from the tests (Fig. 6) show that 2024-T4 aluminum fractured under the roller in a brittle manner, while 6061-T6 aluminum, annealed copper, and low-carbon steel all failed in tension behind the roller. A similar transition in the type of failure has also been observed in shear spinning. The complete agreement between maximum reduction in shear and tube spinning is noteworthy. Therefore, as in shear spinning, maximum reduction in tube spinning can be estimated from the reduction of area in a tension test.

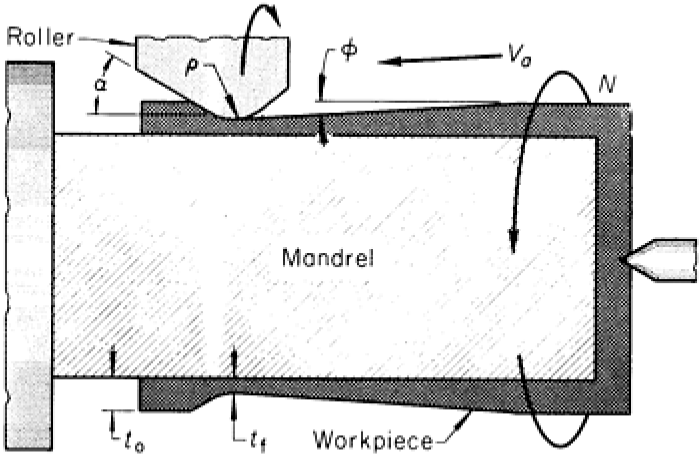

Fig. 5 Setup for testing tube spinnability.

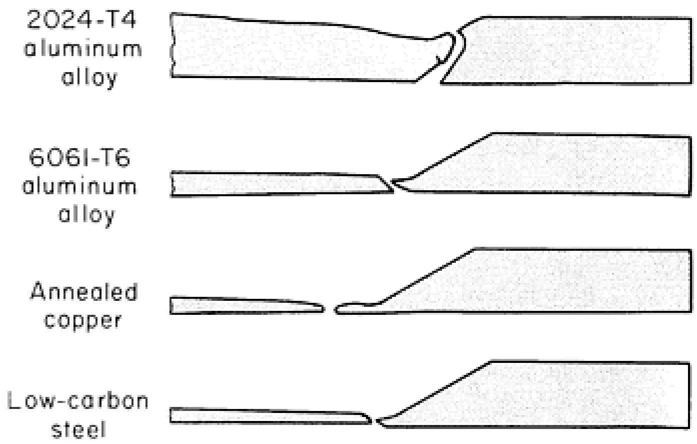

Fig. 6 Locations of fractures in tubes of four different metals tested for spinnability.

In studies of the effects of feed, roller corner radius, and roller angle on maximum tube-spinning reduction, only feed had an adverse influence; the other variables had no appreciable influence. Up to a tensile reduction of area of approximately 45%, maximum reduction in tube spinning depends on the ductility of the metal, and beyond this range, there is a maximum spinning reduction of about 80% regardless of the ductility of the work metal.

Straightening of Bars, Shapes, and Long Parts

Introduction

BARS, bar sections, structural shapes, and long parts are straightened by bending, twisting, or stretching. Deviation from straightness in round bars can be expressed either as camber (deviation from a straight line) or as total indicator reading (TIR) per unit of length. Total indicator reading, which is twice the camber, is measured by rotating a round bar on its axis on rollers or centers and recording the needle travel on a dial gage placed in contact with the bar surface, generally midway between the supports. The indicator reading divided by the distance between the supports gives the straightness in total indicator reading per unit of length. Alternatively, the deviation is expressed in terms of the distance between the supports. The effect that changing the distance between supports has on the reading is illustrated in Fig. 1; the difference in readings illustrates the importance of including support distance and location of indicators in a straightness specification.

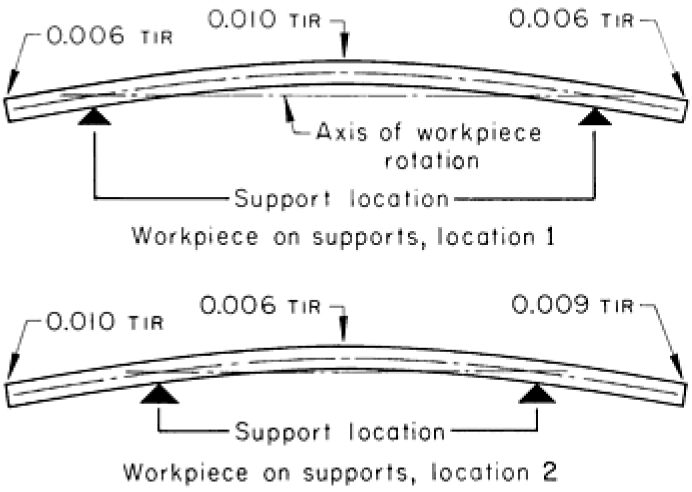

Fig. 1 Effect of distance between supports on straightness readings for round bars.

Sections other than round are usually checked for camber by placing a straightedge against the bar and measuring with suitable gages the distance between the straightedge and the bar at the midpoint of its length. In flat bars and structural members, camber is sometimes referred to as the deviation from straightness parallel to the width, and bow as the deviation parallel to the thickness (Fig. 2).

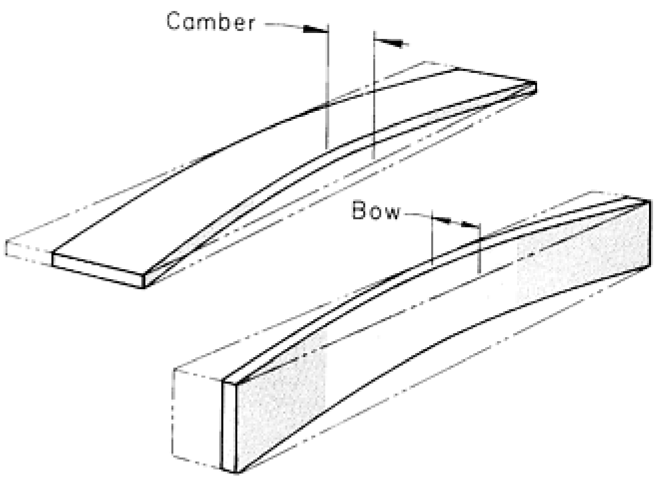

Fig. 2 Camber and bow in flat bars.

Runout is minimal at the nodes of curvature. If a bar has compound curvature, it can be misleading to check for camber or total indicator reading only at the midpoint of the bar length. Serious errors may result unless dial-gage readings are taken at short intervals over the entire length of the bar, or unless gangs of indicators are used at short intervals along the bar.

Straightness Tolerances. Federal Specification 48 ("Tolerances for Steel and Iron Wrought Products") establishes the straightness tolerances on some steels as:

- Hot-rolled carbon steel bars: 6.4 mm deviation per 1.5 m ($\frac{1}{4}$ in. deviation per 5 ft) or 4.2 mm per m (0.050 in. per ft)
- Hot-rolled alloy steel and high-strength low-alloy steel bars: 3.2 mm deviation per 1.5 m ($\frac{1}{8}$ in. deviation per 5 ft) or 2.1 mm per m (0.025 in. per ft)

- Hot-rolled stainless steel and heat-resisting steel bars for machining: 3.2 mm deviation per 1.5 m ($\frac{1}{8}$ in. deviation per 5 ft) but not to exceed 2.1 mm per m (0.025 in. per ft)
- Cold-finished carbon steel bars; turned, ground, and polished bars, or drawn, ground, and polished bars: machine straightened within limits (1.6 mm deviation per 1.5 m or $\frac{1}{16}$in. deviation per 5 ft) reasonable for satisfactory machining in an automatic bar machine
- Cold-finished stainless steel and heat-resistant steel bars for machining: 1.6 mm deviation per 1.5 m ($\frac{1}{16}$ in. deviation per 5 ft) but not to exceed 1.0 mm per m (0.0125 in. per ft)
- Carbon steel, stainless steel, and heat-resistant steel structural shapes (except wide flange sections): 2.1 mm deviation per m (0.025 in. deviation per ft)
- Wide flange sections used as beams: 1.0 mm deviation per m (0.0125 in. deviation per ft)
- Wide flange sections used as columns: up to 14 m (45 ft) long, 1.0 mm deviation per m (0.0125 in. deviation per ft) but not over 9.5 mm ($\frac{3}{8}$ in.); over 14 m (45 ft) long, 9.5 mm ($\frac{3}{8}$ in.) plus 1.0 mm per m (0.0125 in. per ft) beyond the 14 m (45 ft) length

Material Displacement Straightening

Manual Straightening. The original method of hand straightening is still extensively used when accuracy and precision are required or when the shape of the bar or part makes machine straightening impractical. The tools used in manual straightening include hammers and mallets, anvils, surface tables, vises, levers, grooved blocks, grooved rolls, twisting devices, various fixtures, and heating torches. The use of a grooved block (Fig. 3a) illustrates the basic principle of manual straightening by bending.

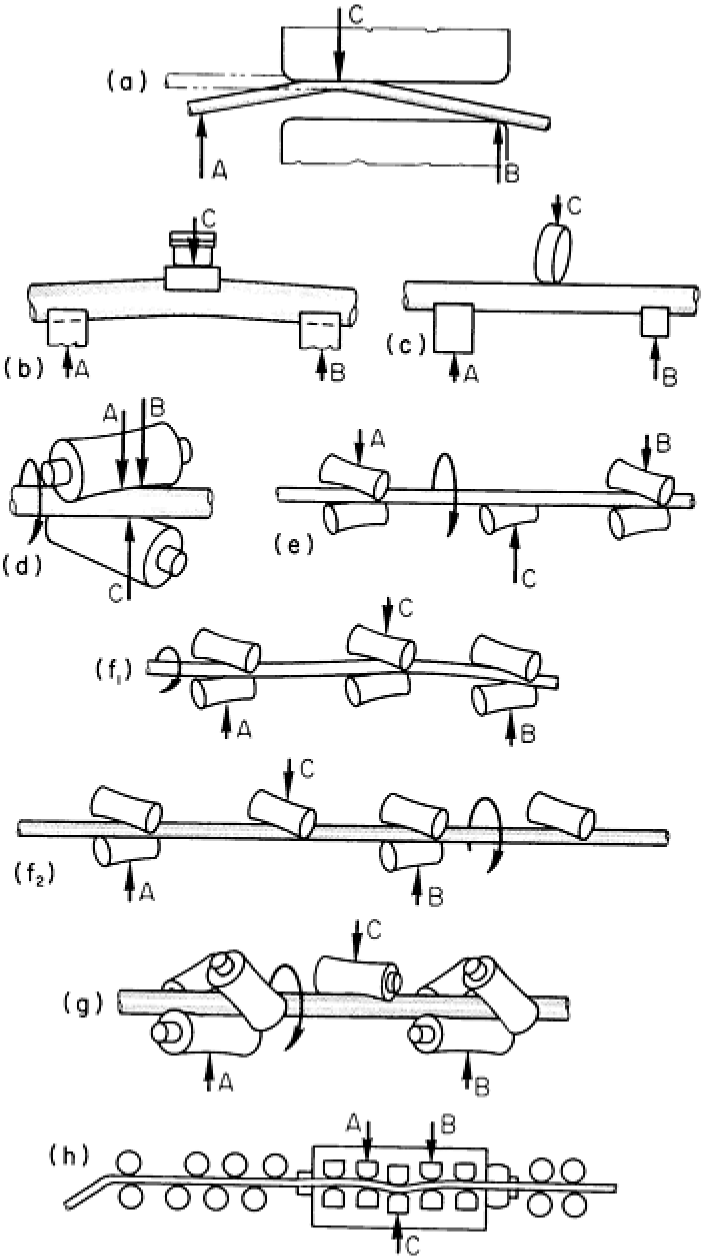

Fig. 3 Principle of straightening by bending. (a) Manual straightening with a grooved block. (b) Straightening in a press. (c) Simplest form of rotary straightening. (d) Two-roll straightening. (e) Five-roll straightening. (f_1 and f_2) Two arrangements of rolls for six-roll straightening. (g) Seven-roll straightening. (h) Wire straightening. In all methods shown, the bar is supported at points A and B, and force at C on the convex side causes straightening. See text and subsequent illustrations for details of the straightening methods shown here.

Shafts for centrifugal irrigation pumps are an example of parts that usually must be manually straightened because of the accuracy required and the necessity of doing the work at the installation site. Most of these shafts are 3.0 to 6.1 m (10 to 20 ft) long, have diameters of 19 to 50 mm ($\frac{3}{4}$ to 2 in.), and are of cold-drawn 1045 steel. The steel supplier generally straightens the cold-drawn stock within 0.13 or 0.25 mm (0.005 or 0.010 in.) TIR in 3.0 m (10 ft), but the shafts are often bent slightly in transport and in handling. It is common to hand straighten the shafts at installation--within 0.13 mm (0.005 in.) TIR in 6.1 m (20 ft). The shafts are rotated on supports and are deflected with a lever.

Special cold-drawn sections as long as 3.7 m (12 ft) are commonly straightened manually. Many special sections are similar enough to standard flats that they can be straightened in standard two-direction roll straighteners, but quantities are often too small to warrant the cost of special rolls. Other special sections may be too complex in shape for machine straightening.

Special sections almost always have twist after cold drawing. The twist must be removed before the section can be straightened. One end of the section is held in a vise or in a special fixture, while the other end is twisted with a wrench or special handle. When the twist is corrected, the bar can be straightened to remove camber and bow.

Manual Peening. Straightening of a workpiece by peening (material displacement) is accomplished manually by placing the workpiece on heavy, flat plates and rapidly hammering on the concave side of the distorted portion of the workpiece surface. Elimination of the distortion allows the workpiece to lie flat. This method is applicable when straightening round parts with a high degree of hardness, such as drill bit blanks. Unfortunately, the technique is time consuming and does require highly skilled operators.

High-Production Peening. In peen straightening, also known as pulse straightening, the workpiece is pulsed on the low side opposite the high point of the bend (Fig. 4). The pulsating tooling compresses the workpiece material and burnishes its surface. To counteract existing stresses in the workpiece, the material expands to straighten the part. The metal structure is stabilized, the part retains its straight configuration in storage, and the material is unaffected by the shock and vibration encountered during subsequent machining operations. This method is gaining wide acceptance in high-volume production operations in which cast and forged steel camshafts, hardened steel transmission shafts, crankshafts, and disk plates require straightening.

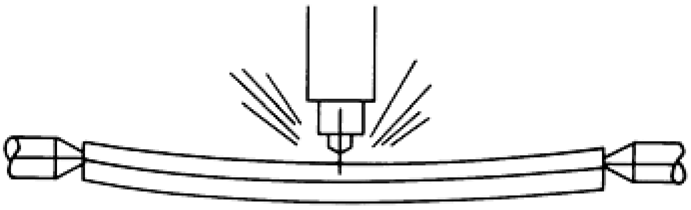

Fig. 4 Schematic of principles involved in straightening by automatic peening.

Stretch Straightening. Many bars and shapes can be easily straightened by stretching. However, this technique is usually confined to the straightening of shapes that are uniform in cross section and length. The advantages of stretch straightening include low costs for tooling and for maintenance, simplicity of operation, and (usually) completion of straightening in one operation. The disadvantages include waste by trimming 152 to 467 mm (6 to 18 in.) from the ends of bars damaged by gripping, the need (usually) for two men to do the straightening, the need for cutoff equipment, and production of only 30 to 40 bars per hour.

A stretch straightener has two heads with grips that clamp on the ends of the bar. One head can be adjusted to suit the workpiece length. The other head (tailstock) is powered for stretching and for rotation to correct twist in the workpiece.

Stretching machines are made in sizes to exert stretching forces of 135 to 4450 kN (15 to 500 tonf) to workpieces that may be from 6 to 30 m (20 to 100 ft) long. Stretching must stress the work beyond its yield strength. For complete straightening, the bar should be stretched 2%. To accomplish this and to overcome the greater strength caused by work hardening, the stretching machine needs a capacity of 10 to 15% beyond the yield strength of the bar.

Some straightening can be done by stretching only to the yield strength of the work, but this would not be sufficient to remove completely some sharp bends and twists. A stretcher with a capacity of 1340 kN (150 tonf) can straighten, to some extent, a low-carbon steel bar with a cross section of 9700 mm^2 (15 $in.^2$), 6450 mm^2 (10 $in.^2$), of austenitic stainless steel, or 4550 mm^2 (7 $in.^2$) of ferritic stainless and can do complete straightening on 8400 mm^2 (13 $in.^2$) of low-carbon steel, 5150 mm^2 (8 $in.^2$) of austenitic stainless, or 3900 mm^2 (6 $in.^2$) of ferritic stainless steel. Figure 5 shows the relationship between stretcher force and the cross-sectional area of the bar. The deviation that remains after stretch straightening can sometimes be corrected by manual straightening.

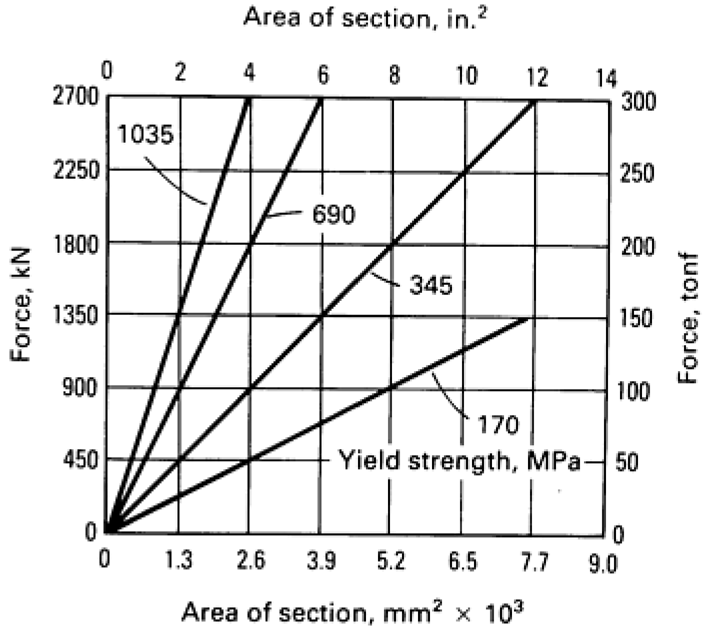

Fig. 5 Relationship between stretcher force and area of bar cross section in the stretch straightening of steel bars of various yield strengths.

Most hot-rolled bars can be straightened by stretching. Straightening by stretching also works well on rolled and extruded bars of aluminum and austenitic and ferritic stainless steels, but not on martensitic stainless steels unless they are first annealed. Low-carbon steels are easy to stretch straighten, but annealing before stretching becomes more necessary as the carbon content increases. Because it is slow and limited in effectiveness, stretch straightening is not widely used.

Straightening by Heating

Alloy steel bars and shapes with a hardness exceeding 50 HRC, as well as fabricated stainless steel parts, frequently warp because of the stress set up during fabrication, machining, or heat treatment. These items can usually be straightened by the application of heat and, in most cases, force. The heat can be localized in the area to be straightened, or the entire piece can be heated--either to the tempering temperature or to about 30 °C (50 °F) below it. (Heating to a temperature above that required for tempering will reduce the hardness, as will prolonged heating at the tempering temperature itself.) Low-carbon steel bars can also be straightened by heating.

Localized Heating. Torches are used to apply heat to the convex side of warped parts. A small area is heated to a dull red. The localized heating causes the workpiece to expand, but some straightening occurs during cooling. Skillful heating, cooling, and gaging of the workpiece can result in reasonable straightness.

Torch heating causes soft spots in hardened steel workpieces. Localized heating with a torch can also cause localized residual tensile stress that can be undesirable even in an unhardened workpiece if it is subjected to cyclic loading.

In press straightening with the use of localized heat, the workpiece is supported at each end with suitable blocks. A stop block is placed directly under the ram to limit the amount of deflection. With the high points of its curvature up, the workpiece is pressed down until it rests lightly on the stop block; heat is then applied. For a heat-treated workpiece, the amount of heat is usually governed by the original tempering temperature, and the distance the workpiece can be deflected and released without fracture depends on the type and hardness of the steel, the heat treatment, and the shape of the workpiece. Another method of controlling deflection without breakage is to place the workpiece on shims while it rests on a flat surface, apply pressure to the surface of the workpiece, then heat and release. If the workpiece is still not straight, it will be necessary to use more shims and reheat or to allow the workpiece to cool longer before releasing the pressure.

Where a flame cannot be effectively directed or may damage the metal, a small weld bead can sometimes be used as the source of heat. Weld beads are applied to the convex area, allowed to cool, and machined off if necessary.

Heating Below Tempering Temperature. Heating and press straightening are generally not applicable to steel at high hardness levels. The force required to cause permanent set is close to the rupture strength of the steel, and even with extreme care, failure is probable. At medium and lower hardness levels, heating to a temperature about 30 °C (50 °F) below the tempering temperature will permit press straightening to be done successfully. Straightening becomes more difficult as the part cools, and only slight corrective straightening should be attempted at the lower temperature levels. Considerable skill is required to perform such operations and to hold tolerances within 0.08 to 0.25 mm (0.003 to 0.010 in.) over a length of 0.45 to 1.22 m (18 to 48 in.).

After the workpiece has been straightened, it is tempered to the required hardness. Tempering relieves stress set up during straightening and during the hardening cycle. This stress will often deform the workpiece; consequently, workpieces straightened by heating and pressing should be clamped in restraining fixtures during tempering. Fixturing can correct a slight distortion and prevent distortion during tempering.

Temper straightening is used to correct the distortion caused by heat treatment. The workpiece is first tempered to a hardness somewhat higher than required, then clamped in a straightening fixture and tempered to the required hardness. The greater the hardness difference between the first and the corrective tempering operations, the more accurate the dimensions will be. Temper straightening is most successful at hardness levels of 55 HRC and lower.

Deep-hardening alloy and tool steels that are being martempered to minimize distortion should be held straight during the cooling period after austenitizing and until the completion of martempering. If straightness is not maintained throughout martempering, the workpiece will warp as martensite continues to form. Straightening should be done below 480 °C (900 °F). Cold bars or chills contacting the high side will more rapidly extract the heat from the workpiece and aid in straightening.

Straightening of Bars, Shapes, and Long Parts

Straightening by Heating

Alloy steel bars and shapes with a hardness exceeding 50 HRC, as well as fabricated stainless steel parts, frequently warp because of the stress set up during fabrication, machining, or heat treatment. These items can usually be straightened by the application of heat and, in most cases, force. The heat can be localized in the area to be straightened, or the entire piece can be heated--either to the tempering temperature or to about 30 °C (50 °F) below it. (Heating to a temperature above that required for tempering will reduce the hardness, as will prolonged heating at the tempering temperature itself.) Low-carbon steel bars can also be straightened by heating.

Localized Heating. Torches are used to apply heat to the convex side of warped parts. A small area is heated to a dull red. The localized heating causes the workpiece to expand, but some straightening occurs during cooling. Skillful heating, cooling, and gaging of the workpiece can result in reasonable straightness.

Torch heating causes soft spots in hardened steel workpieces. Localized heating with a torch can also cause localized residual tensile stress that can be undesirable even in an unhardened workpiece if it is subjected to cyclic loading.

In press straightening with the use of localized heat, the workpiece is supported at each end with suitable blocks. A stop block is placed directly under the ram to limit the amount of deflection. With the high points of its curvature up, the workpiece is pressed down until it rests lightly on the stop block; heat is then applied. For a heat-treated workpiece, the amount of heat is usually governed by the original tempering temperature, and the distance the workpiece can be deflected and released without fracture depends on the type and hardness of the steel, the heat treatment, and the shape of the workpiece. Another method of controlling deflection without breakage is to place the workpiece on shims while it rests on a flat surface, apply pressure to the surface of the workpiece, then heat and release. If the workpiece is still not straight, it will be necessary to use more shims and reheat or to allow the workpiece to cool longer before releasing the pressure.

Where a flame cannot be effectively directed or may damage the metal, a small weld bead can sometimes be used as the source of heat. Weld beads are applied to the convex area, allowed to cool, and machined off if necessary.

Heating Below Tempering Temperature. Heating and press straightening are generally not applicable to steel at high hardness levels. The force required to cause permanent set is close to the rupture strength of the steel, and even with extreme care, failure is probable. At medium and lower hardness levels, heating to a temperature about 30 °C (50 °F) below the tempering temperature will permit press straightening to be done successfully. Straightening becomes more difficult as the part cools, and only slight corrective straightening should be attempted at the lower temperature levels. Considerable skill is required to perform such operations and to hold tolerances within 0.08 to 0.25 mm (0.003 to 0.010 in.) over a length of 0.45 to 1.22 m (18 to 48 in.).

After the workpiece has been straightened, it is tempered to the required hardness. Tempering relieves stress set up during straightening and during the hardening cycle. This stress will often deform the workpiece; consequently, workpieces straightened by heating and pressing should be clamped in restraining fixtures during tempering. Fixturing can correct a slight distortion and prevent distortion during tempering.

Temper straightening is used to correct the distortion caused by heat treatment. The workpiece is first tempered to a hardness somewhat higher than required, then clamped in a straightening fixture and tempered to the required hardness. The greater the hardness difference between the first and the corrective tempering operations, the more accurate the dimensions will be. Temper straightening is most successful at hardness levels of 55 HRC and lower.

Deep-hardening alloy and tool steels that are being martempered to minimize distortion should be held straight during the cooling period after austenitizing and until the completion of martempering. If straightness is not maintained throughout martempering, the workpiece will warp as martensite continues to form. Straightening should be done below 480 °C (900 °F). Cold bars or chills contacting the high side will more rapidly extract the heat from the workpiece and aid in straightening.

Straightening in Presses

Round bars up to 50 mm (2 in.) in diameter and from 0.6 to 3.0 m (2 to 10 ft) in length are often straightened in an arbor press. Larger workpieces are similarly straightened in power presses, which may have power rolls and hoists to move the work.

The principle of press straightening is illustrated in Fig. 3(b). The bar to be straightened is supported at points A and B with the convex side of the bow or kink toward point C. Sufficient force is applied at C to cause the bar to become bowed in the opposite direction. The force must be great enough to exceed the elastic limit of the material, but it must set up just enough strain in the bar to allow it to return to the straight position (but no farther) when the pressure is released. The greater the bow in the bar and the higher its elastic limit, the greater the force required to produce the correct amount of strain. To straighten a bar by press straightening, the metal must be capable of cold deformation, and it must strain harden.

In press straightening, the operator usually locates kinks or bows in round bars by holding a piece of chalk close to the surface of the bar and then rotating the bar so that any high spots will be marked by the chalk. The high spot is then brought under the ram of the straightening press, and sufficient force is applied to remove the kink or bow. In shapes other than rounds, the out-of-straight condition must be detected visually or with the aid of a straightedge. This type of straightening requires considerable skill on the part of the operator. A straightening press is sometimes referred to as a gag press and the straightening operation as gagging.

Hydraulic or mechanical presses are used to straighten bars, shapes, and shaftlike parts before, between, and after heat-treating operations. Some bars that are roll straightened do not meet straightness requirements and must receive a final press straightening. Presses are also used to straighten large diameter bars in preparation for turning or grinding. Finish-ground or turned products with highly finished surfaces are press straightened to avoid the spiral marks produced by rotary straightening. Press straightening does not change the size of the bar, but rotary straightening--because of the rolling action or the alteration in residual stress caused by bending or both--may cause a change in bar size.

Some high-strength steels and stainless steels are too hard to be straightened in any way except in a press, and some metals are too hard to be straightened without heat, unless the bar is first annealed. The cold straightening of bars of these metals may cause the bars to break.

Press straightening is easier when the bar has a hardness of less than 40 HRC. The bar can be retempered to relieve the stress introduced during straightening.

In a straightening press, a round bar is usually set on spring-loaded rollers near the ends of the bar. Thus, the bar can be rotated on its axis while a dial gage shows any deviations from straightness. As the press ram moves down, it presses the bar into V-blocks that support the straightening pressure. This action is repeated, sometimes with the bar shifted or the roller supports moved, until the bar is straight enough to meet specifications. The V-blocks and roller supports can be moved to change the leverage and to adjust the application of the force. A straightening press is better suited to the correction of short bends and kinks than to the correction of long bends. A straightening press can hold the distortion of heat-treated bars and shafts to 0.25 mm (0.010 in.) or less, as shown in Examples 1 and 2.

Example 1: Straightening of a Heat-Treated Shaft in a Press.

A D2 tool steel shaft with a hardness of 63 to 65 HRC and a straightness specification of 0.25 m (0.010 in.) TIR is shown in Fig. 6. The shaft was hung in a vertical furnace and preheated to 205 °C (400 °F), 540 °C (1000 °F), and 815 °C (1500 °F) before heating at 540 °C (1850 °F). The part was air cooled to 260 °C (500 °F). Because inspection at that temperature showed distortion of 0.38 to 0.64 mm (0.015 to 0.025 in.) TIR, the bar was straightened in a manual hydraulic press to 0.18 mm (0.007 in.) TIR before it cooled to 205 °C (400 °F). At 65 °C (150 °F), the shaft was again straightened to within 0.18 mm (0.007 in.) TIR.

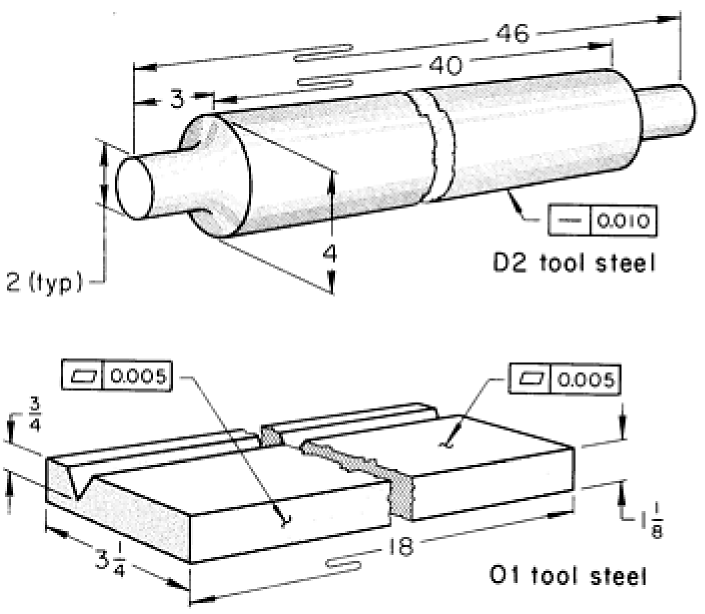

Fig. 6 Shaft and grooved bar that were press straightened after heat treatment. Shaft hardness: 63 to 65 HRC. Bar hardness: 61 to 63 HRC. Dimensions given in inches.

The shaft was clamped in a V-block for tempering at 150 °C (300 °F) for 6 h, then given a subzero treatment and straightened to within 0.20 mm (0.008 in.) TIR. The shaft was again clamped in the V-block, using shims for straightening, while being retempered at 150 °C (300 °F) for 6 h. Final straightening in the press was to 0.18 mm (0.007 in.) TIR, which was better than was required.

Example 2: Straightening of a Heat-Treated Bar in a Press.

A flat bar of O1 tool steel having a 19 mm ($\frac{3}{4}$ in.) deep V-groove along one edge is shown in Fig. 6. The specified hardness was 61 to 63 HRC. The top and sides had to be flat within 0.13 mm (0.005 in.).

The bar was preheated to 595 °C (1100 °F), heated at 805 °C (1480 °F), and marquenched at 190 °C (375 °F). The bar was then clamped in a fixture and cooled to 38 °C (100 °F). Inspection showed 0.15 mm (0.006 in.) maximum variation for the top and side. The bar was reclamped in the fixture and tempered at 150 °C (300 °F) to a hardness of 63 to 64 HRC. The bar was reclamped with shims to straighten it and was retempered at 165 °C (325 °F) to a hardness of 61 to 62 HRC. The bar was then straightened in a press within 0.13 mm (0.005 in.) at the top and side.

Clamping of Workpiece. If the workpieces in Examples 1 and 2 had been heat treated without being clamped, they would have been free to distort and would have needed more press straightening. The straightening of bars and shafts during transformation and during tempering is more efficient and costs less, and it is sometimes the only way in which straightness specifications can be met. Structural parts for aircraft are commonly straightened by a combination of methods, as shown in Examples 3, 4, and 5. Example 6 describes a procedure for heat treating and straightening a long, thin rectangular bar in a press. Round shafts are often straightened before they are ground, as in Example 7 and 8.

Straightening presses are used as accessories to other equipment, such as blooming mills that roll blooms or billets 127 to 178 mm (5 to 7 in.) thick. A 1.8 MN (200 tonf) press with a bed 0.6 × 1.2 m (2 × 4 ft) can straighten such blooms or billets within 6.4 mm per 1.8 m ($\frac{1}{4}$ in. per 6 ft) in lengths as great as 4.9 m (16 ft) without the use of spacers or shims. Many blooms or billets do not need straightening--for example, if they are to be cut into pieces for forging stock.

Example 6 describes a procedure for heat treating and straightening a long, thin rectangular bar in a press. Round shafts are often straightened before they are ground, as in Example 7 and 8.

Example 3:

A structural aircraft part called a cap was made from modified 4330 steel bar 4.7 mm ($\frac{3}{16}$ in.) thick × 1.7 m (66 in.) long (Fig. 7). The part was channel shaped with one flange removed for a portion of its length to produce an angle section. Holes 3.2 mm ($\frac{1}{8}$ in.) in diameter were made in both sides of the angle section and in the channel section. Heat treatment consisted of suspending the workpiece by the angle end in a salt bath at 845 °C (1550 °F), quenching in salt at 245 °C (470 °F), and air cooling. After being heat treated, the parts were cleaned and checked for hardness (aim was 46 to 49 HRC). With hardness less than 50 HRC, a subzero treatment was given prior to tempering; with hardness of 50 HRC or harder, the workpiece was clamped in a fixture, tempered at 315 °C (600 °F) for 5 h, and finally air cooled. The workpiece warped about 25 mm in 1.7 m (1 in. in 66 in.) after quenching, and a warp of about 6.4 mm ($\frac{1}{4}$ in.) remained after fixture tempering. A camber of 6.4 mm ($\frac{1}{4}$ in.) was easily removed manually, but a workpiece with a camber of more than 6.4 mm ($\frac{1}{4}$ in.) was retempered in the fixture before straightening. Shape and straightness were checked in a fixture using a 0.51 mm (0.020 in.) feeler gage. After being tempered at 315 °C (600 °F), the workpiece had a hardness of 46 to 49 HRC.

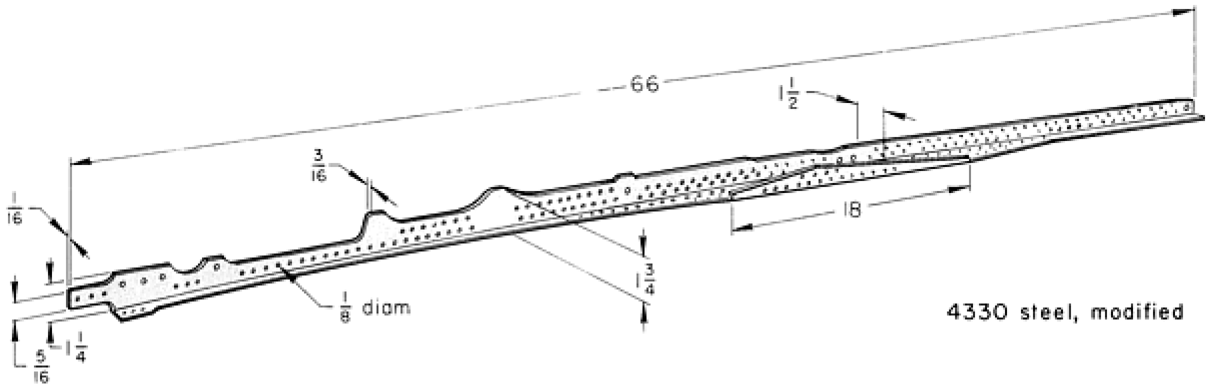

Fig. 7 Aircraft part that was straightened by a combination of methods. Hardness: 46 to 49 HRC. Dimensions given in inches.

Rotation of about 60° was required to correct for 0.76 mm (0.030 in.) twist. An 89 kN (10 tonf) hydraulic press was used to correct short bends. The workpiece was supported on slotted blocks, placed about 360 mm (14 in.) apart, which gave support to the flanges while pressure was applied. A force of about 13 kN (3000 lbf) deflected the channel section 9.5 to 13 mm ($\frac{3}{8}$ to $\frac{1}{2}$ in.) for a camber correction of 3.3 mm/m (0.020 in. per 6 in.). A force of 4.4 to 6.7 kN (1000 to 1500 lbf) on the angle section produced about the same deflection and correction.

Stretching was used to maintain spacing and alignment for the 3.2 mm ($\frac{1}{8}$ in.) diam holes. Because of the thin sections, the part shrank 0.76 to 1.0 mm (0.030 to 0.040 in.) after quenching in salt at 245 °C (470 °F). To correct this shrinkage, the part was preheated at 290 °C (550 °F) for 30 min, then clamped in the tempering fixture and heated at 315 °C (600 °F) for 5 h. As the fixture expanded from the heat, the part was stretched. After slowly cooling in the fixture, the part had a permanent stretch of 0.51 to 0.76 mm (0.020 to 0.030 in.), which corrected hole alignment and spacing. About 8 min was required for clamping the part in the tempering fixture, and 22 min for hand straightening.

Example 4:

A welded double-channel structural member made of 4340 steel 1.8 m (72 in.) long and weighing 5.2 kg (11.5 lb) (Fig. 8) was austenitized at 830 °C (1525 °F) for 40 min, martempered at 245 °C (470 °F), stress relieved at 205 °C (400 °F), and cleaned. The unusual feature of this operation was the simultaneous straightening, bending, and tempering.

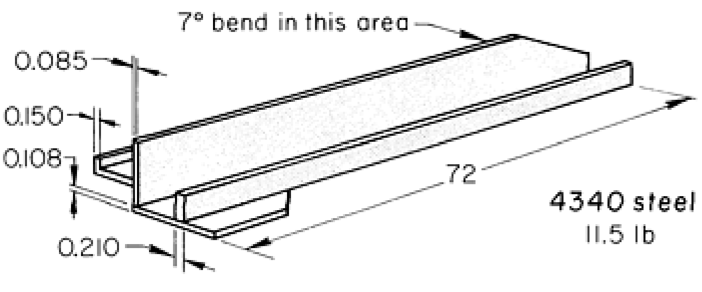

Fig. 8 Welded structural member that was straightened during and after heat treatment. Dimensions given in inches.

The workpiece was machined on a straight plane and then fixture bent 7° on one end during tempering. The fixture was constructed with various gibs and filler blocks milled to fit the contours of the workpiece, including allowance for the 7° bend, which extended for approximately 305 mm (12 in.) (Fig. 8). The workpiece was then placed on the fixture, and all holding clamps were placed in position. The fixture-and-workpiece assembly was then heated to 315 °C (600 °F). At this time, all clamps were tightened, thus making the 7° bend at one end. The assembly was then heated (tempered) to 540 °C (1000 °F for 4 h.

After tempering the channel was straightened in a hydraulic press to achieve final alignment within 0.76 mm (0.030 in.). A special gage was used to inspect alignment and the bend. Time for straightening and gaging was 30 min.

Example 5:

A structural bar with a tapered-width channel 4.8 mm ($\frac{3}{16}$ in.) thick and 1.7 m (66 in.) long was made of 17-4 PH stainless steel (Fig. 9). The part was solution treated to 39 to 42 HRC, finish machined, then aged for 1 h at 480 °C (900 °F). It was straightened to within 0.38 mm (0.015 in.) camber in a hydraulic press upon removal from the aging treatment. The part could be straightened only until it cooled to 370 °C (700 °F), which took 10 min. Because 20 min was required to straighten the part, reheating to 480 °C (900 °F) was necessary.

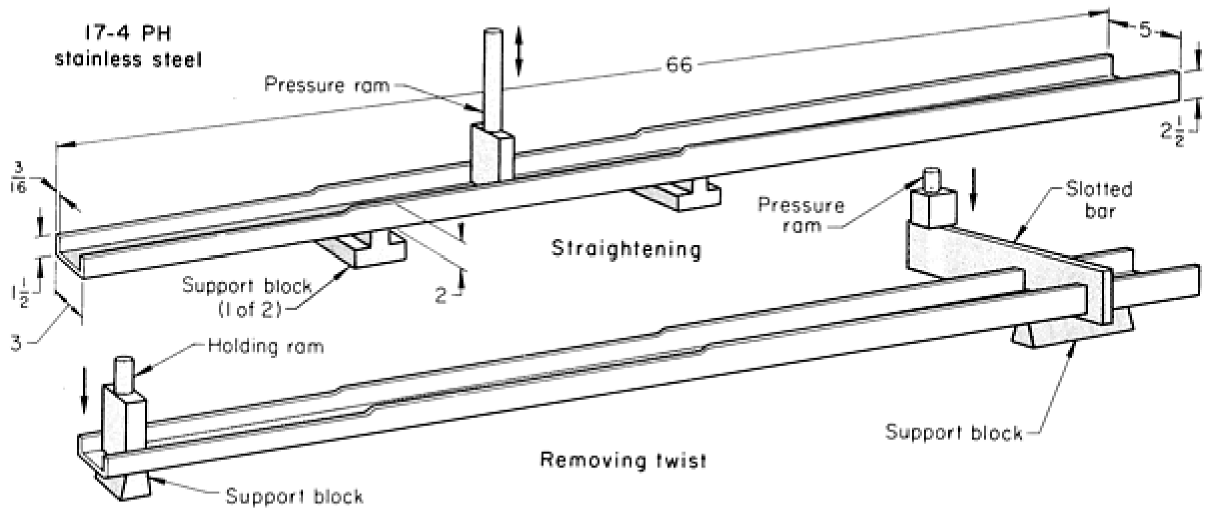

Fig. 9 Setups for straightening and removing twist from a stepped channel. Dimensions given in inches.

The channel was supported on two blocks 406 mm (16 in.) apart while force was applied by a pressure ram through a block fitted to the inside contour (upper view, Fig. 9). A force of 13.3 kN (3000 lbf) deflected the part about 25 mm (1 in.) for a correction of 0.51 mm (0.020 in.). Force was applied at 50 mm (2 in.) increments along the bar.

Two 44 kN (5 tonf) hydraulic presses mounted on a large steel table were used to remove the twist. One ram held one end of the part against a block on the table while the second ram untwisted the part (lower view, Fig. 9). A slotted bar served as a lever to twist the channel 30° for a permanent correction of 0.83 mm per 1 m (0.020 in. per 24 in.) or 1.3 mm (0.050 in.) for the entire length.

Example 6: Straightening a Long, Thin Rectangular Bar in a Hydraulic Press.

A rectangular bar of 17-4 PH stainless steel was 75 mm (3 in.) wide, 2.1 m (84 in.) long, and 6.4 mm ($\frac{1}{4}$ in.) thick (except for 75 mm, or 3 in., at each end, where it was 25 mm, or 1 in., thick). The bar was solution treated and finish machined, which caused a bowing of 6.4 mm ($\frac{1}{4}$ in.). The bar was clamped in a fixture and aged at 480 °C (900 °F), which reduced the bowing to 3.2 mm ($\frac{1}{8}$ in.). After aging, the bar was removed from the fixture, reheated to 425 °C (800 °F), and straightened in an 89 kN (10 tonf) hydraulic press, using 13.3 kN (3000 lbf) of force between support blocks 406 mm (16 in.) apart. This caused deflection of 19 mm ($\frac{3}{4}$ in.) for a correction of 0.76 mm (0.030 in.). It took 20 min and two to three ram strokes per 406 mm (16 in.) setup, as well as five setups per bar, to straighten the bar within 1.5 mm (0.060 in.).

Example 7:

A shaft of medium-carbon steel, 102 mm (4 in.) in diameter × 6.1 m (20 ft) long, was heat treated to 269 to 321 HB, straightened for turning, turned in a lathe, and then straightened for centerless grinding. The shaft lay on rollers beneath the ram of the press, which permitted it to be rotated and to be moved along its axis. Spring-loaded blocks supported the rollers so that straightening pressure would first deflect the springs, letting the shaft down on movable V-block anvils for straightening. The springs pushed the rollers up, lifting the shaft off the anvils when the ram moved up. The shaft was rotated under a dial indicator to find the high spots. The spots were marked with chalk so that they could be moved beneath the ram. The shaft was straightened within tolerance by pressing, moving the shaft, and pressing again. In an 8-h day, 5 to 15 shafts were straightened.

Example 8:

After being heated to 1010 °C (1850 °F) and air cooled, a shaft of D2 tool steel, 50 mm (2 in.) in diameter × 1.7 m (66 in.) long, was straightened within 0.51 mm (0.020 in.). The straightening began when the shaft had cooled to 480 °C (900 °F) from 1010 °C (1850 °F). An 89 kN (10 tonf) hydraulic press applied 8.9 kN (2000 lbf) of force to the shaft, which was supported on anvil blocks 457 mm (18 in.) apart. The shaft was continuously gaged with dial indicators as it was rotated on its axis in order to check the location of the high and low points.

Between 480 and 260 °C (900 and 500 °F), the shaft deflected easily under a load of 910 kg (2000 lb), causing a deflection of 3.2 mm per 508 mm ($\frac{1}{8}$ in. per 20 in.). When the shaft cooled further, straightening was more difficult and required increased force and a longer holding time.

Gaging and straightening continued until the shaft had cooled to 65 °C (150 °F); the shaft was then tempered at 480 °C (900 °F) for 2 h, resulting in a hardness of 59 to 60 HRC. A difficult shaft was sometimes clamped to a 76 × 76 × 1830 mm (3 × 3 × 72 in.) bar with shims and retempered. If the straightness error was 2.0 mm (0.080 in.), a 1.5 mm (0.060 in.) shim was used on each end for a deflection of 3.5 mm (2.0 + 1.5 mm), or 0.140 in. (0.060 + 0.080 in.), and the shaft was retempered at 495 °C (925 °F). The higher tempering temperature made the shaft slightly softer, but generally straightened it within the specified 0.51 mm (0.020 in.).

Parallel-Roll Straightening

Roll straightening is a cold-finishing mill process by which bars and structural shapes are provided with straightness adequate for most applications. For bars and shapes on which close tolerances must be maintained, roll straightening can be followed by press straightening.

In one type of roll straightening, square, flat, hexagonal, and other flat-sided bars are continuously passed between sets of parallel-axis rolls (Fig. 10 and 11). Uniform bends are introduced such that the bar is straight when it leaves the rolls. By varying the distance between roll centers and the amount of offset, the degree of bend can be adjusted according to the section size and yield strength of the metal being straightened.

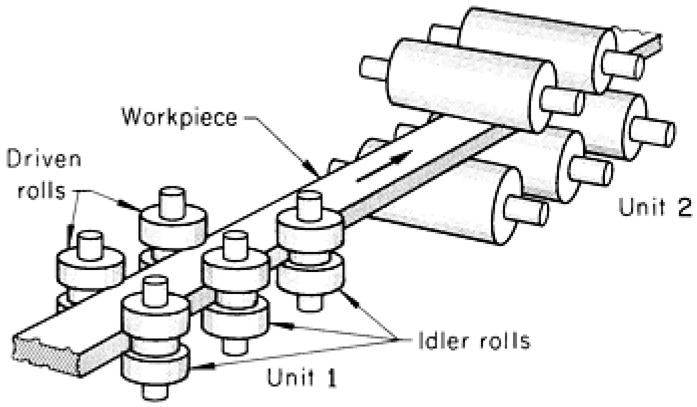

Fig. 10 Arrangement of vertical-shaft and horizontal-shaft rolls in a roll straightener for straightening a rectangular-section bar.

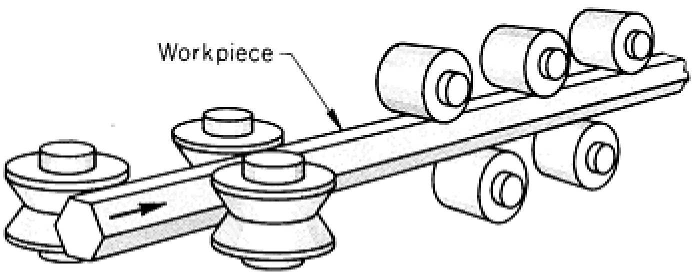

Fig. 11 Straightening of a hexagonal bar in a two-plane roll straightener.

Round bars can be straightened on parallel-axis roll straighteners, but there is no way to prevent a round workpiece from turning on its axis as it passes through the machine. In rotary straighteners, round bars rotate and advance through the rolls so that the bars are bent uniformly in all planes; the rolls are adjustable so that the bars emerge straightened. Rotary straighteners for round bars usually consist of rolls that can be set at variable angles to each other (see the section "Rotary Straighteners" in this article.

Parallel-Roll Straighteners. Square, flat, hexagonal, and other flat-sided bars can be straightened in both directions in one pass through a straightener having two sets of parallel rolls in planes 90° to each other (Fig. 10), or in two passes through a straightener having a set of parallel rolls in only one plane, by turning the bar 90° on its axis between passes.

In machines with a single straightening plane, the rolls are mounted on horizontal shafts as shown in unit 2 of Fig. 10. If the horizontal rolls are grooved (like the vertical rolls of unit 1, Fig. 10), the straightening in one plane also produces some straightening in a plane 90° to the first plane.

For high accuracy of straightness and high production rate, a second unit is added in a plane perpendicular to the first unit (Fig. 10). Unit 1 has vertical shafts for straightening curvature in the horizontal plane; unit 2 has horizontal shafts for straightening curvature in the vertical plane. The two driven rolls rotate, but are otherwise stationary; the three idler rolls are adjustable away from and toward the workpiece.

The first driven roll contacted by the bar is set with enough space between the first two idler rolls to curve the bar uniformly with the concavity toward the first driven roll. As the bar passes over the second idler roll and is held in position by the second driven roll, the concave side of the bar is reversed. The amount of reversal can be controlled by the position of the second idler roll, and with that roll properly positioned, the bar will emerge straight from the third idler roll. With a greater number of rolls, the most severe curvatures are reduced at the entry end of the machine. This results in less work for the remaining rolls and provides for better straightening of small curvatures. The number of rolls in a set of straightening rolls ranges from 4 to as many as 13; the most common number is eight or nine.

The amount of adjustment in roll spacing is determined by:

- The resistance of the work metal to deflection beyond its elastic limit. The greater the resistance, the

- farther apart the rolls must be spaced to provide sufficient shaft and bearing capacities
- The distance must be short enough to produce a permanent set in the smallest bar and to straighten it
- If sections with high width-to-thickness ratios are being straightened, the distance must be great enough so that pressure from the rolls does not upset the edges of the bar

Machines are built with both fixed and adjustable roll-center distances. In adjustable center distance machines, a separate housing carries the roll assembly to permit positioning along the straightener bed. These housings either reduce the space for the shafts or limit the minimum distance between the rolls.

Most sections can be straightened adequately in two planes. A flat bar is shown in Fig. 10 as it passes between grooved straightening rolls on vertical shafts and then through plain-face rolls on horizontal shafts. The bar passes first through the vertical-shaft unit because it is natural for the bar to enter with the flat side lying against the feed table. It is also natural to straighten in the grooved rolls first because the grooves that guide the bar also produce some straightening in the second plane and ensure proper entry of the bar into the second unit. If the machine were reversed, it would be desirable to groove the rolls on the horizontal shafts to make certain that the bar would not "walk off" the rolls.

Grooving the rolls for thin flat bars helps to reduce upsetting of the edge and twisting of the bar. A hexagonal bar is shown in Fig. 11 as it passes between grooved straightening rolls on vertical shafts and through flat-face rolls on horizontal shafts. This roll arrangement follows the same principles as those for flat bars.

Sections that are symmetrical in both planes are easier to roll straighten than nonsymmetrical sections. Sections that are symmetrical in one plane but nonsymmetrical in the plane at 90° are usually best straightened in the symmetrical plane. Axial adjustment of some of the rolls to produce additional straightening in the nonsymmetrical plane is necessary in this method, as in the straightening of the angle section shown in Fig. 12.

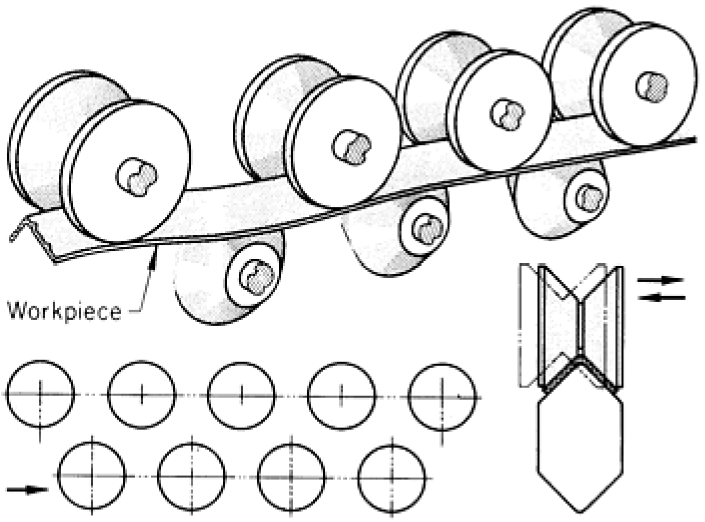

Fig. 12 Roll straightening of a structural angle. The top rolls can be adjusted horizontally and vertically.

Angles are best straightened in horizontal-shaft rolls with the apex of the angle up and roll adjustment made in the vertical plane. The angle lies naturally on the feed table and is straightened in both directions. To take out bends 90° to the plane in which the angle is straightened, one or two top rolls are adjusted axially to deflect the angle in this direction.

A structural channel can be passed through horizontal-shaft rolls with the flanges of the channel up or down. The upper rolls are staggered vertically and horizontally to remove camber in both planes.

Square or nearly square bars can be straightened on the diagonal in a single-plane machine using V-shaped upper and lower rolls (Fig. 13a) similar to the upper rolls used for straightening the angle shown in Fig. 12. In this method of straightening, only the shaded portion of the cross section shown in Fig. 13(b) is stressed beyond the elastic limit; therefore, the results may not be satisfactory. A square is better straightened in a two-plane machine, in which the areas stressed beyond the elastic limit are greater and more nearly symmetrical, as shown in Fig. 13(c). Square and hexagonal bars as large as 102 mm (4 in.) and flat bars as wide as 305 mm (12 in.) are straightened in roll straighteners. Larger bars are usually straightened in presses.

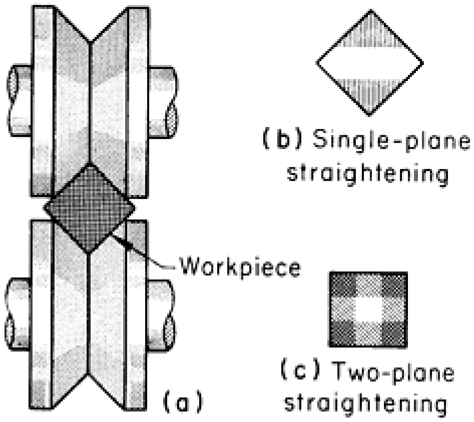

Fig. 13 Roll straightening of square bars. (a) Setup for single-plane roll straightening. (b) and (c) Stress patterns that result from single-plane and two-plane straightening.

Bars of low-carbon steel seldom change size in straightening. Steel having 0.30% C or more may enlarge slightly in section because straightening redistributes the stress that remains from previous operations. For example, a bar of 1045 steel 30 mm ($1\frac{3}{16}$ in.) square may enlarge 0.05 mm (0.002 in.) in one pass through a roll straightener, and 0.10 mm (0.004 in.) in two passes. The bars shorten as they enlarge in section in accordance with the Poisson's ratio of the material.

Square, hexagonal, and flat bars to 19 mm ($\frac{3}{4}$ in.) in cross section are sometimes cold drawn from coils of hot-rolled stock. The drawn bars are straightened in roll straighteners and sheared to length. To correct the curvature resulting from coiling, rotary or two-plane straighteners with sets of six to eight rolls in each plane are used.

Rotary Straighteners

Round bars or shaftlike parts of all types of metal are straightened in rotary straightening machines of two basic types: crossed-axis-roll machines and rotary-arbor machines. The basic principle of rotary straightening is that the workpiece is fed forward and deflected beyond its elastic limit by crossed-axis rolls that also impart the rotary motion. The surface of the bar is alternately subjected to tensile and compressive stresses as it rotates in the straightener. Rotary straighteners are available with two to nine rolls.

A two-roll rotary straightener consists of two rolls that are directly opposed and positively driven. One of the rolls is concave, and the other has a relatively straight face (Fig. 14). The angularity adjustment of the rolls at opposite inclinations rotates and feeds the bar through the machine. Straightening is accomplished by flexing the workpiece into the throat of the concave roll by the modified straight-face roll (Fig. 3d). The bar is positioned vertically by means of a bottom guide or top and bottom guides (not shown in Fig. 14) so that the axis of the bar coincides with the centerline of its path between the rolls.

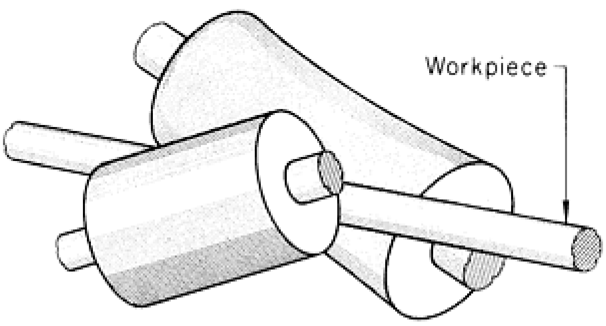

Fig. 14 Arrangement of rolls in a two-roll rotary straightener (top and bottom guides not shown).

The amount of bend given a bar as it passes through the machine depends on two adjustments made by the operator:

- The angle of the rolls to the axis of the bar
- The roll pressure, which is selected by adjusting one of the rolls toward or away from the other

Roll-angle and pressure adjustments depend on the size of the bar being straightened and its mechanical properties. In general, the larger the bar, the greater the roll angle, provided the mechanical properties are about the same. A heat-treated bar (tensile strength: 862 to 1030 MPa, or 125 to 150 ksi) will require a smaller roll angle and more pressure than a bar of the same size and grade that has been annealed, or annealed and cold drawn.

In two-roll rotary straightening, the workpiece is subjected to a continuous straightening action from the point of entrance to the work rolls to the end of the workpiece as it leaves the rolls. Therefore, there is no variation in size within the bar, as is sometimes encountered with multiroll straighteners. Two-roll straighteners can be used for short workpieces, such as rocker-arm shafts and chain-link pins, because all of the flexing is contained within the cavity of one roll. Two-roll straighteners are also used for sizing or for correcting out-of-roundness in hot-rolled bars. Extremely soft metal may be reduced in diameter if too much pressure or too large a roll angle is used. Two-roll straighteners can be used to remove end kinks and to round out squashed ends, both of which sometimes occur when bars are cold sheared to length prior to straightening.

Two-roll rotary straighteners inherently have a lower through speed than multiroll straighteners. The roll inclination must be kept lower (about 20°) in two-roll straighteners; therefore, the rotational speed of the bar is much higher in relationship to the forward speed.

The span over which bending takes place is considerably shorter in two-roll machines than in multiroll rotary straighteners, because in two-roll machines all bending takes place within the length of the rolls and not from roll to roll. With such a short span, much more force must be applied to the bar by the bending equipment than with multiroll machines. Bars from 1.6 to 255 mm ($\frac{1}{16}$ to 10 in.) in diameter can be straightened in two-roll rotary machines.

In addition to finish straightening, the two-roll rotary machine can be used to rough straighten hot-rolled round bars, which may be very crooked and may have sharp hooks and round and scaly surfaces; to straighten and size cold-drawn round bars, which may be bowed but have no sharp bends; and to polish or burnish to improve surface finish after grinding. Additional rolls should be kept for straightening only, sizing only, and polishing only.

Multiroll Rotary Straighteners. Another type of machine used in the straightening of bars is the multiroll rotary straightener. Figure 15 shows a five-roll rotary straightener, which consists of two driven rolls and three idler rolls. The two end idlers oppose the driven rolls, and between them is the middle or pressure roll. All rolls are concave, and the roll inclination is adjustable in order to obtain the maximum length of contact between the roll surface and the workpiece (see also Fig. 3e). Bottom cast iron guide shoes are located at the entry and exit ends between the driven rolls and their respective opposing idlers to position the bar properly.

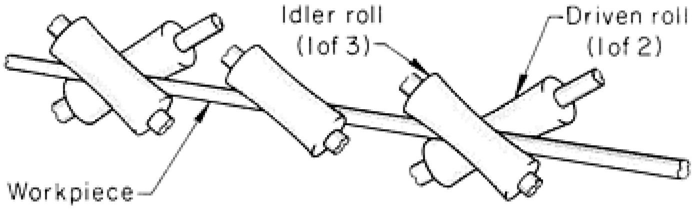

Fig. 15 Arrangement of rolls in a five-roll rotary straightener.

A six-roll rotary straightener has a roll arrangement similar to that of a five-roll machine; the sixth roll is placed either opposite the middle roll or outboard of the exit-end powered rolls (see these roll arrangements in Fig. 3f). Seven-roll arrangements consist of two three-roll clusters with a middle idler roll (Fig. 3g). Small cluster-roll straighteners have been extensively used for specialty work on small workpieces, such as valve push rods (~7.9 mm, or $\frac{5}{16}$ in., in diameter) and rocker-arm shafts; however, these straighteners are used most often for straightening large tubing (60 to 610 mm, or $2\frac{3}{8}$ to 24 in., in diameter).

In operation, the rolls are angularly adjusted to accommodate various bar sizes. With the average angle selected as 30°, the adjustment may vary from about 28 to 30°, depending on the size of the bar being straightened.

In a five-roll straightener, the middle idler roll is adjusted to put enough bend in the bar to exceed the elastic limit of the metal. As the bar is fed through the straightener and rotated by the entrance and exit rolls, the adjustment of the pressure roll causes the bar to bend beyond its elastic limit in all directions perpendicular to its longitudinal axis. This action produces a straight bar with symmetrical stresses.

Optimum settings of roll angle vary somewhat with bar size. Typical settings are given in Table 1.

Table 1 Typical settings of roll angle for five-roll rotary straighteners for use on bars of various diameters

Diameter of bar		Setting of roll angle, degree
mm	**in.**	
19	$\frac{3}{4}$	**26** $\frac{5}{8}$
25	1	**26** $\frac{7}{8}$
32	$1\frac{1}{4}$	**27**
38	$1\frac{1}{2}$	**27** $\frac{1}{4}$
44	$1\frac{3}{4}$	**27** $\frac{1}{2}$
50	2	**27** $\frac{3}{4}$
57	$2\frac{1}{4}$	**28**
64	$2\frac{1}{2}$	**28** $\frac{1}{4}$
70	$2\frac{3}{4}$	**28** $\frac{1}{2}$
75	3	**28** $\frac{3}{4}$
83	$3\frac{1}{4}$	**29**

89	3 1/2	**29 1/4**
95	3 3/4	**29 1/2**
102	4	**29 5/8**
108	4 1/4	**29 7/8**
114	**4 1/2**	**30**

Recommended settings for the starting setup; these will vary slightly in the actual setup used.

Cold-drawn bars that are straightened in a multiroll rotary straightener usually increase in diameter during the straightening operation. Low-carbon steel bars with up to about 0.15% C show a negligible increase in diameter. However, as the carbon content increases, the amount of change increases. It is not uncommon for 50-mm (2-in.) diam cold-drawn bars of 1050 steel to increase as much as 0.1 mm (0.004 in.) in diameter. These bars will decrease in length by about 13 mm per 3.7 m (1/2 in. per 12 ft) as a result of the increase in diameter. This shortening must be considered when bars are cut to exact lengths before straightening.

When cold-drawn bars are to be straightened in a multiroll rotary straightener, selection of the cold-drawing die size is important if the bars are to be held within standard size tolerances. Most grades, particularly those having high carbon content, should be drawn to the low side of the diameter tolerance to compensate for the increase during straightening. The extreme ends of the bars, which do not get the full effect of the bend by the pressure roll, do not increase in diameter. After straightening, the bar ends will remain the same size as when cold drawn.

Straightening in a multiroll rotary straightener does not work harden the bar stock to any appreciable extent. This is desirable when the bars are to be cold headed or cold extruded.

The basic five-roll straightener has been modified so that four of the rolls are driven and only the middle pressure roll is an idler. The heavier feeding pressure obtainable with driven entry and exit pressure rolls is advantageous in that a polishing effect can be obtained on products such as cold-drawn steel. In addition, the driven rolls provide more traction so that a heavier deflection can be exerted by the middle straightening roll.

In a further modification of the five-roll straightener, all five rolls are driven. This eliminates the need for guides between the rolls, but roll speed synchronization becomes important.

Hot-rolled round steel bars are generally straightened commercially in two-roll or multiroll rotary straighteners. Bars as large as 255 mm (10 in.) in diameter and having yield strengths up to 690 MPa (100 ksi) have been straightened in these machines. Some machines are modified by adding hydraulic loading to the straightening mechanisms and by adding a shear pin to provide for any shock loading that might be encountered because of the extreme out-of-roundness of large hot-finished bars.

Rotary-arbor straighteners are used to straighten coiled rod or wire up to 32 mm (1 1/4 in.) in diameter. The straightening is done by an arbor rotating around the wire as it passes through the machine, as shown in Fig. 16 (see also Fig. 3h). The arbor encloses five pairs of cast iron straightening dies. The dies are equally spaced in a fixed spacing that relates to the size capacity of the machine. The greater the capacity, the greater the fixed spacing of the dies.

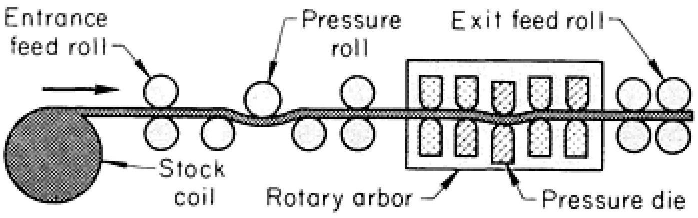

Fig. 16 Arrangement of rolls and dies in a rotary-arbor straightener used for the straightening of coiled rod or wire.

The dies, bell-mouthed for easier entrance of the wire, are locked in place by adjusting screws. The pairs of dies at the two ends of the straightener arbor are set so that the wire is always at the center of the arbor in these dies. The middle die is called the pressure die because it is set to bend the wire slightly, as shown in Fig. 16. The dies on either side bend the wire slightly in the opposite direction.

The machine is set by trial. If the wire comes out bowed, usually the pressure die has not been set to bend the wire enough. If the wire comes out wavy, the pressure die may be bending the wire too far. Helical marks may be caused by lack of lubrication, imperfect dies, or an embedded sliver of metal.

Growth. During straightening in a rotary-arbor machine, most grades of cold-drawn carbon steel and of alloy steel with more than 0.15% C, will increase in diameter (as much as 0.15 mm, or 0.006 in.) unless the wire has been stress relieved before straightening.

Speed of straightening in rotary-arbor straighteners is usually 23 to 61 m (75 to 200 ft) per min, depending on the size capacity of the machine and on the type of wire.

Cut lengths of bars are straightened in mechanisms such as the one shown in Fig. 17. A helical motion is imparted to the bars by pairs of rotating, offset friction disks, which burnish the bar as they feed it through three straightening bushings that turn freely in bearings. The middle bushing is adjusted to deflect the bar, just enough for good straightening action. Such a machine made in various size capacities can straighten bars 2 to 32 mm ($\frac{5}{64}$ to $1\frac{1}{4}$ in.) in diameter at speeds of 28 to 50 m (92 to 164 ft) per min.

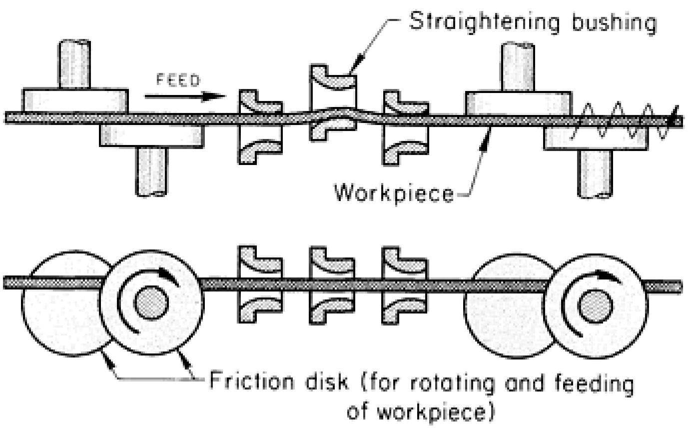

Fig. 17 Plan and side views of a mechanism for straightening cut lengths of bars.

Straightening Stainless Steel for Cold Heading. Coiled stainless steel wire (series 300 and 400) 1.6 to 15.5 mm (0.062 to 0.610 in.) in diameter requires moderate straightness while being fed into cold-heading machines. Wire 1.0 to 3.2 mm (0.040 to 0.125 in.) in diameter can be hand straightened sufficiently for entering the feed rolls. The feed rolls then pull the wire with enough tension to remove the coil radius as the wire leaves the coil reel. For parts having a length-to-diameter ratio of 4 to 1 to 8 to 1, no further straightening is necessary. The feed rolls provide sufficient straightness to permit the blank to be cut to length and transferred to the die station. After cold heading, the part has the straightness obtained in the heading operation.

Parts up to 152 mm (6 in.) long cold headed in open-die headers require a straightness of 0.1 mm in 102 mm (0.004 in. in 4 in.). A single-plane five- or six-roll straightener placed 90° to the feed roll is usually used. Single-plane and two-plane straighteners mounted on portable pedestals are available as machine accessories.

Straightening of Bars, Shapes, and Long Parts

Automatic Press Roll Straightening

One of the fastest straightening processes available is the automatic press roll-straightening method. It is capable of straightening small concentric parts at up to 1200 pieces per hour; larger parts with greater ovality, such as cold extrusion axles and transmission shafts, can be made at 225 pieces per hour.

Roll straightening features support and straightening roll assemblies that resemble those used in a roller V-block, but it includes a headstock unit equipped with a drive mechanism to rotate the workpiece. This process uses a press frame with a hydraulically powered ram (Fig. 18). Two or more lower support roll assemblies are mounted on the bed of the device, while one or more upper support rolls are mounted on the ram. Additional roll assemblies are needed to straighten a series of bows (known as snaking). The headstock consists of a chuck or driver used to rotate the workpiece. The equipment is particularly suited to the straightening of cylindrical solid parts as well as tubular parts having walls that are thick enough to withstand the pressure of the rolls without being deformed (see the article "Straightening of Tubing" in this Volume).

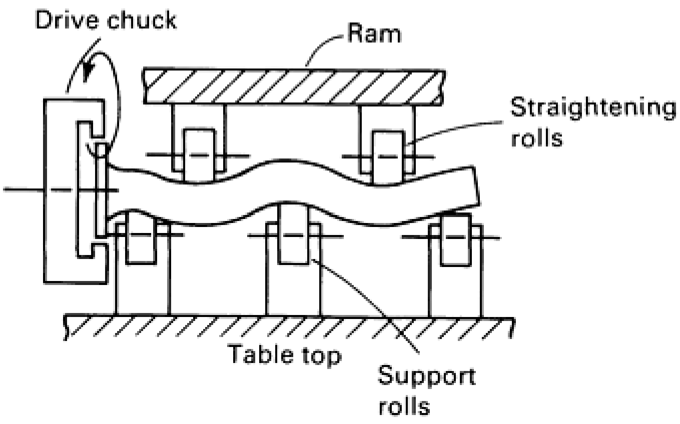

Fig. 18 Illustration of equipment used in automatic press roll straightening.

The process is initiated by placing the workpiece on the lower rolls and having the driver move forward to engage the part and to rotate the workpiece. The overhead rolls situated on the ram are then applied to deflect the part in a bowlike arc while the workpiece rotates. This procedure subjects the material to a plastic strain. When the material exceeds the yield point, the ram action is released to complete the cycle.

The advantages of this method include a stretch-relieving action that accompanies the straightening as well as the ability to handle a wide range of types and degrees of out-of-straightness conditions. Concentric parts with no ovality can be held to a close tolerance and require minimal operator skill.

The disadvantages of this technique are that it cannot be used on nonround parts, thin-wall tubes, or parts having variable diameters. Only hardened shafts with a hardness of 38 HRC or less should be straightened using this method, because the depth of hardness limits its effectiveness.

Moving-Insert Straightening

Designed for use on linear, flat, or irregularly shaped parts, moving-insert straightening is accomplished by reciprocal strokes transmitted to tooling inserts by a rotary-cam action. When positioned between two rows of movable inserts situated on a tool base, a part is subjected to a series of reciprocal strokes that overbend the workpiece by a preset amount (Fig. 19). The amplitude of the movement is progressively reduced during the cycle until it approaches a straight line, at which point the workpiece is also straight. The degree of bending movement and the number of bending cycles are adjustable, and varying insert spacing is available to accommodate a wide range of soft or heat-treated components. The primary advantages of this straightening technique are its ability to straighten flat or irregularly shaped parts, with or without projections, bends, and so on; the ability to produce straightness or slight curves when needed; a tolerance as close as 0.03 mm (0.001 in.) throughout the length of the part, depending on its configuration; and minimal skill requirements imposed on the operator.

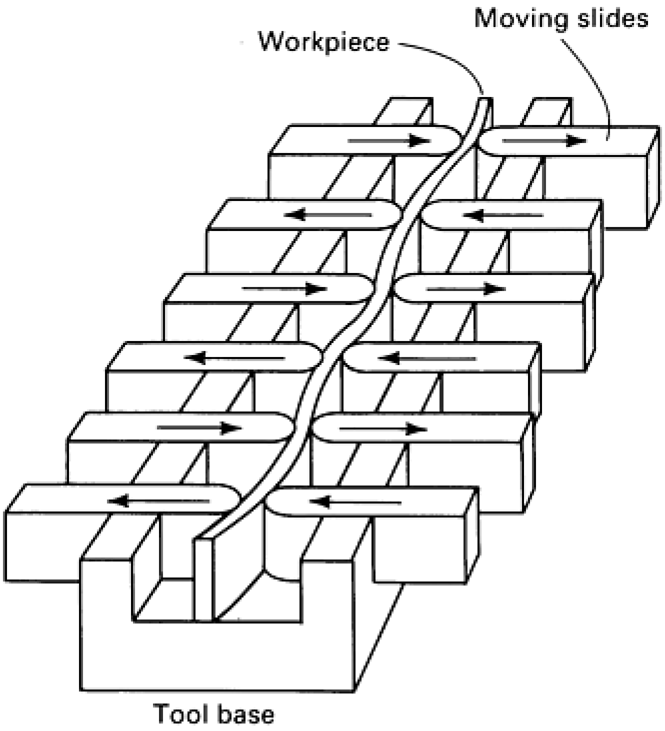

Fig. 19 Moving-insert straightening for linear, flat, or irregularly shaped objects.

Parallel-Rail Straightening

Parts that feature multiple diameters and heads, such as bolts and spindles, require a straightening device that adjusts to the contours of the workpiece. The parallel-rail method performs this function by employing a series of parallel rails. One group of rails is located on a slide, and the other group is located on a ram or head above and between the bottom rails. As shown in Fig. 20, the cylindrical or thick-wall tubular part is positioned between the rails, and the ram is lowered by adjustable hydraulic pressure to overbend the workpiece. Simultaneously, the lower slide moves forward and rotates the workpiece. At the end of the stroke cycle, the pressure decreases to zero, and the part is now straightened. The configuration of the workpiece determines the number and position of the adjustable rails needed to complete the straightening operation.

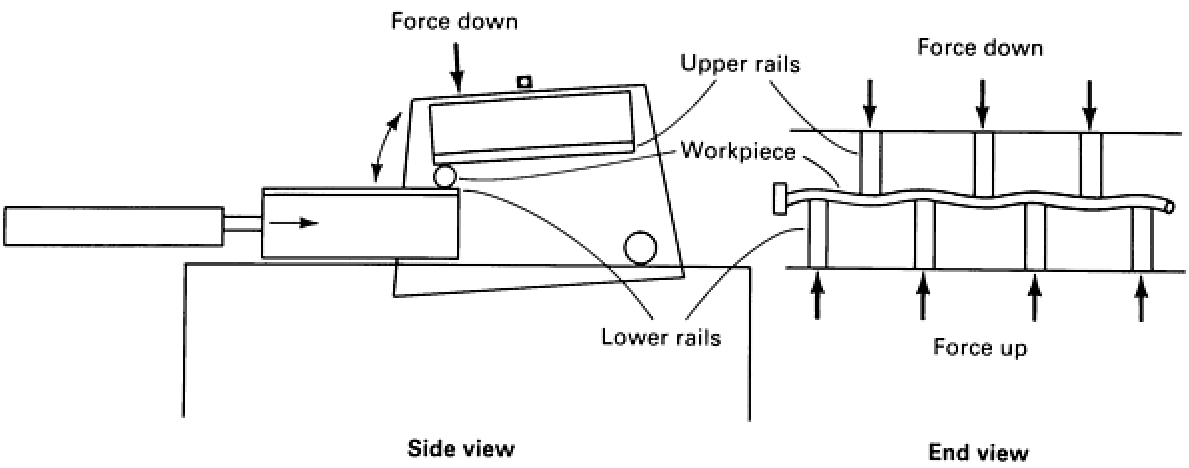

Fig. 20 Parallel-rail straightening for cylindrical or thick-wall tubular parts, either symmetrical or with variations

in diameter.

With this technique, production rates of 500 to 600 pieces per hour can be obtained with manual loading and unloading methods. Production rates of 1000 pieces or more per hour can be obtained with automatic loading and unloading equipment.

Among the advantages of parallel-rail straightening are:

- Minimal operator skill required
- Easy adjustment to make rails conform to workpiece configuration
- Complex parts featuring headed areas and multiple diameters can be straightened
- High production rates combined with low tooling costs

The primary disadvantage of parallel-rail straightening is that workpiece dimensions are limited by the machine width of 610 mm (24 in.) as well as maximum diameters of 20 mm (0.8 in.).

Straightening of Bars, Shapes, and Long Parts

Epicyclic Straightening

Epicyclic straightening is specifically suited to straightening linear parts, tubing, and solid cylindrical parts featuring a variety of cross-sectional shapes. After the workpiece is securely supported by locating fixtures at either end, a straightening arm secures the part in the approximate center of its length (additional straightening arms may be necessary on some parts due to length and configuration considerations). The straightening arm is programmed to move in a circular or elliptical path about the neutral axis of the part. The cross section of the part is taken through its elastic limit as the amplitude of the arm motion is increased. At the elastic limit, the motion decreases, and the arm moves to a stationary position at the neutral axis of the workpiece to produce a straight and stable part.

The motion of the straightening arm is a circular path for round parts, while parts with varying cross sections, such as an I-beam section, require an elliptical path (Fig. 21). The feed rate should be maximized to reach the yield point as quickly as possible. The degree of straightness required determines the feed rate necessary to return the part to its neutral axis.

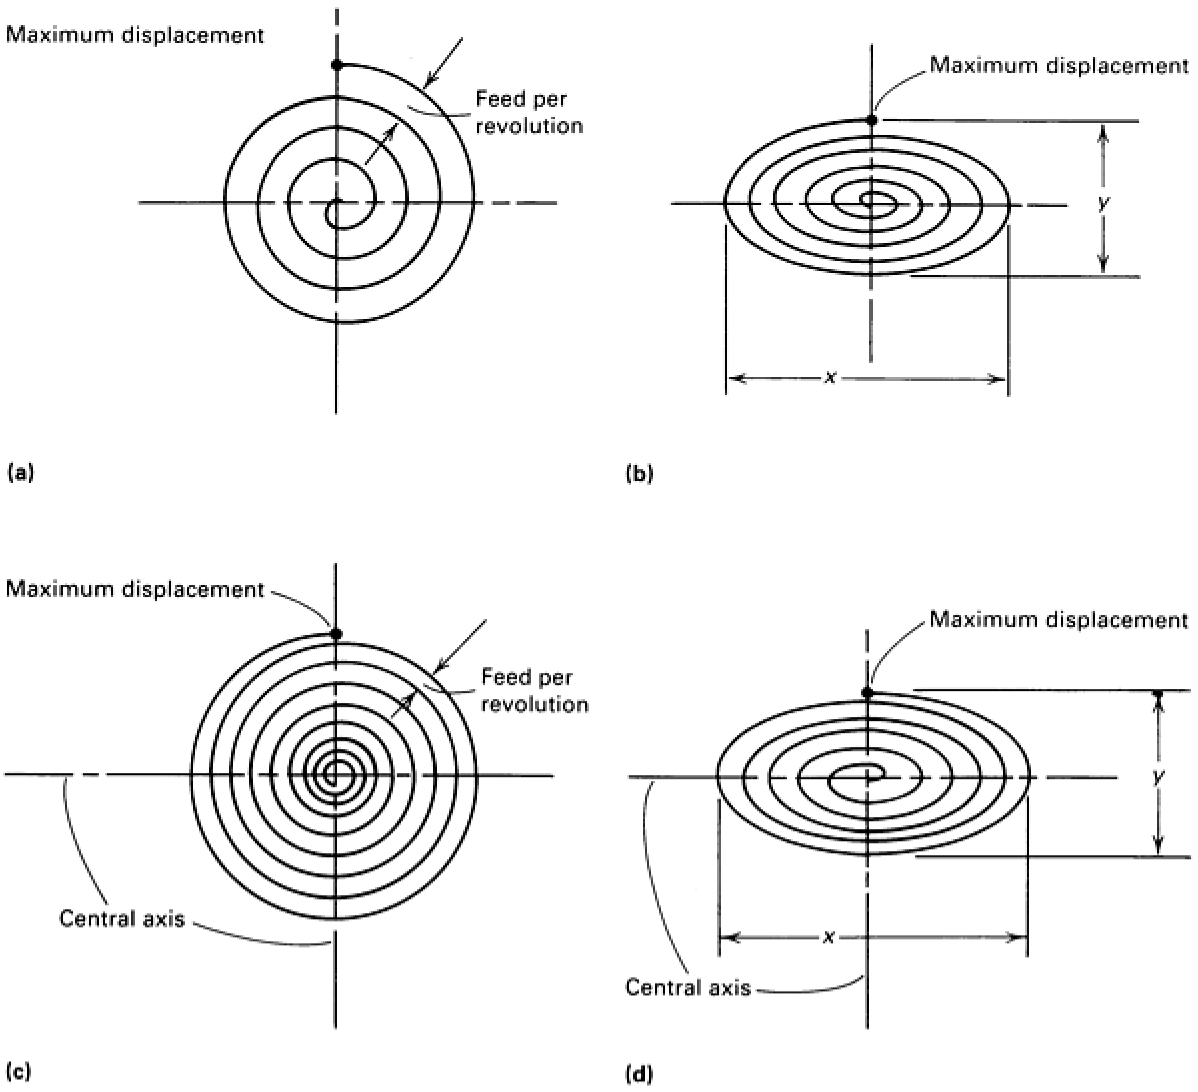

Fig. 21 Circular and elliptical paths of the motion arm on an epicyclic straightener. (a) Displacement circular. (b) Displacement elliptical. Ratio *x*:*y* = 2:1. (c) Feed to central axis circular. (d) Feed to central axis elliptical. Ratio *x*:*y* = 2:1.

Epicyclic straightening can be used on such parts as I-beam axles, trailer axles, asymmetrical forgings, and thin-wall propeller shaft or drive shaft tubes. Production rates range from 80 parts per hour (trailer axles) to 300 parts per hour (propeller shaft tubes).

Straightening of Tubing

Revised by Philippe Delori, SMS Sutton, Inc.

Introduction

TUBING of any cross-sectional shape can be straightened by using equipment and techniques that are basically the same as those discussed in the article "Straightening of Bars, Shapes, and Long Parts" in this Volume. In general, a round tube that has warped in annealing or other heat treatment is given a rough-straightening pass in a press or a roll straightener, followed by one or more passes in a rotary straightener and, if required, a finish pass in a press straightener.

Rough straightening eliminates excessive bow that would cause whipping in the inlet trough. Because the tube does not rotate during rough straightening, almost any amount of bow can be accepted; therefore, both roll and press straightening can be used. If the tube is only slightly bowed, initial rough straightening can be omitted.

A rotary straightening pass is necessary for finish straightening, but need not be used when the tube requires another cold-drawing operation. Two or more rotary passes may be required when the tube has developed excessive out-of-roundness, bow, or multiple kinks in previous processing.

If the tube is considerably out-of-round, a normal straightening pass, with only a middle roll offset, will not be effective. A preliminary pass with no offset in the middle rolls and all rolls set to ovalize may be required before the normal straightening pass.

Most tubing, especially the smaller sizes (32 mm, or $1\frac{1}{4}$ in., in outside diameter and smaller), requires only one or two rotary straightening passes. For larger-diameter tubing (38 mm, or $1\frac{1}{2}$ in., in outside diameter and larger), or when straightness better than standard is required, additional work can be done in a press straightener to remove short end hooks or to secure precision straightness. Press straightening converts long, gentle bows into a series of short bows ending at each point where the punch hits.

Straightening of tubing having shapes other than round is done in roll or press straighteners with much the same considerations governing the choice as those for similar solid shapes. Asymmetrical sections, such as airfoil or teardrop designs, require press straightening. Stretch straighteners are helpful in detwisting and straightening asymmetrical shapes.

Effect of Tubing Material

Procedures and tooling are influenced by the tubing material. The principal factors are the composition and condition of the work metal, wall thickness, type of tubing (seamless or welded), and type and extent of distortion. Greater force and more rugged equipment are required for straightening tubes with thick walls and high elastic limit.

Wall Thickness. The amount of distortion that occurs in the hollow section where it bears against the straightening tools is relatively small in thick-wall tubes, which approach solids in their behavior. Distortion becomes significant as tube walls become thinner, necessitating precautions against permanent distortion. Damage to thin-wall tubing appears as spot dinges or ovality from punch straightening, or as spiral dinges (called rings) or ovality from rotary straightening.

Type of Tubing. Seamless tubes often have a nonuniform wall thickness, which makes the straightening operations more difficult. In a welded tube, the weld and adjacent material may have mechanical properties that differ considerably from those of the rest of the tube. Residual stress from welding may also affect straightening.

Type and Extent of Distortion. Crookedness in tubing can result from distortion during heat treatment or cooling, from distortion during cold drawing as the result of eccentric wall, from hooked ends on hot-finished tubes (usually caused by misalignment or roll wear in the hot-sinking mill), or from accidental bending during processing. End hooks are pronounced bends that appear close (usually within 455 mm, or 18 in.) to the leading or trailing ends of some tubular products.

Straightening of Tubing

Revised by Philippe Delori, SMS Sutton, Inc.

Control of Straightening Pressure

Pressure exerted on the workpiece by the straightening rolls must be carefully controlled to prevent permanent damage, especially to thin-wall tubing. This can be done by increasing the distance between the points at which the tool contacts the workpiece, thus reducing the total force, or by increasing the contact area between tool and tubing, thus reducing the unit pressure on the workpiece.

In the rotary straightening of thin-wall tubing, the length of contact between the roll and the tube and the distance between sets of rolls should both be maximum, and care should be exercised in the adjustment of opposed rolls to avoid excessive ovalizing and pressure on a short section of tubing. In a two-roll machine, the length of curve is limited to the length of the roll, and tubing with very thin walls may be subject to ringing at the roll shoulders where the pressure is greatest. This limits the two-roll machine to a maximum diameter-to-wall thickness ratio of about 15 to 1 for full straightening.

Press Straightening

The straightening press can rough straighten tubing prior to roll straightening or rotary straightening, or it can completely straighten tubing by removing end hooks that cannot be removed easily by any other method. End hooks and large cambers sometimes must be removed to permit the tubing to enter the rotary straightener and to prevent dangerous whipping of the work. A press can also be used to straighten welded tubing before the bead is reduced. It is best to reduce the bead before straightening the welded tubing in a rotary straightener.

Tooling. In the press straightening of thin-wall tubing, there should be a wide spacing between saddles. If there are short kinks in the tube, the spacing is dictated by their length, and operator skill must be relied on to obtain the best possible straightening.

Rolls with a semicircular groove for holding the tubing are sometimes used for end supports. The spacing of these rolls can easily be adjusted to suit the length of the bow. The pressure shoe attached to the press ram is flat, with a semicircular groove to distribute force over a greater area. The diameter of the groove should approximate the diameter of the tube to avoid flattening of the tube under pressure.

Applications. Straightening presses are used on tubes to remove kinks, camber, and other distortions caused by mishandling, cutting off, and heat treatment. Straightening presses can also be used to reduce the out-of-roundness of tubing.

Straightening of Tubing

Revised by Philippe Delori, SMS Sutton, Inc.

Parallel-Roll Straightening

Single-plane and two-plane roll straighteners for tubular products are basically the same as those for solid bars. Machines for tubular products may have somewhat longer center distances than bar straighteners and at the same time may not require shafts and bearings that are as large. The roll-center distance is generally a function of the outside dimensions of the tube, and it increases approximately as the outside dimensions of the tube increase. Less force is required for straightening tubes than solid bars of equal outside dimensions.

Round tubing is best straightened on machines equipped with semicircular grooved rolls. The grooves must conform closely to the tube size, and each size must have its own set of rolls, or set of grooves in a multigrooved roll. Round tubing will twist slightly in the rolls, thus avoiding the effect of straightening and resulting only in rough straightening.

Tubing that is badly warped can be rough straightened as easily in a roll straightener as in a press. The roll straightener operates faster than the press but takes longer to set up. When straightening 50 mm (2 in.) diam, 6 m (20 ft) long tubes, for example, the roll straightener can process 250 to 400 pieces per hour as compared to 100 to 120 pieces per hour in a press. However, changeover time for a roll straightener is 16 min; a press setup can be changed in as little as 6 min.

The cost of roll straightening increases greatly for the larger tube sizes. Therefore, a large tonnage of tubes must be processed to justify the cost of machines for straightening tubes that are larger in outside diameter than approximately 75 mm (3 in.).

Square and rectangular tubing is commonly straightened in either single-plane or two-plane machines (see the article "Straightening of Bars, Shapes, and Long Parts" in this Volume). If the rolls of a single-plane machine are grooved to fit the tube, an appreciable straightening effect in a plane spaced at 90° is provided. When additional straightening is required, square tubes are turned 90° for a second pass through the rolls. A two-plane roll straightener is better suited to rectangular tubing than a single-plane roller because the rolls need not be reset for the second pass.

Straightening of Tubing

Revised by Philippe Delori, SMS Sutton, Inc.

Two-Roll Rotary Straightening

The principle employed in the rotary straightening of round tubes is basically the same as that for solid round bars. The driven rolls, set at a predetermined angle, rotate the tube while conveying it in a lineal direction. The crest of the bow is stressed to, or beyond, the elastic limit once during each revolution, and the maximum stress point is repeated spirally along the length of the tube. The distance between each stress point depends on the lineal travel for each revolution of the tube. Approximate values for lineal travel can be determined by multiplying the tube circumference by the tangent of the angle of the rolls. Special contoured rolls can be used to eliminate stress points, yielding tubes with uniform stresses.

Two-roll rotary straighteners (see the article "Straightening of Bars, Shapes, and Long Parts" in this Volume) are used primarily on tubes having a diameter-to-wall thickness ratio of no more than 15 to 1. The machine is equipped with two skewed rolls, between which two guide shoes are mounted. One roll has a concave contour; the other is straight or convex. The rolls can be arranged in a horizontal or a vertical plane. Machines with rolls arranged in the vertical plane are of relatively new design.

The tube is held between the guide shoes while the straight or convex roll bends the tube between the ends of the concave roll. The maximum deflection depends on the depth and the skew angle of the concave roll.

Two concave rolls have also been used to straighten tubes. The concave rolls are set to make full-length contact along the surface of the tube, and the crest of the bow is ovalized between the rolls several times before the tube emerges from the machine.

Straightening of End Hooks. The two-roll machine can remove most of the sharp bend at the end of tubing if the rolls are ground to suit the deflection requirements of the tube material and are set at an angle to suit the size of tube and length of end hook. The resulting curve in the rolls is suitable for a specific range of tube sizes with a specific elastic limit. Wider variations in tube size and grade of material can be processed by changing the angle setting of one or both rolls to produce the required deflection.

The design of the two-roll machine permits the rolls to be set at a small angle with the centerline of the stock. The smaller the angle, the less through feed per revolution of the tube, and because of the small helix angle created by feed per revolution, a large portion of the tube is subject to maximum bending stress.

Short bends and end hooks can be straightened in a two-roll machine, because all bending takes place within the length of the rolls and not from roll to roll, as is the case with multiple-roll machines. The short span greatly increases the load necessary for straightening, which partly explains why a two-roll machine is unsuccessful in straightening thin-wall tubing.

Roll Angle. Contoured rolls are designed for a specific range of tube sizes and materials. This is approximately the same range of conditions that can be handled by the equivalent multiple-roll straighteners. For most applications, the rolls are set at an angle of 15 to 25°. The contour of the rolls can be varied to suit specific applications. For example, a roll of shallow concavity is used for materials having low elastic limits, while a roll of deeper concavity can be used to straighten materials having higher elastic limits.

Limitations. The two-roll machine is not ordinarily used to finish straighten tubing if the ratio of outside diameter to wall thickness is greater than 15 to 1. The crushing strength of a thin-wall tube in the short span of a two-roll straightener is such that the tube will crush, or ring, before it bends if the rolls are set to remove the maximum bend. However, if the amount of bend to be removed is reduced by a preliminary rough-straightening operation, the machine can be used to finish straighten tubing having a diameter-to-wall thickness ratio considerably greater than 15 to 1, depending on the amount of straightening done in the preliminary operation.

Polishing of the tube surface can be either beneficial or detrimental. The hourglass shape of the rolls presents different diameters to the surface of the tube, resulting in some slipping. This burnishing action improves surface finish, although excessive slipping can produce a burnished spiral on the work surface.

Scratches may result when foreign material becomes embedded in the guide shoes. The use of nylon shoes and a soluble oil as a lubricant will reduce scratches.

Sizing After Derodding. Producers of cold, drawn tubing use internal mandrels to control the inside diameter, and two-roll crossed-axis machines are used to extract the mandrel (derod) after the drawing process. The identical rolls apply heavy pressure on the workpiece, thus expanding the tubing to allow removal of the mandrel.

The expanded tubing does not always return to its drawn diameter. The external dimensions of tubing can be corrected by drawing the tubing through dies that are undersize by an amount equal to the amount by which the tubing expands during derodding.

Straightening of Tubing

Revised by Philippe Delori, SMS Sutton, Inc.

Multiple-Roll Rotary Straightening

Rotary straighteners with five, six, seven, or even more rolls are also used to straighten tubing. The five-roll machine consists of two two-roll clusters and a middle deflecting roll. This machine has two large rolls on one side that are opposed or nearly opposed by three small rolls on the other. Two of the three small rolls and the two large rolls function as entry and exit feed rolls. The third small roll located between the other two small rolls functions as a deflecting roll. The rolls can be arranged in the horizontal or in the vertical plane.

In some machines, only the two large rolls are driven; in others, all rolls except the deflecting roll are driven, and sometimes all five rolls are driven. When more than two rolls are driven, the speed matching of roll surfaces becomes important. Matching can be obtained by maintaining the correct relationship between roll diameters or, more easily and accurately, by a differential drive between the two roll banks or, in some machines, by driving the rolls with individual motors having relay, continuous-feedback, or similar controls.

The six-roll machine has two middle deflecting rolls opposed to one another, similar to the entry and exit rolls in the five-roll straightener, but it differs from the five-roll straightener in that all rolls are of equal diameter. Normally, four or all six of the rolls are powered. Another type of six-roll straightener has a roll arrangement similar to that of a five-roll straightener with an additional outboard roll.

A seven-roll rotary straightener has two three-roll clusters--one at the entry end and one at the exit end of the straightener--and a middle deflecting roll (Fig. 1). Normally, the two bottom rolls are driven and the five others are idlers. The middle roll (deflecting roll) moves vertically, and the four end idler rolls move in a circular path about pivot points in the base and apply pressure to the tube for feeding and straightening. This seven-roll arrangement has the greatest effect at the middle roll because the tube is held perfectly in the pass.

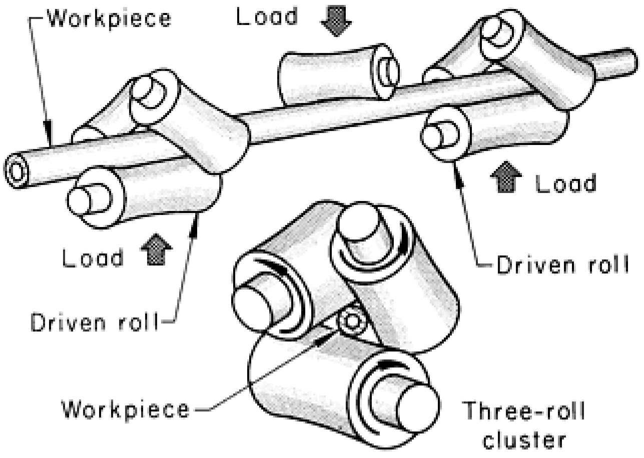

Fig. 1 Arrangement and principles of operation of three-roll clusters in a seven-roll rotary straightener

Various other multiple-roll straighteners have been built for specific applications. The general principles that apply to the use of multiple-roll machines are the same as those already described for two-roll straighteners.

Middle-roll offset straightening bends a straight tube by an amount that stresses the outer fibers of the tube to the elastic limit. When the straightening load is released, the tube springs back to its initially straight position. The outer fibers of an initially bowed tube are stressed beyond the elastic limit, and the tube springs back to a straight position.

Straightening of tubing in this manner can be termed single-pass straightening. It is possible, however, to arrange the rolls in the multiple-roll machine to double straighten each tube as it is conveyed through the machine. The middle roll stand is offset to deflect a bowed tube and to stress its outer fibers beyond the yield point, and in a similar manner, the tube is deflected over the third roll stand by an auxiliary roll or by the discharge table. The tube is stressed at both the middle and third roll stands--or, in effect, double straightened--with each pass through the machine.

Bending the tube, however, creates an area of strain or cold work directly under the bending load. The rotation of the tube as it goes through the machine generates a spiral of strained area around the periphery of the tube. The centerline of the third roll stand should be spaced such that no one point on the tube duplicates itself at the same location on both the middle and third rolls, thus eliminating the possibility of reworking the strained area.

Tube Deflection. The amount δ by which the middle roll or rolls must be offset from the entry and delivery rolls varies inversely with the outside diameter of the tube to be processed, as demonstrated below:

$$\delta = \frac{Sl^2}{6ED}$$

where S is the yield strength of the metal, l is the distance between the outboard rolls, E is the modulus of elasticity, and D is the outside diameter of the tube.

As the diameter of the tube decreases, the deflection requirements increase over a given span. Therefore, the factor that determines the smallest-diameter tube that a machine can process is the deflection requirement of the tube over the span of the rolls. Approximately 19 mm ($\frac{3}{4}$ in.) is the maximum deflection that can be applied to most tubes without adversely affecting travel of the tube through the rolls of a rotary straightening machine.

Applications. Multiple-roll machines are advantageous in processing thin-wall tubes, and thick-wall tubes having a high ratio of diameter-to-wall thickness. This is because of the lower unit loading on the workpiece that is applied across the longer bending spans between adjacent rolls. The multiple-roll straightener has an additional advantage in higher throughput speeds than other rotary straighteners, because of the higher angularity settings of the rolls. Therefore, multiple-roll straighteners are widely used in tube mill production lines.

Multiple-roll machines are ordinarily used for applications in which the primary purpose is the sizing or burnishing of the workpiece. They do not straighten as accurately as two-roll machines, nor do they remove end hooks effectively.

Long bows in medium- and heavy-wall tubes are removed by closing each roll pass and bending the tube with the middle roll. Closed-pass rolling provides full-length support within each roll stand. Straightening in this manner requires less deflection and spreads the bending load over the full length of each roll.

Long bows can sometimes be removed from extra-heavy-wall tubes by opening each roll stand and bending the tube between the two bottom rolls with the top middle roll. The object is to exert a minimum load on the tube.

Thin-wall tubes should be processed with low unit loads applied to the surface of the tube and with minimum deflection. High loads and excessive deflection will ring the interior of the tube. The bending load can be spread across the surface of the tube by angling the middle roll toward the centerline of the pass. Ovalizing and spreading the roll contact lower the required amount of deflection to produce a straight tube. Deflecting a tube over a long span requires a large offset that can make it difficult to convey the tube through the machine. However, proper roll design and roll spacing make it possible to process a wide range of outside diameters in the multiple-roll rotary straightening machine.

End hook can be removed from thin- and medium-wall tubes by ovalizing and bending the tube in the middle roll pass. Removing end hook from thick-wall tubing on multiple-roll straighteners is difficult because the center-to-center distance between the No. 1 and 2 roll stands is usually greater than the length of the end hook.

The roll angle of a straightening machine depends on the outside diameter of the tube to be straightened. In general, a machine used for small-diameter tubing in the range of 6.4 to 19 m ($\frac{1}{4}$ to $\frac{3}{4}$ in.) may have a roll angle of 40 to 45°. In some special highspeed straighteners, when the tubing is almost straight to begin with and is easy to straighten, a 40° angle can be used for tubing as large as 50 mm (2 in.). For machines in the range of 50 to 152 mm (2 to 6 in.), a common angle is 30°. For very large tubing 455 to 610 mm (18 to 24 in.) in diameter, the angle can be as low as 17$\frac{1}{2}$°.

To fit a large tube within the size range of the machine to the roll contour, the angle between the centerline of the tube and the roll must be greater than that required for a small-diameter tube. The angle can be adjusted from 2 to 3° on either side of the nominal angle for a given machine--the lowest angle for the smallest size and the largest angle for the largest size.

Entry and Delivery Tables. Well-designed entry and delivery tables are important in the rotary straightening of tubular products. The rotary straightening machine is designed to support, guide, and straighten a tube within the length between the first and last roll stands. It is not designed to feed, support, or confine a long tube over its full length.

Entry-table guides confine the portion of the tube that is beyond the limits controlled by the rotary straightening machine in order to minimize rotary whipping of the unstraightened portion. The table guides must be designed to suit the size range, grade of material, and travel rate of tube that is to be processed. A combination of entry and delivery tables and guides keeps the amount of straightener deflection, or offset, to a minimum, increases the range of sizes that can be straightened in any one machine, and decreases the possibility of damaging the tube.

The entry table should also feed the tube into the rotary straightener with skewed rolls, so that the tube will be rotating and moving lineally when it enters the straightener. When in-line straighteners are used at the mill, the straightener and tables must be designed to keep up with the speed of the mill.

Straightening of Tubing

Revised by Philippe Delori, SMS Sutton, Inc.

Ovalizing in Rotary Straighteners

Some straightening effect can be produced in certain tubular products not only by bending but also by squeezing them elastically between the opposed straightening rolls as the tubes are processed through a rotary straightening machine. The rolls have a concave curvature through which a line of contact is produced between the roll and the workpiece for almost the full length of the roll.

Machines having sets of two opposed rolls are used to combine bending and ovalizing in the straightening of round tubes. Squeezing results in high residual stresses that can be removed by subsequent bending operations.

Collapse Strength. The cold working of a tubular product by bending and ovalizing in a rotary straightening machine can reduce the collapse strength or external-pressure resistance of the tube. Therefore, cold working should be kept to a minimum. The least amount of bending and/or ovalizing that will still yield a straight tube should be used. It is believed that a round tube obtained by squeezing will result in good collapse resistance.

Introduction

WIRE FORMS are used to give a high strength-to-weight ratio, an open construction (as in fan guards or baskets), resilience to absorb shock, and the economy of automated production of formed parts. When production quantities are small or the size of the finished article is large, the wire may be straightened and cut to length as a preliminary operation before the individual pieces are fed into hand benders, kick presses, power presses equipped with appropriate dies, or coiling devices. For large quantities, the wire is straightened as it comes from the coil and is fed directly and continuously into power presses, automatic forming or spring-coiling machines, multiple-slide machines, or special machines actuated by cams, air, or hydraulic cylinders. Wire drawing is discussed in the article "Wire, Rod, and Tube Drawing" in this Volume.

Operations other than bending that are performed on wire include:

- *Threading* with single-head or multiple-head chasers, or with flat-die or rotary-die roll threaders. Roll dies can also be used for knurling, pointing, and chamfering
- *Heading* in open-die rod headers, to make a variety of heads such as flat, round, slotted, indented hexagon, tee, and ball
- *Swaging or extruding* of long points or reduced-diameter sections on rotary-die swagers or long-stroke headers
- *Welding* with resistance, arc, or gas

Speed of Forming. Increasing the speed of forming can result in out-of-tolerance parts, increased springback, and wear on the tools and machine caused by increased force and torque. With machines in which some of the tools are air-actuated and some are not, enough time must be allowed for the air-actuated tools to cycle to prevent the machine from going out of phase. For example, a machine with a mechanical drive and air-actuated tools was constantly out of phase when making 70 formed and welded assemblies per hour. By reducing the speed by about 5%, the air valves and cylinders had time to complete their cycles, and were in phase with the mechanical devices.

Tools used for forming wire should be made of tool steel hardened to 56 to 61 HRC. Water-hardening tool steels such as AISI W1 are usually adequate. For more severe forming and longer tool life, D2 tool steel is recommended. Surfaces contacting the wire should be polished to prevent marking. They can usually be hardened after tryout in the soft state.

Springback is variable and difficult to control in the forming of wire, as it is in most pressworking operations. Springback varies with the type and temper of wire and may be different for each lot of a specific type and temper. The most practical way to determine springback is to make trial bends either before the tools have been hardened or on temporary tools. The necessary final correction for springback is usually made at the final tool setup, after the tools have been hardened.

Effect of Material Condition

Most wire forming is done at room temperature. Wire made of low-carbon steel is usually formed in the as-drawn condition. Medium-carbon steel wire (1035 to 1060) is usually annealed before severe forming and heat treated after forming.

Surface Finish. A rough surface on the wire may cause short tool life. Plated wire is as easily formed as is bare wire, except that if the plating loosens or peels, it may damage the tools. Platings of gold, tin, solder, or other soft metals may show marks readily; however, soft plating may act as a lubricant during the forming of wire. Whether the wire can be plated before forming may depend on the severity of forming and the subsequent fabricating operations. Welding, for instance, may require that plating be done after forming.

Properties. The strength of wire is important in forming, especially when making steel springs. The required tensile strength is developed in spring wire either by cold drawing through a series of dies with up to 85% reduction in cross section, or by heat treating steel containing 0.60 to 0.70% C, quenching in oil, and tempering the wire. The elastic limit in torsion of spring wire is more important to its use in a spring than is its tensile strength. Information on the mechanical properties of steel spring wire is available in the article "Steel Springs" in *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Volume 1 of the *ASM Handbook.*

Forming of Wire

Rolling of Wire in a Turk's-Head Machine

A Turk's-head machine generally has four rolls that will accommodate wire of one cross section (generally, round) and cold roll it to another shape. Uses of the machine are:

- To make accurate, square, and narrow rectangular wire directly from round wire
- To finish special shapes from round or preformed rough shapes
- To put edge contours on flat metal ribbon

Operation. The machine has a cluster of four rolls with the four axes in the same plane and at right angles to each other, as shown in Fig. 1. In operation, a coil of wire is supported in a pay-off reel; the wire is pulled through the rolls by a capstan and then recoiled. A drawbench can be used for pulling short lengths (up to 30 m, or 100 ft) through the rolls.

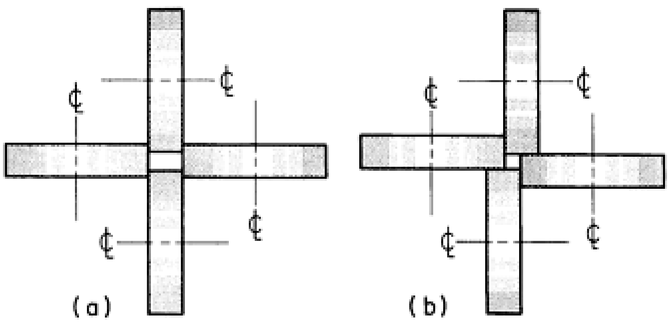

Fig. 1 Turk's-head rolls. (a) Positioned in line to form a rectangular cross section. (b) Offset to form a square section

Depending on the shape to be formed, the narrow rolls can be centered (opposed), as in Fig. 1(a), or they can be offset, as in Fig. 1(b). Although the rolls shown are plain cylinders, these can be replaced with rolls ground to any shape that will form the desired cross section. Some sections require several passes through the machine: It may take two passes to roll an accurate sharp-cornered square wire, and three or more passes may be needed to make a complex section fill properly.

Simple or complex shapes may be drawn through a Turk's-head machine as fast as 180 m/min (600 ft/min), depending on the force and speed available in the drawbench and the amount of heating in the operation. In general, the sections that can be formed depend on the ductility of the wire and are limited to shapes that can be ground into the rolls and shapes that are suited to the roll design, symmetrical, and no wider than twice the round wire thickness (unless preformed wire is used).

Some Turk's-head machines have three rolls to make triangular shapes and other shapes suited to a three-roll design.

Accuracy of forming in a Turk's-head machine depends on:

- Accuracy and uniformity of the initial round wire in size, shape, smoothness, hardness, and ductility
- Dissipation of heat caused by cold working
- Smooth operation of drive in accelerating, running, and decelerating
- The amount of reduction in area or change in section in one pass

Any variation in size of the round wire pulled through the rolls may cause changes in size and shape of the product. If the round wire is oversize in a portion of its length, it may cause a sharper corner in the shape and thus a longer cross-corner dimension, or it may form a fin. If the round wire is undersize, the shape will not be well filled, and the cross-corner dimension will be decreased.

Variations in the hardness and ductility of round wire can also cause variations in the cross-corner dimension of a shape. Hard spots increase the cross-corner dimension; soft spots decrease it. A rough or unlubricated surface increases cross-corner size; a smooth, oiled surface makes it smaller. Heating of the rolls caused by cold working may enlarge the rolls, making the product smaller. A coolant is frequently used to remove heat from the rolls.

Nonuniform acceleration, running and deceleration of the capstan, and changes in tension on the wire may also cause variations in the formed shape. The greater the reduction in section size of the wire as it is drawn through the rolls, the greater the chances of variations in the formed shape.

Tolerances in wire formed in a Turk's-head machine in ordinary production are ±0.05 mm (±0.002 in.), but ±0.013 mm (±0.0005 in.) is a reasonable tolerance if all important factors are controlled.

Spring Coiling

Small quantities of springs may be coiled in a lathe. The arbor around which the spring is wound is held in the chuck, and two wooden friction blocks are mounted on the cross slide. Numerous hand-operated devices are also used. Production coiling is done in single-purpose automatic spring coilers.

In a standard spring-coiling machine, a pair of feed rolls pushes a calculated length of straightened wire through restricting guides against a coiling point and around a fixed arbor into a coil. At the end of the coiling cycle, the feed rolls stop, and a cutoff mechanism actuates a knife, which severs the completed spring against the arbor. A flying knife separates the completed spring from the wire strand.

Standard spring-coiling machines range in size from those that can coil only fine wire to those that can form 19 mm ($\frac{3}{4}$ in.) diam cold-drawn or 15.9 mm ($\frac{5}{8}$ in.) diam pretempered wire. Each coiler can process a range of wire diameters, depending on the number and size of half-round grooves in the feed rolls. A set of feed rolls usually has grooves of three or four different sizes. For example, a machine might coil wire 2.32 to 5.26 mm (0.0915 to 0.207 in.) in diameter and make a spring with an index (ratio of mean spring diameter to wire diameter) ranging from 3 to 18. The length of wire fed is controlled by the feed rolls.

A coiler equipped with a variety of attachments and cams can produce almost any type of spring, including tight-wound extension springs, common compression springs with either open ends or ends closed for grinding, barrel-type springs of various contours, tapered springs, single-coil springs, variable-pitch compression springs, and torsion springs.

A tight-wound extension spring is wound in a standard coiler, but the end loops are formed in one of three ways:

- One or more of the end loops are opened up or pulled out in a secondary operation to form the required end hooks
- End loops are automatically formed by deflecting the wire into shape as a part of the coiling operation
- Automatic handling equipment and attachments are incorporated as additions to a regular coiler to make the loops

The second method is less complicated to set up and operate, but both it and the third method are limited to wire less than 1.27 mm (0.050 in.) in diameter and, because of setup time, to production runs of not less than 10,000 pieces.

A machine equipped with a torsion-spring attachment forms straight extended arms; these arms can be formed and looped as desired in a second operation.

Compression springs are wound in standard coilers equipped with a pitch tool located under the first formed coil. This tool, controlled by cams, regulates the spacing between the coils, which may be either uniform or variable. The ends of compression springs may be plain, plain and ground, square, or square and ground.

The use of round wire predominates in making compression springs, although square, rectangular, or special-section wire is necessary in some applications. Square or rectangular wire is used to obtain the maximum load capacity for a given space. Wire with square corners before coiling will upset at the inside of the coil and become trapezoidal in section after coiling. This limits the deflection per coil, especially with small ratios of mean diameter to wire thickness.

Accuracy. The cams, gears, and other parts of a coiling machine become worn as the machine is used, resulting in a less accurate product. Some product inaccuracies can be reduced by control of the speed of the machine.

Dimensional variations for different materials are caused by variations in springback and by distortion during heat treatment. Variations in pitch and diameter depend on the speed of coiling. Dimensional variation depends also on the ratio of wire size to diameter and the ratio of pitch to spring diameter. By increasing the limits slightly, coiling speed and production rate may be increased.

Many springs are acceptable with inaccuracies or with a wide tolerance in dimensions and performance, but some springs (valve springs, for instance) must be more accurate. Variations in mechanical properties of wire will result in nonuniform springs. Standard spring wire has a permissible tensile-strength variation of 172 to 241 MPa (25 to 35 ksi); wire for valve springs has a limit of variation of 138 MPa (20 ksi). The range for any one coil seldom exceeds 35 MPa (5 ksi).

Coiling must be fast enough to produce an even flow of wire from the pay-off reel. If the wire flow is jerky or nonuniform, the dimensions of the spring may vary excessively.

Forming of Wire

Manual and Power Bending

Manual and power bending are done in rotary benders, pneumatic or hydraulic formers, and special fixtures to locate the bend and hold the part. The blanks are straightened and cut to length before forming.

A rotary bender can be either manual or power operated. The precut blank is placed between a center pin or form block and a stop pin. The arm supporting the wiper block is rotated clockwise, thus forming the wire around the center pin. An adjustable stop controls rotation of the arm so that uniformity is maintained from piece to piece. The eyebolt shown in Fig. 2 was formed in a rotary bender from 12.7 mm ($\frac{1}{2}$ in.) diam cold-drawn stock at a production rate of 300 pieces per hour.

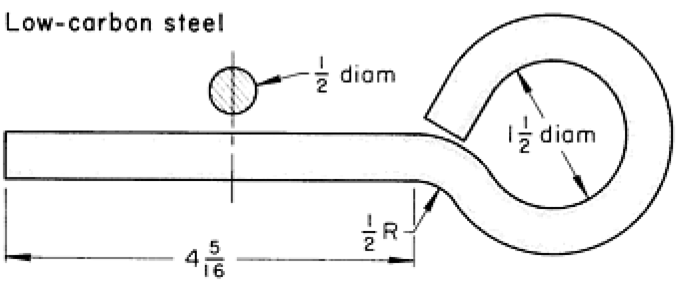

Fig. 2 Eyebolt formed in a rotary bender. Dimensions given in inches

The center pin can be changed to suit the bend radius. Form blocks can be used for larger radii. The stop pin is movable to accommodate different bend radii and stock thicknesses. Round, square, or rectangular wire can be bent in this equipment.

A more complex wire form, such as the scroll shown in Fig. 3, can be formed around blocks mounted in a rotary bender. The compact shape at each end could be formed by holding the wire taut while it is wrapped around a rotating form block, or in a machine with a spring-loaded or air-loaded wiper block. Another form block could be used for the long curves. The form blocks in these two operations must be designed to compensate for springback. The sharp bends at the outer ends can be made in a rotary bender around a center pin.

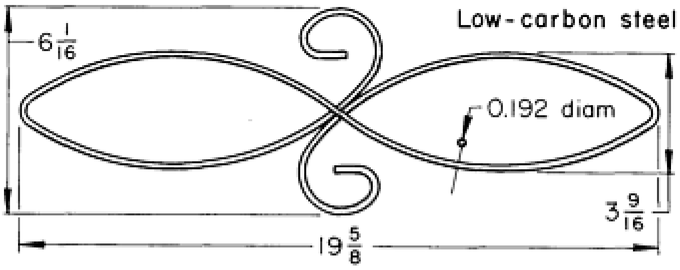

Fig. 3 Complex wire scroll formed in a rotary bender. Dimensions given in inches

A new development in wire-bending machines is a hydraulic, computer-controlled (CNC), three-axis wire bender. This machine is completely automatic, taking wire directly from the coil, straightening it, making any number of bends through any angle and curvature and in any plane, and cutting the finished product. The three-axis CNC wire bender can handle mild steel, spring steel, or aluminum wire from 2 to 7 mm (0.078 to 0.275 in.) in diameter. Bending is by a single head that rotates to give the third dimension. When the wire diameter is unaltered, changeover from one bend to another can take as little as 5 s because bending programs are stored in a built-in memory. When the wire diameter varies, change-overs can be accomplished in about 15 min.

Forming in Multiple-Slide Machines

Multiple-slide machines are automatic mass-production machines that make completed wire (or sheet metal) products from coiled stock. They can straighten, feed, cut, stamp, and form the wire, all in one continuous operation. Attachments are used for additional operations on wire up to 12.7 mm ($\frac{1}{2}$ in.) in diameter. Feed lengths of wire used to make one part may be as much as 915 mm (36 in.).

Most multiple-slide machines are horizontal, but some are vertical and some are inclinable. Production lots of 10,000 pieces usually justify the use of a multiple-slide machine, but smaller lot sizes may also be economical.

A multiple-slide machine usually includes a wire straightener, feed mechanism, and stock clamp, and has a bed with four forming slides, a center post, and a stripper. The bed has room for a press head (an attachment that does presswork) and may have provision for other attachments. More information on forming in multiple-slide machines is available in the article "Forming of Steel Strip in Multiple-Slide Machines" in this Volume.

Production Problems and Solutions

Problem: A small garment eye was produced at the rate of 300 parts per minute, but desired flatness was not obtained. The eye was to be formed in one plane.

Solution: The tooling was changed to form the eye on a plate, confining the wire. Forming sections were supported in the plate and were retracted below the surface of the plate before ejection.

Problem: Broaching of a flat on a small formed part for a business machine caused fine chips to collect in the forming tools, interfering with the work.

Solution: Forming was done on the upper level, and broaching was accomplished on the lower level of the machine. A small jet of air blew the chips down and away from the forming tools.

Problem: A small electronics part was formed around a fragile center post that broke after a few thousand pieces were formed.

Solution: The tooling was changed so that the part was made in two stages. A heavy center post was used for the first form, where the greatest pressure was exerted. A center post having the shape of the smaller section controlled final closing of the part.

Problem: Ordinary forming tools could not form brass wire of 1.02 mm (0.040 in.) diam into a 9.53 mm (0.375 in.) OD ring.

Solution: The formed ring was sized by being pushed through a die below the forming level, by means of a ring-setting attachment.

Problem: Steel wire 5.71 mm (0.225 in.) in diameter was formed into seat wire in a large multiple-slide machine, using an 860 mm (34 in.) feed length. The front toot was 510 mm (20 in.) wide. The bearings of the front shaft became hot, and the cam roller of the front forming slide had to be replaced often.

Solution: The addition of auxiliary front slides at each side of the standard front slide provided more direct application of the forming pressure, with three motions from the front position, reducing the load on each tool. Forming loads were exerted at different points in the machine cycle, reducing bearing pressure and allowing faster machine speed.

Problem: A specially arranged multiple-slide machine for forming and welding handles from low-carbon steel wire 2.4 mm ($\frac{3}{32}$ in.) in diameter made imperfect welds. There were also variations in forming. The wire varied in diameter and tensile strength, which affected the feed length and forming. Operators had not been trained to adjust and maintain the machine.

Solution: The wire was specified to closer tolerances and inspected before use. Operators were trained, and a program of preventive maintenance was initiated. Production efficiency increased to 75% from as low as 25%.

Lubricants

Requirements of lubricants for wire-forming operations are more severe than for most other metalworking operations. The exceptionally high working pressures that may be reached require special lubricants to prevent galling, seizure, or fracture of the wire, as well as excessive tool wear. Improper lubricating oils or compounds interfere with close-tolerance work and cause variations in the finished parts. The lubricant varies with the type of wire. Aluminum, copper alloys, basic steel wire, and steel spring wire each require a different lubricant. Lubricants for wire forming can generally be classed in three groups: inorganic fillers, soluble oils, and boundary lubricants.

Inorganic fillers include solids such as white lead, talc, graphite, and molybdenum disulfide in a vehicle such as a neutral oil or paraffin oil.

Soluble oils include mineral oils to which agents such as sodium sulfonates have been added to make the oil emulsifiable in water. Soluble oils are good for cooling and corrosion prevention.

Boundary lubricants are thin, adsorbed films and are usually subjected to high unit pressures. Thin-film lubricants are of two basic types:

- *Polar Lubricants.* Lubricants, or constituents of lubricants, capable of either physical or chemical adsorption on a solid surface to form a thin film that resists mechanical removal and provides lubrication under high unit pressures
- *Extreme-Pressure Lubricants.* Lubricants capable of reacting chemically with solid surfaces under rubbing conditions, to prevent welding and provide lubricant reaction products on the surface. Extreme-pressure lubricants permit high unit loading with a minimum of surface wear and damage

Chemically active constituents of typical boundary lubricants are sulfur, chlorine, and phosphorus compounds.

Applications. Certain types of oil, wax, and tallow are used to lubricate aluminum and scaly steel wire. Mixtures of lard oil or of paraffin oil in kerosine, or of oil and a soap solution, have been used as lubricants for wire forming.

Often the lubricant used in drawing wire is expected to stay on the drawn wire in a quantity that is adequate for subsequent forming operations. Many severe operations, such as upsetting and spring coiling, may be done without additional lubrication, but additional lubricant may be used in some press and rolling operations.

The lubricant remaining after wiredrawing should be enough to lubricate a wire formed over a form tool or a mandrel. The lubricant should be a hard, dry coating, such as a mixture of lime and metal soaps. This will protect the wire from damage in forming and will extend the life of the tools without sticking to them.

Zinc phosphate is often used to coat wire before it is redrawn into smaller sizes. It is also used in coiling thick, high-tensile spring wire into a closed helix. In other difficult forming, such as a large upset, a zinc phosphate coating is a good lubricant for all tools.

Wire for forming into products to be electroplated is usually drawn with a lubricant that can be easily removed and that does not contain small particles that could become embedded in the surface of the wire. After drawing, the wire may be sprayed or dipped in thin oil. The oil protects the wire from corrosion and serves as a lubricant in the forming operations.

Steel wire with a metal coating, such as zinc, tin, copper, brass, or lead, is often used in forming. In some operations, the metal coating provides all the lubrication necessary.

When lubricant must be added to the wire, it can be applied at the uncoiler or at the tools. Soluble oil or wax in water is most practical and is easy to remove in cleaning. Some formed wire must be completely clean.

Spring wire is supplied with a coating that acts as a lubricant. The coating may be a mixture of soap and lime or of borax or phosphate, or it may be a plating (or displacement coating) of cadmium, zinc, tin, or copper. When the coil is to be electrically normalized, a borax coating is specified; other coatings insulate the wire from good electrical contact.

The most unusual lubricant may be the one that comes on the oil-tempered grade of valve spring wire. During heat treatment, oxidation of the surface is permitted under carefully controlled conditions. The scale thus formed acts as a lubricant during coiling. Its characteristics must be carefully controlled with respect to thickness, adherence, and flakiness, for not only must it supply the required lubrication during coiling, but it should detach from the surface at the same time.

Shearing of Plate and Flat Sheet

Revised by Robert A. Westerkamp, Cincinnati Inc.

Introduction

SHEARING of sheet and plate is broadly classified according to the type of knife (cutter) used--straight or rotary. Straight-knife shearing is used for squaring and cutting flat stock to the required shape and size. It is usually used for square and rectangular shapes, although triangles and other straight-sided shapes are also sheared with straight knives. Rotary shearing (not to be confused with slitting, which is discussed in the article "Slitting and Shearing of Coiled Sheet and Strip" in this Volume) is used for producing circular or other contoured shapes from sheet or plate.

Shearing of Plate and Flat Sheet

Revised by Robert A. Westerkamp, Cincinnati Inc.

Straight-Knife Shearing

In straight-knife shearing, the work metal is placed between a stationary lower knife and a movable upper knife. As the upper knife is forced down, the work metal is penetrated to a specific portion of its thickness. The unpenetrated portion then fractures, and the work metal separates (Fig. 1). The amount of penetration depends largely on the ductility and thickness of the work metal. The knife will penetrate 30 to 60% of the work metal thickness for low-carbon steel, depending on thickness (see the section "Capacity" in this article). The penetration will be greater for a more ductile metal such as copper. Conversely, the penetration will be less for metals that are harder than low-carbon steel.

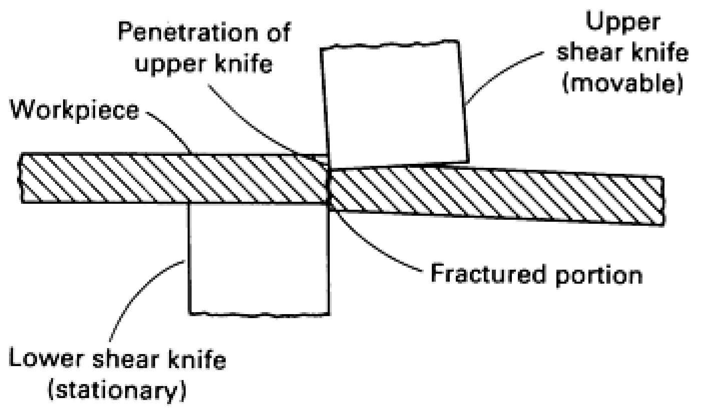

Fig. 1 Schematic showing the mechanism of straight-knife shearing.

A sheared edge is characterized by the smoothness of the penetrated portion and the relative roughness of the fractured portion. Sheared edges cannot compete with machined edges, but when knives are kept sharp and in proper adjustment, it is possible to obtain sheared edges that are acceptable for a wide range of applications. The quality of sheared edges generally improves as work metal thickness decreases.

Applicability

Straight-knife shearing is the most economical method of cutting straight-sided blanks from stock no more than 50 mm (2 in.) thick. The process is also widely used for cutting sheet into blanks that will subsequently be formed or drawn. Because shear gaging can be set within ±0.13 mm (±0.005 in.), the shearing process is generally limited to ±0.4 mm ($\pm\frac{1}{64}$ in.) tolerances in 16 gage material. The tolerance range increases with thickness.

Straight-knife shearing is seldom used for shearing metal harder than about 30 HRC. When extremely soft, ductile metal (especially thin sheet) is sheared, the edges of the metal roll and large burrs result. As the hardness of the work metal increases, knife life decreases for shearing a given thickness of metal.

In general, it is practical to shear flat stock up to 38 mm (1 $\frac{1}{2}$ in.) thick in a squaring shear. Squaring shears up to 9 in (30 ft) long are available (even longer shears have been built), and some types are equipped with a gap that permits shearing of work metal longer than the shear knife.

Machines for Straight-Knife Shearing

Punch presses and press brakes are sometimes used for shearing a few pieces or are used temporarily when more efficient equipment is not available. Production shearing, however, is usually done in machines that are designed for this operation.

Squaring shears are usually used for trimming and cutting sheet or plate to specific size (Fig. 2). Squaring shears (also called resquaring or guillotine shears) are available in a wide range of sizes and designs. Some types permit slitting by moving the work metal a predetermined amount in a direction parallel with the cutting edge of the knife after each stroke of the shear.

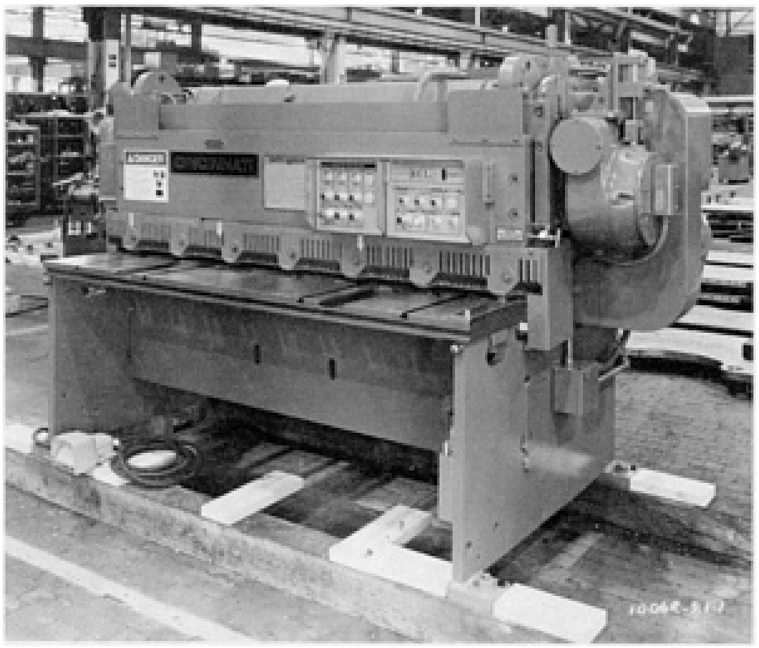

Fig. 2 Typical squaring shear. Courtesy of Cincinnati Inc.

The sheet or plate is held rigid by hold-down devices while the upper knife moves down past the lower knife. Most sheet or plate is sheared by setting the upper knife at an angle. The position of one knife can be adjusted to maintain optimal clearance between the knives. Squaring shears can be actuated mechanically, hydraulically, or pneumatically.

Mechanical Shears. The power train of a mechanical shear consists of a motor, the flywheel, a worm shaft that is gear driven by a flywheel, a clutch that connects the worm gear drive to the driveshaft, and a ram actuated by the driveshaft through eccentrics and connecting links. Under most operating conditions, a mechanical shear can deliver more strokes per minute (spm) than a hydraulic shear. Some mechanical shears cycle as fast as 100 spm.

Another advantage of the mechanical shear is that, because of the energy stored in the flywheel, a smaller motor can be used for intermittent shearing. For example, a mechanical shear with a no-cutting or free-running speed of 65 spin can make approximately six full shearing strokes (maximum thickness and length of cut) per minute with a standard motor. However, when the same shear is cutting at full capacity in a rapid shear mode, a much larger motor is required. For such rapid cutting, there is not enough time between cuts for the smaller motor to restore the speed of the flywheel.

An additional advantage of the mechanical shear is that its moving knife travels faster than the moving knife of a hydraulic shear. In some cases, greater knife speed can decrease work metal twist, bow, and camber.

Hydraulic shears are actuated by a motor-driven pump that forces oil into a cylinder against a piston; the movement of the piston energizes the ram holding the upper knife. A hydraulic shear can make longer strokes than a mechanical shear. In general, long shears and shears with low-carbon steel capacities above 12.7 mm ($\frac{1}{2}$ in.) are almost all hydraulic.

Hydraulic shears are designed with a fixed load capacity. This prevents the operator from shearing material that exceeds capacity and therefore saves costly damage to the machine structure. This is a basic advantage of hydraulic shears.

The total load that is experienced during the cut is related to the rake angle, sharpness of the knives, mechanical properties of the material, type of material, knife clearance, and the depth of the back piece. It is possible to stall the machine on a rated-capacity cut if the clearance is incorrect, the knife is dull, or the back piece is excessively deep. In this way, the hydraulic shear is protected from damage caused by overloading. A mechanical shear would not be constrained by an overload prevention system and would continue to cut under nearly all conditions.

Most mechanical shears are provided with enough horsepower to build up the flywheel speed after each cut, but not enough to allow the operator to run full-capacity cuts in a high-speed manner. Mechanical shears are rated in strokes per minute, not cuts per minute. Most shearing applications do not require high-speed cutting.

Hold-down pressure must be greater than the forces generated in cutting the work material. These forces depend on the knife clearance, rake angle, and depth of material back piece.

Greater knife clearance must be used to prevent the hydraulic shears from stalling when shearing large-area work, especially at or near maximum thickness capacity. For example, in cutting a 3 × 3 m (10 × 10 ft) plate into two equal parts, greater shearing force is required than for trimming a narrow strip from a 3 m (10 ft) long plate.

Pneumatic shears are used almost exclusively for shearing thin metal (seldom thicker than 1.52 mm, or 0.060 in.) in relatively short pieces (seldom longer than 1.5 m, or 5 ft).

Alligator shears have a shearing action similar to that of a pair of scissors. The lower knife is stationary, and the upper knife, held securely in an arm, moves in an arc around a fulcrum pin. This type of machine is most widely used for shearing bars and bar sections and for preparing scrap.

Alligator shears are available in various sizes, including those that can shear plate up to 32 mm ($1\frac{1}{4}$ in.) thick by 762 mm (30 in.) long and plate up to 50 mm (2 in.) thick in shorter lengths. These machines vary in weight from about 1130 to 19,500 kg (2500 to 43,000 lb). The lighter machines can be made portable; the heavier machines, however, must be firmly anchored in concrete, especially if they will be used in conjunction with roller conveyor tables in the shearing of plate.

Capacity. Most shearing machines are rated according to the section size of low-carbon steel they can cut. The tensile strength of low-carbon steel sheet and plate is generally no higher than 520 MPa (75 ksi); the yield strength, no greater than 350 MPa (51 ksi). Shears frequently are rated in terms of their ability to cut low-carbon steel with a tensile strength of 414 MPa (60 ksi) and yield strength of 276 MPa (40 ksi). An allowance for normal over-tolerance material thickness is included in the capacity rating of the machine. The use of a machine for shearing other metals is primarily based on the relationship of the tensile strength and ductility of low-carbon steel to that of the metal to be sheared. Metals with a tensile strength greater than that of low-carbon steel almost always reduce the capacity of the machine. For example, the machine capacity for shearing high-strength low-alloy steels is reduced to about two-thirds to three-quarters of the rated capacity for low-carbon steel. Conversely, for shearing aluminum alloys, machine capacity can range from $1\frac{1}{4}$ to $1\frac{1}{2}$ times the rated capacity for low-carbon steel.

Table 1 compares the shearing capacities of various metals with those of low-carbon steel. The metal thicknesses given in Table 1 are based on the thickness of low-carbon steel that can be sheared with the same shearing capacity. For example, a specific force is required to shear 6.4 mm ($\frac{1}{4}$ in.) thick low-carbon steel. Table 1 shows that the same force can shear only a 4.8 mm ($\frac{3}{16}$ in.) thickness of type 302 stainless steel, but can shear a 9.5 mm ($\frac{3}{8}$ in.) thickness of aluminum.

Table 1 Shearing capacities for various metals compared to those for low-carbon steel

(a) Also applicable to soft to half-hard strip steel, alclad steel, and copper and copper alloys.

(b) Also applies to most other austenitic stainless steels, normalized alloy steels such as 4130 or 8630, annealed high-carbon steels, and annealed tool steels

Ductility, measured by the elongation of the work metal, can also affect machine capacity. For example, annealed copper, because of its high elongation, requires as much shearing effort as low-carbon steel, even though copper has considerably lower tensile strength. Similarly, carbon steel with very low carbon (<0.1% C) and higher-than-normal elongation will reduce the capacity of a machine.

Power Requirements. The energy consumed during shearing is a function of the average stress, the cross-sectional area to be sheared, and the depth of maximum knife penetration at the instant of final fracture of the work metal. For any metal, the amount of energy consumed is proportional to the area under the shearing stress-strain curve for that metal.

Figure 3 shows typical shearing stress-strain curves for hot-rolled and cold-rolled steels. The distance through which the force acts (knife penetration) is near 35% of the work metal thickness for hot-rolled steel and 18.5% for cold-rolled steel. For example, in the curve for hot-rolled steel, the average stress under the curve is 73.5% of the maximum shearing stress S_{max}, and the distance through which the force acts is 35% of the work metal thickness. Therefore, the energy E used in shearing hot-rolled steel is:

$$\begin{aligned} E &= 0.735\, S_{max} \cdot Wt \cdot 0.35\, t \\ &= 0.257\, S_{max} \cdot Wt^2 \end{aligned} \quad \textbf{(Eq 1)}$$

where W is work metal width and t is work metal thickness. Applying Eq 1 to the curve for cold-rolled steel in Fig. 3 yields an energy consumption of $0.136S_{max} \cdot Wt^2$.

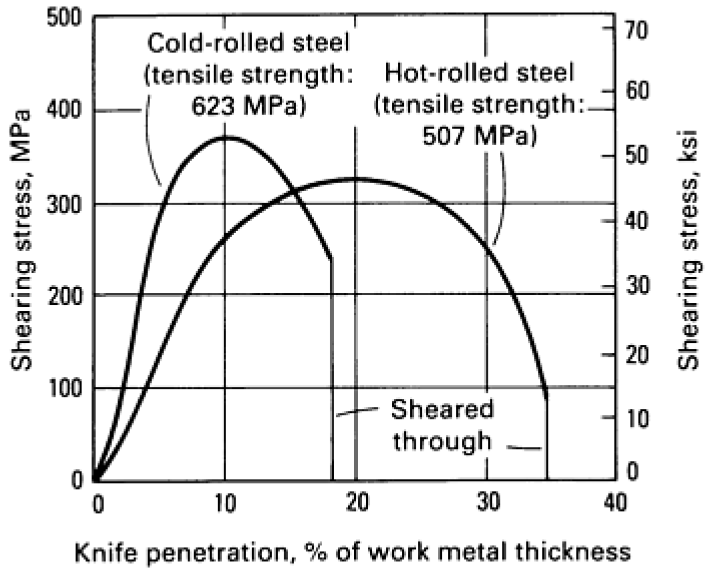

Fig. 3 Typical shearing stress-strain curves for hot-rolled and cold-rolled steels.

The maximum instantaneous horsepower HP_{max} required for cutting work metal in a shear is determined by:

$$HP_{max} = \frac{Wt \cdot S_{max} \cdot V}{33\,000} \quad \textbf{(Eq 2)}$$

where V is the speed of the shear knife and the other variables are as previously defined.

The average power requirement HP_{ave} for a shear making n cuts per minute in hot-rolled steel is:

$$HP_{ave} = \frac{Wt^2 \cdot n \cdot S_{max}}{1\,540\,000} \quad \textbf{(Eq 3)}$$

Equations 2 and 3 determine the net power required for actual shearing of the workpiece. The amount of power needed to operate the hold-down system and to overcome friction must be added to net power.

Friction depends on the design of the shearing machine and the knife, type of bearings, alignment, lubrication, temperature of operation, and size of the machine in relation to the area of the section to be sheared. When shearing metal of nearly the maximum size for which a shear is designed, the loss of horsepower by friction for well-designed machines seldom exceeds 25% of the gross horsepower.

Accessory Equipment for Straight-Knife Shearing

Certain pieces of accessory equipment have been incorporated into most shear designs and are required for efficient and accurate straight-knife shearing.

Hold-downs (Fig. 2) are mechanical or hydraulic devices that hold the work metal firmly in position to prevent movement during shearing. The most efficient hold-down system is a series of independent units that securely clamps stock of varying thickness automatically and without adjustment.

The force on each hold-down foot must be substantial and can range from several hundred pounds on a machine for shearing sheet to several tons for shearing plate. Hold-downs must be timed automatically with the stroke of the ram so that they clamp the work metal securely before the knife makes contact and release their hold instantly after shearing is completed.

Back gages are adjustable stops that permit reproducibility of dimensions of sheared workpieces in a production run. Most gages are controlled electrically. Push-button control provides a selection of fast traverse speeds and slow locating movements for accurate final positioning. The addition of a microcomputer (Fig. 4) permits gage positions to be quickly entered. An LED display enables the operator to confirm immediately the gage position entered, the current gage position, or the final gage location after positioning. Accurate gage screws, compensating nuts, precision slides and guides, and decimal indicators permit repeatable gage settings to an accuracy of 0.025 to 0.05 mm (0.001 to 0.002 in.).

Fig. 4 Microprocessor-controlled shearing machine, with inset (lower right) showing LED display. Courtesy of Cincinnati Inc.

For thin sheet, magnetic overhead rollers eliminate sag and support the sheet for accurate gaging to a depth of 1.2 m (4 ft) into the shear. For rapid and accurate cutting, back gages are equipped with electronic sensors that automatically trip the shear only when the sheet is accurately positioned.

Pneumatic sheet supports are used to support ferrous and nonferrous thin sheet. Sheet support arms are designed to elevate into a horizontal position, flush with the shear table, permitting material to be supported in the correct position against the backgage stop. Blank inaccuracies due to unsupported and poorly positioned sheets are virtually eliminated.

Back gages are also equipped with retractable stops for shearing mill plate. With the stops out of the way, mill plate of almost any length can be fed into the shear and cut to the desired length. When stops are not used, the workpiece can be notched or scribed to indicate the cutoff position.

Front Gages. When gaging from the front of the machine, the operator locates the work metal by means of stops secured in the table or in the front support arms. Power operation of the front support arms allows the blank dimensions to be entered digitally using a microcomputer-based control. Front gaging is often done by means of a squaring arm.

Squaring arms (Fig. 5) are extensions attached to the entrance side of a shearing machine that are used to locate long sections of work metal in the proper position for shearing. Each arm is provided with a linear scale and with stops for accurate, consistent positioning of the work metal. Squaring arms are reversible to allow use of the shear at either end and to distribute the wear on the shear knives. Power operation can be added to the squaring arm for increasing blank accuracy and reducing setup time. This type of squaring arm prevents the arm from moving from side to side.

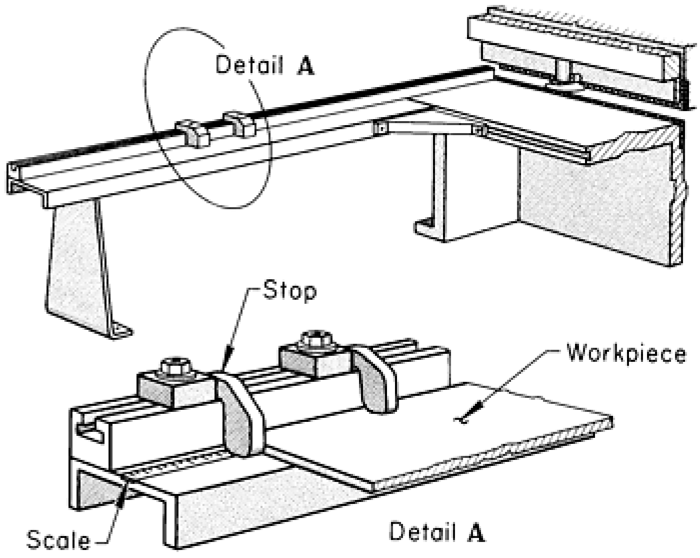

Fig. 5 Squaring arm attachment for positioning long pieces in a shearing machine.

Straight Shear Knives

Most shear knives are made in one piece from tool steel; some are made of carbon or alloy steel. The composition, thickness, and quantity of metal being sheared are the most important factors in the selection of knife material. In Table 2, AISI D2 tool steel is often recommended for cold shearing metals up to 6.4 mm ($\frac{1}{4}$ in.) thick. Knives made of modified A8 or H13 and S5 tool steels are recommended for low-volume production or for occasional shearing of metals up to 6.4 mm ($\frac{1}{4}$ in.) thick (except the more highly abrasive metals such as silicon steel). Knives made of A2 tool steel have been satisfactory for the high-production cold shearing of soft nonferrous metals, but D2 knives are usually more economical because of better wear resistance. Knives made of D2 tool steel are usually not recommended for cold shearing materials more than 6.4 mm ($\frac{1}{4}$ in.) thick, because they are likely to break under impact loads. However, depending mainly on knife design and length of cut, knives made of D2 tool steel have been successfully used for cold shearing aluminum alloys up to 32 mm (1 $\frac{1}{4}$ in.) thick.

Table 2 Recommended materials for straight shear knives cold shearing of flat metals

Metal to be sheared	**Thickness, ·6.4 mm ($\frac{1}{4}$ in.)**		**Thickness, 6.4-12.7 mm ($\frac{1}{4}$ - $\frac{1}{2}$ in.)**		Thickness, >12.7 mm ($\frac{1}{2}$ in.)
	Low production	**High production**	**Low production**	**High production**	
Carbon and low-alloy steels (up to 0.35% C)	Modified A8; H13; L6	D2	Modified A8; H13; L6	A2	**S5**[(a)]
Carbon and low-alloy steels (0.35% C)	Modified A8; H13; L6	D2	Modified A8; H13; L6	S5	**S5**[(a)]
Stainless steels and heat-resistant alloys	Modified A8; H13; L6	D2	S5	A2	**S5**[(a)]
Silicon electrical steels	D2	D2; carbide	S5	S5	[(b)]
Copper and alloys; aluminum and alloys	Modified A8; H13; L6	A2; D2	Modified A8; H13; L6	A2	**S5**[(a)]
Titanium and titanium alloys	**D2**	**D2**	. . .	. . .	. . .

(a) S5 is preferred for stock thicker than 19 mm ($\frac{3}{4}$ in.).

(b) Seldom sheared thicker than 12.7 mm ($\frac{1}{2}$ in.)

Modified A8 or H13 tool steels are suitable for knives for some cold-shearing applications in which the work metal is more than 6.4 MM ($\frac{1}{4}$ in.) thick, as indicated in Table 2. However, the shock-resistant grades S2 and S5 are usually recommended for shearing heavy sections of all metals.

The length and the design of the knife sometimes influence the selection of knife material. Although water-hardening tool steels such as W1 and W2 are suitable for many cold-shearing applications, heat treatment causes greater distortion in these steels than in the oil-hardening or air-hardening grades. A bar 4.16 m (164 in.) long is needed to make a shear knife 4.16 m (164 in.) long from D2 tool steel. The same knife made from W2 requires a bar 4.17 m (164 $\frac{1}{4}$ in.) long. Both steels elongate when heat treated, but W2 will bow more readily than D2. Because straightening is difficult, the W2 knife must have more grinding stock. The additional grinding decreases the depth of the hardened shell and shortens the useful life of the knife.

Hardness. The rate at which a knife wears in cold shearing depends primarily on its carbon content, alloy content, and hardness. Insufficient hardness in a knife that is used for cold shearing will shorten its service life. In one application, a knife made of S5 tool steel with a hardness of 44 HRC wore three times as fast as one with a hardness of 54 HRC used under the same conditions. Despite the desirability of having shear knives as hard as possible to minimize wear, it is often necessary to sacrifice some hardness to prevent knife breakage as the hardness or thickness of the metal being sheared increases.

Recommendations for the hardness of knives for cold shearing cannot always be made without knowledge of the details of the operation. For example, a D2 knife performed satisfactorily at a hardness of 61 HRC in one application, but knives at this hardness broke under similar operating conditions in a different plant. Knives made of D2 steel will usually operate successfully at 58 to 60 HRC for shearing low-carbon steel up to 6.4 mm ($\frac{1}{4}$ in.) thick, and knives made of D2 have often been successfully used at 60 to 62 HRC. However, in shearing high-strength low-alloy steel, the hardness of a D2 knife must be kept below 58 HRC to prevent breakage.

The shock-resistant S-grade tool steels are used in the hardness range of 50 to 58 HRC. The higher end of this range is applicable to the shearing of steels 6.4 to 12.7 mm ($\frac{1}{4}$ to $\frac{1}{2}$ in.) thick and to nonferrous metals. As shock loading increases with the shearing of harder or thicker metals, knife hardness is decreased toward the low side of the above hardness range.

Rake is the slope of the angle formed by the cutting edges of the upper and lower knives (Fig. 2). It is usually expressed as the ratio of the amount of rise to a given linear measurement. For example, a rake of 21 mm/m ($\frac{1}{4}$ in./ft) means that the upper knife rises 21 mm for each meter ($\frac{1}{4}$ in. for each foot) of linear distance along the knives. Rakes below 21 mm/m ($\frac{1}{4}$ in./ft) are rarely used; a rake of 42 mm/m ($\frac{1}{2}$ in./ft) or higher is typical of many plate shears.

Rake is used to permit progressive shearing of the work metal along the length of the knife. This reduces the amount of force required and allows the use of a smaller machine than would be necessary if the cutting edges of the knives were parallel.

It is not possible, however, to calculate the required force for different work metal thicknesses based solely on change of rake, because knife penetration varies for different thicknesses. Even for low-carbon steel, the amount of knife penetration before fracture occurs can be as great as 60% of the work metal thickness for 3.43 mm (0.135 in.) thick stock and as little as 30% for 19 mm ($\frac{1}{4}$ in.) thick stock.

The primary disadvantage of using a high rake angle is that it increases the distortion of the work. Large rake angles can also cause slippage and therefore require high hold-down forces.

Clearance. Excessive knife clearance causes the work metal to be wiped down between the knives during cutting and results in heavy burring or flanging of the work metal. The burrs and deformed metal are objectionable because of their interference with subsequent processing. A more serious consequence of excessive clearance is that it can cause the workpiece to be pulled between the knives, and this in turn causes overloading of the machine and may result in failure of machine components or shear knives.

When soft metals are sheared, insufficient clearance causes double (secondary) shearing, which appears as a burnished area at the top and bottom of a sheared edge with a rough area between the burnished edges. Because of the difference in action, greater tolerances are usually required when shearing plate than when shearing sheet--all other conditions being equal. Some mechanical shears are constructed to operate with a fixed clearance, and no adjustments are made for variations in work metal composition or thickness. The knife clearance is set for the thinnest material to be sheared, and double shear is avoided if the range of thicknesses sheared is not too large.

Because of deflection, clearance at the center of the knife is usually set less than that at the ends. Knife clearance (except on machines using a fixed clearance) is generally increased as work metal thickness increases. For example, in one plant, a clearance of approximately 0.076 mm (0.003 in.) is used for squaring shears with a capacity of up to 6.4 mm ($\frac{1}{4}$ in.) thick low-carbon steel. To minimize knife deflection, clearance at the center of the knife is reduced to 0.051 mm (0.002 in.). Similarly, the clearance for shearing 6.4 to 25 mm ($\frac{1}{4}$ to 1 in.) thick low-carbon steel is 0.36 mm (0.014 in.) at each end of the knives and 0.30 mm (0.012 in.) at the center of 3 to 3.7 m (10 to 12 ft) long knives used in a mechanical shear.

Ram Speed in Straight-Knife Shearing

The speed of the ram (and, in turn, that of the knife) has a slight effect on results in the shearing of flat stock. Low linear speed produces a rough sheared surface. As speed is increased, a cleaner sheared surface is obtained. In general, speeds to 21 to 24 m/min (70 to 80 ft/min) can be used without difficulty when shearing annealed metals. Regardless of the speed used, adequate hold-down force is mandatory.

Accuracy in Straight-Knife Shearing

The dimensional accuracy obtained in shearing is influenced by the capacity and condition of the machine, condition of the knives, knife clearance, work metal thickness, and work metal condition. Expressed as total tolerance, sheets no thicker than approximately 3.43 mm (0.135 in.) can be cut to size within 0.25 mm (0.010 in.), and strips can be sheared to width at the same total tolerance. These tolerances apply to stock up to 3.7 m (12 ft) long that is essentially free from stress and is flat within commercial limits. Sheets that are not flat or that have residual stress, or both, cannot be sheared with the same accuracy.

Greater tolerances are required in shearing plate. A total tolerance of 0.5 to 1.0 mm (0.020 to 0.040 in.) can be maintained when plate is sheared in squaring shears. Dimensions can be held to tolerance of about ±1.6 mm (±$\frac{1}{16}$ in.) when shearing in alligator shears.

Shearing of Plate and Flat Sheet

Revised by Robert A. Westerkamp, Cincinnati Inc.

Rotary Shearing

Rotary shearing, or circle shearing (not to be confused with slitting), is a process for cutting sheet and plate in a straight line or in contours by means of two revolving, tapered circular cutters. Table 3 lists recommended cutter materials.

Table 3 Recommended knife materials for the rotary shearing of flat metals

Metal to be sheared	Thickness to be sheared		
	4.8 mm ($\frac{3}{16}$ in.) or less	**4.8-6.4 mm ($\frac{3}{16}$ - $\frac{1}{4}$ in.)**	6.4 mm ($\frac{1}{4}$ in.)
Carbon, alloy, and stainless steels	D2[(a)]	A2[(b)]	**S4; S5**
Silicon electrical steels	M2[(c)]; D2[(d)]	D2	. . .
Copper and aluminum alloys	A2; D2	A2; D2	**A2[(e)]**

Titanium and titanium alloys	**D2(f); A2(g)**	. . .	. . .

(a) L6 is also recommended for shearing carbon and alloy sheet containing >0.35% C.

(b) D2 is also recommended for low-carbon and low-alloy sheet.

(c) For sheet >0.8 mm ($\frac{1}{32}$ in.) thick.

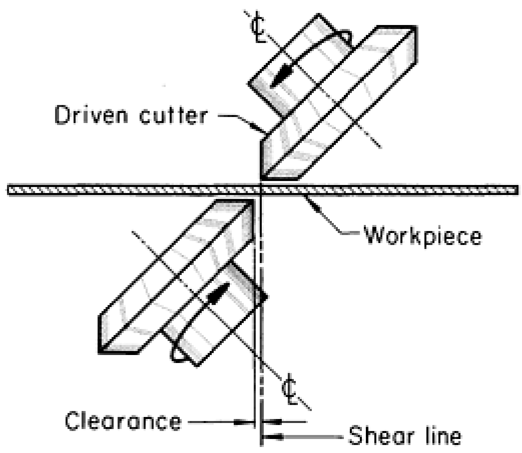
(d) For sheet >0.8 mm ($\frac{1}{32}$ in.) thick.

(e) S5 is recommended for sheet >12.7 mm ($\frac{1}{2}$ in.) thick.

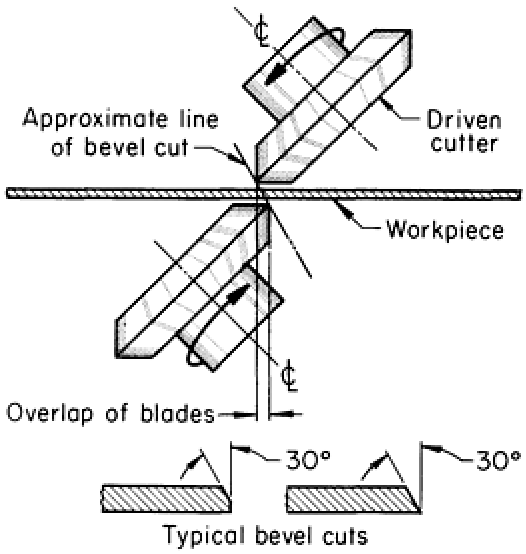
(f) For sheet <3.2 mm ($\frac{1}{8}$ in.) thick.

(g) For sheet >3.2 mm ($\frac{1}{8}$ in.) thick

For conventional cutting to produce a perpendicular edge, the cutters approach each other and line up vertically at one point (Fig. 6a). The point of cutting is also a pivot point for the workpiece; because of the round shape of the knives, they offer no obstruction to movement of the workpiece to the right or left. This feature permits the cutting of circles and irregular shapes that have small radii, as well as cutting in straight lines.



(a)



(b)

Fig. 6 Two types of rotary shearing. (a) Conventional arrangement of cutters for producing a perpendicular edge. (b) Overlap of cutters for producing a beveled edge.

Overlapping of the cutters to the position shown in Fig. 6(b) permits the shearing of smooth beveled edges in straight lines or circular shapes. With the cutters positioned as shown in Fig. 6(b), a bevel can be cut across the entire thickness of the workpiece, resulting in a sharp edge on the bottom of the workpiece, or (by varying the overlap of the cutters) only a corner of the workpiece can be sheared off, leaving a vertical edge (or land) for approximately half the workpiece thickness.

The shearing of workpieces into circular blanks requires the use of a holding fixture that permits rotation of the workpiece to generate the desired circle. For straight-line cutting in a rotary shear, a straight-edge fixture is used, mounted in the throat of the machine behind the cutter heads.

Applicability. Any metal composition or hardness that can be sheared with straight knives can be sheared with rotary cutters. In general, rotary shearing in commercially available machines is limited to work metal 25 mm (1 in.) thick or less. There is no minimum thickness. For example, wire cloth made from 0.025 mm (0.001 in.) diam wire can be successfully sheared by the rotary method.

Circles up to 3 m (10 ft) in diameter or larger can be produced by using special clamping equipment. Minimum diameters depend on the thickness of the work metal and the size of the rotary cutters. With material up to 3.2 mm ($\frac{1}{8}$ in.) thick, the minimum circle that can normally be cut is 152 mm (6 in.) in diameter. For 6.4 mm ($\frac{1}{4}$ in.) thick stock, the minimum diameter is 230 mm (9 in.), and for 25 mm (1 in.) thick stock, the minimum diameter is 610 m (24 in.).

Rotary shearing is limited to cutting one workpiece at a time. As in straight-knife shearing, multiple layers cannot be sheared, because each layer prevents the necessary breakthrough of the preceding workpiece.

Rotary shearing, plasma cutting, laser cutting, gas cutting, and electric-arc cutting are competitive for some operations. Each can produce straight or beveled edges of comparable accuracy. The selection of one of the four processes depends largely on the thickness of the work metal. In general, rotary shearing and laser cutting are used for sheet and plate less than 12.7 mm ($\frac{1}{2}$ in.) thick, and gas cutting is used for thicknesses of 12.7 mm ($\frac{1}{2}$ in.) or more (see the articles "Laser Cutting" and "Thermal Cutting" in this Volume).

Gas cutting is less suitable for cutting a single thickness of sheet or thin plate because the heat causes excessive distortion, but it is often feasible to minimize this problem by stack cutting (cutting several thicknesses at a time). Gas cutting is more versatile than rotary shearing; it can produce smaller circles than rotary shearing and can produce rings in one operation. Gas cutting, however, produces a relatively large heat-affected zone on the workpiece.

Laser cutting produces an extremely narrow kerf that provides unmatched precision for cutting small holes, narrow slots, and closely spaced patterns. Complex openings, contours, and patterns, which are impossible to cut with conventional tools, are routinely cut using a laser and require little if any additional processing. A smaller heat-affected zone than traditional thermal cutting processes minimizes distortion and improves part quality.

Circle Generation. For cutting circles, the workpiece is placed in a special fixture consisting of a C-shaped, deep-throated frame having a rotating pin or clamp point at its outer extremity. The maximum circle that can be sheared is governed by the depth of the throat of the clamp and by the amount of clearance necessary to permit the rotating workpiece to clear the deep part of the C-frame on the machine. Therefore, when using square blanks, removal of the corners allows a larger circle to be cut.

There are two methods of holding the center point of the work metal during circular shearing. In one method, the work metal is clamped by a screw-type handwheel or by an air cylinder, each of which incorporates two pivoting pressure disks--one above and one below the workpiece. The disks permit the workpiece to rotate in a horizontal plane. The other method is by center pinning. In this method, a hole is drilled or punched in the work metal for locating and rotating it on a pin in the center clamping attachment. The hole is at the predetermined center of the circle to be produced.

Of the two methods, center pinning provides greater rigidity because the work metal cannot slip off center during shearing. The circle generated when the work metal is held by the clamping method may not be perfectly true if the clamping fixture has not been properly located or if it has shifted because of pressure on the cutters. The disadvantage of center pinning is that a hole must be made in the work and must be closed by plug welding if it is not wanted in the finished product.

Adjustment of Rotary Cutters. The upper cutter head and drive of a rotary shear is raised and lowered by power. A clutch mechanism limits upward and downward travel. Power movement of the upper cutter is essential (especially when cutting plate stock) because the shearing edges of the cutters must be moved toward each other in proper alignment to create the initial shearing action. In setting up, the work metal is often rotated in the clamp attachment, with the cutter exerting light pressure to determine whether a true circle is being generated. Additional pressure is then applied by the vertical screwdown of the upper cutter to cause shearing.

Only the upper cutter is rotated by the power-drive system. The pinching and rotating action of the upper cutter causes the work metal to rotate between the cutters, and the work metal causes the bottom cutter to rotate.

The position of the upper cutter in relation to the lower cutter is important. Figure 6(a) shows the setting for shearing a straight edge. Clearance between the cutters is just as important as it is with straight knives.

Overlap of the cutters, as shown in Fig. 6(b), produces a bevel cut. The degree of bevel up to a maximum of 30° can be adjusted by changing the amount of overlap of the cutters.

Accuracy of the sheared circle depends on the rigidity of the center clamping device, sharpness of the cutters, maintenance of optimal clearance between the cutters, thickness of the work metal, and cutting speed. For work metal up to about 3.2 mm ($\frac{1}{8}$ in.) thick, dimensional accuracy within ±0.8 mm ($\pm\frac{1}{32}$ in.) can be obtained when generating a 762 mm (30 in.) diam circle. With proper setup of equipment, the sheared edge will show only a slight indication of the initial penetration.

Speeds of 2.4 to 6.7 m/min (8 to 22 ft/min) are most commonly used for the rotary shearing of metal up to 6.4 mm ($\frac{1}{4}$ in.) thick. Speeds of 1.5 to 3 m/min (5 to 10 ft/min) are used for rotary shearing metal that is 6.4 to 25 mm ($\frac{1}{4}$ to 1 in.) thick.

Flanging and Joggling. With cutters replaced by forming tools, the rotary shear can be used to form flanges and joggles on flat stock. The maximum joggle that can be produced is usually limited to the thickness of the work metal. Because the work metal is made to flow into a different shape during flanging or joggling, the amount of energy required reduces the capacity of the machine to 75% of the rated capacity for shearing. Figure 7 shows a typical setup for forming a joggle.

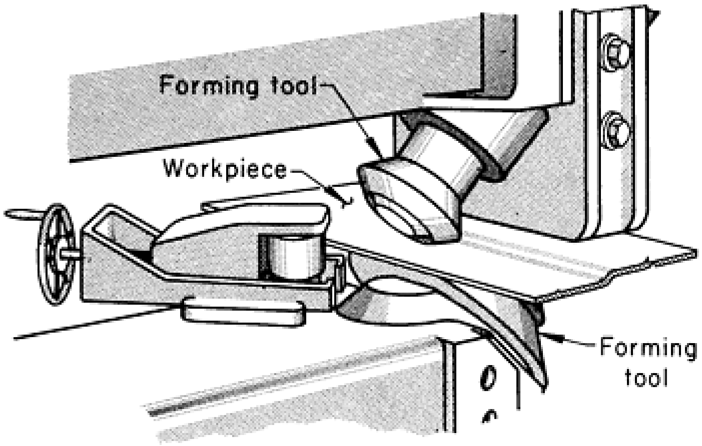


Fig. 7 Setup and tooling for forming a joggle in plate stock using a rotary shear.

Shearing of Plate and Flat Sheet

Revised by Robert A. Westerkamp, Cincinnati Inc.

Safety

Shearing machines must be equipped with devices for protecting personnel from the hazards of shear knives, flywheels, gears, and other moving parts. The guards and safety devices used must be rigid enough to withstand damage from operating personnel moving heavy material into position.

The squaring shears used for sheet metal should have guards on all moving parts, including flywheels, hold-downs, and knives. The treadle, whether mechanical or electrical, should have a lock for supervisory control. Knife and hold-down guard openings should be large enough to provide visibility but small enough to keep the operator's fingers out of the danger area. Proper opening dimensions are outlined in ANSI standard B11.4-1983.

The shears used for shearing plate are more difficult to safeguard because of the greater clearances needed under the hold-downs and upper knife to permit entry of the plate (especially when it is bowed or buckled). Guards on shears for plate should be of the type that raises only when the plate is inserted and then rests on the surface of the plate. When there is no workpiece in the machine, the guards rest within 6.4 mm ($\frac{1}{4}$ in.) of the surface of the table.

Shears should comply with the construction requirements of the Occupational Safety & Health Act and National Safety Standards such as ANSI B11.4-1983. Additional safety information can be obtained from the loss prevention group of major insurance carriers for Workman's Compensation and the National Safety Council. Safety regulations also cover the maximum noise level permitted from a shearing operation to prevent permanent impairment of hearing.

Slitting and Shearing of Coiled Sheet and Strip

Revised by Eric Theis, Herr-Voss Corporation

Introduction

COILED SHEET OR STRIP is cut to size for further processing by slitting longitudinally, dividing it into narrower coils, and shearing transversely for cutting into flat pieces of specified length.

Slitting and Shearing of Coiled Sheet and Strip

Revised by Eric Theis, Herr-Voss Corporation

Slitting

Slitting is accomplished by passing the strip between slightly overlapping circular blades mounted on rotating arbors. A slitting line for cutting wide coiled stock into narrower widths consists essentially of an uncoiler for holding the coil, a slitter, and a re-coiler for re-coiling the slit strips (Fig. 1). Other equipment can be added to the line for automatic feed-up and handling, steering, shape correction, slit-coil tensioning, and packaging.

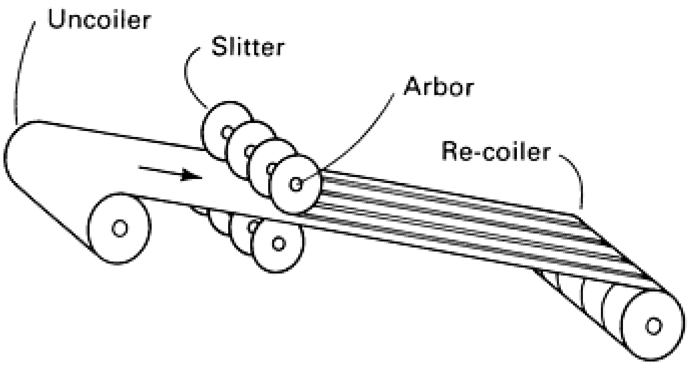

Fig. 1 Principal components for slitting wide coiled stock into narrower widths

Slitting lines are broadly classified as pull-through or driven types. The choice between pull-through and driven lines depends largely on strip shear strength and thickness, number of slits, and slitting speed. In general, when the metal to be slit is less than 0.25 mm (0.010 in.) thick, a drive or helper-drive slitter is preferred because thin-gage metal is likely to tear.

In pull-through slitting lines (Fig. 2), drive motors on the slitter and uncoiler are used only to feed the coil stock through the slitter up to the re-coiler gripper. After the strips are attached to the re-coiler, the motors for the uncoiler and slitter are disengaged, and the driven re-coiler pulls the strip from the uncoiler through the slitter. Some lines use drag devices on the uncoiler to increase strip tension during slitting.

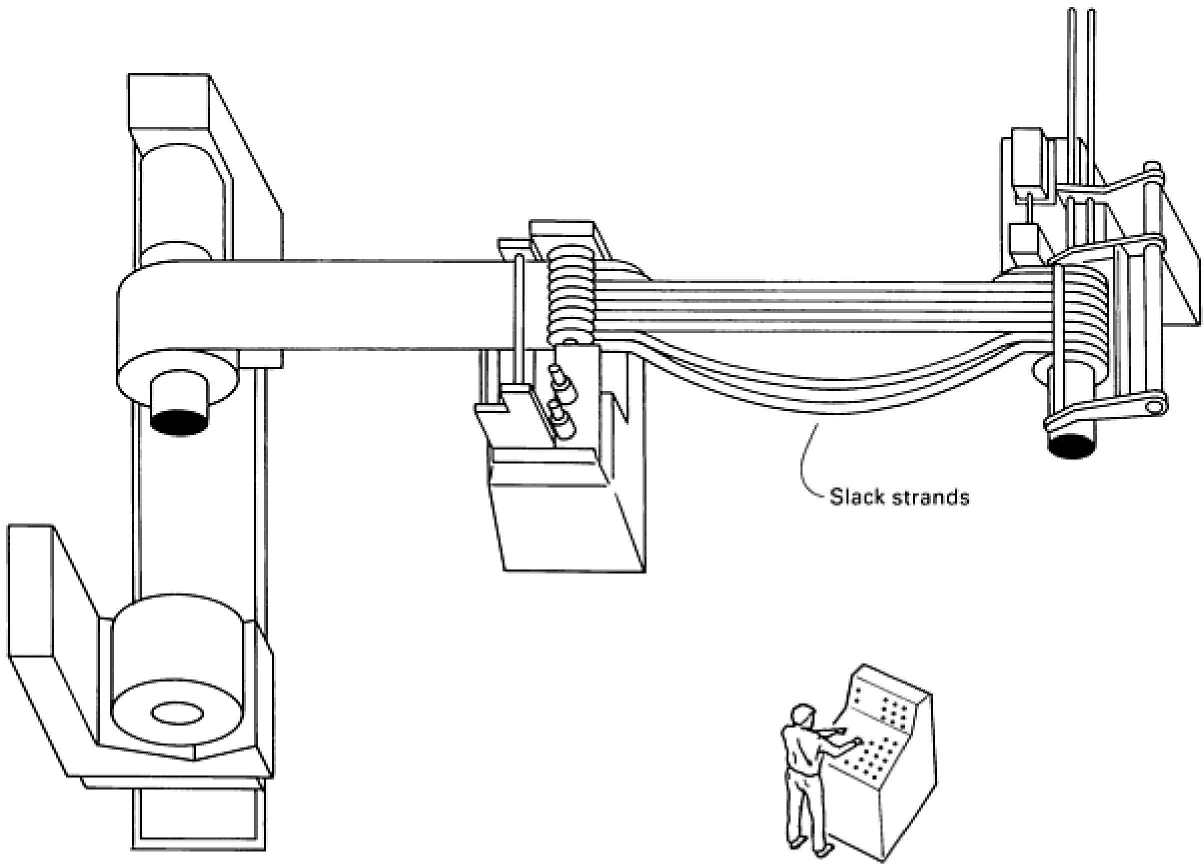

Fig. 2 Pull-through slitting line in which motor-driven re-coiler pulls strip through slitter. Motors for the uncoiler and the slitter are used only to attach uncoiled sheet to the re-coiler through the slitter device and are then disengaged.

A pull-through slitter with a helper drive is also available. In this case, the torque applied to the slitter arbors, from the slitter drive motor, reduces the tension on the pulled strip to avoid snagging at the entry slitter knives. The helper torque is insufficient to drive the slitters alone, thus eliminating the speed-match problems of a pure, driven slitter.

In the driven-type line (Fig. 3), the slitter and the re-coiler are driven by separate motors. These motors are synchronized to maintain approximately constant speed of the metal as it travels through the slitting line. However, a slack loop must be maintained--especially on lighter materials--between the slitter and the re-coiler to allow for minor differences in strip speed.

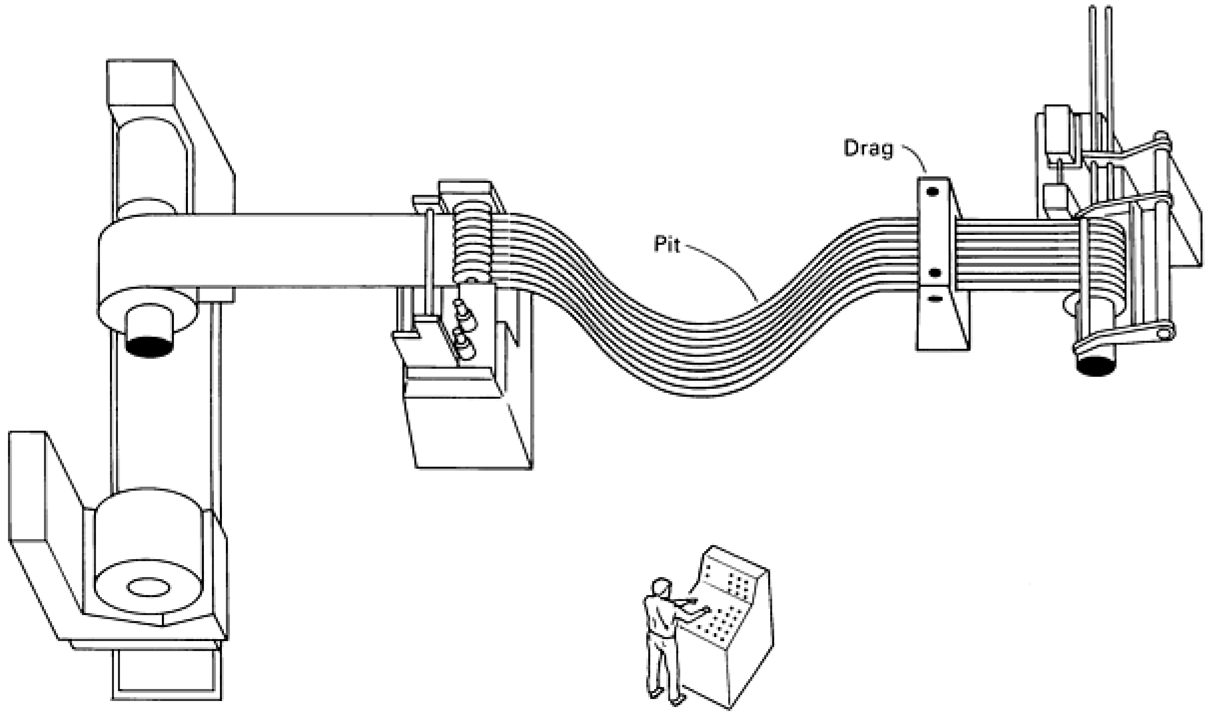

Fig. 3 Driven-type slitting line with uncoiler, slitter, and re-coiler all driven by separate motors synchronized to maintain constant speed of sheet materials. Minor differences in speed still require the use of slack loops in the pit.

Burrs are normally found to some extent on all slit edges. The severity of the slitting burr depends primarily on the sharpness of the slitting knives and the horizontal and vertical clearance between them. These factors are influenced by machine rigidity, machine and knife maintenance, knife and stripper setup, number of cuts and location on the arbor, and thickness and hardness of the material being slit. If burr-free edges are required, subsequent equipment can be installed in the line or downstream to roll down or to remove the burr.

Knives must be maintained in a sharpened and clean condition, free of nicks and metal pickup on the slitting edge. Knife setup is critical. Computer programs and modern tooling are available for establishing the precise location of slitting knives on the machine arbors for various materials and material thicknesses.

Knife clearances may be very different under slitting loads than during the unloaded condition at time of setup. Vertical deflection of the slitter arbors is a function of arbor diameter and loading, which are both related to the number of cuts, the type of material, and compression of the elastic strippers. Horizontal deflection, in the direction of slit-coil travel, can be caused by insufficient arbor diameter relative to pulling tension in the case of a pull-through machine. Side-to-side knife clearances can be affected by the type and condition of the arbor bearing housing. Simple slitter designs accomplish vertical arbor adjustment with vertical screws adjusting the up/down position of either end of one of the arbors. The clearances required in this type of arbor control arrangement provide the least slitter knife control for precision slitting. Slitter housing designs incorporating bearings mounted in eccentric sleeves, which can be rotated for vertical adjustment, generally provide the best control for precision cutting. Designs incorporating a single, fixed arbor with the other arbor vertically adjustable through eccentrics provide close control of knife arbor position, but change the passline to an off-horizontal orientation at various points in the adjustment process. The most accurate system is one employing eccentric vertical adjustments of both upper and lower arbors (one clockwise and the other counterclockwise) so that the passline always remains in the horizontal orientation.

Minimum burr height can be achieved only through careful control of all of the variables, especially machine design, maintenance, tooling, and setup. Table 1 shows the vertical (positive and negative) and horizontal clearances used in slitting operations at one plant.

Table 1 Vertical and horizontal clearances of slitter blades

Camber (Fig. 4) is present to some extent in almost all coiled metal. Cambered strip has one side longer than the other, therefore, it tends to sweep to the left or the right. The slitting line can also induce camber in the slit strands. Slitters generally have small metal disks, called separators, to control recoiling of slit strands on the re-coil mandrel. Where a number of strands are being slit from a master coil, the insertion of separators at the re-coiler necessitates the fan out of the slit strands after they leave the slitter (Fig. 5). If the slitting equipment is properly aligned, the center strands will be straight, with the outer strands cambered to the outside (left toward left and right toward right) on a pull-through or helper-drive line.

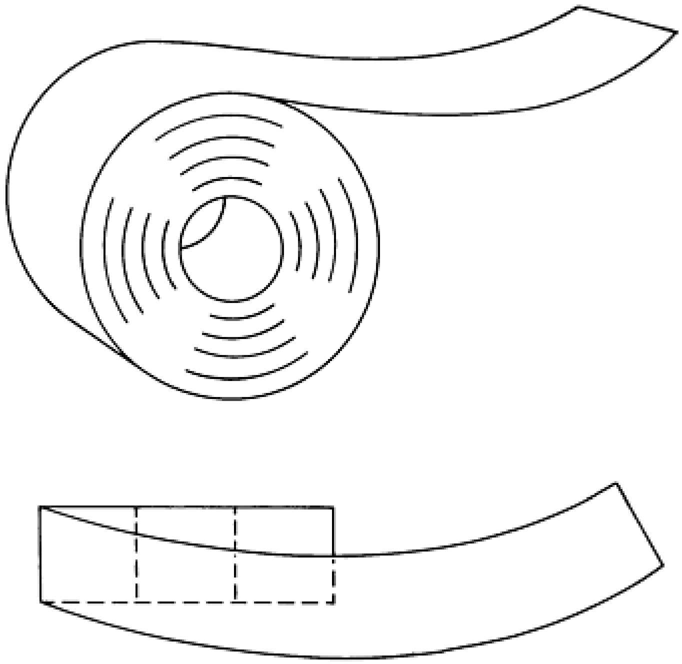

Fig. 4 Illustration of camber in a coil of metal showing one side actually longer than its opposite parallel side.

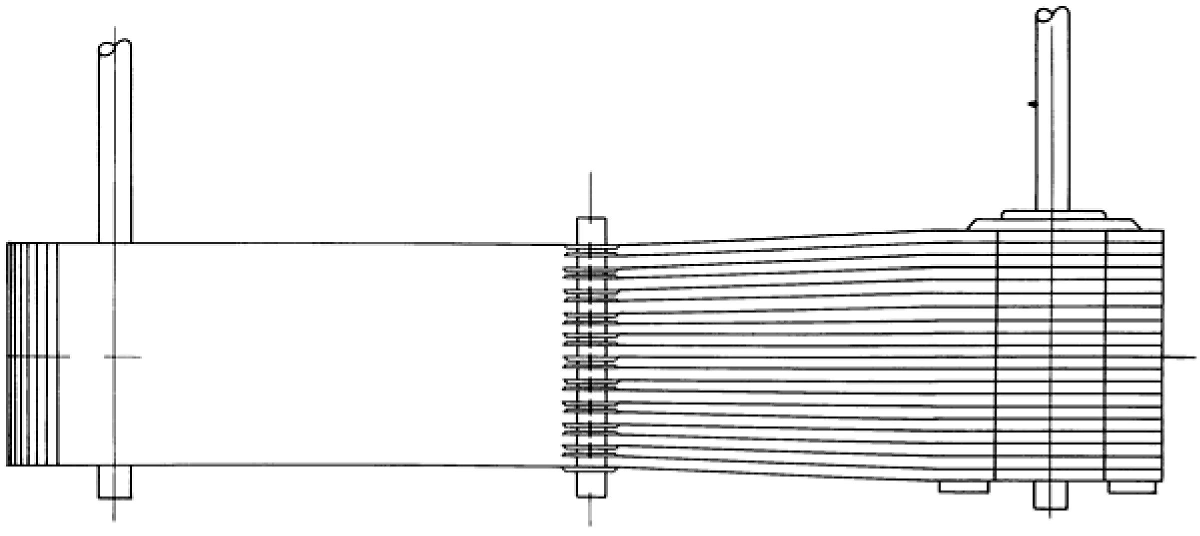

Fig. 5 Slitting-induced camber caused by insertion of separators at re-coiler, necessitating fan out of slit strands

Most slitters follow the camber in the original master coil during the slitting process. Slitter-induced camber, on the other hand, can be controlled by proper line design, maintenance, and tooling setup. The technology is available for controlling or eliminating most of the camber subsequent to slitting and prior to re-coiling.

The camber of the outer slit strands, combined with wavy edges in the master coil, can produce slit coils, which are sometimes referred to as snakes. These are particularly objectionable to stamping shops. Shape correction devices in modern slitting lines can often control or eliminate these problems.

Re-Coiling of Slit Stock. Variation in thickness across the width of coil stock often causes problems upon re-coiling. The center of the master coil is generally thicker than the edges. Thicker center strands will build up on the re-coiler at a faster rate than the thinner strands at the sides, resulting in tighter center coils. The apparent strand length differential on the outside strands can be substantial on lighter-gage materials. If they are too loose, the outer slit coils will sag after removal from the re-coiler. The wraps of loose coils can slip and telescope during subsequent handling. Telescoped and unstable coils are difficult to handle during uncoiling.

Paper stuffing (Fig. 6) is one method of preventing loose coils caused by different rewind speeds. The operator inserts pieces of paper or cardboard into the wrap as the outer slit-coil strands are re-coiled. This procedure is dangerous to personnel, but it does increase the effective diameter of the coil and therefore the tension on the strand. However, the material used may prove objectionable to the end user, because it could cause jamming of feeding devices in subsequent operations.

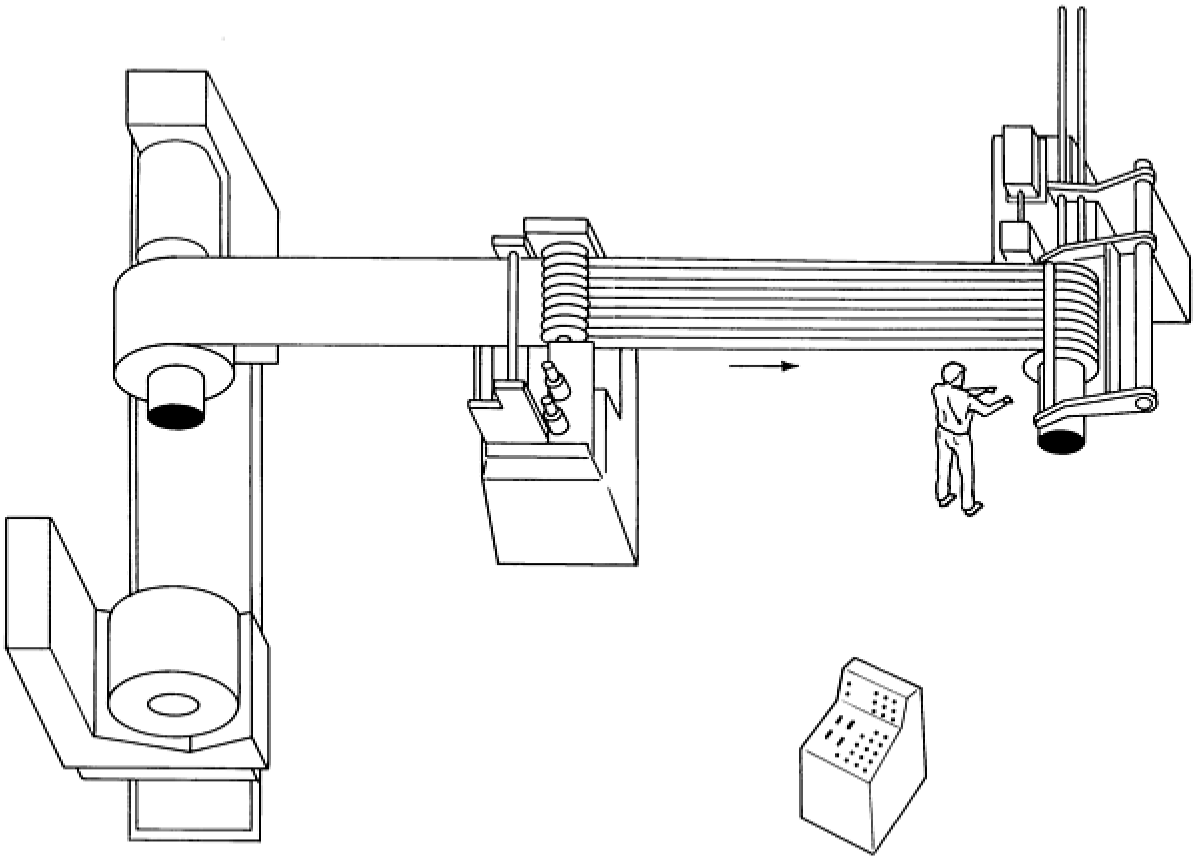

Fig. 6 Operator inserting pieces of paper or cardboard into wrap as outer slit-coil strands are re-coiled in order to increase strand tension. This procedure is known as paper stuffing.

There are two possibilities for producing the tight coils normally found in modern slitting lines. One technique involves a drag-producing friction device, placed just before the re-coiler, with a deep pit to accumulate the excess strand length differential from the outer slit multiples. The other method, a patented process (Fig. 7), involves slight elongation of the tighter strands so that all slit strands rewind at the same rate and tightness, eliminating the apparent strand length differential and the need for friction drags or accumulator pits.

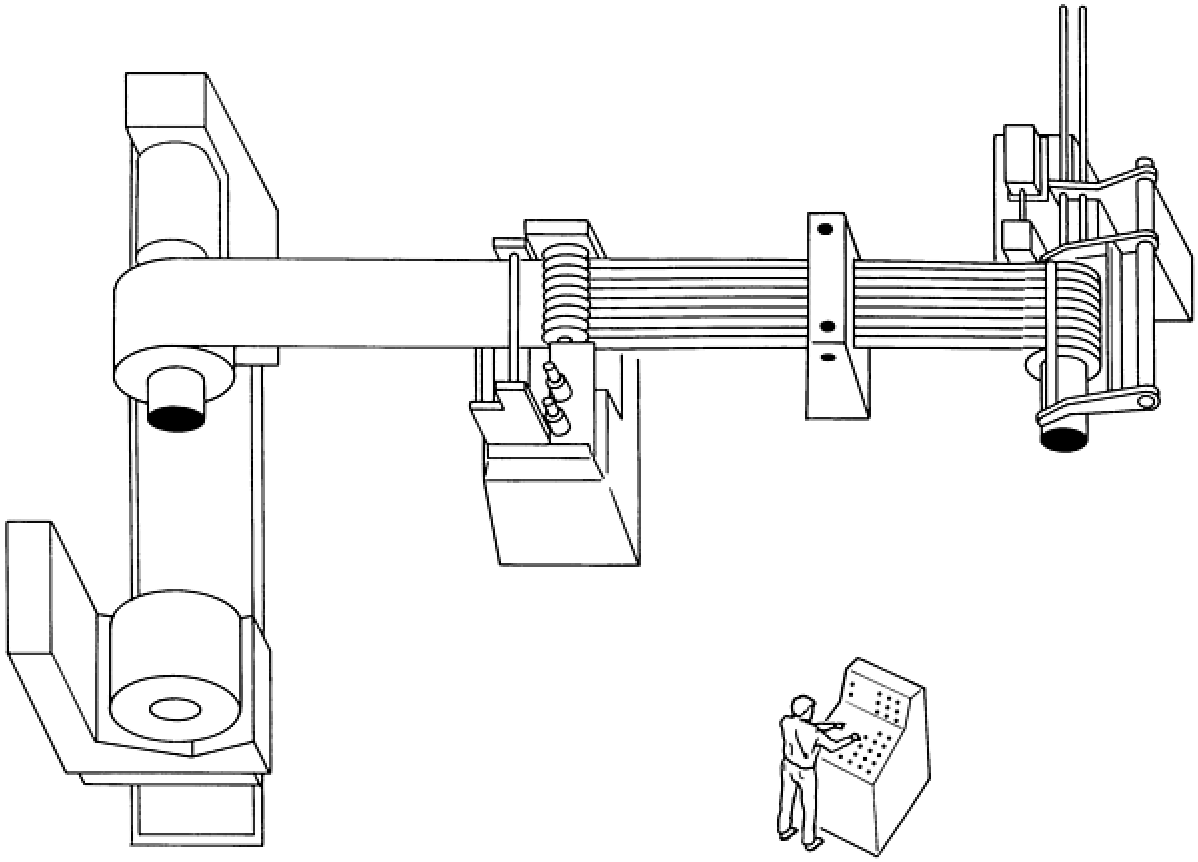

Fig. 7 Mechanism introduced as an additional component between slitter and re-coiler to elongate the tighter strands slightly so that all slit strands rewind at the same rate and tightness

The capacity of slitting lines is usually stated in terms of the number of cuts of a certain thickness of a specified metal. Thicker material can often be slit if fewer cuts are being made.

Effect of Slitting Speed on Productivity. There are many more linear feet of material in a thin-gage coil than in a coil of thicker material. Therefore, for practicality, lightgage lines generally run at higher speeds. On older lines, increasing the slitting speed may have a small effect on overall productivity because the slitting phase of the operation may occupy only a small fraction of the total time. On lines with manual feed-up and tool change, the greatest proportion of the total operating time by far is consumed in handling operations. Table 2 shows a breakdown of the time for slitting three lengths of coils at average speeds of 99 to 198 m/min (325 and 650 ft/min) on one of these simple lines. As the data show, doubling the slitting speed results in only a 3 to 12% reduction in overall cycle time for any length of coil.

Table 2 Effect of speed and coil length on slitting time versus total cycle time

For slitting coiled sheet 914 mm (36 in.) wide and 1.6 mm (0.062 in.) thick, using seven cuts

Operation	Time, min, at average speed of:	
	99 m/min (325 ft/min)	198 m/min (650 ft/min)
Coil length: 210 m (690 ft)[(a)]		
Slitting	2	**1**

Coil handling[b]	28	**28**
Total cycle	**30**	29
Coil length: 610 m (2000 ft)[c]		
Slitting	6	**3**
Coil handling[b]	28	**28**
Total cycle	**34**	31
Coil length: 910 m (3000 ft)[d]		
Slitting	9	**4.5**
Coil handling[b]	28	**28**
Total cycle	37	32.5

(a) 813 mm (32 in.) OD coil; weight: 2380 kg (5240 lb).

(b) Removing bands from coil and loading it on uncoiler, threading, attaching six strands and placing separators on re-coiler drum, placing one band on each coil, and stripping it off the re-coiler.

(c) 1220 mm (48 in.) OD coil; weight: 6800 kg (15,000 lb).

(d) 1520 mm (60 in.) OD coil; weight: 10,200 kg (22,500 lb)

Modern slitting lines can provide fully automatic slit-coil feed-up in 3 to 6 min. Lines employing automatic cartridge-type slitter-head exchange can exchange tooling stands in 1 min or less. These factors represent a substantial reduction in downtime between coils. In such a case, increases in slitting speed may have a more profound effect on overall productivity (measured in tons per hour).

Slitting and Shearing of Coiled Sheet and Strip

Revised by Eric Theis, Herr-Voss Corporation

Cut-to-Length Lines

Cut-to-length lines (also called blanking lines or shearing lines) are used to produce cut-to-length sheets from coil stock. These machines uncoil the strip, flatten or level it (see section "Flatteners and Levelers for Strip" in this article), cut it to length, and then stack the sheets. There are two basic types of shear employed: stationary and flying die or rocker type.

Flying-die or rocker shear lines continuously feed the coil, with the cutoff blades arranged to travel in the same direction and speed as the strip during the cutoff process. Because of the difficulties involved in synchronizing this speed match with accurate length positioning, these lines are generally used where length tolerances are less critical.

Stationary Shears. Most cut-to-length lines employ stationary shears. The strip is stopped at the shear during the cut. These lines are generally more accurate than other types. There are three types of feeding arrangements for fixed shear lines: start/stop, hump table, and looping pit.

Stop/start cut-to-length lines (Fig. 8) are usually arranged so that the coil is fed into the shear to a prescribed length and then stopped during the cut. Upon completion of the cut, the coil feed accelerates until it stops for the next cut. Close tolerances can be obtained, and line configuration is simple; however, the speed in meters per minute or sheets per minute is slow. Therefore, these lines are generally confined to heavy-gage requirements. Stopping the coiled sheet in the flattener or leveler prior to shearing may also leave a mark on lighter-gage materials.

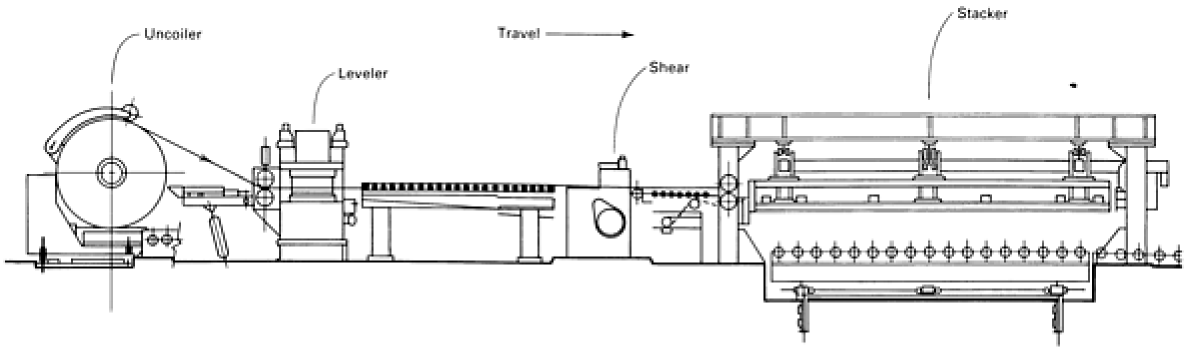

Fig. 8 Stop/start cut-to-length line in which coil travel is stopped to allow material to be cut to a prescribed length in the shear and then restarted until material is again at the prescribed length, when the stop/start cycle is repeated

With the hump or loop-feed configuration, the uncoiler and flattening equipment operates continuously. The strip is stopped at the shear, and this causes excess material to rise above the passline in a hump or fall below the passline into a looping pit just before the shear.

Hump Table. Stationary shear lines with hump tables (Fig. 9) consist of an uncoiler, a flattener, and/or a leveler to correct for strip shape and to feed the strip over a hump table, a stationary shear, a gage table with retractable stop, and a stacker that stacks the cut sheets as they are delivered from the gage table.

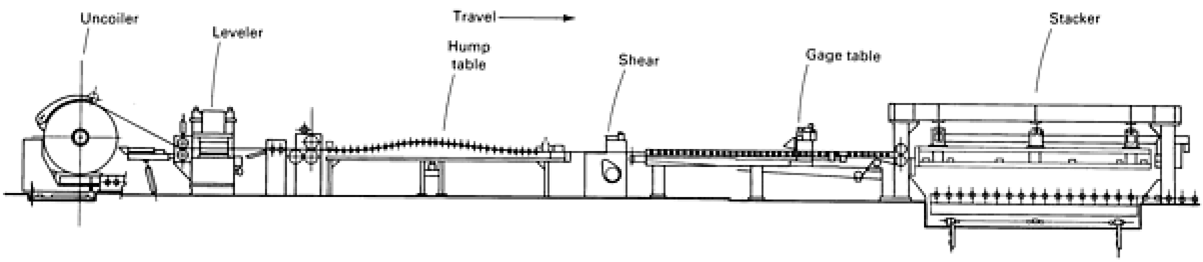

Fig. 9 Stationary shear lines with hump table operate with strip continuously moving from uncoiler even during shearing sequence, causing the coil sheet to form a loop above the passline and over the hump table. A limit switch actuates shear when the uncoiled strip touches a retractable stop.

The retractable stop with gage table, which follows the shear sequence, is used to control the length of the cut sheets. When the uncoiled strip touches the gage stop, it trips a limit switch that actuates the shear. Because the strip continues to flow from the uncoiler, it causes a loop to form above the hump table in front of the shear. When shearing is completed, the gage stop retracts, and the cut sheet is delivered to the stacker. As the cut sheet is removed, it trips a limit switch that resets the gage stop. Then, the shear opens, permitting the strip to slide out of its loop through the shear and onto the gage table against the gage stop again, and the cycle is ready to be repeated.

Looping Pit. As shown in Fig. 10, many stationary shear lines have precision measuring feeder rolls just before the shear, instead of hump and gage tables. In these lines, there is a looping pit below the passline, after the straightener/leveler and before the feed rolls and shear. The flattener and/or leveler runs continuously, with coil stock accumulating in the pit during the cut cycle. Side guides control the feed angle of the strip for maximum cut squareness as it exits the looping pit and enters the shear. On some lines, the shear knives can be pivoted to cut trapezoidal blanks.

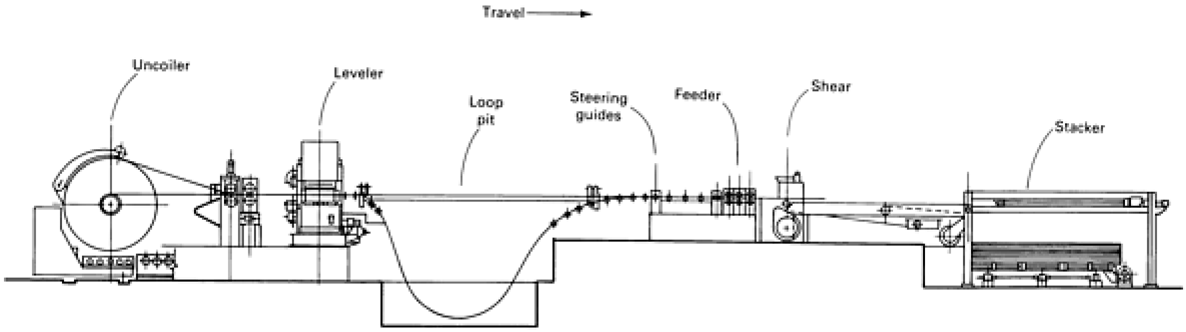

Fig. 10 Stationary shear lines with looping pit located below passline and between straightener/leveler and feed rolls and shear

A stationary shear line generally provides the best squareness and length tolerance and most productivity for lighter-gage materials. Because of the nature of the loop, this feeding method is not practical for strip over about 6.4 mm ($\frac{1}{4}$ in.) thick. A hump line may be somewhat less expensive when the costs of installation are included, but tolerance, squareness, and productivity may be sacrificed.

Rotary drum shears are sometimes used in high-production sheet mills at speeds to 300 m/min (1000 ft/min). The tinplate flying shear, a special type of rotary drum shear, is made specifically for cutting coils of tinplate into lengths for use in the manufacture of cans.

Blanking lines are a special derivation of shearing lines. Most shearing lines, of any of the above configurations, are designed for cutting sheets ranging in length from 0.6 m (2 ft) to 8 to 9 m (25 to 30 ft). Because these sheets are to be fabricated later into an end product, length tolerance requirements may not be critical. Blanking lines have the special capability of rapidly cutting and stacking relatively short and dimensionally accurate blanks.

Edge-trim slitters are incorporated into some line configurations. However, these follow the camber or sweep found in almost all master coils obtained from the mill. These slitters cannot be counted on to eliminate or even control camber or to provide improved sequences.

Cut-to-length line capacity may be limited by the shear. Most shears include a raked blade. As a result, the shear, and therefore the cut-to-length line, does not have a short/thick capacity. If, for example, the line capacity were 6.4 × 1830 mm ($\frac{1}{4}$ × 72 in.), the maximum thickness for 305 mm (12 in.) wide material would still be only 6.4 mm ($\frac{1}{4}$ in.).

Dimensional accuracy of the cut sheet length depends on the line configuration, condition of the equipment, speed and length of sheet, and the condition of the master coil. In previous generations of equipment, an accuracy of ±1.6 mm (± $\frac{1}{16}$ in.) was acceptable. Most modern lines are accurate to ±0.8 mm (± $\frac{1}{32}$ in.), except on very long sheets. Sophisticated equipment is also available that can produce sheets or blanks with tolerances of ±0.4 mm (± $\frac{1}{64}$ in.).

Cut-to-Length Lines

Cut-to-length lines (also called blanking lines or shearing lines) are used to produce cut-to-length sheets from coil stock. These machines uncoil the strip, flatten or level it (see section "Flatteners and Levelers for Strip" in this article), cut it to length, and then stack the sheets. There are two basic types of shear employed: stationary and flying die or rocker type.

Flying-die or rocker shear lines continuously feed the coil, with the cutoff blades arranged to travel in the same direction and speed as the strip during the cutoff process. Because of the difficulties involved in synchronizing this speed match with accurate length positioning, these lines are generally used where length tolerances are less critical.

Stationary Shears. Most cut-to-length lines employ stationary shears. The strip is stopped at the shear during the cut. These lines are generally more accurate than other types. There are three types of feeding arrangements for fixed shear lines: start/stop, hump table, and looping pit.

Stop/start cut-to-length lines (Fig. 8) are usually arranged so that the coil is fed into the shear to a prescribed length and then stopped during the cut. Upon completion of the cut, the coil feed accelerates until it stops for the next cut. Close tolerances can be obtained, and line configuration is simple; however, the speed in meters per minute or sheets per minute is slow. Therefore, these lines are generally confined to heavy-gage requirements. Stopping the coiled sheet in the flattener or leveler prior to shearing may also leave a mark on lighter-gage materials.

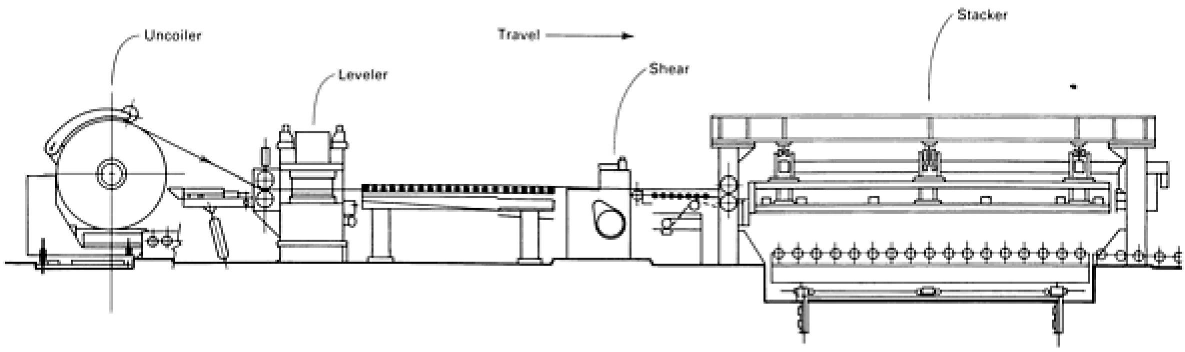

Fig. 8 Stop/start cut-to-length line in which coil travel is stopped to allow material to be cut to a prescribed length in the shear and then restarted until material is again at the prescribed length, when the stop/start cycle is repeated

With the hump or loop-feed configuration, the uncoiler and flattening equipment operates continuously. The strip is stopped at the shear, and this causes excess material to rise above the passline in a hump or fall below the passline into a looping pit just before the shear.

Hump Table. Stationary shear lines with hump tables (Fig. 9) consist of an uncoiler, a flattener, and/or a leveler to correct for strip shape and to feed the strip over a hump table, a stationary shear, a gage table with retractable stop, and a stacker that stacks the cut sheets as they are delivered from the gage table.

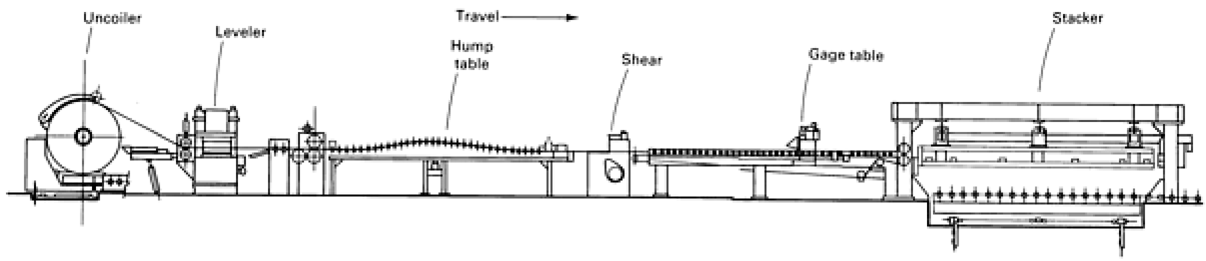

Fig. 9 Stationary shear lines with hump table operate with strip continuously moving from uncoiler even during shearing sequence, causing the coil sheet to form a loop above the passline and over the hump table. A limit switch actuates shear when the uncoiled strip touches a retractable stop.

The retractable stop with gage table, which follows the shear sequence, is used to control the length of the cut sheets. When the uncoiled strip touches the gage stop, it trips a limit switch that actuates the shear. Because the strip continues to flow from the uncoiler, it causes a loop to form above the hump table in front of the shear. When shearing is completed, the gage stop retracts, and the cut sheet is delivered to the stacker. As the cut sheet is removed, it trips a limit switch that resets the gage stop. Then, the shear opens, permitting the strip to slide out of its loop through the shear and onto the gage table against the gage stop again, and the cycle is ready to be repeated.

Looping Pit. As shown in Fig. 10, many stationary shear lines have precision measuring feeder rolls just before the shear, instead of hump and gage tables. In these lines, there is a looping pit below the passline, after the straightener/leveler and before the feed rolls and shear. The flattener and/or leveler runs continuously, with coil stock accumulating in the pit during the cut cycle. Side guides control the feed angle of the strip for maximum cut squareness as it exits the looping pit and enters the shear. On some lines, the shear knives can be pivoted to cut trapezoidal blanks.

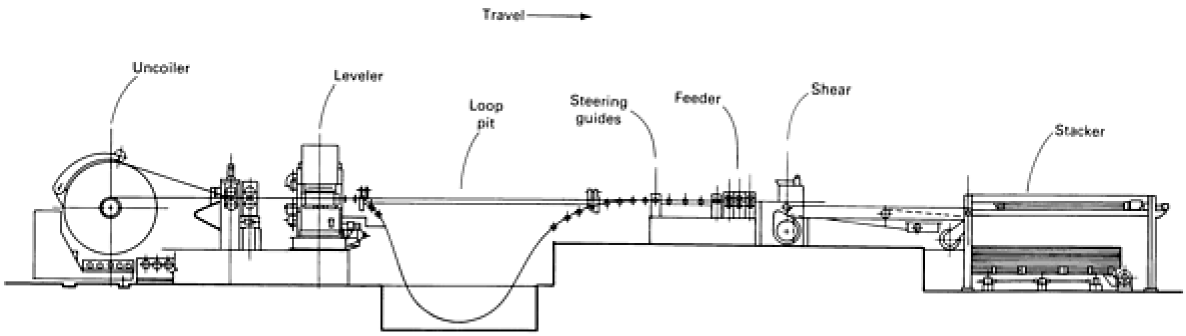

Fig. 10 Stationary shear lines with looping pit located below passline and between straightener/leveler and feed rolls and shear

A stationary shear line generally provides the best squareness and length tolerance and most productivity for lighter-gage materials. Because of the nature of the loop, this feeding method is not practical for strip over about 6.4 mm ($\frac{1}{4}$ in.) thick. A hump line may be somewhat less expensive when the costs of installation are included, but tolerance, squareness, and productivity may be sacrificed.

Rotary drum shears are sometimes used in high-production sheet mills at speeds to 300 m/min (1000 ft/min). The tinplate flying shear, a special type of rotary drum shear, is made specifically for cutting coils of tinplate into lengths for use in the manufacture of cans.

Blanking lines are a special derivation of shearing lines. Most shearing lines, of any of the above configurations, are designed for cutting sheets ranging in length from 0.6 m (2 ft) to 8 to 9 m (25 to 30 ft). Because these sheets are to be fabricated later into an end product, length tolerance requirements may not be critical. Blanking lines have the special capability of rapidly cutting and stacking relatively short and dimensionally accurate blanks.

Edge-trim slitters are incorporated into some line configurations. However, these follow the camber or sweep found in almost all master coils obtained from the mill. These slitters cannot be counted on to eliminate or even control camber or to provide improved sequences.

Cut-to-length line capacity may be limited by the shear. Most shears include a raked blade. As a result, the shear, and therefore the cut-to-length line, does not have a short/thick capacity. If, for example, the line capacity were 6.4 × 1830 mm ($\frac{1}{4}$ × 72 in.), the maximum thickness for 305 mm (12 in.) wide material would still be only 6.4 mm ($\frac{1}{4}$ in.).

Dimensional accuracy of the cut sheet length depends on the line configuration, condition of the equipment, speed and length of sheet, and the condition of the master coil. In previous generations of equipment, an accuracy of ±1.6 mm (± $\frac{1}{16}$ in.) was acceptable. Most modern lines are accurate to ±0.8 mm (± $\frac{1}{32}$ in.), except on very long sheets. Sophisticated equipment is also available that can produce sheets or blanks with tolerances of ±0.4 mm (± $\frac{1}{64}$ in.).

Slitting and Shearing of Coiled Sheet and Strip

Revised by Eric Theis, Herr-Voss Corporation

Flatteners and Levelers for Strip

Coiled sheet or strip often contains three distinct shape defects (Fig. 11):

- When uncoiled, the strip retains some of the residual longitudinal curvature from its original coiled condition or a related across-the-strip curvature
- A longitudinal length differential within the strip causing wavy edges or center buckle
- Variations in thickness of the strip

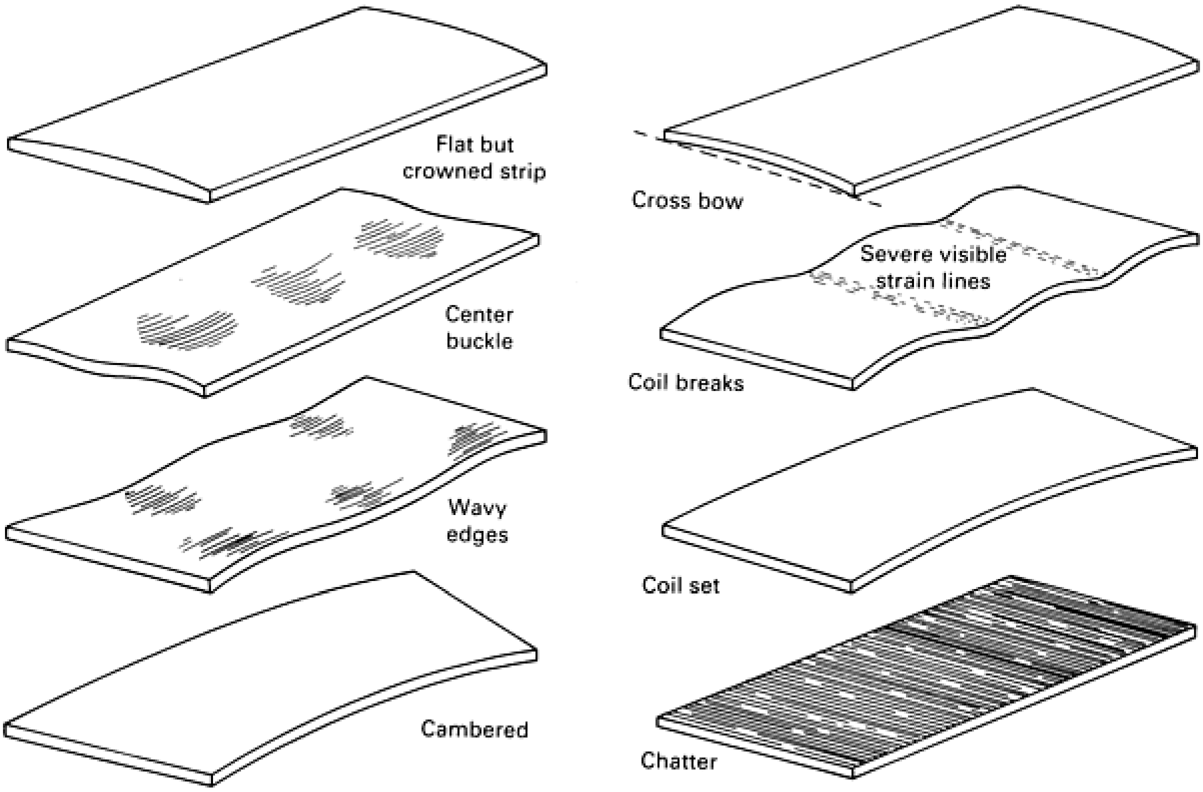

Fig. 11 Defects inherent in the manufacture of coiled sheet or strip

Properly designed and operated flatteners, such as the one illustrated in Fig. 12, can control or eliminate residual longitudinal curvature conditions, which are termed coil set and cross bow. Roller revelers (Fig. 13), properly designed and operated, can control or eliminate both residual longitudinal curvature and longitudinal length differential. Neither flatteners nor roller levelers, however, can significantly affect thickness variation.

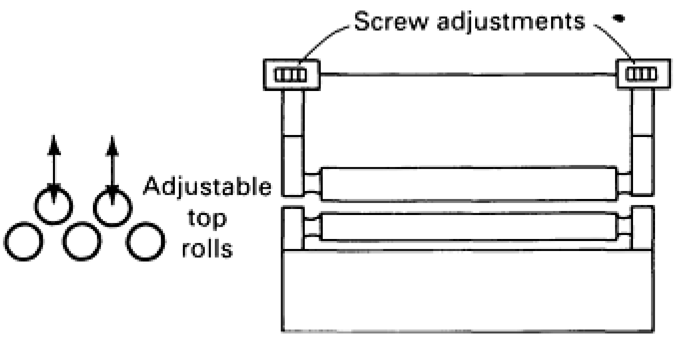

Fig. 12 Five-roll flattener used to eliminate such defects as coil set and cross bow in coiled sheet or strip

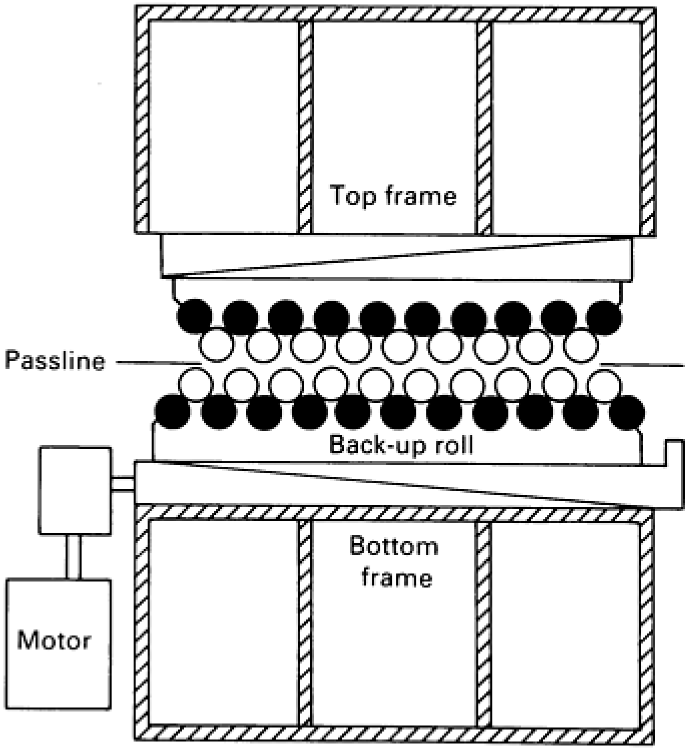

Fig. 13 Corrective leveler with adjustable backup rollers used to eliminate coil set, crossbow, edge-wave, and center or quarter buckles conditions in coiled sheet or strip

In each case, strip is passed between sets of upper and lower offset rolls, alternately bending the strip up and down. Levelers have the ability to control the deflection of these rolls so that one portion of the strip can be subjected to more deformation than another (Fig. 14).

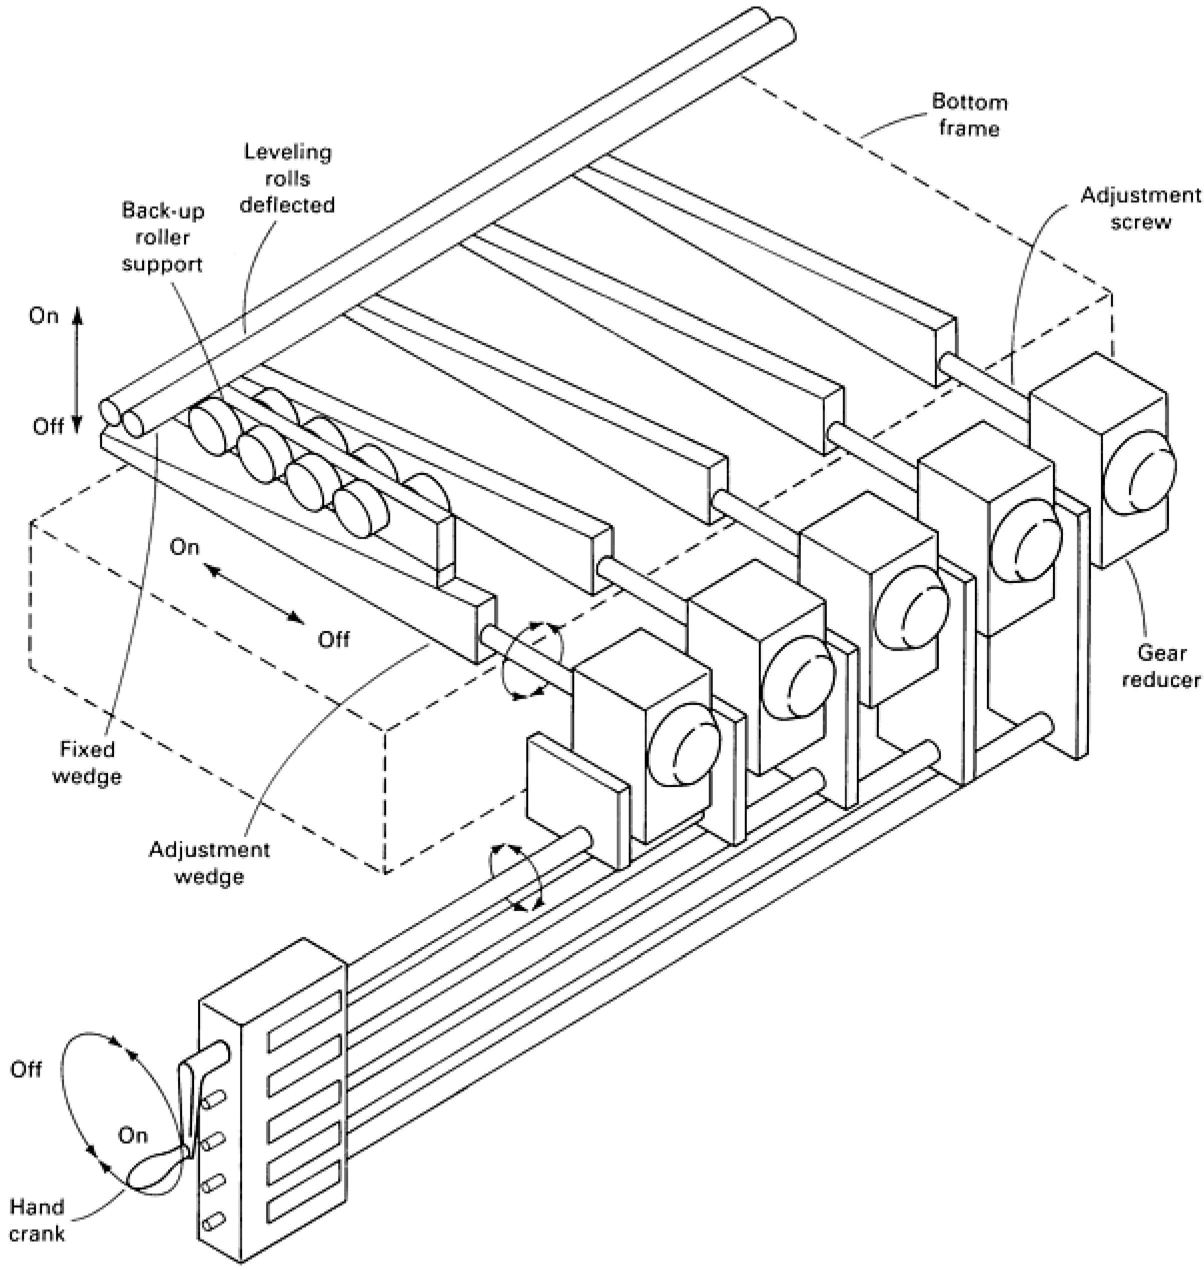

Fig. 14 Wedge-type backup roller adjustment for the most accurate control of leveling roll deflection

The process of leveling strip calls for a high-precision piece of equipment, with absolutely minimal machine deflection during operation. The flattener and leveler in any coil-processing line is the first step in producing quality strip or blank shapes. Gaging systems, feeding systems, and so forth cannot maintain optimal accuracy if the strip itself is not consistently flat initially.

Shearing of Bars and Bar Sections

Introduction

BARS AND BAR SECTIONS are sheared between the lower and upper blades of a machine in which only the upper blade is movable. As the upper blade is forced down, the work metal is distorted and caused to fracture. There are also shears, such as impact cutoff machines, which utilize a horizontal knife movement to shear the bar sections. Figure 1 shows the appearance of a sheared round bar. The burnished area, or depth of shear action by the blade, is usually one-fifth to one-fourth the diameter of the bar. In visual examination of a sheared edge, the burnished portion appears smooth, while the fractured portion is comparatively rough.

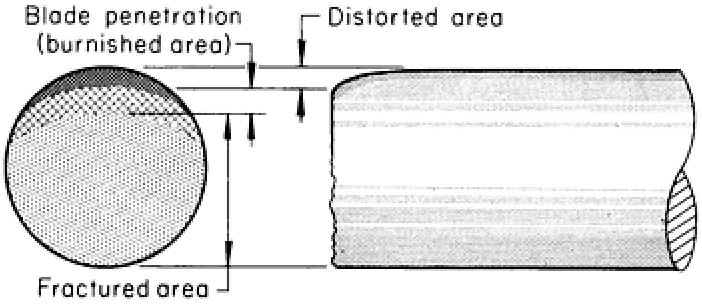

Fig. 1 Effects of shearing a round bar with a straight blade.

Applicability. In general, any metal that can be machined can be sheared, but power requirements increase as the strength of the work metal increases. Further, blade design is more critical and blade life decreases as the strength of the work metal increases. Equipment is available for shearing round, hexagonal, or octagonal bars up to 152 mm (6 in.) in diameter or thickness, rectangular bar and billets up to 75 × 305 mm (3 × 12 in.) in cross section, and angles up to 203 × 203 × 38 mm (8 × 8 × $1\frac{1}{2}$ in.).

Straight blades can be used to shear bars and bar sections, although a considerable amount of distortion occurs, as shown in Fig. 1. In addition, the concentration of shock on the blades is high when shearing with straight blades (particularly when shearing round bars). Preferred practice is to use blades that conform to the shape of the work metal, as discussed in the section "Blade Design and Production Practice" in this article. Angles are usually sheared in a special machine, or in a special setup with conforming blades.

Because of the conditions illustrated in Fig. 1, the edges sheared with straight blades are not as high quality as edges that are sawed or otherwise machined. However, when blades are sharp and accurately adjusted, sheared edges that are acceptable for a wide range of applications can be obtained. The quality of sheared edges usually increases as thickness of the work metal decreases.

Accuracy of Cut. Workpieces properly supported on both sides of the shear blades by a roller conveyor table and placed squarely against a gage stop securely bolted to the exit side of the machine can ordinarily be cut to lengths accurate to +3.2, -0 mm (+$\frac{1}{8}$, -0 in.) on shears that can cut bars up to 102 mm (4 in.) in diameter. When larger shears are used, the breakaway of the metal can cause a variation of ±4.8 mm (±$\frac{3}{16}$ in.). Fairly consistent accuracy in the shearing of slugs can be obtained by careful adjustment of the gage setting, especially if the slugs are produced on a weight-per-piece basis. Supporting the free end of the material on a spring-supported table will minimize bending during the shearing operation, thus providing better control over the length of cut.

Selection of Cutoff Method. The method of cutting off bars can be determined by the edge condition required for subsequent operations. Sawing usually produces a uniform cut edge with little or no damage to the microstructure in the immediate area. Gas cutting produces an edge that resembles a sawed edge in smoothness and squareness. However, the cut edge of some steels becomes hardened during gas cutting, thus making subsequent machining difficult. A sheared edge is usually easy to machine, but can make the fit-up of parts of a weldment more difficult and can increase warpage because of wider gaps.

Power Requirements. The net horse-power required for shearing can be estimated from the following formula:

$$\text{hp} = \frac{AVS}{33\ 000} \quad \textbf{(Eq 1)}$$

where A is the cross-sectional area of the workpiece (in square inches), V is the speed of the shear blade (in feet per minute), and S is the shear strength of the work metal (in pounds per square inch). The 33,000 is foot-pounds per minute per horsepower. For metric use, the power in English units (hp) should be multiplied by 0.746 to obtain kilowatts. It may be necessary to increase the calculated value as much as 25% to compensate for machine inefficiency.

Although Eq 1 is used for estimating, it is of limited value because it does not consider the ductility of the metal. The formula is based on shearing low-carbon steel. Copper, for example, is more ductile than steel; therefore, the distance of blade penetration before fracture in copper will be greater than that in steel. Conversely, when shearing metals that are less ductile than low-carbon steel, the distance of blade penetration before breakaway will be less. Power requirements are also affected by the ductility of the work metal.

Cutting Speed. The speed at which material is sheared without adverse effect can range from almost zero to 21 or 24 m (70 or 80 ft) per min. However, as speed increases above 6.1 or 7.6 m (20 to 25 ft) per min, problems are encountered in holding the workpiece securely at the blade without the far end whipping, especially with material 6.4 mm ($\frac{1}{4}$ in.) thick or more. When bars harder than 30 HRC are cut at speeds of 12 to 15 m (40 to 50 ft) per min or higher, chipping of the blade is common (see Example 1).

Shearing of Bars and Bar Sections

Machines

The production shearing of bars and bar sections is usually done in machines with a throat opening designed for large, bulky workpieces. These machines include alligator and guillotine shears, and a multipurpose machine with interchangeable punches and dies for shearing, punching, and coping. Squaring shears, normally used for sheet and plate, can also be used for cutting bar stock to length. Punch presses and press brakes can be provided with appropriate tooling for shearing operations.

In alligator shears (also known as pivot or nutcracker shears), the lower blade is stationary, and the upper blade, held securely in an arm, moves in an arc around a fulcrum pin (Fig. 2). The shearing action is similar to that of a pair of scissors. A crankshaft transmits power to the shearing arm, and the leverage applied produces the force for shearing. Maximum shearing force is obtained closest to the fulcrum, and the mechanical advantage decreases as the distance between the point of shearing and the fulcrum increases. Therefore, with the maximum opening (largest rake angle), capacity is maximum for any shear. As the blade begins downward travel and rotation about its fulcrum, the cross-sectional area engaged by the blade is increased; therefore, more energy is expended, and the upper blade is slowed down until the breakaway point is reached. At this point, the mechanical forces have overcome the resistance of the metal, and the remainder of the cross-sectional area breaks off.

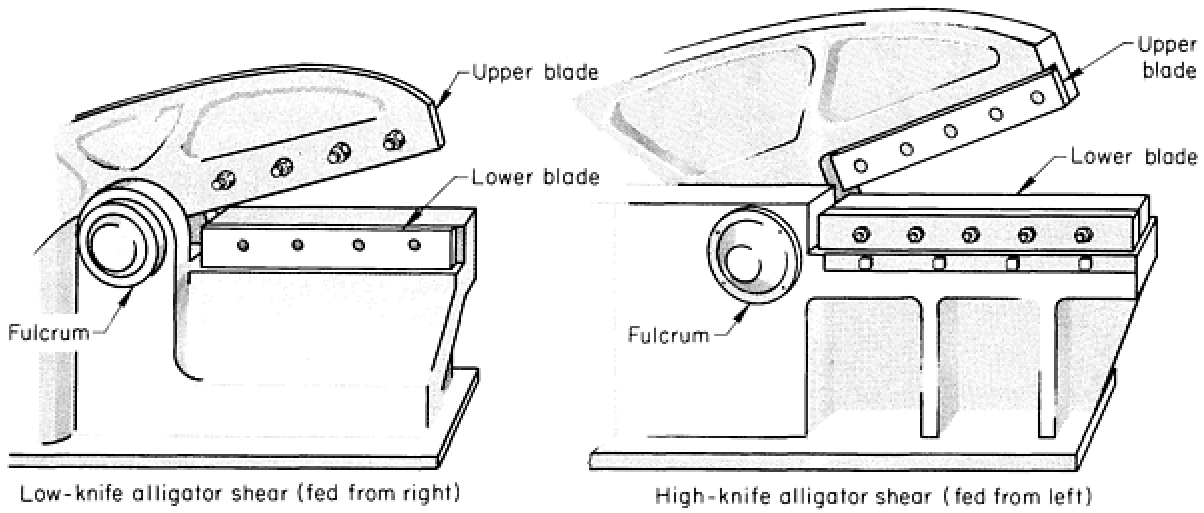

Fig. 2 Low-knife and high-knife alligator shears. See text for discussion.

The capacity of an alligator shear is designated as the maximum cross-sectional area of flat plate or round bar that can be sheared, based on work metal having a tensile strength of 275 MPa (40 ksi). An alligator shear can be used not only for bars and bar sections but also for plate, sheet, and strip within the limitations of the blade length of the machine. Alligator shears are extensively used for preparing scrap because the single pivot point allows the blades to open wide enough to accept bulky objects. For example, on a machine with 305 mm (12 in.) long blades, the opening between upper and lower shear blades is approximately 133 mm ($5\frac{1}{4}$ in.); on a machine with 914 mm (36 in.) long blades, the opening can be as great as 279 mm (11 in.).

The two types of shearing arms used on alligator shears are low-knife and high-knife (Fig. 2). In the low-knife type, the cutting edge of the lower blade is in line with the center of its fulcrum pin; in high-knife shear, the cutting edge of the lower blade is on a plane above the centerline of the fulcrum pin. In general, the low-knife shear is preferred for cutting bars and bar sections. The high-knife shear is preferred for cutting flat stock and for use in scrap yards. A high-knife shear, by making successive cuts, can shear flat stock that is wider than the length of the shear blades. An alligator shear is further classified as either right-hand or left-hand (each is shown in Fig. 2), depending on the side from which it is fed.

The weight of alligator shears ranges from about 1100 to 19,500 kg (2500 to 43,000 lb). The lighter shears can be made portable on wheels, on a sled-type skid, or on blocks. The heavier machines must be anchored in concrete.

The speed of alligator shears ranges from approximately 50 strokes per minute for the smallest power-driven machine to about 18 strokes per minute for the largest heavy-duty shear. Except for small hand-operated types, alligator shears are usually mechanically driven; a flywheel provides uniform, sustained power during cutting.

The number of strokes per minute can be reduced by changing either the motor speed or the diameter of the flywheel pulley. An increase in the number of strokes may affect the stored energy of the flywheel and reduce the shearing capacity. On continuously cutting shears, greater speed will reduce workpiece-positioning time for the operator and therefore may reduce output rather than increase it. On single-stroke machines, cutting time is minimal compared to the time required for accurate positioning of the stock.

Guillotine shears are designed for cutting bars and bar sections to desired lengths from mill stock. They are extensively used throughout the fabricating industry. Two general types are available: open end (Fig. 3) and closed end. The shear illustrated in Fig. 3 is termed an open-end shear because it has a C-frame construction with one end open and unsupported. Open-end shears are either single end, for one operator, or double end, for two operators. On double-end machines, both ends can be right-hand or left-hand, or one end can be right-hand and the other end left-hand, depending on the type of shearing to be done. A closed-end guillotine shear, on the other hand, is basically the same as the one shown in Fig. 3 except that it has frame supports on both sides.

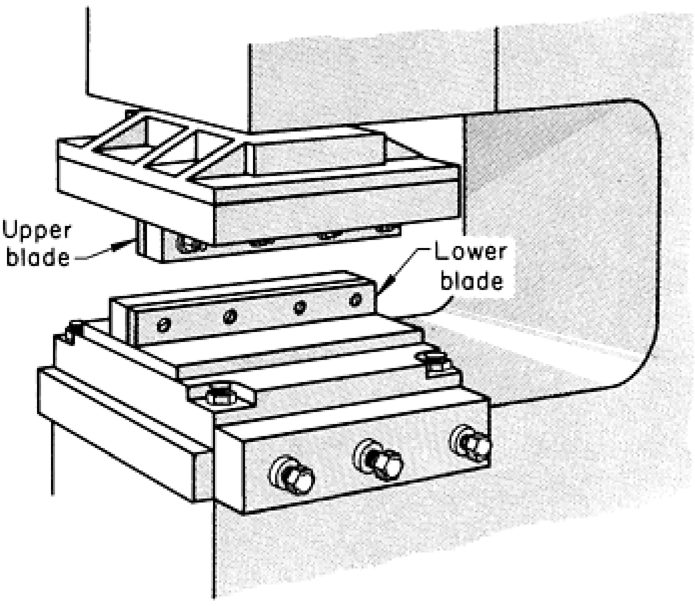

Fig. 3 Open-end guillotine shear.

An open-end shear has the advantage of giving the operator a clear view of the blades. However, because one end is open, a heavier frame and more floor space are required than for a closed-end shear of equal capacity.

Guillotine shears for bars and angles are available in capacities to 2700 kN (300 tonf). Either intermittent or continuous operation is possible. Guillotine shears can be equipped with simple straight blades (Fig. 3) or with two or more short blades having specific shapes.

Guillotine shears are actuated mechanically, hydraulically, or pneumatically. Hydraulic and pneumatic machines are lighter in weight for a specific shearing power, are more economical, and operate with less vibration than mechanical shears. Therefore, hydraulic or pneumatic machines up to 89 kN (10 tonf) capacity are completely portable, and units of 1800 to 2700 kN (200 to 300 tonf) capacity are semiportable (need not be solidly mounted in concrete).

Combination machines are multipurpose machines used primarily in metal-fabricating shops where there is a constant need for shearing small quantities (often two or three pieces) of a variety of shapes and sizes from bars or bar sections. Some combination machines can also be used for punching, slotting, and notching.

Many combination machines incorporate several devices within the frame for performing different operations; therefore, a new setup is not required for each. A holder for an interchangeable punch and die is located in an area with a deep throat. This facilitates the punching of holes, slots, or notches in plates and bars, and in webs or legs of structural members.

A slide moving at 45° from vertical carries a blade for shearing angles. The support bed is on a swivel so that the ends of the angle section can be varied as desired from 45 to 90°. In two strokes of the machine, angles can be sheared to produce miter joints for subsequent welding (see the section "Shearing of Angles" in this article).

Combination machines can be used for cutting square and rectangular notches in the leg of an angle. These machines can be set up to cut a 90° V-shaped notch in angles that subsequently will be bent into frames. Other shapes, such as beams and channels, can be notched in a similar manner if the machine can accommodate the vertical height between the upper and lower legs of the workpiece. Provision is also made for shearing bars with guillotine-type blades or special blades (see the section "Conforming Blades" in this article).

Combination machines are available in capacities ranging from 110 to 890 kN (12 to 100 tonf).The 110 kN (12 tonf) machine can punch a 14 mm ($\frac{9}{16}$ in.) diam hole through a 6.4 mm ($\frac{1}{4}$ in.) thick section and can shear 75 × 75 × 6.4 mm (3 × 3 × $\frac{1}{4}$ in.) angles, 22 mm ($\frac{7}{8}$ in.) diam rounds, 19 mm ($\frac{3}{4}$ in.) squares, and 102 × 6.4 mm (4 × $\frac{1}{4}$ in.) flats. The 890 kN (100 tonf) machine can shear 152 × 152 × 16 mm (6 × 6 × $\frac{5}{8}$ in.) rounds, 50 mm (2 in.) squares, and 203 × 19 mm (8 × $\frac{3}{4}$ in.) flats.

Punching and shearing machines are deep-throat C-frame machines for the punching, shearing, notching, or coping of plates, bars, and structural sections. Shoes, into which punches, dies, and shear blades can readily be inserted, are mounted on the bed and ram.

The shoes either rest on the bed or are overhung; the overhanging type is designed so that structural shapes can be punched in both web and flange. The plain type of shoe is primarily used for plate work; however, plates can be worked with the overhanging shoes. Both types of die blocks are fitted with die sockets that hold dies of different inside diameters. The punch holder is adjustable to suit the location of the dies. Table 1 lists the capacities for punching and shearing with this type of machine.

Table 1 Maximum workpiece dimensions that can be accommodated in vertical open-cap punching and shearing machines of various tonnage ratings

Machine rating		**Punching**				Shearing

Fixturing is an important consideration in the shearing of bars. For safety and the proper functioning of open-end shears (Fig. 3) and for shearing units such as those shown in the center and at the right in Fig. 7, hold-down fixtures are essential. Guide pins are also helpful, especially when shearing with conforming blades as shown in Fig. 7.

Shear Blades

Shock-resistant tool steels such as S2 or S5 are most commonly used as blade materials for cold shearing, although L6 has also been successfully used for some applications. Some plants use shear blades made from carbon or alloy steel with hardfaced shearing edges.

The hardness of tool steel blades usually ranges from 45 to 55 HRC (sometimes as high as 58 HRC). The upper end of this range can be used when work metal thickness does not exceed 13 mm ($\frac{1}{2}$ in.). As work metal thickness increases, the hardness of the blade should be decreased to the lower end of this range, but not below 45 HRC unless experience with previous applications warrants it. The practice in most plants is to start with blades near the lower end of the range, increasing their hardness only after experience proves it safe. Excessive blade wear is usually preferable to blade breakage.

Blade Material for Hot Shearing. Blades for the hot shearing of bar stock are usually made of H11, H12, or H13 hot-work tool steel (see the article "Wrought Tool Steels" in *Properties and Selection: Irons, Steels, and High-Performance Alloys*, Volume 1 of the *ASM Handbook*). Tool steel for blades can also be made of compositions manufactured by powder metallurgy processes. There are no data to prove the superiority of one of these steels over the others. Grades H21 and H25 are sometimes used, but they are more costly and are recommended only when H11 has been tried and found to be inadequate.

The hardness of blades for hot shearing varies considerably with the thickness and temperature of the metal to be sheared and with the type and condition of the shearing equipment. However, hardness is usually maintained at 38 to 48 HRC.

For high-alloy metals to be sheared at high temperatures, higher-alloy blades may be needed. High-temperature engine-valve alloys have been sheared with T1 high-speed steel blades.

Hardfaced blades are satisfactory for hot shearing and are used exclusively in some plants. The material for the blade body is usually 1030 or 1045 steel. Additional information on hardfacing technology is available in the articles "Hardfacing, Weld Cladding, and Dissimilar Metal Joining" in *Welding, Brazing, and Soldering*, Volume 6, and "Metal and Alloy Powders for Welding, Hardfacing, Brazing, and Soldering" in *Powder Metal Technologies and Applications*, Volume 7 of the *ASM Handbook.*

Blade Profile. The cross section of an alligator shear blade for cutting bars and shapes is normally rectangular. Light-duty blades are about 32 mm ($1\frac{1}{4}$ in.) wide by 102 mm (4 in.) deep by 305 mm (12 in.) long. Blades for machines of about maximum size are commonly about 50 × 127 × 914 mm (2 × 5 × 36 in.). For mounting, blades are provided with countersunk holes as shown in Fig. 4 that allow bolt heads to be sunk sufficiently to prevent interference between blades.

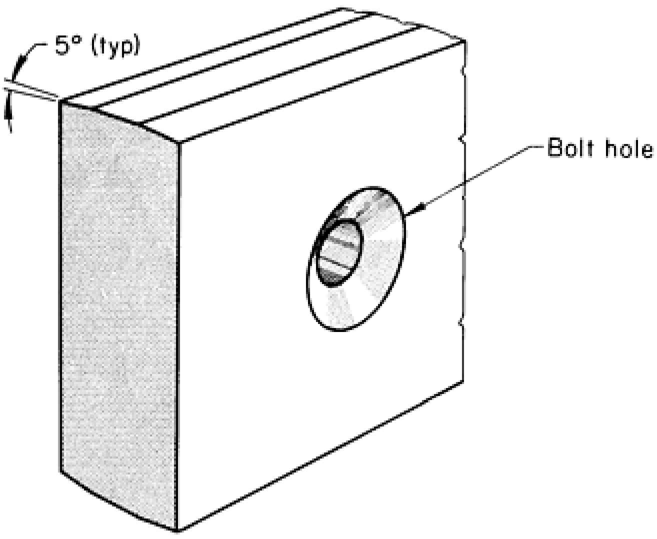

Fig. 4 Straight shear blade ground with negative rake on all four cutting edges.

Blade clearance for shearing bars and bar sections ranges from 0.13 to 0.38 mm (0.005 to 0.015 in.). The smaller clearance is used for shearing clean work metal; the larger clearance is preferred for shearing scaly products to prevent scale or other foreign material from lodging between blades and scoring the surfaces.

Blades for alligator shears are available with grooves across the width to prevent forward movement of the work metal when the upper blade descends, so that more of the cutting length of the blade can be used. Most blades have four cutting edges that are identically ground (Fig. 4); therefore, by inverting the blade and reversing its direction, all four cutting edges can be used before the blade is returned for sharpening. Resharpening any of the four edges requires grinding of one or both faces of an edge. Consequently, a blade that shows severe damage, such as breakout of a section, must be ground to a new, clean and sharp edge. To avoid such major regrinding, blades should be kept free from large nicks and mushrooming.

Most blades are ground to a slight negative rake, as shown in Fig. 4. The intent is to cause the work metal to begin to flow from a slight bending action before actual shearing takes place. Blades provided with a negative rake of 5 to 10° are often less susceptible to chipping at the cutting edge than those ground with a 90° edge (zero rake).

Shear Blade Life. Service data on shear blade life are scarce because maintenance programs in most high-production mills call for removal of blades and redressing during scheduled shutdowns, regardless of the condition of the blades at the time. Blade life in number of cuts before regrinding has been variously reported at 5000 to more than 2 million. Even when an attempt is made to make blade material and cutting conditions as nearly identical as possible, variations in blade life of 100% or more have been reported.

Blade life depends to a great extent on the composition and hardness of the work metal (see the article "Selection of Materials for Shearing and Slitting Tools" in *Properties and Selection: Stainless Steels, Tool Materials, and Special-*

Purpose Metals, Volume 3 of the 9th Edition of *Metals Handbook*). The angle of the cutting edge often affects blade life, and in some cases, shearing speed has a marked effect on blade life. For example, harder work metal usually requires a lower shearing speed in order to avoid blade chipping and premature dulling. When work metal hardness is 30 HRC or higher, speeds greater than 15 m (50 ft) per min are not recommended, and much slower speeds may be required for acceptable blade life. The following example demonstrates the effects of blade angle and speed on blade life.

Example 1: Reduction in Speed for Prolonged Blade Life.

When 1085 flat spring steel 3.2 and 4.8 mm ($\frac{1}{8}$ and $\frac{3}{16}$ in.) thick and 50 mm (2 in.) wide, ranging in hardness from 30 to 34 HRC, was sheared to lengths of 1.2 and 1.5 m (4 and 5 ft) at a blade speed of 21 m (70 ft) per min in a punch press, blades had to be replaced every 2 to 3 weeks (200 to 500 cuts) because of chipping. In addition, regrinding was required during this period. When the procedure was changed to shearing at 3 m (10 ft) per min in a C-frame shear, blade life was increased to an average of 10,000 cuts before regrinding was required, and chipping was eliminated. Blades for both the punch press and the shear were made from S1 tool steel and ranged in hardness from 54 to 56 HRC.

Cost. Because of the relatively small amount of machining needed to make a shear blade, compared with the machining needed to make an intricate impression in a die block or a forming die, the cost of the material is an important part of the total cost of a blade. A blade made from S2 tool steel costs 1.8 times as much as one made from W2 tool steel, and 0.7 times as much as one made from D2 tool steel.

Shearing of Bars and Bar Sections

Blade Design and Production Practice

The straight-edge blades described in the preceding section and illustrated in Fig. 4 can shear almost any bar or shape that is within the capacity of the machine. However, unacceptable distortion may result in some shapes of workpieces when they are sheared with blades that are not designed for cutting specific shapes.

Conforming Blades. One method of minimizing distortion in sheared bars employs two hardened blades mounted face-to-face, with identical holes through each blade. The holes should conform to the shape of the work metal and should be large enough to allow easy passage through the blades (Fig. 5a). One blade is movable vertically and one is stationary. Relatively little movement of the machine is required when blades of this type are used. In addition, because the blades completely encircle the work metal, hold-downs are not needed. However, these blades are usually limited for use on specially built or combination machines.

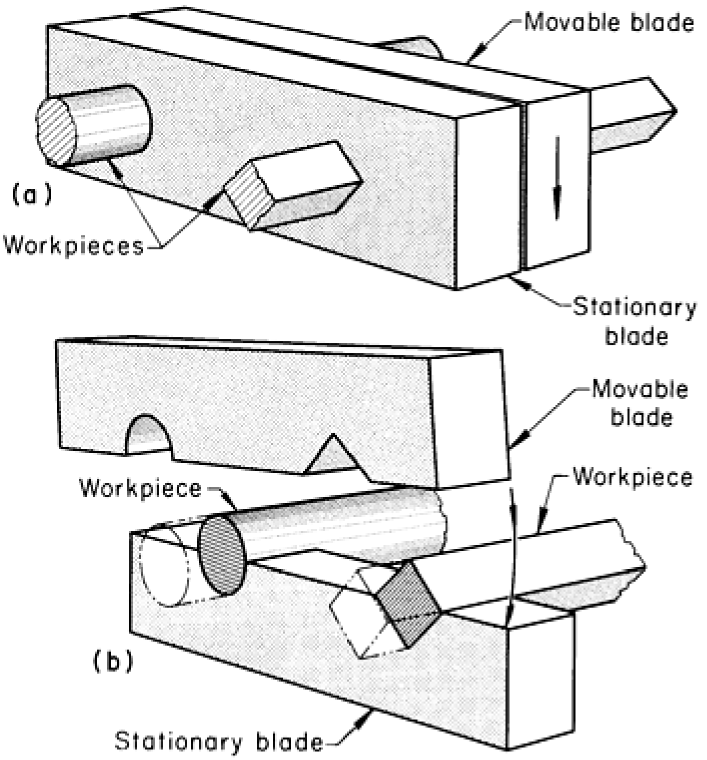

Fig. 5 Two types of blades for the shearing of bars. See text for discussion.

The shearing of round and square bars is more frequently done with the open-type blades illustrated in Fig. 5(b). Each blade is contoured to accommodate one-half the cross section of the work metal. The upper blade moves in a vertical direction, while the lower blade remains stationary. When using this technique, some type of hold-down is needed. Because of the stiffness of the work metal, the hold-down for bars should permit slight movement of the work metal in the axial direction to avoid double shearing. The hold-down can be a simple set screw (to permit adjustment) in a bracket or can be a more elaborate unit, such as a handwheel assembly utilizing an Acme thread.

For shearing square bars with any type of blade, the work metal should be placed so that the movement of the blade is across the diagonal of the square. With this technique the shearing force is applied to four sides instead of two, resulting in a smoother sheared surface. Shearing across the diagonal provides support on two sides of the square shape, which minimizes distortion, and permits more than one size of bar stock to be sheared in a given hole.

Best practice for shearing round bars is to use blades with holes for each size of stock to be cut. Blade holes appreciably larger than the stock size cause excessive distortion of the workpiece.

Shearing of angles is done either in a combination machine or by double cutting. In a combination machine--the more common method--two blades such as those shown in Fig. 6(a) are used. One blade, usually the one that is stationary, is L-shaped and is positioned as shown. The movable blade is square or rectangular and is mounted with its two cutting edges parallel to those of the stationary blade. Figure 6(a) also shows that the space between the blades in the loading position is the same shape as the workpiece.

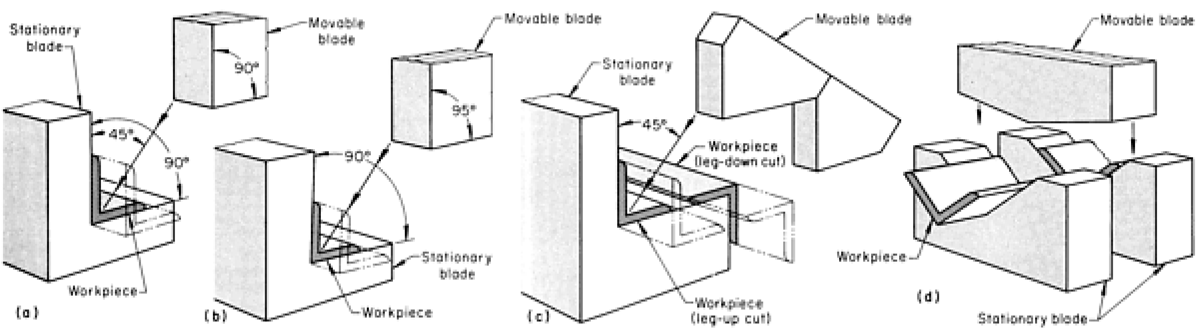

Fig. 6 Four types of blades for the shearing of angle sections. (a) to (c) Shearing in a combination machine. (d) Double-cutting method.

The movable blade travels at 45° toward the stationary blade, and both blades contact the work metal uniformly. Shearing by this technique is essentially a blanking cut, and distortion of the workpiece is minimal. One disadvantage of the method is that all cutting occurs at once, resulting in a high shear load. This condition is not important when small angle sections are cut; however, for work metal larger than 102 × 102 × 13 mm (4 × 4 × $\frac{1}{2}$ in.), the movable blade should be provided with rake to prevent excessive loading.

To provide a rake angle between the movable and stationary blades, the included angle between the cutting edges of the upper or movable blade is increased to 95°, as shown in Fig. 6(b). Shearing begins at the extremity of each leg and progresses toward the root of the angle. The increase in the included angle of the movable blade results in some distortion of the drop-cut piece; the amount of distortion is about equal to the difference in angle between the movable and stationary blades (5° is normal). The part remaining on the table or stationary blade is not distorted.

Most combination shearing machines use a more versatile blade arrangement than those shown in Fig. 6(a) and 6(b). The setup shown in Fig. 6(c) is used to shear angle sections in both the leg-up and the leg-down positions. A swiveling table locates and holds the workpiece during shearing. With the swiveling table and two positions for the workpiece, the flanges can be easily mitered to any specific angle. For example, when shearing angle sections for a frame having the leg on the inside, the table would be set and locked at 45°. One end is mitered by placing the section in a leg-down position on the table and shearing off enough to make a clean cut. The other end is mitered by placing the section leg-up on the table and shearing to the proper length. The opposite positions are applicable when angle sections for a frame having the leg on the outside are being cut.

Shearing at a 45° angle reduces the capacity of the machine because a greater length of metal is cut at one time when a 90° cut is made. For example, a machine with a capacity of 203 × 203 × 32 mm (8 × 8 × 1$\frac{1}{4}$ in.) when making a 90° cut has a capacity of only 203 × 203 × 25 mm (8 × 8 × 1 in.) when cutting at 45°.

Double cutting of angle sections, also called slugging, is used less frequently than shearing in a combination-type machine. This technique uses two stationary blades, spaced 13 mm ($\frac{1}{2}$ in.) apart, and one movable V-shaped blade arranged as shown in Fig. 6(d). The movable blade has a shallow V-shape that does not conform to the shape of the workpiece. Shearing starts at the extremity of each leg and progresses to the root of the angle, producing a 13 mm ($\frac{1}{2}$ in.) wide slug that is pushed out the bottom between the stationary blades.

In the double-cutting method of shearing, distortion occurs only in the slug, because the work metal is supported by the two stationary blades. There are two disadvantages of using the double-cutting method. First, increased power is required for making two cuts at the same time, and second, some metal is lost in the slug. The two stationary blades must be firmly supported to prevent their spreading during the cutting operation.

A similar tool can be used for shearing a channel section. The stationary blades should closely fit the contour of the channel section. Double cutting is adaptable to a guillotine shear, a combination machine, or a press.

Multiple Setups. Fabricating shops often must shear small quantities to a variety of shapes. To handle such work, many shops use a machine with a multiple setup such as the one shown in Fig. 7. Without changing blades, the following operations can be performed:

- Double shearing of angle sections (Fig. 7, left)
- Straight-blade shearing (Fig. 7, center)
- Shearing of round and square bars and single shearing of L-sections (Fig. 7, right)

All movable blades are attached to a single ram.

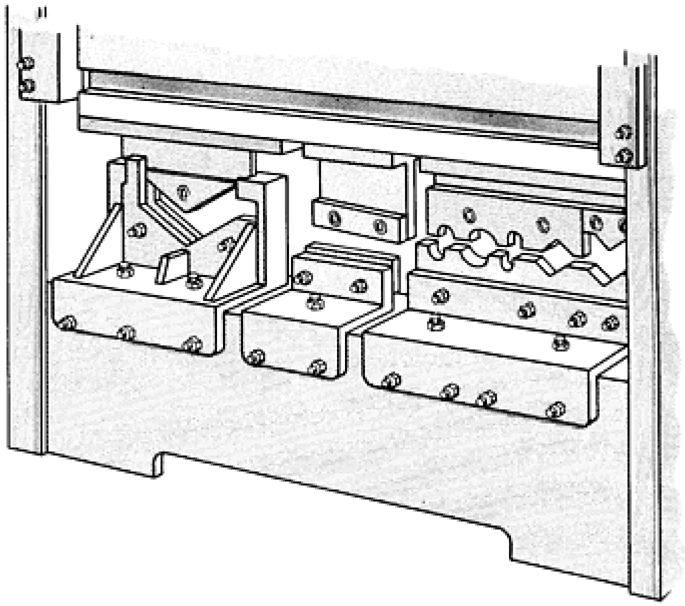

Fig. 7 Multiple setup for various types of shearing--singly or in combination.

Impact Cutoff Machines

Impact cutoff machines produce high-quality cut slugs or blanks of precise length from round, square, or specially shaped bars or coils. Two precision cutoff dies are engaged in opposite directions within the impact block, with short simultaneous strokes fracturing the metal. The result (Fig. 8) is a clean cut at the interface of the two dies, producing slugs or blanks with length tolerances of well within ±0.13 mm (±0.005 in.) and virtually no deformities at reduction speeds of 300 cuts per minute.

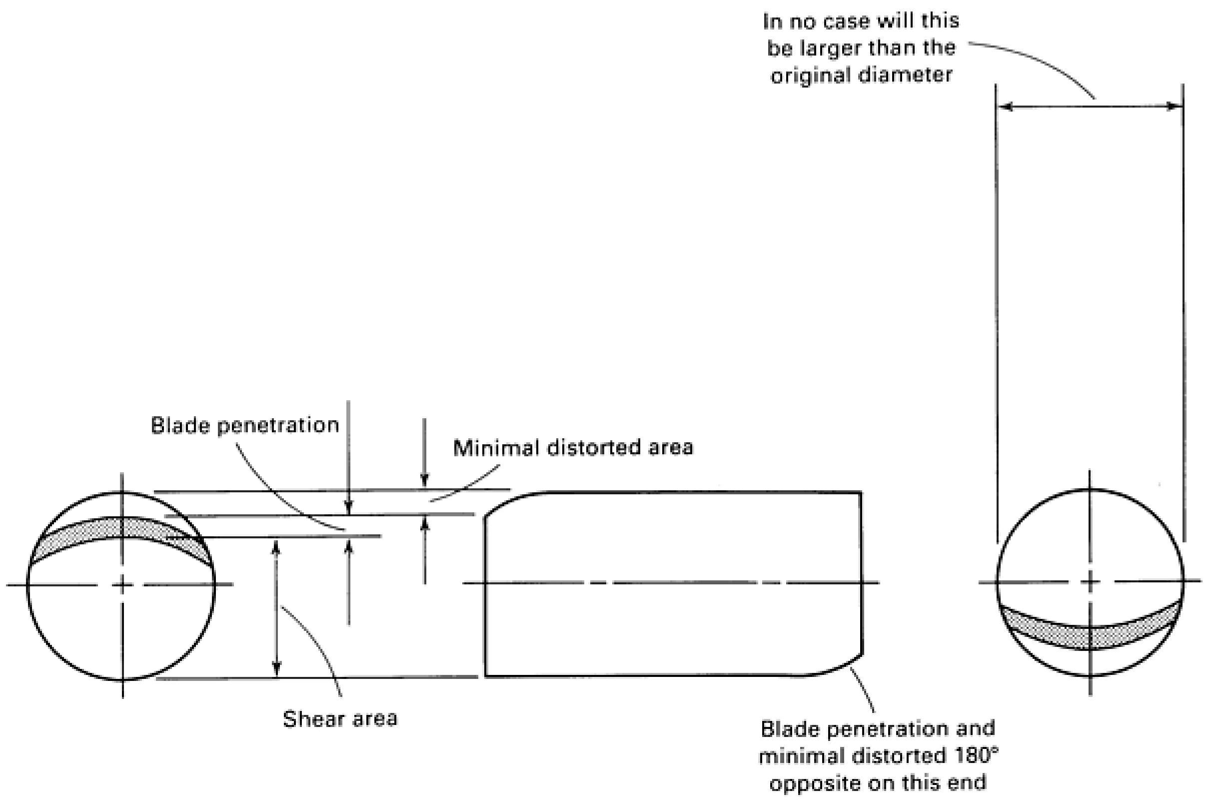

Fig. 8 Effects of shearing a round bar with double-die impact cutoff-type shear.

The quality of cut obtained surpasses that produced by any other known shear-type cutoff device. Squareness is held to close tolerances, and the cut pieces are virtually free of burrs, distortion, and edge rollover.

On materials such as carbon steel of 414 MPa (60 ksi) tensile strength, impact cutoff machines are capable of cutting 64 mm ($2\frac{1}{2}$ in.) diam stock up to 914 mm (36 in.) long. Doubling the tensile strength of the material to 818 MPa (120 ksi) reduces the maximum diameter capacity to 44 mm ($1\frac{3}{4}$ in.).

Principle and Machine Construction. Impact cutoff machines utilize a unique double-impact cutting principle (Fig. 9). Stock is fed into a pair of precision cutoff dies that have a cavity shaped to the same configuration as the stock. These opposed dies are actuated with short, simultaneous strokes by two flywheel-cam assemblies. This double impact fractures the metal, cleanly cutting the confined stock at the interface of the two dies.

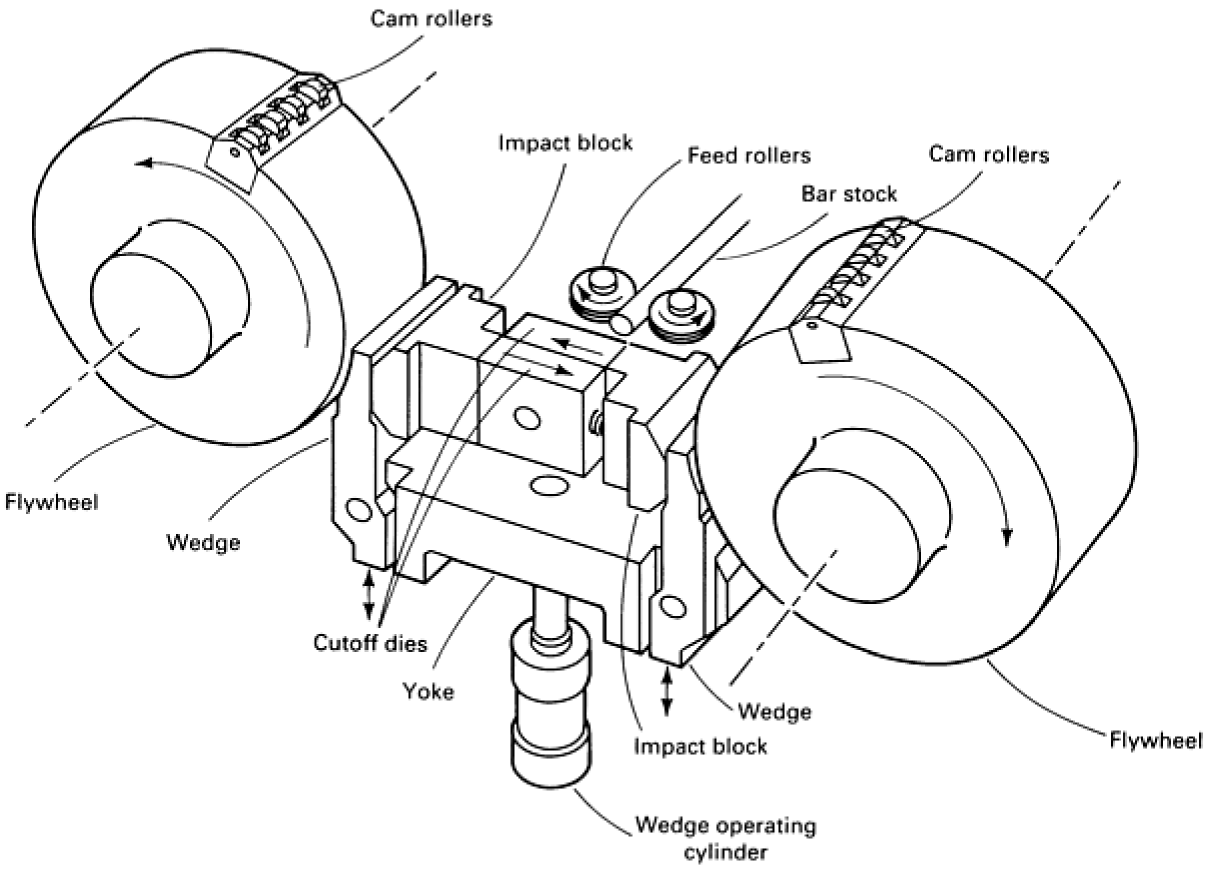

Fig. 9 Impact cutoff machine shearing bar stock with twin cutoff dies that are actuated by cam rollers on identical flywheel-cam assemblies.

The cutoff dies are located within an impact block. The flywheels rotate at a constant speed, and a cut takes place only when a pair of air-operated wedges are brought into position to close the gap. Wedge elevation is triggered by a positive stop that controls the length of cut. The positive stop features a micrometer adjustment for precise control of the blank length.

Either a short or a long target--stock-stop or length gage--is used, depending on the length of cut. In actual operation, the target moves out of the way when the leading edge of the workpiece engages it. This motion activates the circuit that controls the wedges to make the cut. Stock is fed into the dies and up to the positive stop by a hydraulically driven roll feed.

Die life is excellent in impact cutoff machines and ranges from tens of thousands to hundreds of thousands of cuts before resharpening is required. A number of variables affect this, with the most important being the amount of clearance between the workpiece and the die.

The dies are usually of the inserted type. The longest service life has been obtained with inserts made of M2 high-speed steel hardened to 60 to 62 HRC.

When resharpening of the cutoff die is required because of wear, the insert is first removed and then replaced in the holder with a 0.51 mm (0.020 in.) shim behind it. The protruding portion of the insert is then sharpened by a simple surface grinding operation. Removing the die blocks for sharpening or replacement is fast and simple. The die-retaining plate unbolts, allowing the cutting dies to be easily lifted out.

Introduction

THERMAL CUTTING processes differ from mechanical cutting (machining) in that the cutting action is initiated either by chemical reaction (oxidation) or melting (heat from arc). All cutting processes result in the severing or removal of metals. Additional information on cutting processes used in metal-forming operations can be found in the articles "Laser Cutting" and "Abrasive Waterjet Cutting" in this Volume.

Oxygen cutting is accomplished through a chemical reaction in which preheated metal is cut, or removed, by rapid oxidation in a stream of pure oxygen. Typical oxygen cutting processes are oxyfuel gas, oxygen lance, chemical flux, and metal powder cutting. Oxyfuel gas cutting and its modifications, chemical flux cutting and metal powder cutting, which are used to cut oxidation-resistant materials, are discussed in this article.

Arc cutting melts metal by heat generated from an electric arc. Because extremely high temperatures are developed, arc cutting can be used to cut almost any metal. Modifications of the process include the use of compressed gases to cause rapid oxidation (or to prevent oxidation) of the workpiece, thus incorporating aspects of the gas cutting process. Arc cutting methods include air carbon arc, gas metal arc, gas tungsten arc, shielded metal arc, plasma arc, and oxygen arc cutting. The methods of industrial importance that are covered in this article include plasma arc cutting, air carbon arc cutting, electric arc cutting using consumable tubular electrodes (Exo-Process), and oxygen arc cutting.

Thermal Cutting

Revised by Ed Craig, AGA Gas, Inc.

Oxyfuel Gas Cutting

Oxyfuel gas cutting includes a group of cutting processes that use controlled chemical reactions to remove preheated metal by rapid oxidation in a stream of pure oxygen. A fuel gas/oxygen flame heats the workpiece to ignition temperature, and a stream of pure oxygen feeds the cutting (oxidizing) action. The oxyfuel process, which is also referred to as burning or flame cutting, can cut carbon and low-alloy plate of virtually any thickness. Castings more than 750 mm (30 in.) thick commonly are cut by the oxyfuel process. With oxidation-resistant materials, such as stainless steels, either a chemical flux or metal powder is added to the oxygen stream to promote the exothermic reaction. Equipment for such cutting is somewhat awkward, however, and speeds and cut quality are lower than those obtained with plasma arc cutting.

The simplest oxyfuel gas cutting equipment consists of two cylinders (one for oxygen and one for the fuel gas), gas flow regulators and gages, gas supply hoses, and a cutting torch with a set of exchangeable cutting tips. Such manually operated equipment is portable and inexpensive. Cutting machines, employing one or several cutting torches guided by solid template pantographs, optical line tracers, numerical controls, or computers, improve production rates and provide superior cut quality. Machine cutting is important for profile cutting, that is, the cutting of regular and irregular shapes from flat stock.

Principles of Operation

Oxyfuel gas cutting begins by heating a small area on the surface of the metal to the ignition temperature of 760 to 870 °C (1400 to 1600 °F) with an oxyfuel gas flame. Upon reaching this temperature, the surface of the metal appears bright red. A cutting oxygen stream is then directed at the preheated spot, causing rapid oxidation of the heated metal and generating large amounts of heat. This heat supports the continued oxidation of the metal as the cut progresses. Combusted gas and the pressurized oxygen jet flush the molten oxide away, exposing fresh surfaces for cutting. The metal in the path of the oxygen jet burns. The cut progresses, making a narrow slot, or kerf, through the metal.

To start a cut at the edge of a plate, the edge of the preheat flame is placed just over the plate edge to heat the material. When the plate heats to red, the cutting oxygen is turned on, and the torch moves over the plate to start the cut.

During cutting, oxygen and fuel gas flow through separate lines to the cutting torch at pressures controlled by pressure regulators, adjusted by the operator. The cutting torch contains ducts, a mixing chamber, and valves to supply an oxyfuel gas mixture of the proper ratio for preheat and a pure oxygen stream for cutting to the torch tip. By adjusting the control valves on the torch handle or at the cutting machine controller, the operator sets the precise oxyfuel gas mixture desired. Depressing the cutting oxygen lever on the torch during manual operation initiates the cutting oxygen flow. For machine cutting, oxygen is normally controlled by the operator at a remote station or by numerical control. Cutting tips have a single cutting oxygen orifice centered within a ring of smaller oxyfuel gas exit ports. The operator changes the cutting capacity of the torch by changing the cutting tip size and by resetting pressure regulators and control valves. Because different fuel gases have different combustion and flow characteristics, the construction of cutting tips, and sometimes of mixing chambers, varies according to the type of gas.

Oxyfuel gas flames initiate the oxidation action and sustain the reaction by continuously heating the metal at the line of the cut. The flame also removes scale and dirt that may impede or distort the cut.

The rate of heat transfer in the workpiece influences the heat balance for cutting. As the thickness of the metal to be cut increases, more heat is needed to keep the metal at its ignition temperature. Increasing the preheat gas flow and reducing the cutting speed maintain the necessary heat balance.

Oxygen flow must also be increased as the thickness of the metal to be cut increases. To maintain a steady-state reaction at a satisfactory cutting speed, the velocity and volume, as well as the shape of the oxygen jet, must be closely controlled. Because the cutting-oxygen jet is surrounded by preheating flames, it is affected by these gases and the surrounding atmosphere. The jet must have sufficient volume and velocity to penetrate the depth of the cut and still maintain its shape, force, and effective oxygen content. There is also a relationship between the purity of the cutting oxygen and the time required for oxidation. This invariably has an influence on the ultimate cutting speed.

Quality of Cut. The limits within which the cutting reaction can effectively operate are determined by many factors besides those mentioned. Oxyfuel gas cutting involves control of more than twenty variables. Suppliers of cutting equipment provide tables that give approximate gas pressures for various sizes and styles of cutting torches and tips, along with recommended cutting speeds; these are the variables that the operator can control. Other variables include type and condition (scale, oil, dirt, flatness) of material, thickness of cut, type of fuel gas, and quality and angle of cut. (When not otherwise defined, a cut is usually taken to mean a through or "drop" cut, made in horizontal plates with the cutting tip in the vertical position.)

Higher cutting speeds with good cut quality are obtained during the oxyfuel process using a special tip and torch configuration that provides a curtain of oxygen around the cutting oxygen. The protective curtain maintains a higher level of cutting oxygen purity, which speeds up the oxidation process. Cutting speeds can be increased by approximately 25% for thicknesses up to 25 mm (1 in.).

When dimensional accuracy and squareness of the cut edge are important, the operator must adjust the process to minimize the kerf (the width of metal removed by cutting) and to increase the smoothness of the cut edge. Careful balancing of all cutting variables helps attain a narrow kerf and smooth edge. The thicker the work material, the greater the oxygen volume required and, therefore, the wider the cutting nozzle and kerf.

Process Capabilities

Oxyfuel gas cutting processes are primarily used for severing carbon and low-alloy steels. Other iron-base alloys and some nonferrous metals can be oxyfuel gas cut, although process modification may be required and cut quality may not be as high as is obtained in cutting the more widely used grades of steel. High-alloy steels, stainless steels, cast iron, and nickel alloys do not readily oxidize and therefore do not provide enough heat for a continuous reaction. As the carbon and alloy contents of the steel to be cut increase, preheating or postheating, or both, often are necessary to overcome the effect of the heat cycle, particularly the quench effect of cooling.

Some of the high-alloy steels, such as stainless steel, and cast iron can be cut successfully by injecting metal powder (usually iron) or a chemical additive into the oxygen jet. The metal powder supplies combustion heat and breaks up oxide films. Chemical additives combine with oxides to form lower temperature melting products that flush away.

Applications. Large-scale applications of oxyfuel cutting are found in shipbuilding, structural fabrication, manufacture of earth-moving equipment, machinery construction, and the fabrication of pressure vessels and storage tanks. Many machine structures originally made from forgings and castings can be made at less cost by redesigning them for oxyfuel gas cutting and welding, with the advantages of quick delivery of plate material from steel suppliers, low cost of oxyfuel gas cutting equipment, and flexibility of design.

Structural shapes, pipe, rod, and similar materials can be cut to length for construction or cut up in scrap and salvage operations. In steel mills and foundries, projections such as caps, gates, and risers can be severed from billets and castings. Mechanical fasteners can be quickly cut for disassembly using oxyfuel gas cutting. Holes can be made in steel components by piercing and cutting. Machine oxyfuel gas cutting is used to cut steel plate to size, to cut various shapes from plate, and to prepare plate edges (bevel cutting) for welding.

Gears, sprockets, handwheels, clevises and frames, and tools such as wrenches can be cut out by oxyfuel gas torches. Often, these oxyfuel cut products can be used without further finishing. However, when cutting medium- or high-carbon steel or other metal that hardens by rapid cooling, the hardening effect must be considered, especially if the workpiece is to be subsequently machined.

Thickness Limits. Steel less than 3 mm ($\frac{1}{8}$ in.) thick to over 1.5 in (60 in.) thick can be cut by oxyfuel gas cutting, though some sacrifice in quality occurs near both ends of this range. With very thin material, operators may have some difficulty in keeping heat input low to avoid melting the kerf edges and to minimize distortion. Steel under 6 mm ($\frac{1}{4}$ in.) thick often is stacked for cutting of several parts in a single torch pass. Procedures for light cutting (<9.5 mm, or $\frac{3}{8}$ in. thick), medium cutting (9.5 to 250 mm, or $\frac{3}{8}$ to 10 in. thick), heavy cutting (>250 mm, or 10 in. thick), and stack cutting are discussed in "Oxyfuel Gas Cutting" in *Welding, Brazing, and Soldering*, Volume 6 of the *ASM Handbook*.

Advantages and Disadvantages. A number of advantages and disadvantages are apparent when oxyfuel gas cutting is compared to other cutting operations such as arc cutting, milling, shearing, or sawing. The advantages of the oxyfuel process are:

- Metal can be cut faster. Setup is generally simpler and faster than is the case for machining and about equal to that of mechanical severing (sawing and shearing)
- Oxyfuel gas cutting patterns are not confined to straight lines as in sawing and shearing, or to fixed patterns as in die-cutting processes. Cutting direction can be changed rapidly on a small radius during operation
- Manual oxyfuel gas cutting equipment costs are low compared to those for machine tools. Such equipment is portable and self-contained, requiring no outside power, and well suited for field use
- When properties and dimensional accuracy of gas cut plate are acceptable, oxyfuel gas cutting can replace costly machining operations. It offers reduced labor, overhead, material, and tooling costs, and faster delivery
- With advanced machinery, oxyfuel gas cutting lends itself to high-volume parts production
- Large plates can be cut in place quickly by moving the gas torch rather than the plate
- Two or more pieces can be cut simultaneously using stack cutting methods and multiple-torch cutting machines

The disadvantages of the oxyfuel process include:

- Dimensional tolerances are poorer than they are for machining and shearing
- Because oxyfuel gas cutting relies on oxidation of iron, it is limited to cutting steels and cast iron
- Heat generated by oxyfuel gas cutting can degrade the metallurgical properties of the work material adjacent to the cut edges. Hardenable steels may require preheat and/or postheat to control microstructure and mechanical properties
- Preheat flames and the expelled red hot slag pose a fire hazard to plant and personnel

Factors Affecting Oxyfuel Gas Cutting

Oxygen consumption varies widely in practice, depending on whether maximum economy, speed, or accuracy is sought. Literature supplied by torch and related equipment suppliers provides general guidelines for the amount of oxygen consumed for varying metal thicknesses.

As the cutting oxygen flows down through the cut, the quantity available for reaction decreases. If the flow of oxygen is relatively large and sharply coherent, the rate of cutting through the depth of the cut is not affected; that is, the cutting face will remain vertical if the oxygen is in excess and the cutting speed is not too great.

However, if the oxygen flow is insufficient, or the cutting speed is too high, the lower portions of the cut will react more slowly. As a result, the cutting face will become curved, as shown in Fig. 1. The horizontal distance between the points of entry and exit is called drag. Drag often is expressed as a ratio or as a percentage of the metal thickness.

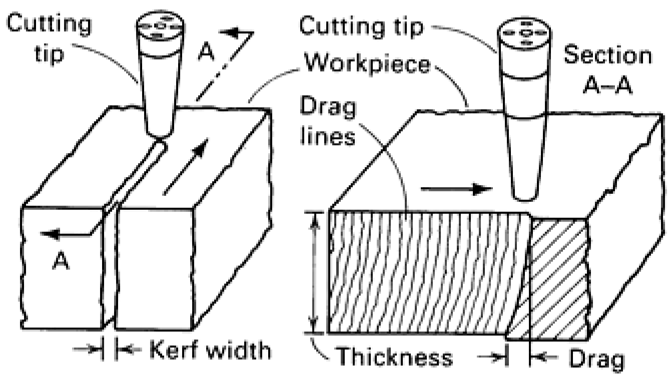

Fig. 1 Cross section of work metal during oxyfuel gas cutting showing drag on cutting face.

Drag can be stabilized; at the proper drag ratio, the heat from the molten metal flowing down the curve is efficiently used. Drag is a rough measure of cutting quality and of economy in oxygen consumption. In metal thicknesses up to 50 or 75 mm (2 or 3 in.), a 10 to 15% drag is associated with good quality of cut and good economy. Higher quality demands less drag; more drag indicates poorer quality and low oxygen consumption. Too much drag may lead to incomplete cutting.

In very thin sections, drag has little meaning; the main problem is control of high heat input compared to low heat sink. In very thick sections, the opposite is true; the problem is to avoid excessive drag. All the input variables controlled by the operator (size and type of cutting tip, preheat flames, oxygen flow, and cutting speed) can be used to control drag.

Oxygen purity, as well as the alloy content of the steel being cut, affects the chemical reaction in oxyfuel gas cutting. Oxygen purity also affects combustion heat. The oxygen supplied from cylinders for oxyfuel gas cutting is usually at least 99.5% pure. A 0.5% departure from this purity (99% O_2) decreases the cutting efficiency. At 90% purity, cutting is very difficult, and at lower purities it is often impossible. The impurities consist of inert gases and water vapor. The effective purity of oxygen can also be reduced by gaseous combustion products from the preheat flames and from the metal being cut.

Alloying of iron affects oxyfuel gas cutting, usually by reducing the rate of oxidation. The total alloy content in low-alloy steel usually does not exceed 5%, and the effect on cutting speed is slight. Alloying elements affect oxyfuel gas cutting of steel in two ways. They may make the steel more difficult to cut, or they harden the cut edge, or both. In highly alloyed steel, the oxidizing characteristics of alloying elements and the constituents formed in alloying may make sustained oxidation difficult or even impossible. The effects of alloying elements on cutting are evaluated in Table 1. In any steel, preheat accelerates the chemical reaction; higher alloy steels, therefore, may need preheating beyond that provided by the preheat flames of the gas torch to promote cutting.

Table 1 Effects of alloying elements on resistance of steel to oxyfuel cutting

Element	Effect on oxyfuel cutting
Aluminum	**Extensively used as a deoxidizer in steelmaking; has no appreciable effect on oxygen cutting unless present in amounts above 8 to 10%; above this percentage, plasma arc cutting or metal powder cutting should be used**

Carbon	**Steels containing up to 0.25% C can readily be flame cut; higher-carbon steels should be preheated to prevent hardening and cracking; graphitic carbon makes flame cutting of cast iron difficult; cast iron containing up to 4% C can be flame cut when a powder, flux, or filler rod is used as a supplemental oxidizing agent**
Chromium	**Steels containing up to 5% Cr can be flame cut without difficulty; steels with chromium content of 10% or more require metal powder, chemical flux, or plasma arc cutting**
Cobalt	**When present in the amounts normally used in steelmaking, cobalt has no noticeable effect on flame cutting**
Copper	**Up to 3% Cu has no effect on flame cutting**
Manganese	**Has no effect on flame cutting of carbon steels; steel containing 14% Mn and 1.5% C are difficult to cut and must be preheated**
Molybdenum	**Steels with up to 5% Mo can be cut easily; this is true of AISI 41XX steels; high molybdenum-tungsten steels require metal powder or plasma arc cutting**
Nickel	**Steels with up to 3% Ni and less than 0.25% C may be readily cut by OFC; up to 7% Ni requires flux additions to the oxygen stream; stainless steels, from 18-8 to 35-15 types, require chemical flux, metal powder, or plasma arc cutting**
Phosphorus	**The amount usually found in steel has no effect on flame cutting**
Silicon	**No effect in steels with up to 4% Si; in higher-silicon steels with high carbon and manganese contents, preheating and postannealing are usually needed to avoid hardening and cracking**
Sulfur	**Amounts usually found in steel have no effect; higher sulfur content slows cutting speed and emits sulfur dioxide fumes**
Tungsten	**Steels containing up to 14% W are readily flame cut, but cutting is more difficult with a higher percentage; high red-hardness tungsten steels are difficult to flame cut and require preheating**
Vanadium	**The amounts normally found in steel do not interfere with flame cutting**

Preheating may consist of merely warming a cold workpiece with a torch or it may require furnace heating of the work beyond 540 °C (1000 °F). For some alloy steels, preheat temperatures are 200 to 315 °C (400 to 600 °F). Carbon steel billets and other sections occasionally are cut at 870 °C (1600 °F) and higher.

In oxyfuel gas cutting, preheating is accomplished by means of the oxyfuel gas flame, which surrounds the cutting oxygen stream. At cut initiation, the preheat flame, the result of oxygen and fuel gas combustion, brings a small amount of material to ignition temperature so that combustion can proceed. After cutting begins, the preheat flame merely adds heat to compensate for heat lost by convection and radiation or through gas exhausted during cutting. The flame also helps to remove or burn off scale and dirt on the plate surface; the hot, combusted gases protect the stream of cutting oxygen from the atmosphere.

Preheating may also be applied over a broader area of the work. It may include soaking the entire workpiece in a furnace to bring it up to 100 to 200 °C (200 to 400 °F), or a simple overall warm-up with a torch to bring cold plate to room temperature. A preheat significantly improves cutting speed, allowing faster torch travel for greater productivity and reduced consumption of fuel gas. Broader preheat smooths the temperature gradient between the base metal and the cut edge, possibly reducing thermal stress and minimizing hardening effects in some steels.

Combustion of Gases

Each cutting job entails a different type or volume of work to be completed. Consequently, the best gas for all cutting in a fabricating plant is found through experimentation. Evaluating a gas for a single job requires a test run that monitors fuel gas and oxygen flow rate, labor costs, overhead, and the amount of work performed. If plant production varies from week to week, gas performance should be measured over a long enough period to achieve an accurate cost analysis. Any of the fuel gases may perform well over a range of flow rates. When comparing gases, performance should be rated at the lowest flow rate that gives acceptable results for each gas. The most important preheat fuel gases are acetylene, natural gas, propane, propylene, and Mapp. Their properties are given in Table 2. These gases are hydrocarbons, which give off carbon dioxide and water vapor as the products of complete combustion. Flames of hydrocarbon gases are complex, displaying successive cones as a result of stepped chemical reactions. With acetylene, the products of complete combustion cannot exist at the temperature of the inner cone. Combustion is completed in the cooler, outer sheath of the flame. Chemical equations for combustion reactions of hydrocarbon gases often are simplified by treating the reactions as though the products were formed in only one step.

Table 2 Properties of common fuel gases

	Acetylene	**Propane**	**Propylene**	**Methylacetylene-propadiene (Mapp)**	Natural gas

Acetylene (C_2H_2) combustion produces a hot, short flame with a bright inner cone at each cutting-tip port; the hottest point is at the tip of this inner cone. Combustion starts in the inner cone and is brought to completion in a cooler, blue, outer flame. The sharp distinction between the two flames helps to adjust the ratio of oxygen to acetylene.

Depending on this ratio, the flame may be carburizing (reducing), neutral, or oxidizing. A neutral flame results when just enough oxygen is supplied for primary combustion, yielding carbon monoxide (CO) and hydrogen (H_2). These products then combine with oxygen in ambient air to form the blue, outer flame, yielding carbon dioxide (CO_2) and water (H_2O). The neutral ratio of oxygen to acetylene is about 1 to 1, and the flame temperature at the tip of the inner cone is about 3040 °C (5500 °F). This flame is used for manual cutting.

When the oxygen-to-acetylene ratio is reduced to about 0.9 to 1, a bright streamer begins to appear, and the flame becomes carburizing, or reducing. A carburizing flame is sometimes used for rough cutting of cast iron.

When the oxygen-to-acetylene ratio is increased to more than 1 to 1, the inner cones are shorter, "necked in" at the sides, and more sharply defined; this flame is oxidizing. Flame temperature increases until, at a ratio of about 1.7 to 1, the temperature is maximum, or somewhat over 3095 °C (5600 °F) at the tip of the cones. An oxidizing flame can be used for preheating at the start of the cut, and for cutting very thick sections.

According to the equation:

$$2C_2H_2 + 5O_2 \rightarrow 4CO_2 + 2H_2O$$

an oxygen-to-acetylene ratio of 2.5 to 1 is required for a complete reaction. For complete combustion, however, as much as 1.5 parts of oxygen is taken from ambient air. In oxyacetylene cutting, part of this oxygen may be supplied from the cutting oxygen, but total oxygen consumption is relatively low, an advantage of acetylene over all other fuel gases. Operation of oxyacetylene equipment in confined spaces, such as the inside of a closed tank or vessel, requires forced ventilation to supply the additional air needed for breathing and for flame combustion.

Acetylene must be used at pressures below 105 kPa (15 psi), which is a stable operating range. Safety codes specify equipment and handling practices for acetylene. When supplied in special cylinders, acetylene is dissolved in acetone, which is contained in a porous mass that fills the cylinder. This technique eliminates the sensitivity of acetylene at pressures over 105 kPa (15 psi). Such cylinders can be filled to pressures exceeding 105 kPa (15 psi), but not greater than 1725 kPa (250 psi). Acetylene may also be supplied from generators. With either means of supply, safety regulations must be observed to avoid sudden decomposition and explosion.

Despite some disadvantages, acetylene has been used for cutting for a longer time than any other gas. Its performance is well understood, equipment for it is perfected and widely marketed, and it is readily available. It has become the standard against which other gases are compared.

Natural gas is a mixture of gases, but consists principally of methane, and therefore is usually given the chemical symbol for methane (CH_4). One source defines the most widely used mixture as 85% methane (CH_4), 4% ethane (C_2H_6), and 11% (N_2, H_2, O_2, H_2O). Some wells produce natural gas with large proportions of ethane and propane.

The chemical equation for complete combustion:

$$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O$$

indicates an oxygen-to-methane ratio of 2 to 1; this ratio is used for the preheat flame. Maximum flame temperature at the tip of the inner cones is about 2760 °C (5000 °F). Both higher and lower temperatures have been reported; also, the optimum oxygen-to-gas ratio is about 2 to 1. The flame is more diffuse than with acetylene; heat intensity is lower; and adjustment for carburizing, neutral, and oxidizing flame is less clearly defined. Initial cutting speeds are slower, and oxygen consumption is greater. Also, more time is required for preheating with natural gas than with acetylene. An excess of oxygen shortens preheat time, but increases consumption of oxygen. Furthermore, natural gas cannot be used for welding of steel, so extra installations are needed if this operation is to be performed.

Despite these disadvantages, the use of natural gas for cutting has increased. It is the lowest-cost commercial fuel gas and, with careful torch adjustment, produces excellent cuts in light-to-heavy-gage material.

Neither acetylene nor natural gas accumulates in low pockets. When burned alone in air, the flame of natural gas does not produce soot.

Propane (C_3H_8) is a petroleum-base fuel usually supplied as a liquid in storage tanks from which it is drawn off as a gas. The gas is dispensed from bulk storage tanks through pipelines. It has a narrow range of flammability and is relatively stable, but is heavier than air. Complete combustion requires an oxygen-to-propane ratio of 5 to 1. However, about 30% of the oxygen needed is taken from the ambient air. When the ratio of oxygen to propane is 4.5 to 1, the flame temperature is about 2760 °C (5000 °F) at the tip of the inner cones. At 4.25 to 1, the flame temperature is about 2650 °C (4800 °F). Flame properties are similar to those of natural gas, with respect to diffuseness, heat intensity, flame adjustment, and cutting speed. When burned alone in air, the flame is soot-free.

Propylene is a liquefied gas similar to propane. It has a higher flame temperature than propane. The flame temperature of propylene is about equal to Mapp gas, although its heat content is slightly less. On a volume basis, propylene is usually less expensive than acetylene; it does, however, consume more oxygen during combustion. The combustion equation for propylene is:

$$2C_3H_6 + 9O_2 \rightarrow 6CO_2 + 6H_2O$$

The combustion ratio for propylene is 4.5 to 1. Line oxygen for a neutral flame is about 3.5 to 1. Distributors sell propylene under various trade names, either pure or as improved mixtures with propane and other hydrocarbon additives.

Mapp gas (stabilized methylacetylene-propadiene) is a proprietary gas mixture; it is shipped and stored as a liquid, either in bulk storage tanks or in portable cylinders.

Both methylacetylene and propadiene have the chemical symbol C_3H_4 and by themselves are unstable, giving off their heat of formation during decomposition. As with acetylene, this heat is in addition to the heat of combustion. However, the methylacetylene-propadiene mixture in Mapp gas is stabilized by the addition of other hydrocarbons. The composition of Mapp gas is not disclosed, so the chemical equation for complete combustion in oxygen is not given. However, when the flame is neutral, the ratio of oxygen to fuel gas is about 2.3 to 1; the normal operating ratio for cutting varies from 2.5 to 1 to 4 to 1, depending on speed and thickness. Maximum flame temperature at the tips of the inner cones, reported as 2925 °C (5300 °F), occurs at oxygen-to-fuel ratios from 3.5 to 1 to 4 to 1. Flames can be adjusted for carburizing, neutral, or oxidizing conditions.

Mapp gas is heavier than air, but it has a strong odor to reveal its presence in case it leaks or has collected in low pockets. At low temperatures, Mapp gas withdrawal rates from the cylinder are reduced. At about 0 °C (32 °F), methylacetylene has a vapor pressure of only 14 kPa (2 psi).

Effect of Oxyfuel Cutting on Base Metal

During the cutting of steel, the temperature of a narrow zone adjacent to the cut face is raised considerably above the transformation range. As the cut progresses, the steel cools through this range. The cooling rate depends on the heat conductivity and mass of the surrounding material, on loss of heat by radiation and convection, and on speed of cutting. When steel is at room temperature, the rate of cooling at the cut is sufficient to produce a quenching effect on the cut edges, particularly in heavier cuts in large masses of cold metal. Depending on the amount of carbon and alloying elements present and on the rate of cooling, pearlitic steel transforms into structures ranging from spheroidized carbides in ferrite to harder constituents. The heat-affected zone (HAZ) may be 0.8 to 6.4 mm ($\frac{1}{32}$ to $\frac{1}{4}$ in.) deep for steels 9.5 to 150 mm ($\frac{3}{8}$ to 6 in.) thick. Approximate depths of the HAZ in oxyfuel gas cut carbon steels are given in Table 3. Some increase in hardness usually occurs at the outer margin of the HAZ of nearly all steels.

Table 3 Approximate depths of HAZ in gas-cut carbon steels

Plate thickness		HAZ depth	
mm	**in.**	**mm**	in.

Low-carbon steels			
<13	$<\frac{1}{2}$	<0.8	$<\frac{1}{32}$
13	$\frac{1}{2}$	0.8	$\frac{1}{32}$
150	6	1.4	$\frac{1}{18}$
High-carbon steels			
<13	$<\frac{1}{2}$	<0.8	$<\frac{1}{32}$
13	$\frac{1}{2}$	0.8-1.6	$\frac{1}{32}-\frac{1}{16}$
150	**6**	**1.4-6.0**	$\frac{1}{18}-\frac{1}{4}$

Note: The depth of the fully hardened zone is considerably less than the depth of the HAZ. For most applications of gas cutting, the affected metal does not have to be removed.

Low-Carbon Steel. For steels containing 0.25% C or less, cut at room temperature, the hardening effect is usually negligible, although at the upper carbon limit it may be significant if subsequent machining is required. Short of preheating or annealing the workpiece, hardening may be lessened by ensuring that the cutting flame is neutral to slightly oxidizing, the flame is burning cleanly, and the inner cones of the flame are at the correct height. By increasing the machining allowance slightly, the first cut usually can be made deep enough to penetrate below the hardened zone in most steels. Mechanical properties of low-carbon steels generally are not adversely affected by oxyfuel gas cutting.

Medium-Carbon Steels. Steels having carbon contents of 0.25 to 0.45% are affected only slightly by hardening caused by oxyfuel gas cutting. Up to 0.30% C, steels with very low alloy content show some hardening of the cut edges, but generally not enough to cause cracking. Over 0.35% C, preheating to 260 to 315 °C (500 to 600 °F) is needed to avoid cracking. All medium-carbon steels should be preheated if the gas cut edges are to be machined.

High-Carbon and Alloy Steels. Gas cutting of higher-carbon (over 0.45% C) and hardenable alloy steels at room temperature may produce, on the cut surface, a thin layer of hard, brittle material that is susceptible to cracking from the stress of cooling. The cooling stress that causes cracking is similar to the stress that causes distortion.

Microcracks, or even incipient cracks, can be dangerous, because in service under tension they can develop into large fractures. The problems of hardening and the formation of residual stress can be alleviated by preheating and annealing.

Preheating serves three purposes. It:

- Reduces the temperature gradient near the cut during cutting. This lowers differential expansion, which may cause distortion or upsetting of the metal. Metal upset during the heating cycle can produce excessive stress in cooling
- Increases the cutting speed and improves the surface of the cut, especially in heavier sections and in the difficult-to-cut steels
- Reduces the cooling rate in the annealing range for the heat-affected portion of the cut during the cooling cycle.

By slower cooling, more ductile microstructures are obtained, and the formation of the hard martensitic structures is suppressed

If the higher-carbon and alloy steels are adequately preheated (and, in certain instances, annealed afterward), no cracks will occur. Ordinarily, a preheat temperature of 260 to 315 °C (500 to 600 °F) is sufficient for high-carbon steels; alloy steels may require preheating as high as 540 °C (1000 °F). Preheat temperature should be maintained during cutting. Thick preheated sections should be cut as soon as possible after the piece has been withdrawn from the furnace.

Local preheating involves heating that area of the workpiece that encloses what will become the HAZ of the cut. If the area to be heated is small and the section is not too thick, the preheating flame of a cutting torch may be used, but usually a special heating torch is required.

Local preheating is used when it is impossible or impractical to preheat the entire workpiece. It is important to heat the workpiece uniformly through the section to be cut, without causing too steep a temperature gradient. A multiflame heating torch is sometimes mounted ahead of the cutting torch in machine-guided cutting. Local preheating also can be accomplished using a preheat adaptor.

Annealing serves two main purposes in controlling the effects of gas cutting in carbon and low-alloy steels. It restores the original structure of the steel, whether it be predominantly pearlitic or predominantly ferritic with spheroidized carbide, and it also provides stress relief. Many steels do not require annealing if they have been properly preheated. (See *Heat Treating,* Volume 4 of the *ASM Handbook*, for annealing practices for specific steels.)

Local annealing, also called flame annealing, is a localized postheat treatment that can be used to prevent hardening or to soften an already hardened cut surface. Either the preheating flame of the cutting torch or a special heating torch may be used for local annealing, depending on the mass of the workpiece and the area to be covered. The heat-affected portion of the workpiece should be heated uniformly, and the temperature gradient at the boundary of the heated mass should be gradual enough to avoid distortion of the workpiece.

Local annealing is not a substitute for preheating; it cannot correct damage done during cutting, such as upsetting of the metal or cracking at the cut edges. Local annealing is limited to steel plate up to 40 mm ($1\frac{1}{2}$ in.) thick. From 40 to 75 mm ($1\frac{1}{2}$ to 3 in.) thick, heat should be applied to both sides of the plate. This method is not suitable for thicknesses over 75 mm (3 in.). If local annealing cannot be done simultaneously with cutting, the cut edges should be tempered after cutting with a suitable heating torch.

Stainless steels do not support oxyfuel combustion and therefore require metal powder cutting, chemical flux cutting, or plasma arc cutting processes. Except for stabilized types, stainless steels degrade under the heat of metal powder or chemical flux processes. Carbide precipitation occurs in the HAZ about 3 mm ($\frac{1}{8}$ in.) from the edge, where the metal has been heated to 425 to 870 °C (800 to 1600 °F) long enough for dissolved carbon to migrate to the grain boundaries and combine with the chromium to form chromium carbide. The chromium-poor (sensitized) regions near grain boundaries are subject to corrosion in service. This type of corrosion can be prevented by a stabilizing anneal, which puts the carbon back into solution. However, the required quench through the sensitizing temperature range may distort the material.

Water quenching of the cut edge directly behind the cutting torch may avert sensitization. Because it takes about 2 min at sensitizing temperature for carbide precipitation to occur, water quenching must be done immediately. Distortion is more likely with this method than with the stabilizing anneal. Still another procedure is to remove the sensitizing zone entirely by chipping or machining.

Distortion, which is the result of heating by the gas flame, can cause considerable damage during cutting of thin plate (<8 mm, or $\frac{5}{16}$ in., thick), cutting of long narrow widths, close-tolerance profile cutting, and cutting of plates that contain high residual stresses. The heat may release some of the locked-in stress, or may add new stress. In either case, deformation (warpage) may occur, thereby causing inaccurate finished cuts. Plates in the annealed condition have little or no residual stress.

Deformation. In cuts made from large plates, the cutting thermal cycle changes the shape of narrow sections and leaves residual stress in the large section (see Fig. 2). The temperature gradient near the cut is steep, ranging from melting point at the cut to room temperature a short distance from it. The plate does not return to its original shape unless the entire plate is uniformly heated and cooled.

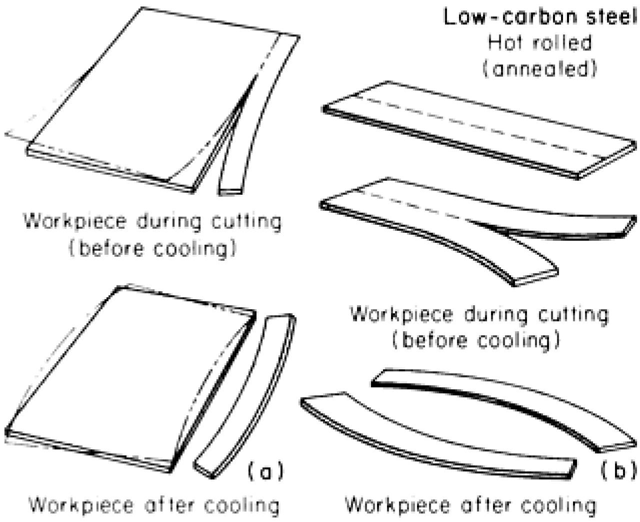

Fig. 2 Effects of oxyfuel gas cutting thermal cycle on shape of sections. (a) Plate with large restraint on one side of kerf, little restraint on the other side. Phantom lines indicate direction of residual stress that would cause deformation except for restraint. (b) Plate with little restraint on either side.

As the metal heats, it expands, and its yield strength decreases; the weakened heated material is compressed by the surrounding cooler, stronger metal. The hotter metal continues to expand elastically in all directions until its compressive yield strength is reached, at which point it yields plastically (upsets) in directions not under restraint. The portion of this upset metal at about 870 °C (1600 °F) is virtually stress-free; the remainder is under compressive stress that is equal to its yield strength. Metal that expands but does not upset is under compressive strength below yield. The net stress on the heated side of the neutral axis causes bowing of a narrow plate during cutting, as shown in Fig. 2.

As the heated metal begins to cool, it contracts, and its strength increases. First, the contraction reduces the compressive stress in the still-expanded metal. When the compressive stress reaches zero and the plate regains its original shape, previously upset metal also has regained strength. This metal is now in tension as it cools, and its tensile yield strength increases. Tension increases until the metal reaches room temperature. Residual tensile stress in the cooling side of the neutral axis causes the bowing of narrow plates after cooling (Fig. 2). Controlled upsetting is the basis of flame straightening.

Control of Distortion. Preheating the workpiece can reduce distortion by reducing differential expansion, thereby decreasing stress gradients. Careful planning of the cutting sequence also may help. For example, when trimming opposite sides of a plate, both sides should be cut in the same direction at the same time. When cutting rings, the inside diameter should be cut first; the remaining plate restrains the material for the outside-diameter cut. In general, the larger portion of material should be used to retain a shape for as long as possible; the cutting sequence should be balanced to maintain even-heat input and resultant residual stresses about the neutral axis of the plate or part.

Equipment

Commercial gases are usually stored in high-pressure cylinders. Natural gas--primarily methane--is supplied by pipeline from gas wells. The user taps into local gas lines. Acetylene, dissolved in acetone, is available in clay-filled cylinders. High-volume users often have acetylene generators on site. For heavy consumption or when many welding and cutting stations use fuel gas, banks of gas cylinders are maintained at a central location in the plant, and the gas is manifolded and piped to the point of use.

Manual gas cutting equipment consists of gas regulators, gas hoses, cutting torches, cutting tips, storage tanks, reverse flow check valves, and flashback arrestors. Auxiliary equipment may include a hand truck, tip cleaners, torch ignitors, and protective goggles. Machine cutting equipment varies from simple rail-mounted "bug" carriages to large bridge-mounted torches that are driven by computer-directed drives.

Gas regulators reduce gas pressure and moderate gas flow rate between the source of gas and its entry into the cutting torch to deliver gas to the cutting apparatus at the required operating pressure. Gas enters the regulating device at a wide range of pressures. Gas flows through the regulator and is delivered to the hose-torch-tip system at the operating pressure, which is preset by manual adjustment at the regulator and at the torch. When pressure at the regulator drops below the preset pressure, regulator valves open to restore pressure to the required level. During cutting, the regulator maintains pressure within a narrow range of the pressure setting.

Regulators should be selected for use with specific types of gas and for specific pressure ranges. Portable oxyacetylene equipment requires an oxygen regulator on the oxygen cylinder and an acetylene regulator on the acetylene cylinder, which are not interchangeable.

High-low regulators conserve preheat oxygen when natural gas or propane is the preheat fuel used in oxyfuel gas cutting. These gases require a longer time to start a cut than do acetylene or Mapp gas. High-low regulators reduce preheat flow to a predetermined level when the flow of cutting oxygen is initiated. When the regulator switches from high to low, preheat cutback may range from 75 to 25% as plate thicknesses increase from 9.5 to 200 mm ($\frac{3}{8}$ to 8 in.). High-low regulators are used for manual and automatic cutting with natural gas propane and liquefied petroleum gas (LPG).

Hose. Flexible hose, usually 3 to 13 mm ($\frac{1}{8}$ to $\frac{1}{2}$ in.) in diameter, rated at 1380 kPa (200 psig) maximum, carries gas from the regulator to the cutting torch. Oxygen hoses are green; the fittings have right-hand threads. Fuel gas hoses are red; the fittings have left-hand threads and a groove cut around the fitting. For heavy cutting, two oxygen hoses may be necessary, one for preheat and one for cutting oxygen. Multiple-torch cutting machines often have three-hose torches.

Cutting torches, such as the one shown in Fig. 3, control the mixture and flow of preheat oxygen and fuel gas and the flow of cutting oxygen. The cutting torch discharges these gases through a cutting tip at the proper velocity and flow rate. Pressure of the gases at the torch inlets, as well as size and design of the cutting tip, limits these functions, which are operator controlled.

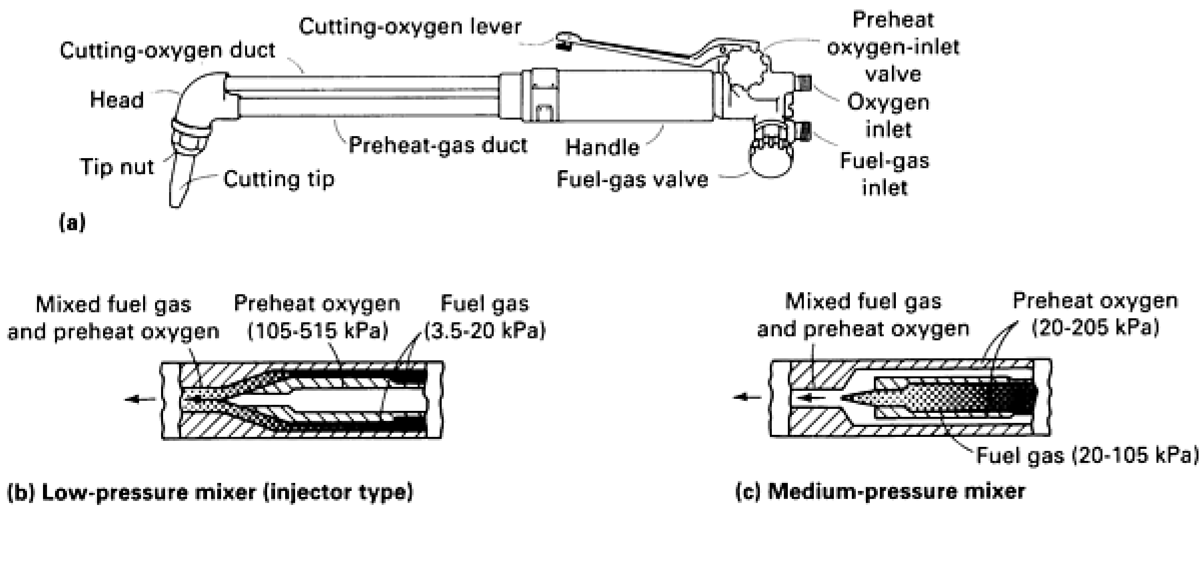

Fig. 3 (a) Typical manual cutting torch in which preheat gases are mixed before entering torch head. (b) and (c) Sections through preheat gas duct showing two types of mixers commonly used with the torch shown. After the workpiece is sufficiently preheated, the operator depresses the lever to start the flow of cutting oxygen. Valves control the flow of oxygen and fuel gas to achieve the required flow and mixture at the cutting tip.

Oxygen inlet control valves and fuel gas inlet control valves permit operator adjustment of gas flow. Fuel gas flows through a duct and mixes with the preheat oxygen; the mixed gases then flow to the preheating flame orifices in the cutting tip. The oxygen flow is divided: A portion of the flow mixes with the fuel gas, and the remainder flows through the cutting-oxygen orifice in the cutting tip. A lever-actuated valve on the manual torch starts the flow of cutting oxygen; machine cutting starts the oxygen from a panel control.

Fuel gases supplied at low pressure (usually below 21 kPa, or 3 psi), such as natural gas tapped from a city line, require an injector-mixer (Fig. 3b) to increase fuel gas flow above normal operating pressures. Optimum torch performance relies on proper matching of the mixer to the available fuel gas pressure.

Cutting tips are precision-machined nozzles, produced in a range of sizes and types. Figure 4(a) shows a single-piece acetylene cutting tip. A two-piece tip used for natural gas (methane) or LPG is shown in Fig. 4(b). A tip nut holds the tip in the torch. For a given type of cutting tip, the diameters of the central hole, the cutting-oxygen orifice, and the preheat ports increase with the thickness of the metal to be cut. Cutting tip selection should match the fuel gas; hole diameters must be balanced to ensure an adequate preheat-to-cutting-oxygen ratio. Preheat gas flows through ports that surround the cutting-oxygen orifice. Smoothness of bore and accuracy of size and shape of the oxygen orifice are important to efficiency. Worn, dirty bores reduce cut quality by causing turbulence in the cutting-oxygen stream.

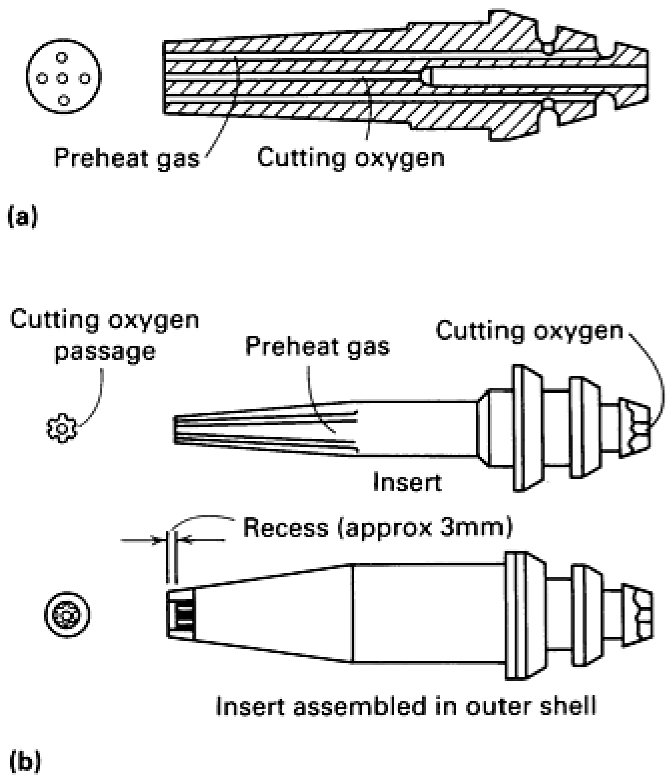

Fig. 4 Types of cutting tips. (a) Single-piece acetylene cutting tip. (b) Two-piece tip for natural gas or LPG. Fuel gas and preheat oxygen mix in tip. Recessed bore promotes laminar flow of gas and anchors the flame when natural gas or propane is used.

The size of the cutting-tip orifice determines the rate of flow and velocity of the preheat gases and cutting oxygen. Flow to the cutting tip can be varied by adjustment at the torch inlet valve or at the regulator, or both.

Increasing cutting-oxygen flow solely by increasing the oxygen pressure results in turbulence and reduces cutting efficiency. Turbulence in the cutting oxygen causes wide kerfs, slows cutting, increases oxygen consumption, and lowers quality of cut. Consequently, larger cutting tips are required for making heavier cuts.

Standard tips, as shown in Fig. 5(a), have a straight-bore oxygen port. Oxygen pressures range from 200 to 400 kPa (30 to 60 psi) and are used for manual cutting. High-speed tips, or divergent cutting tips (Fig. 5b), use a converging, diverging orifice to achieve high gas velocities. The oxygen orifice flares outward. High-speed tips operate at cutting-oxygen pressures of about 700 kPa (100 psi) and provide cutting jets of supersonic velocity. These tips are precision made and are more costly than straight-drilled tips, but they produce superior results: improved edge quality and cutting speeds 20%

higher than standard tips. Best suited to machine cutting, high-speed tips produce superior cuts in plate up to about 150 mm (6 in.) thick. Above this thickness, advantages of their use decrease, and they are not recommended for cutting metal more than 250 mm (10 in.) thick.

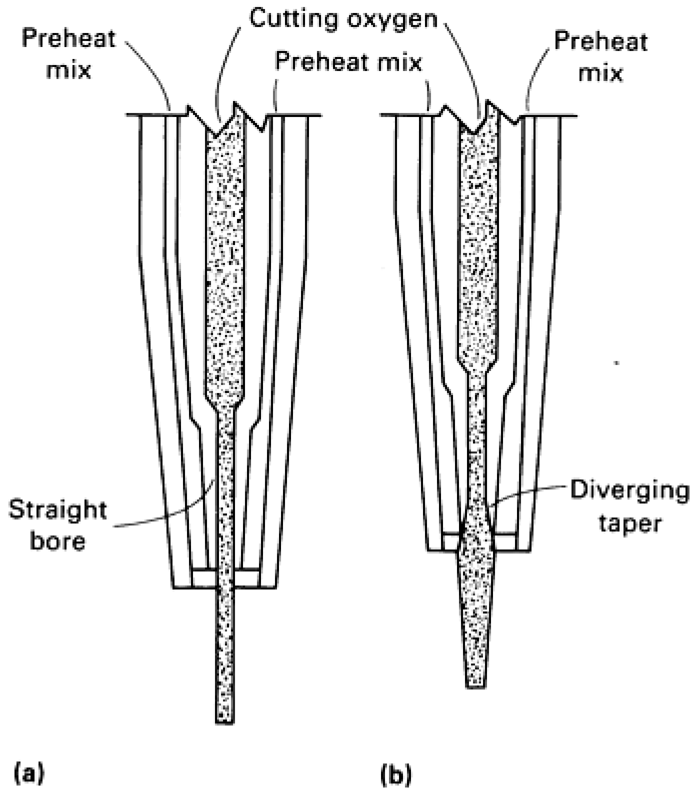

Fig. 5 Oxyfuel cutting tips. (a) Standard cutting tip with straight-bore oxygen orifice. (b) High-speed cutting tip with divergent-bore oxygen orifice.

Equipment Selection Factors. Natural gas and liquefied petroleum gases operate most efficently with high-low gas regulators; injector-type cutting torches; and two-piece, divergent, recessed cutting tips. Acetylene cutting is most efficient with divergent single-piece tips. If acetylene is supplied by low-pressure generators, an injector-type torch is ideally suited to most cutting applications.

Two-piece divergent cutting tips are best suited for use with Mapp gas; the tip recess should be less than one used for natural gas or propane. Injector-type torches and high-low regulators are not required with Mapp gas.

Guidance Equipment. In freehand cutting, the operator can usually follow a layout accurately at low speeds, but the cut edges may be ragged. For accurate manual cutting at speeds over 250 mm/min (10 in./min), the torch tip should be guided with a metal straightedge or template. Circles and arcs are cut smoothly with the aid of a radius bar, a light rod clamped and adjusted to the torch at one end, while the other end is held at the circle center.

Machine guidance equipment includes magnetic tracing of a metal template, manual spindle tracing, optical tracing of a line drawing, guidance by numerically controlled tape or by programmable controllers, and computer-programmed guidance equipment (Fig. 6).

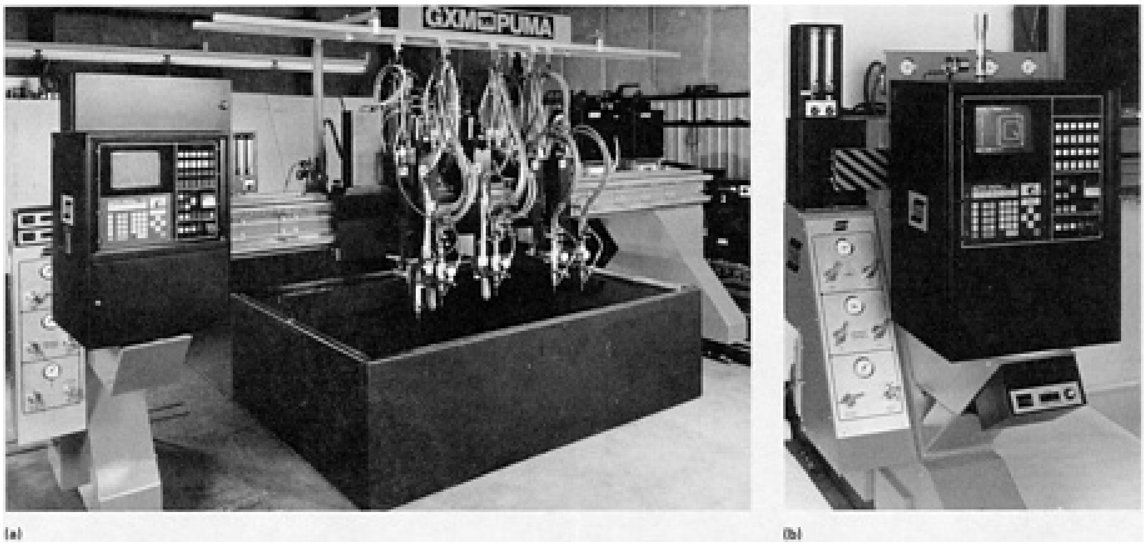

Fig. 6 Gantry shape cutting system. (a) CNC-controlled cutting tool incorporating oxyfuel torches, plasma arc torches, 90° indexing triple-torch oxyfuel stations for straight-line beveling, and zinc powder or punch markers. (b) Close-up of CNC control console. Courtesy of ESAB North America, Inc.

Portable cutting machines are used primarily for straight-line and circular cutting. Components include a torch mounted on a motor-driven carriage that travels on a track or other torch guidance device. The operator adjusts travel speed and monitors the operation.

Machine cutting torches are of heavy construction of in-line design. The torch casing has a rack, which fits into a gear on the torch holder, for raising and lowering the torch over the work. Ducts and valves are encased in a single tube. The cutting tip is mounted axially with the tube. A valve knob or a lever-operated poppet valve replaces the spring-loaded cutting-oxygen lever of the manual torch.

On some portable machines, gases are supplied to connections on the carriage, rather than directly to the torch to avoid hose drag on the torch. Short hoses are used from machine connections to the torch. Some carriages can accommodate two or more torches operating simultaneously, for such operations as squaring and beveling.

The operator follows the carriage to make adjustments. When plates are wavy or distorted, the operator may need to adjust torch height to avoid losing the cut. When carefully operated, track-guided torches can produce cuts at speeds and quality approaching those obtainable with stationary cutting machines.

Stationary cutting machines, as shown in Fig. 6 and 7, are used for straight-line and circular cuts, but their primary use is for cutting complex parts, that is, for cutting shapes. Plate to be cut is moved to the machine.

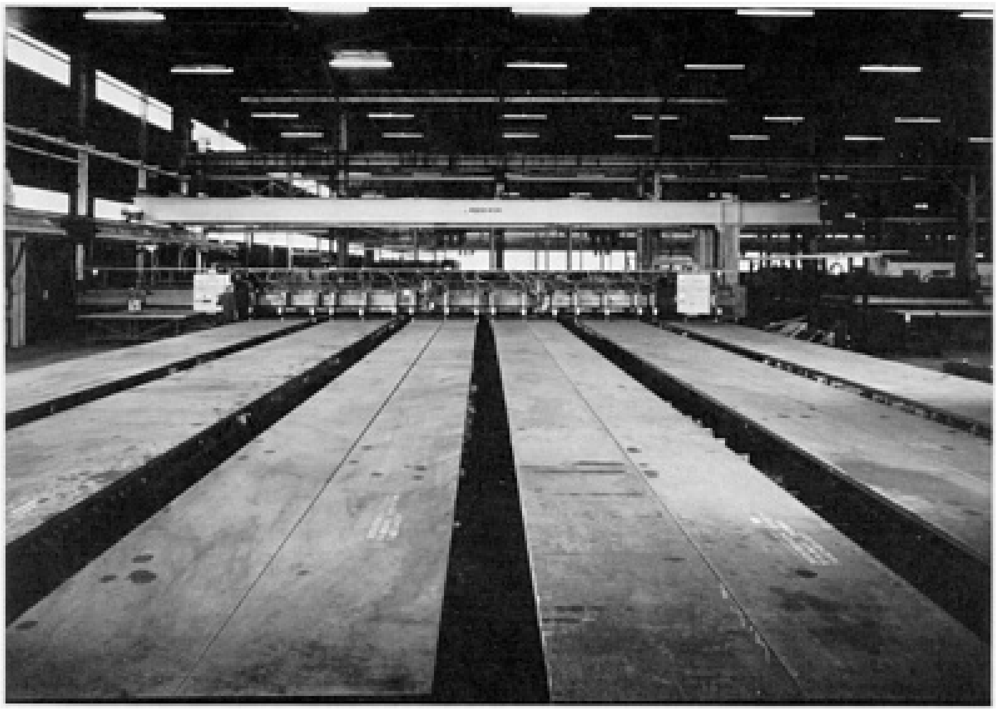

Fig. 7 Stationary oxyfuel gas cutting machine.

On shape-cutting machines, cutting torches move left and right on a bridge mounted over the cutting table. The bridge moves back and forth on supports that ride on floor-mounted tracks. The combined movement of the torches on the bridge and the bridge on the track allows the torch to cut any shape in the *x*-*y* plane. Bridges are either of cantilever or gantry design. Suppliers classify cutting-machine capacity by the maximum width of plate that can be cut.

Machine Directions. Methods for directing the motion of shape cutting machines have become increasingly sophisticated and include manual, magnetic, and electronic means of control. The simplest machines have one or two torches and use manual or magnetic tracing.

For manual tracing, the operator either steers an idler wheel or spindle around a template or guides a wheel or focused light beam around an outline on paper. Cutting speed is controlled by setting the speed of the tracing head (pantograph director) or by setting the speed of the torch carriage (coordinate drive). Cutting speed in manual tracing is about 350 mm/min (14 in./min), depending on operator skill.

Magnetic tracing is done with a knurled magnetized spindle that rotates against the edge of a steel template. The spindle is linked to a pantograph. Direct-reading tachometers, showing cutting speed in inches per minute, assist in adjusting cutting speed. These control methods are relatively slow.

Faster, electronic tracers use a photo-electric cell that scans the reflection of a beam of light directed on the outline of a template. Templates are line drawings on paper, white-on-black paper cutouts, or photonegatives of a part outline. To hold tolerances closer than $\frac{1}{16}$ in. continuously, templates of plastic film, glass cloth, or some other durable, dimensionally stable material should be used.

In scanning the edge of a white-on-black template, the circuit through the photoelectric cell balances when the cell senses an equal amount of black and white. A change in this balance sends an impulse to a motor that moves the tracing head back to balance. In line tracing, the photoelectric cell scans the line from side to side. As long as the light reflects equally from both sides of the line, the steering signals balance. When the photocell scans more light on one side of the line than on the other, the scanner rotates to balance.

Some machines adjust to permit parts to be cut about $\frac{1}{32}$ in. larger or smaller than the template. This feature, called kerf compensation, is useful for cutting to close tolerances, especially when the template has insufficient kerf allowance.

Coordinate-drive machines translate motion 1 to 1 or in other ratios. Such ratio cutting permits the use of templates in any proportion, from full-scale to one-tenth of part size.

Tape Control. Cutting machine movement may be controlled by electronic signals from punched tape (numerical control). These machines do not require templates, and the tape may be easily stored and used many times.

Some cutting machines receive directions from a microprocessor, programmed directly or from punched tape. The most sophisticated machines take directions from a computer (computerized numerical control, or CNC) and use computer graphics (Fig. 6).

Nesting of Shapes

Savings in material, labor, and gas consumption can be gained by nesting parts in the stock layout for single-torch or multiple-torch operation. Savings can be realized whenever one cut can be made instead of two. Sometimes a shape can be modified for better nesting. The advent of computer graphics allows cutting-machine programmers to create layouts of part patterns on cathode ray tube screens (Fig. 8), manipulating cutting patterns for greatest plate use. Several firms offer programs that closely optimize parts nesting.

Fig. 8 Parts programming system for nesting of shapes. Layouts of part patterns can be performed on-screen using such a system, resulting in optimum material use. Courtesy of ESAB North America, Inc.

Metal Powder Cutting

Finely divided iron-rich powder suspended in a jet of moving air or dispensed by a vibratory device is directed into the gas flame in metal powder cutting. The iron powder passes through and is heated by the preheat flame so that it burns in the oxygen stream. Heat generated by the burning iron particles improves cutting action. Cuts can be made in stainless steel and cast iron at speeds only slightly lower than those used for equal thicknesses of carbon steel. By adding a small amount of aluminum powder, cuts can be made through copper and brass. For information on the types of metal powder used for cutting operations, see the article "Metal and Alloy Powders for Welding, Hardfacing, Brazing, and Soldering" in *Powder Metal Technologies and Applications*, Volume 7 of the *ASM Handbook.*

Equipment. In metal powder cutting, a gas torch with an external powder attachment (Fig. 9), or a torch with built-in powder passages, is used. A vibratory or pneumatic powder dispenser (Fig. 10), air supply, and powder hose are required, in addition to fuel and oxygen lines. The equipment may be used manually for removing metal, such as risers from castings, or mechanized for straight-line or shape cutting by machine. Powder cutting torches mounted on gas cutting machines are capable of cutting stainless steel.

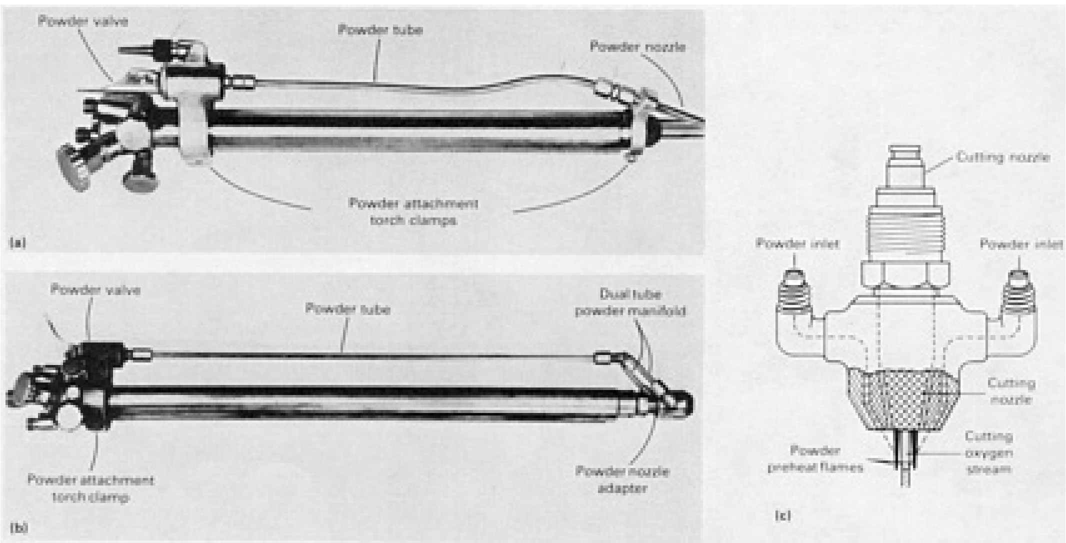

Fig. 9 Powder cutting attachments. (a) Single-tube attachment. (b) Multijet attachment. (c) Enlargement of powder nozzle adapter.

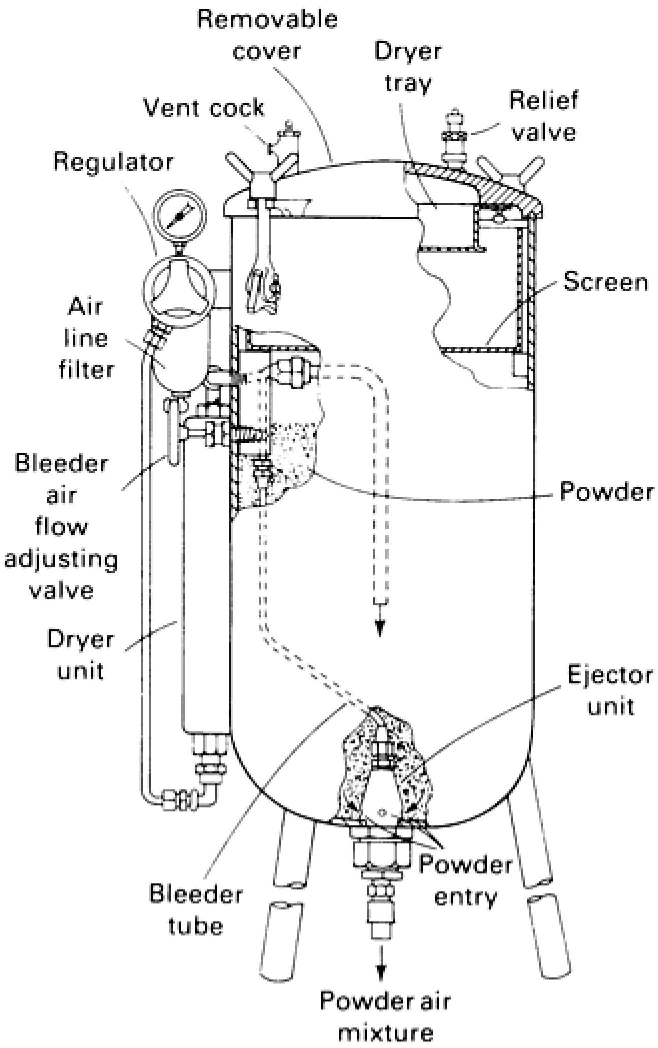

Fig. 10 Pneumatic powder dispenser for use in metal powder cutting.

Thickness. In plate 25 to 100 mm (1 to 4 in.) thick, powder cuts can be produced by machine to an accuracy of 0.8 to 1.6 mm ($\frac{1}{32}$ to $\frac{1}{16}$ in.). Heavier sections are seldom cut except for the trimming of castings; in this application, hand cutting requires greater allowances to avoid damage. Typical metal powder cutting applications include removal of risers; cutting of bars, plates, and slabs to size; and scrapping.

Quality of Cut. The kerf has a layer of scale which, on stainless steel, flakes off as the workpiece cools. The surface exposed after scale removal has the texture of sandpaper. Light grinding is normally sufficient to smooth high spots and remove iron particles and oxide. Unstabilized austenitic stainless steel may become sensitized by the heat of cutting. Powder cut cast iron develops a hardened case at the surface, which may require annealing or removal by grinding.

Thermal Cutting

Revised by Ed Craig, AGA Gas, Inc.

Chemical Flux Cutting

Chemical flux cutting processes are well suited to materials that form refractory oxides. Finely pulverized flux is injected into the cutting oxygen before it enters the cutting torch. The torch has separate ducts for preheat oxygen, fuel gas, and cutting oxygen. When the flux strikes the refractory oxides that are formed when the cutting oxygen is turned on, it reacts with them to form a slag of lower melting temperature compounds. This slag is driven out, enabling oxidation of the metal to proceed.

Chemical fluxing methods are used to cut stainless steel. The operator should have an approved respirator for protection from toxic fumes generated by the process.

Thermal Cutting

Revised by Ed Craig, AGA Gas, Inc.

Plasma Arc Cutting

Plasma arc cutting employs an extremely high-temperature, high-velocity, constricted arc between an electrode contained within the torch and the piece to be cut. The arc is concentrated by a nozzle onto a small area of the workpiece. The metal is continuously melted by the intense heat of the arc and then removed by the jetlike gas stream issuing from the torch nozzle. Because plasma arc cutting does not depend on a chemical reaction between the gas and the work metal, because the process relies on heat generated from an arc between the torch electrode and the workpiece, and because it generates very high temperatures (28,000 °C, or 50,000 °F, compared to 3000 °C, or 5500 °F, for oxyfuel), the transferred arc cutting mode can be used on almost any material that conducts electricity, including those that are resistant to oxyfuel gas cutting. Using the nontransferred arc method, nonmetallic objects such as rubber, plastic, styrofoam, and wood can be cut with a good quality surface to within 0.50 to 0.75 mm (0.020 to 0.030 in.) tolerances.

The past decade has seen a great increase in use of plasma arc cutting, because of its high cutting speed (Fig. 11). The process increases the productivity of cutting machines over oxyfuel gas cutting without increasing space or machinery requirements.

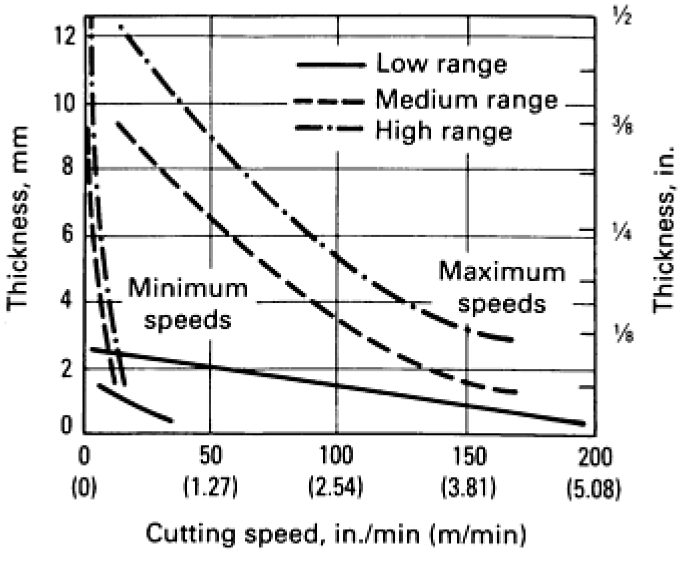

Fig. 11 Typical cutting speeds for plasma arc cutting of carbon steel or stainless using 6.8 m^3/h (240 ft^3/h) of air at 345 kPa (50 psi) from a single source. This information represents realistic expectations using recommended practices and well maintained systems. Other factors such as parts wear, air quality, line voltage fluctuations, and operator experience may also affect system performance.

Operating Principles and Parameters (Ref 1)

The basic plasma arc cutting torch is similar in design to that of a plasma arc welding torch. For welding, a plasma gas jet of low velocity is used to melt base and filler metals together in the joint (see the article "Plasma Arc Welding" in *Welding, Brazing, and Soldering,* Volume 6 of the *ASM Handbook*). For the cutting of metals, increased gas flows create a high-velocity plasma gas jet that is used to melt the metal and blow it away to form a kerf. The basic design and terminology for a plasma arc cutting torch are shown in Fig. 12.

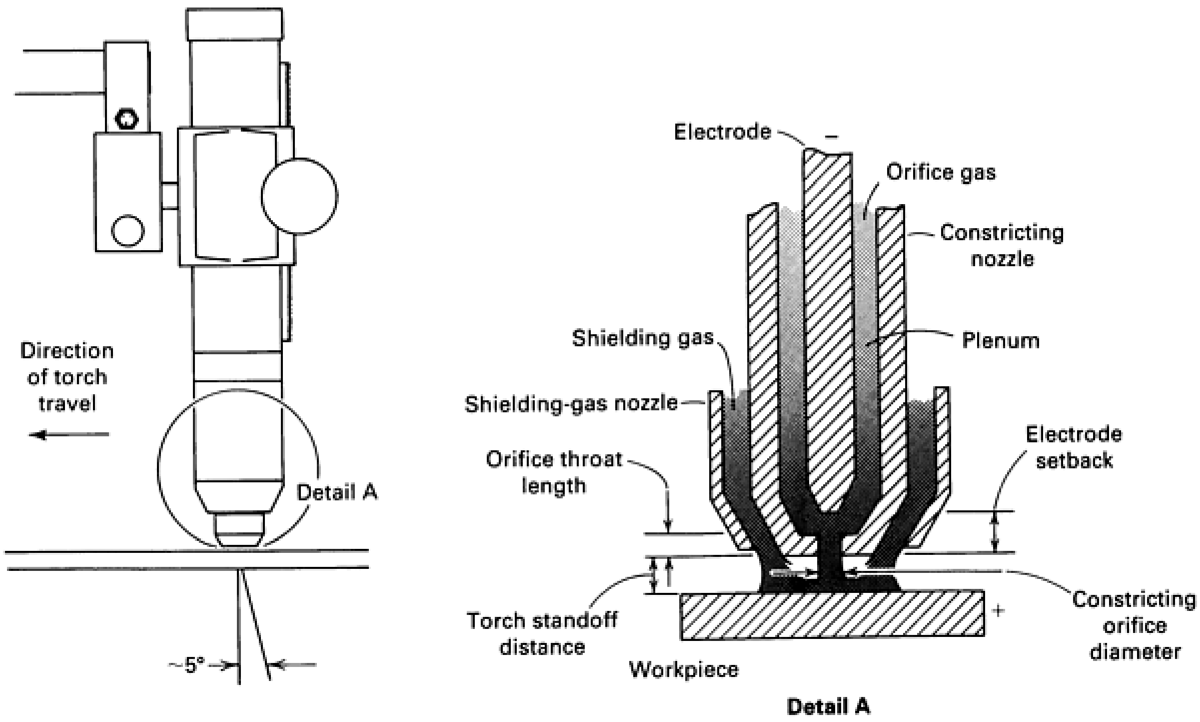

Fig. 12 Components of a plasma arc cutting torch.

All plasma arc torches constrict the arc by passing it through an orifice as it travels away from the electrode and toward the workpiece. As the orifice gas passes through the arc, it is heated rapidly to high temperature, expands, and accelerates as it passes through the constricting orifice. The intensity and velocity of the arc plasma gas are determined by such variables as the type of orifice gas and its entrance pressure, constricting orifice shape and diameter, and the plasma energy density on the work.

The basic plasma arc cutting circuitry is shown in Fig. 13. The process operates on direct current, straight polarity (dcsp), electrode negative, with a constricted transferred arc. In the transferred arc mode, an arc is struck between the electrode in the torch and the workpiece. The arc is initiated by a pilot arc between the electrode and the constricting nozzle. The nozzle is connected to ground (positive) through a current-limiting resistor and a pilot arc relay contact. The pilot arc is initiated by a high-frequency generator connected to the electrode and nozzle. The welding power supply then maintains this low current arc inside the torch. Ionized orifice gas from the pilot arc is blown through the constricting nozzle orifice. This forms a low-resistance path to ignite the main arc between the electrode and the workpiece. When the main arc ignites, the pilot arc relay may be opened automatically to avoid unnecessary heating of the constricting nozzle.

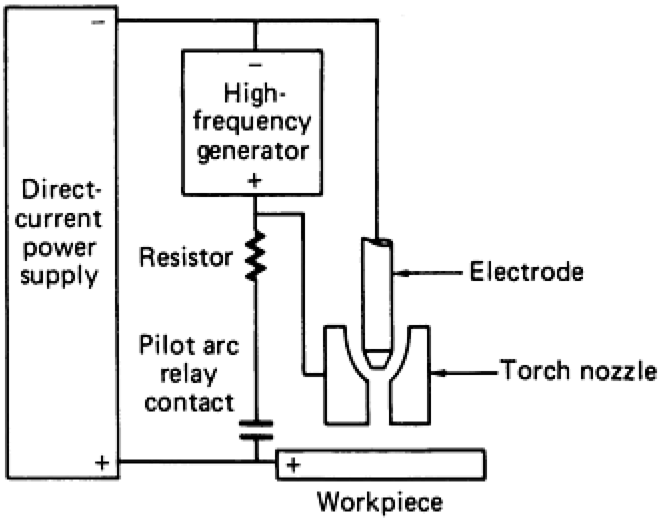

Fig. 13 Plasma arc cutting circuit. The process operates on direct current electrode negative (straight polarity). The arc is initiated by a pilot arc between the electrode and torch nozzle. Pilot arc is initiated by the high-frequency generator, which is connected to the electrode nozzle.

Plasma arc cutting was originally developed for severing nonferrous metals using inert gases. Modifications of the process and equipment to allow the use of oxygen or compressed air in the orifice gas permitted the cutting of carbon and alloy steel with improved cutting speeds and a cut quality similar to that obtained with oxyfuel cutting.

Because the plasma constricting nozzle is exposed to the high plasma flame temperatures (estimated at 10,000 to 14,000 °C, or 18,000 to 25,000 °F), the nozzle is sometimes made of water-cooled copper. In addition, the torch should be designed to produce a boundary layer of gas between the plasma and the nozzle.

Several process variations are used to improve the plasma arc cutting quality for particular applications. They are generally applicable to materials in the 3 to 38 mm ($\frac{1}{8}$ to $1\frac{1}{2}$ in.) thickness range, depending on the current rating of the plasma machine. Auxiliary shielding in the form of gas or water is used to improve cutting quality.

Dual-flow plasma cutting provides a secondary gas blanket around the arc plasma, as shown in Fig. 14. The usual orifice gas is nitrogen or compressed air. The shielding gas is selected for the material to be cut. It may be compressed air for mild steel, CO_2 for stainless steels, and an argon-hydrogen mixture for aluminum.

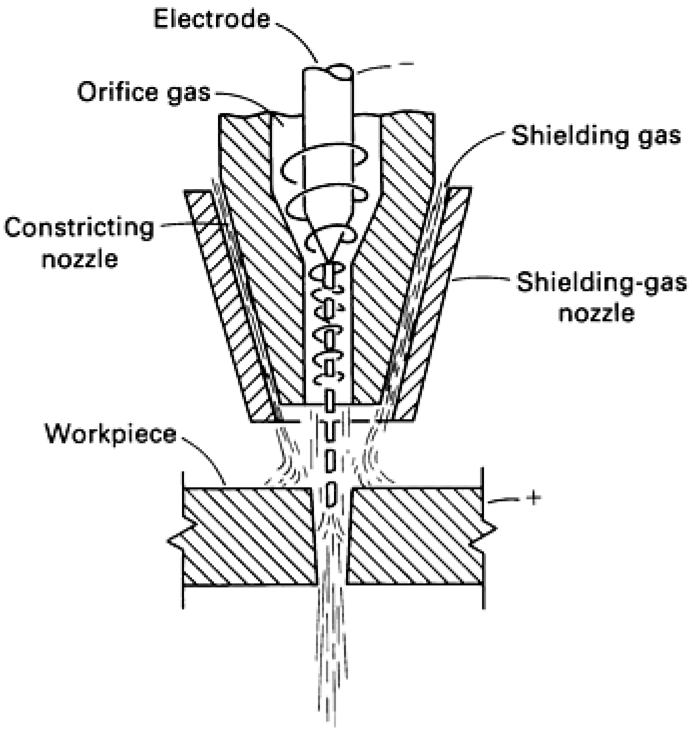

Fig. 14 Dual-flow plasma arc cutting.

Water Shield Plasma Cutting. This technique is similar to dual-flow plasma cutting. Water is used in place of the auxiliary shielding gas.

Water Injection Plasma Cutting. This modification of the plasma arc cutting process uses a symmetrical impinging water jet near the constricting nozzle orifice to further constrict the plasma flame. The arrangement is shown in Fig. 15. The waterjet also shields the plasma from turbulent mixing with the surrounding atmosphere.

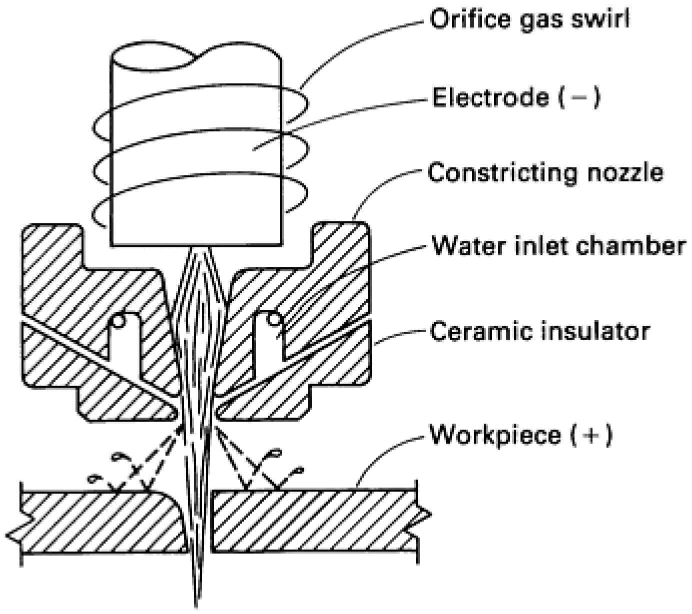

Fig. 15 Water injection plasma arc cutting arrangement.

Selection of Gas. Any gas or gas mixture that does not degrade the properties of the tungsten electrode or the workpiece can serve as a plasma gas. The gas mixture varies according to the plasma equipment design criteria. The most commonly used gas is compressed air; all common metals, such as carbon and alloy steels, stainless steels, and aluminum, can be cut with compressed air. As the metal thickness increases (over 25 mm, or 1 in., with steels and stainless steels), benefits are derived from the use of nitrogen plasma with CO_2 shielding. Aluminum cut quality is improved using argon-hydrogen plasma and nitrogen as the secondary gas blanket. When high-duty cycles are used, a change from compressed air to nitrogen/CO_2 prolongs the consumable life.

Machine Ratings. In selecting a plasma cutting unit, the thickness of plate to be cut and the required cutting speed should be considered. Table 4 shows thickness capacity and midrange cutting speeds of four plasma units. These ratings are an average of speeds quoted by two manufacturers of plasma arc cutting equipment.

Table 4 Cutting speed of plasma arc cutting machines for stainless steel

Machine rating, A	Cutting speed, m/min (in./min)							
	Plate thickness, mm (in.)							
	1.5 ($\frac{1}{16}$)	**3 ($\frac{1}{8}$)**	**6 ($\frac{1}{4}$)**	**9 ($\frac{3}{8}$)**	**13 ($\frac{1}{2}$)**	**25 (1.0)**	**50 (2.0)**	75 (3.0)
30	0.75-1.5 (30-60)	0.5-0.75 (20-30)	0.13-0.25 (5-10)	. . .	. . .	. . .	. . .	**. . .**
50	1.5-3.0 (60-120)	1.3-2.5 (50-100)	0.6-1.3 (25-50)	0.13-0.25 (5-10)	0.025-0.13 (1-5)	. . .	. . .	**. . .**
100	. . .	1.5-2.8 (60-110)	0.75-1.5 (30-60)	0.5-1.0 (20-40)	0.4-0.5 (15-20)	0.13-0.25 (5-10)	. . .	**. . .**
400	**. . .**	**3-4 (120-150)**	**4-4.3 (150-170)**	**3-3.5 (120-140)**	**2.5-3 (100-120)**	**1.0-1.5 (40-60)**	**0.25-0.5 (10-20)**	**0.08-0.2 (3-8)**

The thickness capacity of a cutting unit should first be examined to determine the cutting speed it can achieve for a given application. Next the speeds quoted for the next-larger unit should be studied to see whether the greater speed justifies its higher cost. For example, a 30 A unit cuts 6 mm ($\frac{1}{4}$ in.) stainless steel plate at 125 to 250 mm/min (5 to 10 in./min); the 50 A unit cuts 6 mm ($\frac{1}{4}$ in.) plate at 635 to 1270 mm/min (25 to 50 in./min), a significant increase. If the average required cutting thickness exceeds 75% of the maximum thickness capacity of a unit, the next larger size should be considered.

Pierce capacity is usually half the cutting thickness capacity, an important consideration in selection of plasma equipment. To cut plate thicker than 75 mm (3 in.), connecting 400 A or 500 A units in parallel extends thickness capacity.

Technique. With a machine-operated plasma arc torch, standoff distance from the work metal is about 5 to 20 mm ($\frac{1}{4}$ to $\frac{5}{8}$ in.). In manual operation, the current and rate of gas flow are set, and the arc is struck by pressing a button on the torch, which is guided manually over the work. At the end of the cut, the arc is automatically extinguished, and the control opens the contactor and closes the gas valves. The operator can extinguish the arc at any time by moving the torch away from the work metal.

Quality of Cut. Most plasma cutting torches impose a swirl on the orifice gas flow pattern by injecting gas through tangential holes or slots (Fig. 14 and 15). As a result of the swirl of the plasma gas, walls of plasma arc cuts have a V-shaped included angle of 2 to 4° on one of the cut edges. When a straight edge is required on the cut part, the operator must operate the torch carefully so that the bevel is on the scrap side of the cut. When the operator is facing the direction of torch travel, if the gas swirls clockwise, the bevel will be on the left side of the cut. In many cases, a small bevel is acceptable; it may even be used as a weld preparation. The relationship of torch travel direction to the part with clockwise swirl of the orifice as is illustrated in Fig. 16.

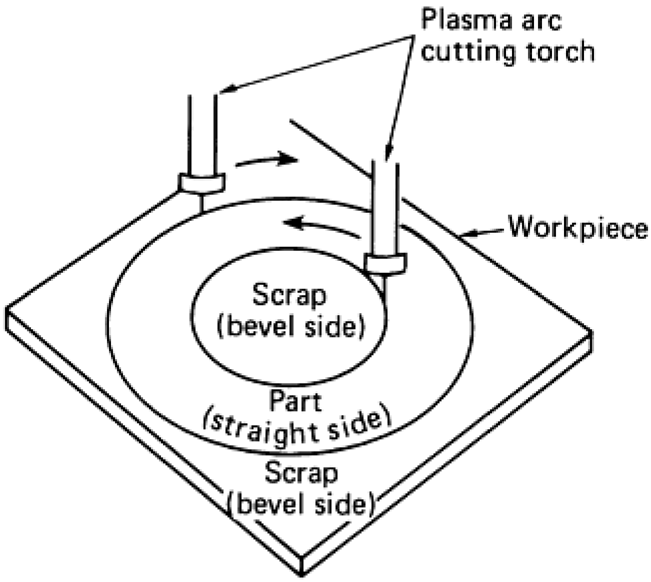

Fig. 16 Relationship of torch travel direction to the part with clockwise swirl of the orifice gas. With the clockwise swirling plasma gas, the bevel side of the cut is on the left when the operator is looking in the direction of the torch travel. To achieve straight cuts on the inner diameter and the outer diameter of the ring, torch directions must reverse to keep the right side of the cut on the part edge.

Quality of cut includes surface smoothness, kerf width, degree of parallelism of the cut faces, dross adhesion on the bottom of the cut, and sharpness of top and bottom faces. Table 5 provides data on the causes of imperfections in plasma arc cutting of low-carbon steel, stainless steel, and aluminum.

Table 5 Causes of imperfections in plasma arc cuts

Type of imperfection	Cause of imperfection		
	Low-carbon steel	**Stainless steel**	Aluminum
Top edge rounding	Excessive speed, excessive standoff	Excessive speed, excessive standoff	**Seldom occurs**
Top edge dross	Excessive standoff, dross easily removed	Excessive standoff, excessive hydrogen	**Excessive standoff, dross easily removed**
Top side roughness	Seldom occurs	Excessive hydrogen or standoff, insufficient speed	**Insufficient hydrogen**
Side bevel--positive	Excessive speed, excessive standoff	Excessive speed, excessive standoff	**Excessive speed, insufficient hydrogen**
Side bevel--negative	Seldom occurs	Seldom occurs	**Excessive hydrogen**

Top side undercut	Excessive hydrogen	Excessive hydrogen	**Insufficient speed, insufficient hydrogen**
Bottom side undercut	Seldom occurs	Slight effect at near-optimum conditions	**Seldom occurs**
Concave surface	Seldom occurs	Excessive hydrogen	**Excessive hydrogen, insufficient speed**
Convex surface	Excessive speed	Insufficient hydrogen, excessive speed	**Seldom occurs**
Bottom edge rounding	Excessive speed	Seldom occurs	**Seldom occurs**
Bottom dross	Excessive hydrogen or speed, insufficient standoff	Insufficient speed, excessive hydrogen	**Excessive speed**
Bottom side roughness	**Insufficient standoff**	**Seldom occurs**	**Insufficient hydrogen**

Width of kerf is $1\frac{1}{2}$ to 2 times the kerf of conventional oxyfuel gas cutting. The range is usually 5 to 10 mm ($\frac{3}{16}$ to $\frac{3}{8}$ in.), although some users achieve 0.8 mm ($\frac{1}{32}$ in.). For thick work metal, width of kerf may exceed 9 mm ($\frac{3}{8}$ in.).

Heat-Affected Zone. The high speeds possible with plasma arc cutting result in relatively low heat input to the workpiece. Heat-affected zones are therefore narrow. The HAZ on stainless steel plate 25 mm (1 in.) thick cut at 1270 mm/min (50 in./min) is 0.08 to 0.13 mm (0.003 to 0.005 in.). Sensitization is usually avoided.

Bevel cutting for weld preparation is an important application of plasma arc cutting. The intense heat of the process makes it suitable for all types of beveling at a higher efficiency than oxyfuel gas cutting.

Applications

Plasma arc cutting can be used to cut any metal. Most applications are for carbon steel, aluminum, and stainless steel. It can be used for stack cutting, plate beveling, shape cutting, and piercing.

In stack cutting, the plates should be clamped together as closely as possible. However, plasma arc cutting can usually tolerate wider gaps between carbon steel plates than can oxyfuel gas cutting. When high plasma arc cutting speeds are used, there is less distortion of the top plate. Several plates of 1.5 to 6 mm ($\frac{1}{16}$ to $\frac{1}{4}$ in.) thickness can be economically stack cut.

For shape cutting, plasma arc cutting torches are used on shape cutting machines similar to those used for oxyfuel gas cutting (Fig. 6). Generally, plasma arc shape cutting machines can operate at higher travel speeds than is possible with oxyfuel gas cutting machines. Because of the fumes and heat produced by the cutting action, water tables are sometimes used with plasma arc shape cutting machines. The water just touches the bottom of the plate, where it traps the fumes, slag, and dross as they emerge from the bottom of the kerf. It also helps reduce noise.

Plasma arc cutting of carbon steel plate can be done faster than with oxyfuel gas cutting processes in thicknesses below 75 mm (3 in.) if the appropriate equipment is used. For thicknesses under 25 mm (1 in.), plasma arc cutting speed can be up to five to eight times greater than that for oxyfuel gas cutting (Fig. 17). For thicknesses over 38 mm ($1\frac{1}{2}$ in.), the choice of plasma arc or oxyfuel gas cutting depends on other factors such as equipment costs, load factor, and applications for cutting thinner plates and nonferrous metals. Characteristics of plasma arc cutting and oxyfuel gas cutting are compared in Table 6.

Table 6 Comparison of OFC and PAC processes

	Oxyfuel	Plasma arc
Flame temperature	3040 °C (5500 °F)	**28,000 °C (50,000 °F)**
Action	Oxidation, melting, expulsion	**Melting, expulsion**
Preheat	Yes	**No**

Air Carbon Arc Cutting and Gouging

Air carbon arc cutting and gouging severs or removes metal by melting it with the heat of an arc struck between a carbon-graphite electrode and the base metal. A stream of compressed air blows the molten metal from the kerf or groove. Its most common uses are for weld joint preparation; removal of defective welds; removal of welds and attachments when dismantling tanks and steel structures; and removal of gates, risers, and defects from castings. The process cuts almost any metal, because it does not depend on oxidation to keep the cut going. A holder clamps the carbon-graphite electrode in position parallel to an air stream, which issues from orifices in the electrode holder to strike the molten metal immediately behind the arc. The electrode holder contains an air flow control valve, an air hose, and a cable. The cable connects to the welding machine; the air hose connects to a source of compressed air. Cutting action in the air carbon arc process is illustrated in Fig. 18.

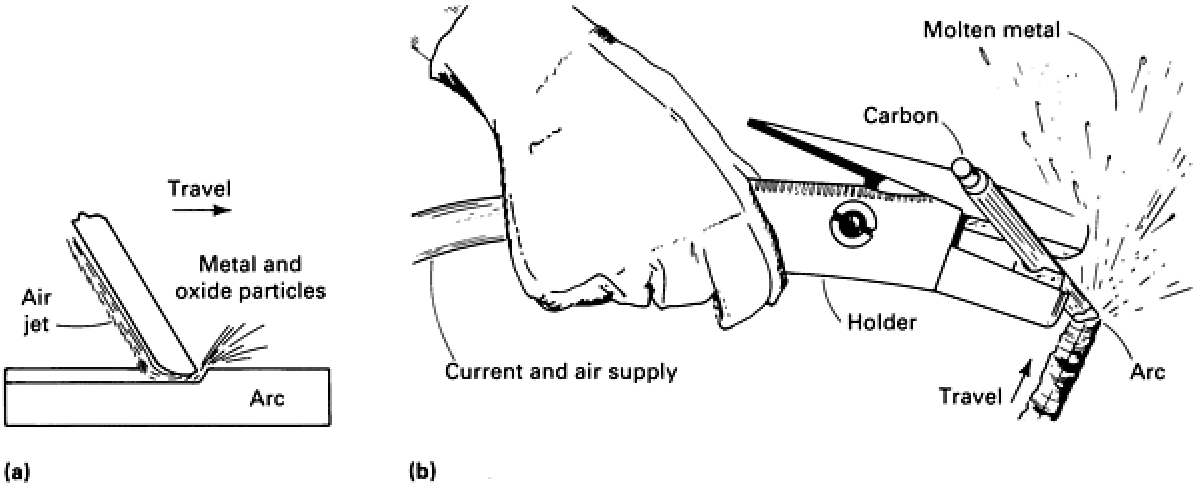

Fig. 18 (a) Air carbon arc cutting action. (b) Manual air carbon arc cutting.

The low heat input of air carbon arc gouging makes this process ideal for joint preparation and for weld removal on high-strength steels. Base-metal temperatures rise very little, about 80 °C (150 °F) in most applications.

Rough cutting is done manually. Accurate work calls for electrode holders mounted on motor-driven carriages.

Pipe Fabrication. Fabricators of structural steel, pressure vessels, tanks, and pipe use hand torches, semiautomatic torches, and fully automatic torches. A typical pipe fabrication plant uses two automatic air carbon arc torches. One, mounted on a large traveling manipulator, works with several sets of turning rolls and in tandem with submerged arc welding units. Longitudinal and circumferential seams are square butted, welded on the inside, backgouged to sound weld metal, then welded on the outside. The second torch, mounted on a pedestal, backgouges circumferential seams at another station.

Power Supply. Constant-voltage direct current with a flat to slightly rising voltage characteristic is best for most air carbon arc cutting applications. Direct current is preferred; copper alloys, however, cut better with alternating current. Table 7 provides data on power sources for air carbon arc cutting and gouging.

Table 7 Power sources for AAC and gouging

Equipment	**Polarity**	Use
Variable-voltage motor-generator, resistor, and resistor grid	Direct current	**All electrode sizes**
Constant-voltage motor generator, rectifier	Direct current	**Electrodes > $\frac{1}{4}$ in. in diameter**
Transformer	Alternating current	**Alternating current electrodes only**
Rectifier	**Alternating current, direct current**	**Direct current from three-phase transformer only; single-phase source not recommended. Use alternating current with alternating current electrodes only.**

Air Supply. Compressed air from a shop line or a compressor at 550 to 700 kPa (80 to 100 psi) should be used; pressure as low as 275 kPa (40 psi) is suitable for light work. Deep grooves in thick metal require pressures up to 860 kPa (125 psi). Air hoses should have a minimum inside diameter of 6 mm ($\frac{1}{4}$ in.) with no constrictions. Air pressure is not critical in air carbon arc cutting; the process requires a sufficient volume of air to ensure a clean, slag-free surface. The amount of air required depends on the type of work (0.08 to 0.9 m^3/min, or 3 to 33 ft^3/min, for manual operations and 0.7 to 1.4 m^3/min, or 25 to 50 ft^3/min, for mechanized operations).

Air carbon arc cutting electrodes are made from mixtures of carbon and graphite. The three basic types of air carbon arc cutting electrodes are:

- Direct current copper-coated electrodes, which are used most frequently because of long life, stable arc characteristics, and groove uniformity. These electrodes are produced in diameters from 4 to 20 mm ($\frac{5}{32}$ to $\frac{3}{4}$ in.)
- Direct current uncoated electrodes, which have limited use. These electrodes, although generally restricted to diameters of less than 9 mm ($\frac{3}{8}$ in.), are available with diameters from 3 to 25 mm ($\frac{1}{8}$ to 1 in.)
- Alternating current copper-coated electrodes, which have additions of rare-earth metals to provide arc stabilization with alternating current. These electrodes are produced in 5, 6, 9, and 13 mm ($\frac{3}{16}$, $\frac{1}{4}$, $\frac{3}{8}$, and $\frac{1}{2}$ in.) diameters

Cross sections vary; round electrode rods are most common. Electrodes also come in flat, half-round, and special shapes to produce specially designed groove shapes.

Technique. The angle of the electrode, speed of cut, and amount of current determine depth and contour of the cut or groove. The electrode is held at an angle, and an arc is struck between the end of the electrode and the work metal. The electrode is then pushed forward. Data on groove depth, electrode size, current, and travel speed for air carbon arc gouging is available from various equipment manufacturers.

For through-cutting, the electrode is placed at a steeper angle, almost vertically inclined. Plate thicknesses greater than 13 mm ($\frac{1}{2}$ in.) may require multiple passes.

Grooves as deep as 25 mm (1 in.) can be made in a single pass. A steep angle, approaching that used for through-cutting, and rapid advance produce a deep, narrow groove; a flatter angle and slower advance produce a wide, shallow groove. Electrode diameter directly influences groove width. Operators should use a wash or weave action to remove excess metal such as risers and pad stubs, or in surfacing. Smoothness of the gouged or cut surface depends on the stability of electrode positioning, as well as on the steadiness of the electrode as it advances during the cutting operation. Mechanized gouging, with the electrode and holder traveling in a carriage on a track, produces smoother surfaces five times faster than does manual work.

Absorption of Carbon. Reverse polarity air carbon arc cutting removes metal faster than does straight polarity. However, the current carries carbon from the electrode to the base metal, increasing its carbon content. To minimize hardenability, the air stream must be adjusted to ensure removal of all molten metal.

Thermal Cutting

Exo-Process

A relatively new electric arc cutting process, called the Exo-Process, has been developed. Similar to flux-cored processes, it uses a consumable tubular electrode and a specially designed gun that feeds high-speed compressed air to the arc (Fig. 19). The air flow functions to push molten metal from the gouge cavity, to constrict the arc for more precise control, and to cool the electrode. The system can be adapted to conventional gas metal arc welding equipment (it requires a direct current constant-voltage power source--150 A minimum--and a conventional wire feeder).

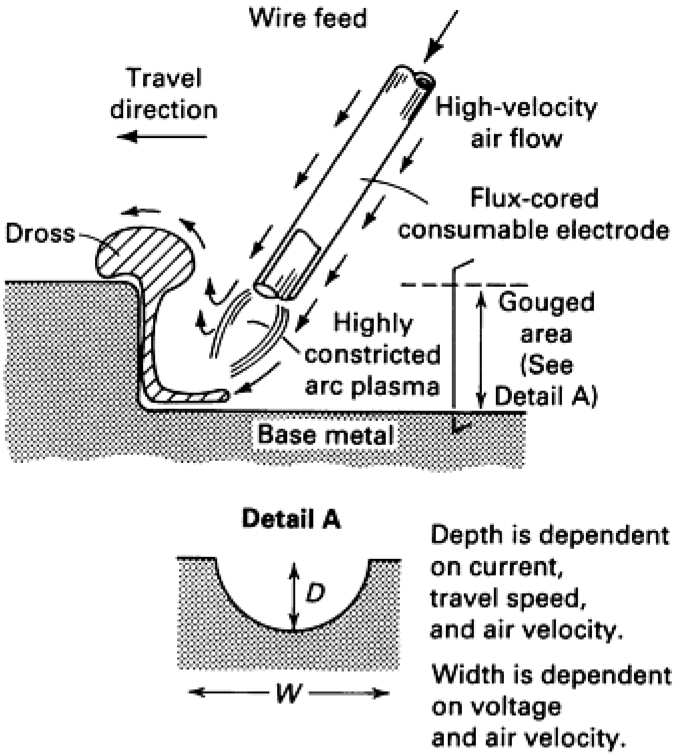

Fig. 19 The Exo-Process for gouging.

The velocity of the air flow at the arc is the key factor for straight cutting. A 1.5 mm ($\frac{1}{16}$ in.) wire size can cut up to 6 mm ($\frac{1}{4}$ in.) thick carbon steel. Speed and edge cut quality on most commercial metals and alloys is good, particularly for sheet metal thicknesses. Gouge quality on carbon steels is also good. The process would be well suited for automated equipment, in that high travel speeds may be attained. An obvious benefit of the process is that it can be mounted on a gas metal arc dual-wire feed system to provide the operator with a multifunctional welding and cutting unit.

Thermal Cutting

Revised by Ed Craig, AGA Gas, Inc.

Oxygen Arc Cutting

Oxygen arc cutting uses a flux-covered tubular steel electrode. The covering insulates the electrode from arcing between it and the sides of the cut. The arc raises the work material to combustion temperature; the oxygen stream burns the material away. Oxidation, or combustion, liberates additional heat to support continuing combustion of sidewall material as the cut progresses. The electric arc supplies the preheat necessary to obtain and maintain ignition at the point where the oxygen jet strikes the surface of the work. The process finds greatest use in underwater cutting.

When cutting oxidation-resistant metals, melting action occurs. The covering on the electrode acts as a flux; it functions in a manner similar to that of powdered flux or powdered metal injected into the gas flame in the flux-injection method of oxyfuel gas cutting of stainless steel.

Equipment. Oxygen arc cutting uses direct or alternating current, although direct current electrode negative (DCEN) is preferred. The electrode and the electrode holder convey the electric current and oxygen to the arc. Electrode holders must be fully insulated; underwater cutting requires a flashback arrester, and the electrode must have a watertight plastic coating. Components of an oxygen arc electrode are shown in Fig. 20.

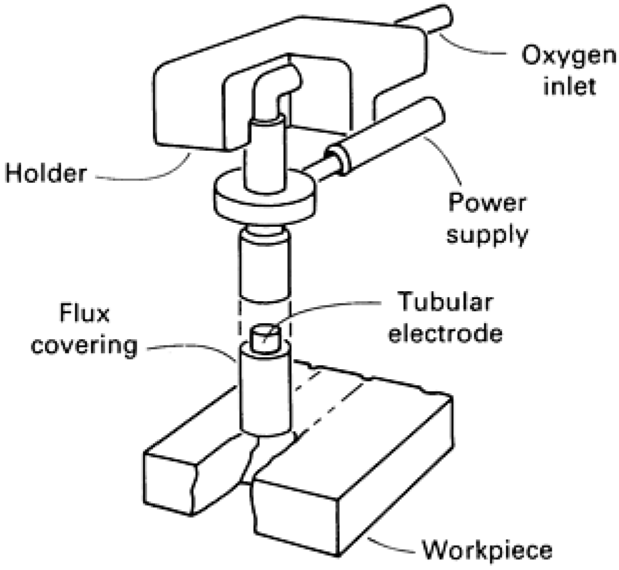

Fig. 20 Components of an oxygen arc electrode.

---

Introduction

INDUSTRIAL LASERS are being used in numerous material processing applications. They can weld microswitches and auto transmission gears, scribe and machine ceramic substrates, and drill jet engine turbine blades and baby bottle nipples. They are also used in heat treating, cladding, ablating, and marking. However, cutting represents their largest single application.

The versatility of the laser in cutting operations is responsible for its widespread use. The same laser can be used to cut men's suits, newspapers, circuit boards, motorcycle fenders, circular saw blades, stainless steel auto exhaust tubing and 13 mm (0.5 in.) thick alloy steel for aircraft disc brakes.

Its flexibility makes the laser an ideal tool for prototype or production work. Because laser cutting is a noncontact process, no tool wear occurs. Laser systems can cut intricate parts with accuracies of ±0.025 mm (±0.001 in.) and with surface finishes better than 1.3 μm (50 μin.) for some steels, and better than 0.50 μm (20 μin.) for some nonmetals.

Laser Cutting

Definition of a Laser

First, the word laser is an acronym for light amplification by stimulated emission of radiation. Second, there are essentially three components that are necessary for lasing action. There must be an active media that can be excited, a method of exciting the media, such as an electrical discharge between an anode and cathode, and a resonator.

The molecules of the active media must be excited in order to stimulate the emission of radiant energy or light. As the molecules are charged to a higher energy state, they excite their electrons into a higher energy level. Because unstable electrons seek their lowest energy state, they release this added energy as light particles, known as photons.

The resonator consists of two parallel mirrors that reflect light particles between them, thereby amplifying the stimulated emission of light. Of the two mirrors in the resonator, the rear mirror is 100% reflective, while the front, or output, mirror is typically only 50% reflective and therefore 50% transmissive. The percentage of light that is transmitted through the front mirror is commonly known as the laser beam. It is this parallel, monochromatic, intense beam of light particles that is used for material processing. The percentage of light remaining inside the resonator is necessary to maintain the continuous stimulated emission of photons.

Laser Cutting

Gregg P. Simpson, Peerless Laser Processors Division, Peerless Saw Company; Thomas J. Culkin, Lumonics Materials Processing Corporation

Laser Types

The carbon dioxide (CO_2) laser and the neodymium-yttrium aluminum garnet (Nd-YAG) laser are by far the most commonly used material-processing lasers. The CO_2 laser relies on a gas mixture of CO_2, helium (He), and nitrogen (N) as its active media. It usually uses an electrical discharge between an anode and cathode as the method of media excitation, and the standard two-mirror resonator. The CO_2 laser produces a wavelength of 10.6 μin (420 μin.), which is invisible to the human eye. Visible light falls between 0.4 and 0.7 μm (15 and 28 μin.). Although practical material-processing lasers have powers ranging from 150 W to 8 kW, CO_2 lasers have been built with powers above 25 kW. Most lasers used for cutting have powers that range from 150 W to 3 kW. Figure 1 shows a typical CO_2 gas laser design.

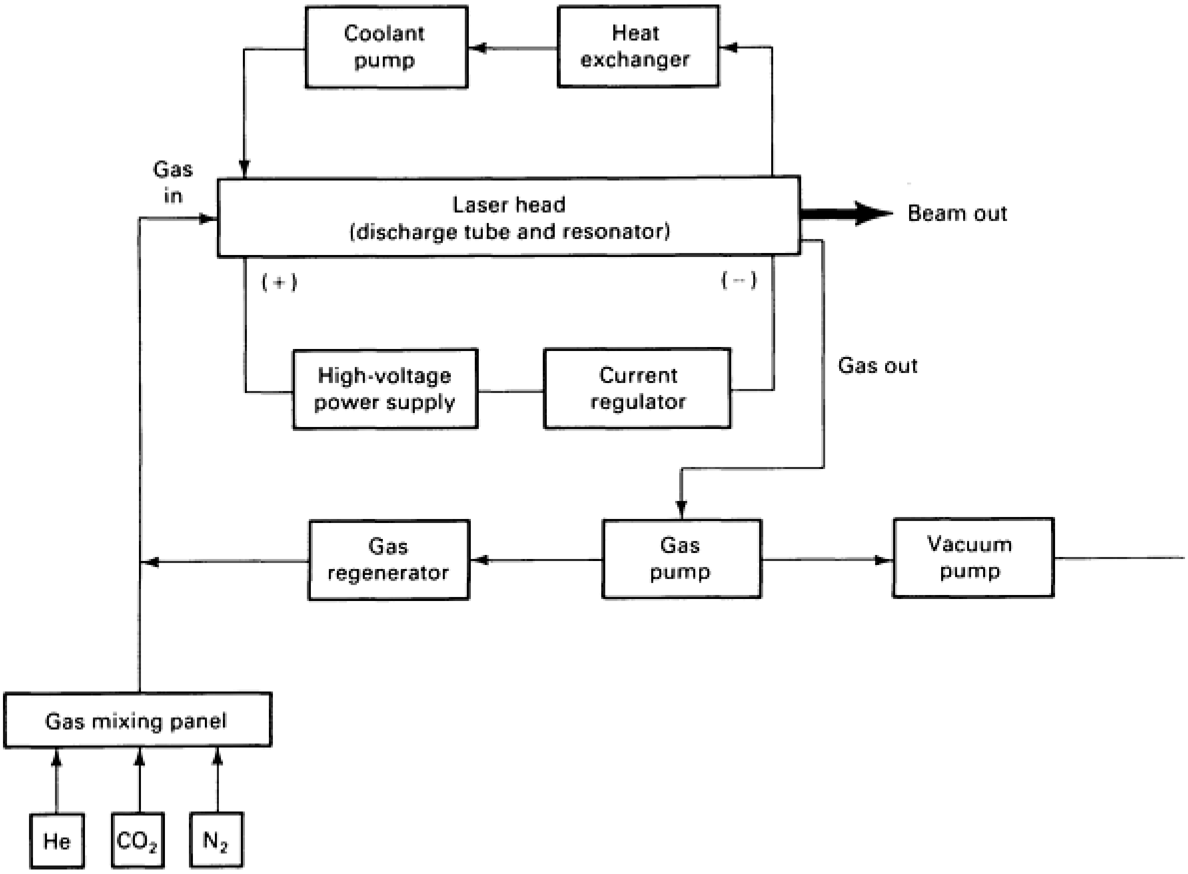

Fig. 1 General CO_2 laser design.

CO_2 Lasers. There are three basic types of CO_2 gas lasers: slow axial flow, transverse flow, and fast axial flow.

The slow axial flow laser is an older, proven design that has excellent mode, stability and pulsing capabilities. They are available with powers up to approximately 800 W, allowing them to cut steels up to 6.5 mm (0.25 in.) thick. Figure 2 shows the typical design theory of a slow axial flow laser. The lasing action occurs by injecting laser gas at a pressure of approximately 2.7 kPa (20 torr) into an evacuated glass tube. The tube has a rear mirror and an output coupler at either end. A high-voltage glow discharge is then passed down the tube between an anode and cathode, causing lasing to occur. This design, which can only create 70 W/m (20 W/ft) of tube length, requires a long resonator cavity to produce high power levels.

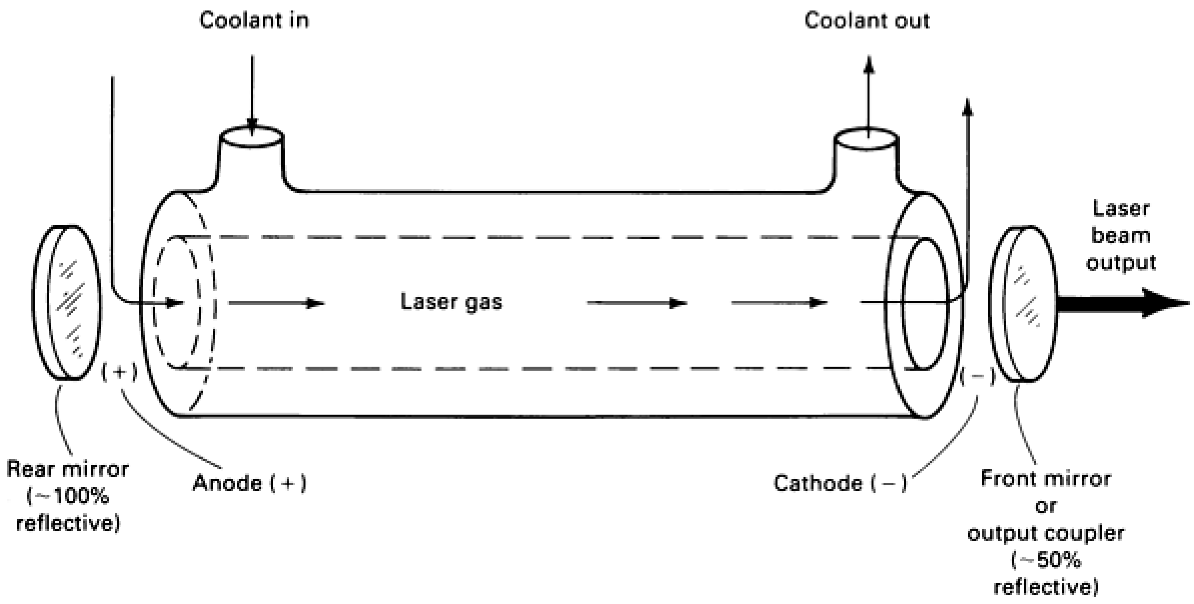

Fig. 2 Slow axial flow CO_2 laser.

The transverse-flow laser was developed in response to the size versus power limitations of the slow axial flow laser. Transverse-flow laser design allows power to be generated to approximately 25 kW. The transverse laser accomplishes this by using a tangential blower to move a high volume of laser gas transversely across the anode-cathode electrical path, as shown in Fig. 3. The basis of this design is that power is directly related to the volume of laser gas that is excited at any one time. The drawbacks are that these lasers cannot be electronically pulsed for cutting very intricate geometries, and the beam quality, or mode, is not ideal for high quality cutting applications.

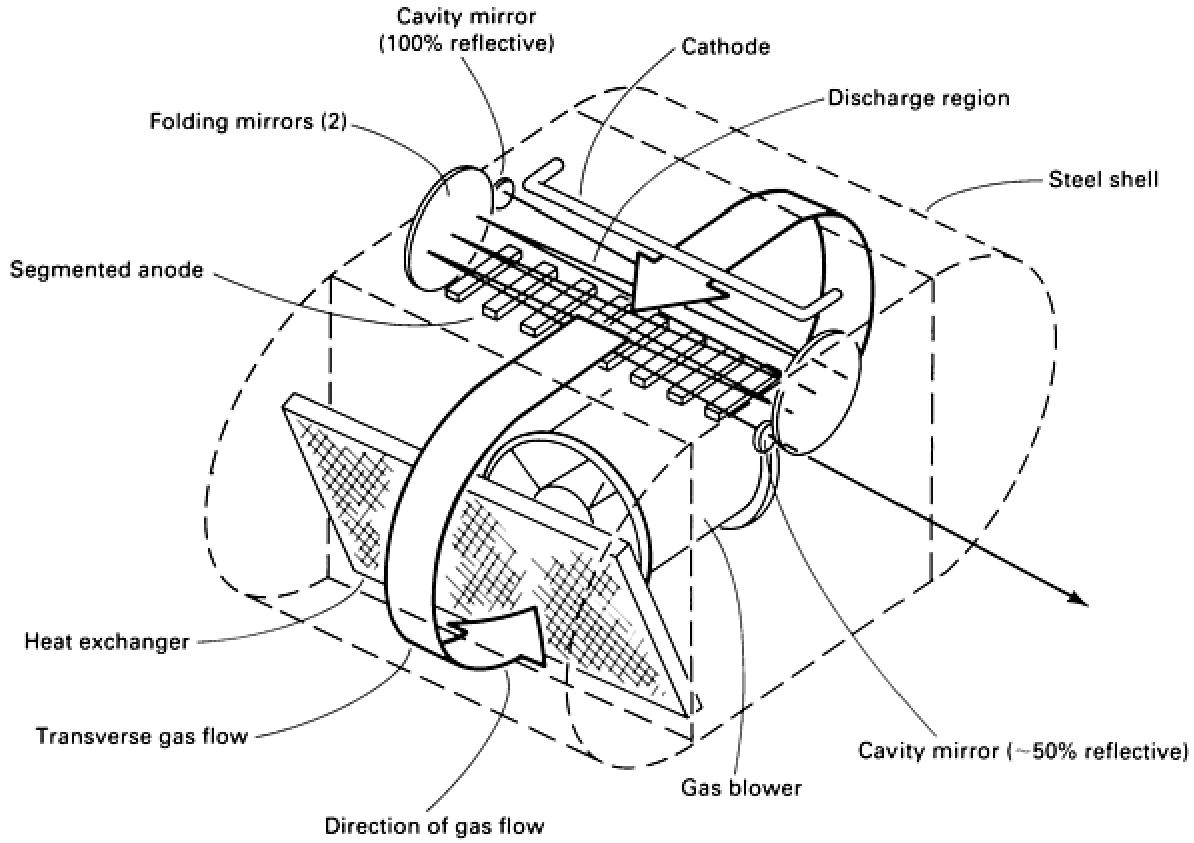

Fig. 3 Transverse or cross-flow CO_2 laser.

The fast axial flow laser is the newest CO_2 type. It combines the high power of the transverse flow laser with the beam quality and some of the pulsing capabilities of the slow axial flow laser. Its design is similar to the slow axial flow laser, except that a tangential blower forces a large amount of laser gas axially down the resonator, as shown in Fig. 4. This increases the available power to 700 W/m (210 W/ft) of active laser resonator. This laser type is currently being built with power up to 3 kW, and is becoming increasingly popular as a cutting laser because of its increased power, excellent beam quality, and pulsing capabilities.

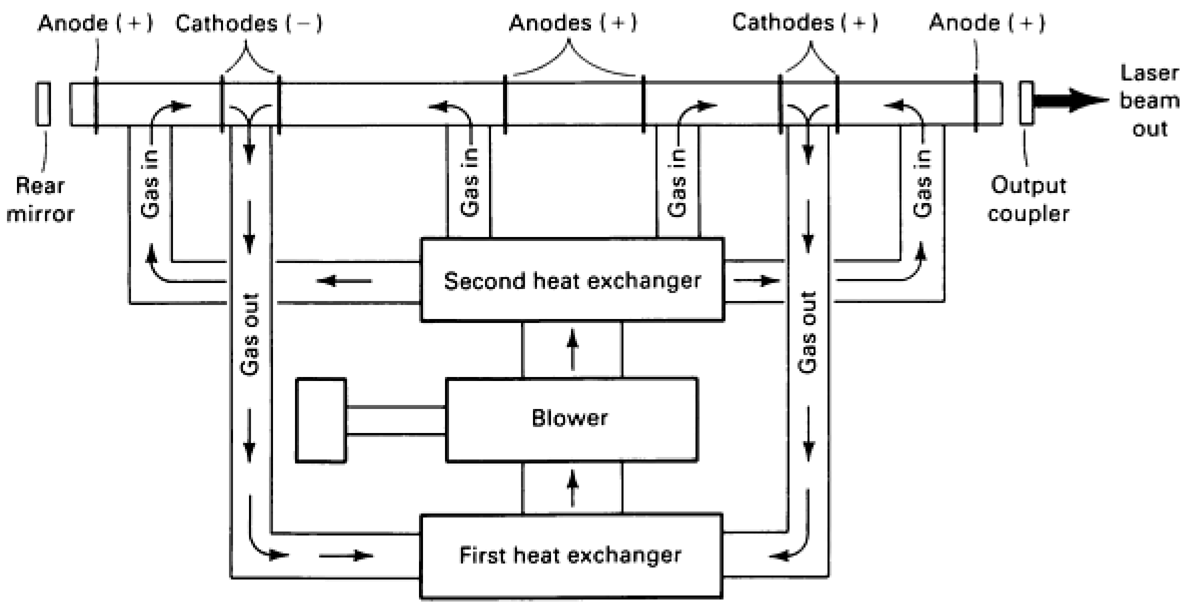

Fig. 4 Typical fast axial flow CO_2 laser.

Both the slow and fast axial flow lasers can operate in either the continuous wave (CW) or electronically pulsed modes. In CW operation, the laser operates at a continuous power level. This type of operation provides the highest cutting travel speeds. Because of the high speeds required to cut thinner material above 3175 mm/min (125 in./min), a loss of accuracy can occur on intricate parts because of motion system limitations. Overheating will also occur on any thickness if the part is very complex. The solution to these problems is to pulse the laser electronically, thereby allowing intermittent high peak powers (approximately two to eight times the peak CW power) and overall lower average powers, as shown in Fig. 5. This results in controlled heat input and higher accuracies, but at reduced feed rates, compared to CW operation. Typical pulse rates for CO_2 laser cutting range from 100 Hz to 1000 Hz.

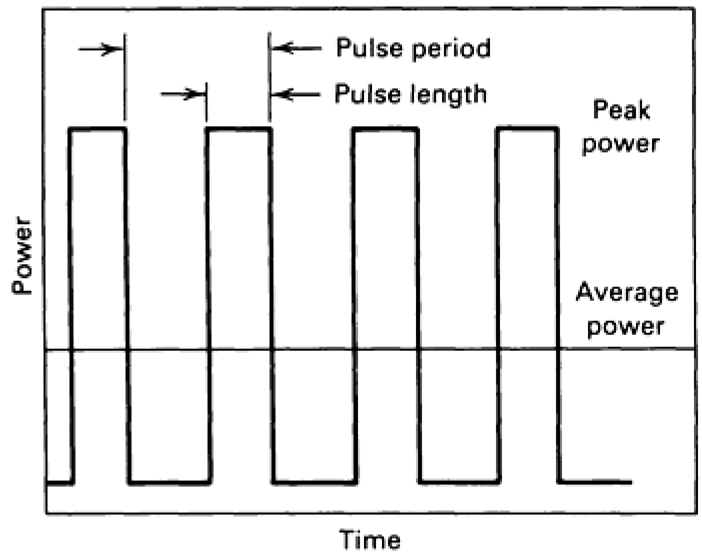

Fig. 5 Pulsed waveform.

The Nd-YAG is the second type of industrial laser. It is a solid-state laser in which the active medium is neodymium, which is dissolved in a matrix of yttrium aluminum garnet. The resulting crystal is formed into a rod, which is excited by external flash lamps using xenon or krypton. As the lamps flash, the light is absorbed by the rod, exciting the medium to emit photons. This laser uses the same type of two-mirror resonator described earlier. The Nd-YAG laser is a pulse-only laser with a cutting speed limited to about 762 mm/min (30 in./min). This laser also emits invisible infrared light, but with a wavelength of 1.06 μm (41.7 μin.), compared to 10.6 μm (417 μin.) for a CO_2 laser. Because of this shorter wavelength, the Nd-YAG beam is more readily absorbed by metals, and is therefore used to cut gold, silver, copper, platinum, and other metals that would be very reflective to a CO_2 laser. The Nd-YAG laser also does a superb job of drilling and trepanning small holes in metals and is typically used on aircraft jet engine parts made from high-temperature superalloys and titanium. Figure 6 shows a typical Nd-YAG laser system design.

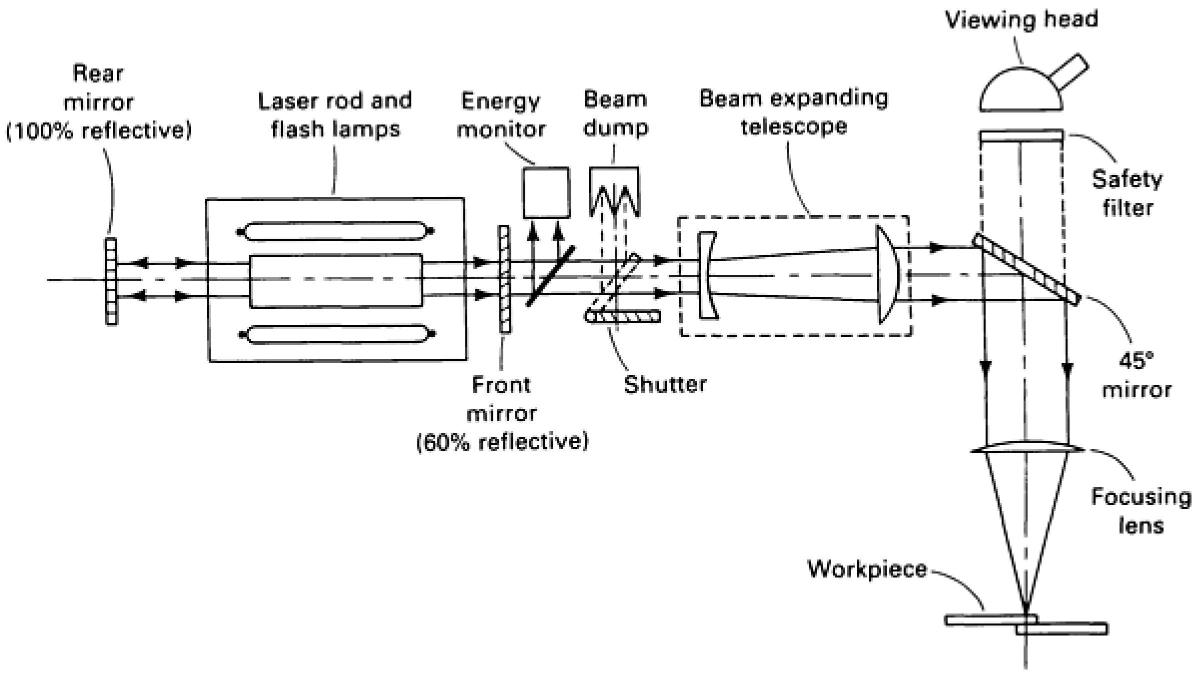

Fig. 6 Typical Nd-YAG laser design.

Competing Cutting Methods

The advantages and disadvantages of several conventional metal-shaping processes that compete with the laser are shown in Table 1. While the laser does not displace any of these processes in terms of their special capabilities, laser cutting does fill a very important void. For example, the laser is the ideal method for producing short-run or prototype blanked parts of large, complex or small, intricate shapes (see Fig. 7). The choice to laser cut these parts is based on cost. The expense of temporary tooling or edge finishing far exceeds the cost of laser cutting.

Table 1 Advantages and disadvantages of laser cutting versus traditional metal cutting methods

Cutting method	**Advantages**	Disadvantages
Laser	Good edge quality, good accuracy, small kerf, narrow HAZ, no distortion, little noise; cuts nonmetals, cuts small and complex shapes	**High equipment cost, limited to under 13 mm (0.5 in.) thick, slower feed rates over 6.4 mm (0.25 in.); cuts single layer**
Plasma arc	Lower equipment costs, faster feed rates over 6.4 mm (0.25 in.); cuts over 13 mm (0.5 in.) thick	**Lower accuracy, decreased edge quality, larger kerf, wider HAZ, noisy, higher operating costs; only cuts metal**
Laser	Good edge quality, good accuracy, lower scrap rate, no distortion, small kerf, no tooling or tool wear, increased part nesting; cuts complex shapes, cuts up to 13 mm (0.5 in.) thick, cuts tempered materials and nonmetals	**Higher equipment costs, lower process rate, higher costs on larger part quantities**
Nibbling (turret punch press)	Good process rate, lower equipment costs, economical on medium to high production runs	**Lower edge quality, high tool wear, high tooling costs, low accuracy, distortion, scrap; only cuts 10 mm (0.38 in.) thick**
Laser	Good edge quality, no tooling or dies, short setup times, rapid and low-cost design changes, noncontact cutting; cuts complex shapes and three-dimensional shapes, cuts tempered materials	**Higher equipment costs, low rate on high volumes**
Punch press	High volume rates; lower costs at high volumes; cuts over 13 mm (0.5 in.) thick	**Greater tool fabrication time, higher tool costs and maintenance, more setup time, poorer tool design, part stresses, lower edge quality; only cuts annealed steel**
Laser	High feed rate, economical on small and medium quantities; cuts nonmetals and nonconductive metals	**Lower edge quality, higher equipment costs, thickness limitations**
Wire electric discharge machining	Good edge quality, good accuracy, lower equipment costs, cuts over 13 mm (0.5 in.) thick, cuts very fine and complex shapes	**Very slow on any thickness, fixturing**

Laser	Narrow kerf, faster feed rates, good accuracy, good edge quality	**Small HAZ, fumes; cuts limited materials**
Abrasive water jet	No HAZ, cuts up to 152 mm (6 in.) material thickness, no distortion, cuts all materials	**Abrasive disposal, noisy, high-pressure plumbing, slow feed rates**
Laser	Flexibility, faster feed rate, short setup time	**Small HAZ, accuracy, high equipment costs**
Numerically controlled milling	**No HAZ, good accuracy, good edge quality, low equipment costs**	**Limited feed rate, high tool costs and maintenance**

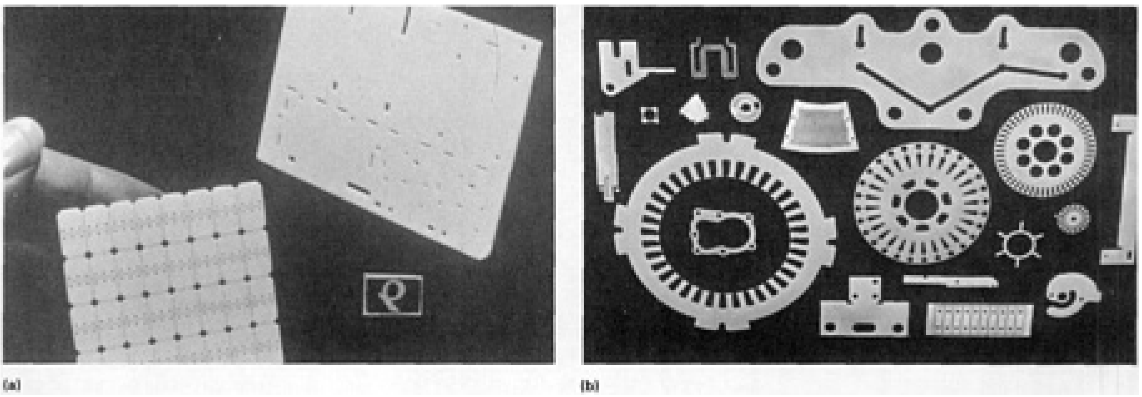

Fig. 7 Typical laser-cut parts. (a) Ceramic. (b) Metal.

A second, broader example is the cutting of industrial-quality circular saw blades. Several years ago a major manufacturer of such blades purchased a two-axis laser system to blank out the entire saw blade. These saw blades are being produced in sizes ranging from 50 mm (2 in.) to 915 mm (36 in.) in diameter, with an average order quantity of 22 pieces. Because of the small order quantity and the highly customized tooth profiles, many setups and operations were required to punch the geometries. However, by using the laser, which cut the saw geometry in just one operation, the manufacturer was able to reduce the cost on many items up to 30% over conventional punching, milling, turning, and blanking methods.

Laser cutting does have limitations for many applications. In the case of the heat-affected zone and fusion layer present in some aerospace hardware, laser cutting can only be used to produce a semifinished part that requires further processing using a different method.

Laser cutting advantages and disadvantages must be carefully considered for each particular application before deciding whether use of the laser is advantageous. Because applications are too far-ranging to generalize, in-depth information should be obtained from a laser manufacturer, systems house, laser job shop, or consultant.

Laser Cutting

Gregg P. Simpson, Peerless Laser Processors Division, Peerless Saw Company; Thomas J. Culkin, Lumonics Materials Processing Corporation

General Cutting Principles

The mechanism for cutting steel with a laser is basically the same as cutting steel with an oxygen-fuel process in which the fuel gas acts to heat the material so the oxygen can oxidize and react exothermically with the steel to produce the cutting action. The oxygen also helps to sweep the molten material out of the kerf. In laser cutting, the fuel gas is replaced with a laser beam focused to about 0.1 mm (0.004 in.), resulting in a power density of 1 MW/cm^2 (6.5 MW/in.^{2}). It is this characteristic that allows a 3.94 mm (0.155 in.) thick alloy steel chain saw bar to be cut out at 2.54 m/min (100 in./min) with a 0.15 mm (0.006 in.) kerf width and without part distortion.

Laser cutting can also be accomplished on nonferrous and nonmetallic materials using assist gases. In the case of nonferrous metals (aluminum, copper, brass, and bronze), which have high thermal conductivities, but do not react with assist gases and are reflective to the laser beam, cutting occurs when the laser beam heats the material well above its melting point, and an assist gas, such as air, argon, or helium, is used to sweep the molten material out of the cut. The inert gases are used only when the cut edge of the material must be free of any impurities that would reduce its serviceability in a very harsh environment.

In the case of nonmetallic materials with low thermal conductivities and high beam absorption, such as wood, cloth, and paper, vaporization of the material upon cutting is nearly 100%. Because material vapors have a tendency to rise, an assist gas, such as compressed air, is used at a low pressure to protect the focusing lens from the damaging vapors. Organic materials such as plastics and woods are also cut with lower gas pressures. Acrylic plastic will yield a fine polished edge if cut with an inert gas or compressed air at 70 kPa (10 psi) pressure. Table 2 summarizes the general purposes of assist gases.

Table 2 Assist gas usage

Gas	**Major function**	Usage
Oxygen	Promotes chemical reaction	**Cutting ferrous metals**
Argon, helium, and nitrogen	Inhibit chemical reaction	**Cutting thin metal for oxide-free edge; cutting chemically reactive metals and materials**
Air and inert gases	**Remove excess by-products**	**Lens protection, absorptive plume removal; cooling to clear hot gases away from thermally sensitive materials; cutting nonmetals**

Process Variables. There are seven basic parameters in the laser-cutting process: beam quality (mode), power (CW or pulse), travel speed, assist gas, nozzles, focusing lens, and focal-point position. Slight changes in any one of these parameters can yield significant changes in cut quality. To fine-tune excellent cut quality, it is recommended that only one parameter at a time be varied, while the others remain constant.

Beam quality, or mode, is a very important parameter. A laser should be used with a TEM_{00} or Gaussian mode, which is ideal for cutting (Fig. 8a). A Gaussian mode has most of its energy in its center. Figures 8(b) and 8(c) illustrate the power density versus the radial distance from the beam centerline for both TEM_{00} and TEM_{01*} modes. The TEM_{00} mode can be focused to a smaller spot size than can TEM_{01*}, and has greater energy density of power per unit area, thereby increasing cutting efficiency. This TEM_{00} mode decreases the heat input to the part, which allows faster cutting speeds and a smaller heat-affected zone (HAZ). Because the beam can be focused to a smaller spot size, kerf width is also reduced.

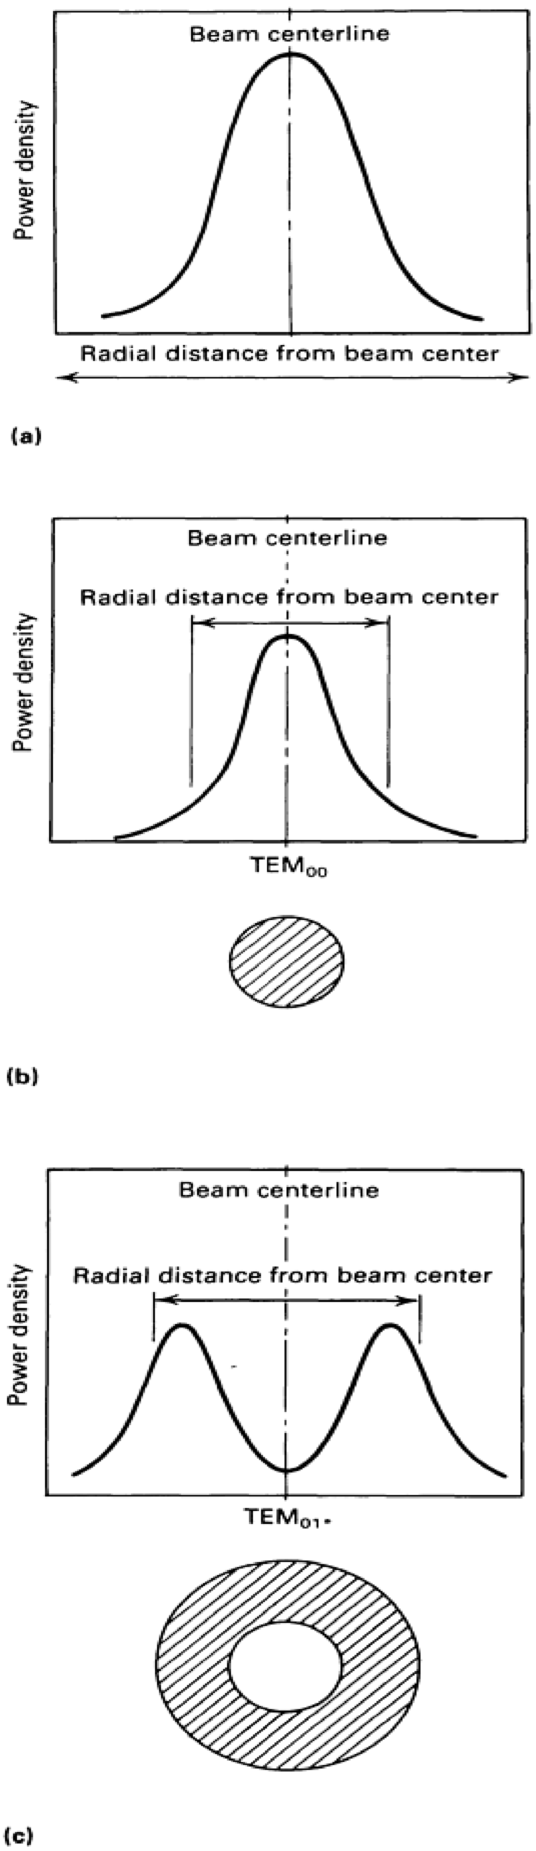

Fig. 8 (a) TEM_{00} or Gaussian mode energy distribution. (b) TEM_{00} power density (sharp tool). (c) TEM_{01*} power

density (blunt tool).

Power plays a significant role in respect to both feed rates and thicknesses. For example, Fig. 9 shows that increasing power increases speed and thickness for a given material, while holding all other parameters constant. Figure 9 also shows that the maximum material thickness to be cut also increases with increasing power. When pulse cutting is used, the average powers decrease, while the peak powers of each pulse increase from two to eight times the maximum CW power. This reduction of average power reduces the feed rate by about 60 to 80%.

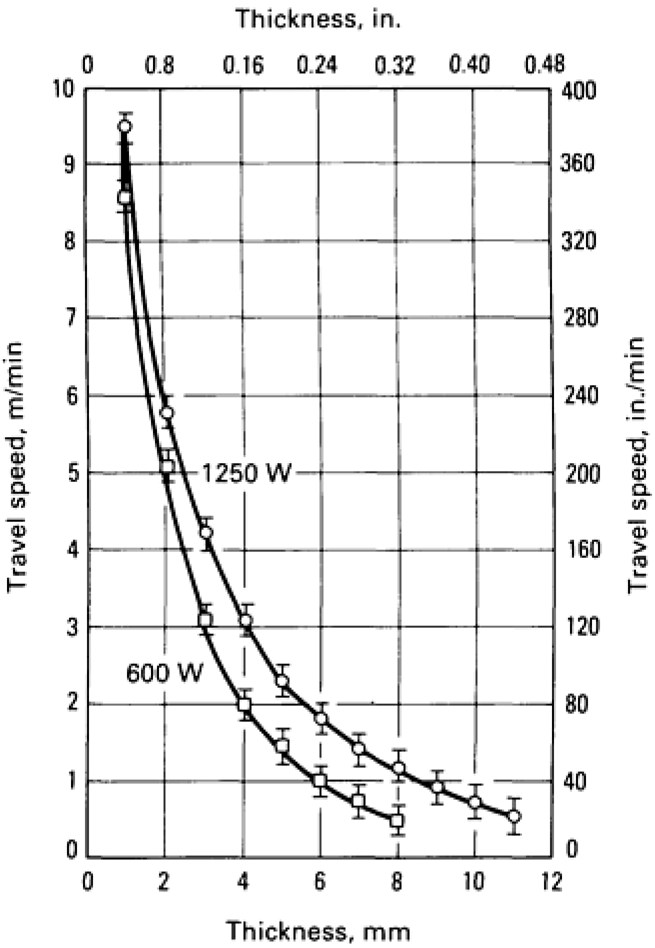

Fig. 9 Travel speed versus thickness for 600 W and 1250 W CO_2 lasers. Focused power at workpiece using 65 mm ($2\frac{1}{2}$ in.) focal length lens. Oxygen assist gas at 350 kPa (50 psi). Carbon and alloy steels used.

An optimum travel speed exists that yields the best cut quality, while holding all other parameters constant. Because feed rate is very material dependent, experimentation is needed in order to obtain the best results. However, for most metals, the best cut is obtained at the maximum achievable speed, which also helps to minimize the HAZ. If the feed rate is too low, burning will occur and a large HAZ with slag formation will be present. In nonmetals such as wood or cloth, excessive charring will be present on the cut face. If the feed rate is too fast, the beam will climb out of the cut and only partial cutting will occur.

Use of oxygen as the assist gas for cutting steel and stainless steel increases cutting speeds by 20 to 40% compared to use of air. Air is used mostly to cut nonmetals because it helps reduce oxidation and burning. When cutting stainless steel with an oxygen assist gas, slag or a fusion layer occurs, which is not tolerable in some applications. Although argon or helium assist gases eliminate oxidation, they reduce travel speeds by up to 50%.

The gas nozzle design and standoff distance, which is the distance between the workpiece and the nozzle, can significantly affect cut quality. A property designed nozzle will produce a laminar, high flow rate assist gas through the cut. The laminar flow can be affected by the standoff distance. If the standoff distance is too great, the smoothly flowing gas tends to break up. This disrupts the flow through the kerf and decreases the edge quality. Typical nozzle diameters are 1 to 2 mm (0.040 to 0.080 in.) with 0.5 to 3 mm (0.020 to 0.12 in.) standoff distances.

A focusing lens is used to focus the beam on the workpiece. This increases the power density of the beam. The lens is used because the output beam of a laser is typically 11 to 21 mm ($\frac{7}{16}$ to $\frac{13}{16}$ in.) in diameter and does not possess enough energy per unit area to melt and vaporize materials. The lens can focus the beam to a spot size of 0.1 mm (0.004 in.) in diameter. The same principle is in operation as when using a magnifying glass to focus sunlight on a piece of paper, causing it to burn.

Lenses are classified by focal length, or the distance from the lens to the point at which the spot size is smallest (Fig. 10). Typical lenses come with focal lengths that range from 38 to 254 mm (1.5 to 10 in.). Shorter focal length lenses, have higher energy densities because they have a smaller spot size, as shown in Fig. 11. These lenses, however, have a limited depth of field, or usable beam. Depth of field is the area of the focused beam that has enough energy density to process materials. This spot size limitation can be offset by using a larger input beam on a longer focal length lens, as shown in Fig. 12. Short lenses are typically used on reflective materials, such as aluminum, or on thin materials, for faster feed rates and an improved surface finish. Longer focal length lenses are usually used on materials 6.4 mm (0.25 in.) or more thick because of their greater depth of field, which produces a squarer cut and sharper geometry definition at the bottom of the cut. Because of increased spot size, these lenses decrease feed rate, and overall surface finish quality, while increasing the HAZ. Most lenses in use are between 64 and 127 mm (2.5 and 5.0 in.) in focal lengths.

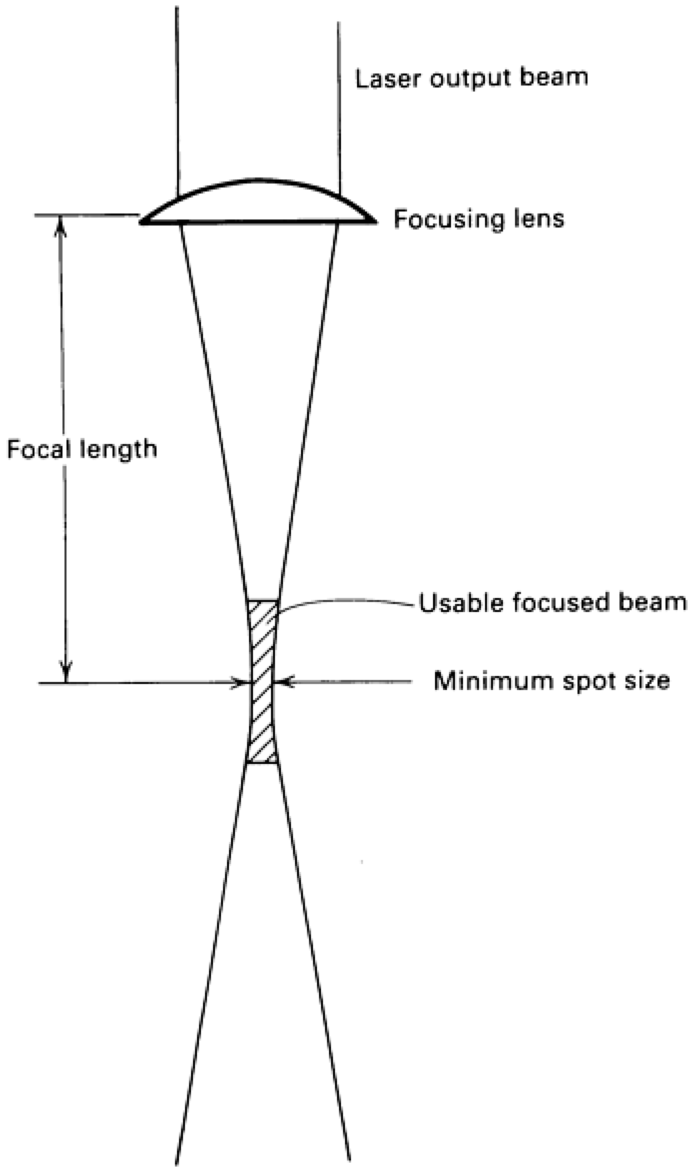

Fig. 10 Geometry of focused beam.

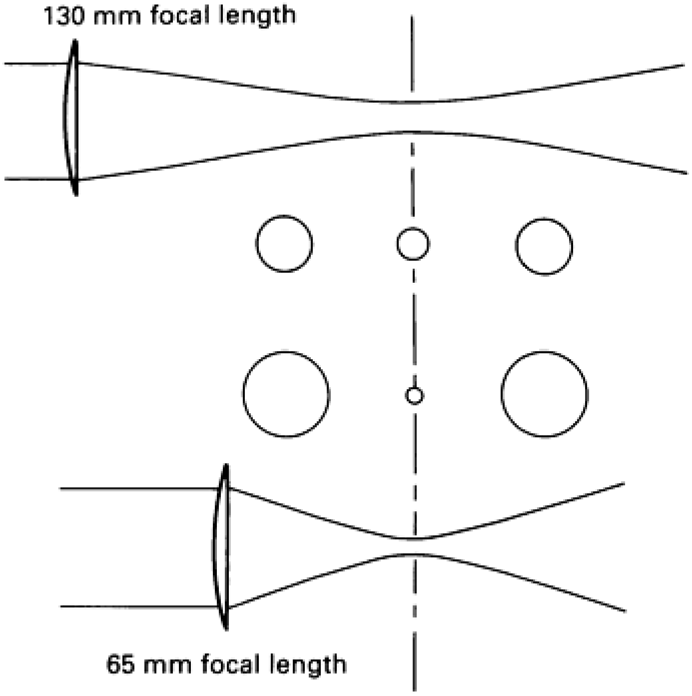

Fig. 11 Beam diameters at equal distances from focus position for lenses of different focal length.

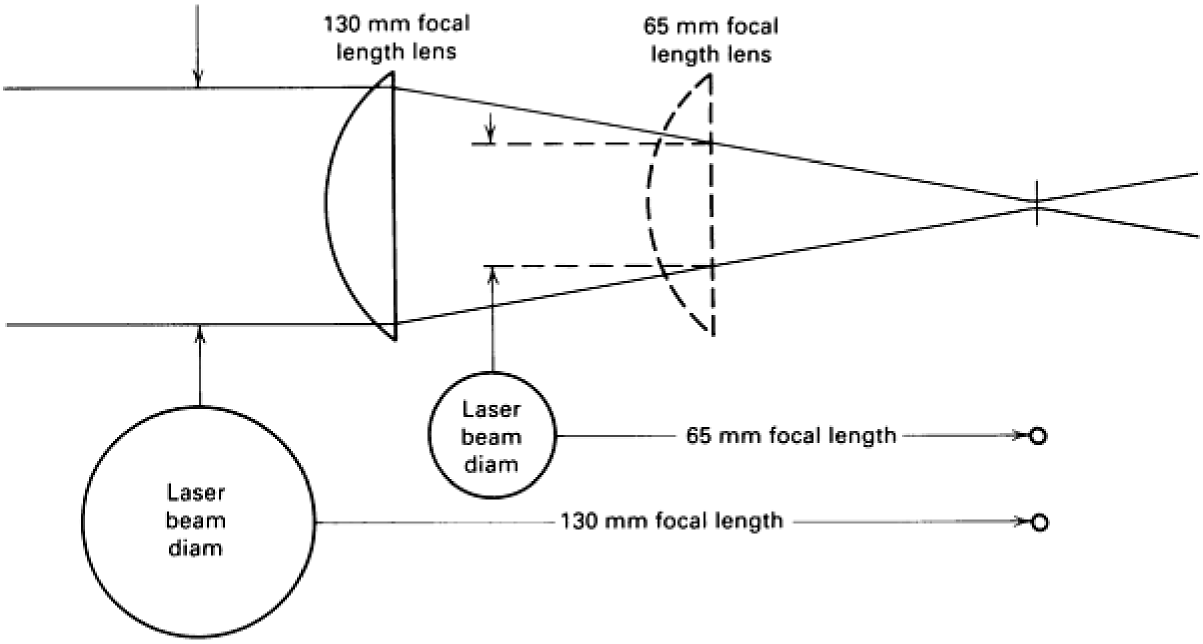

Fig. 12 Beam expansion for some spot size.

The focal point position greatly affects the surface finish and dimensional accuracy of the part. Accuracy is affected because the beam is never parallel (Fig. 11); hence, as the focal point is moved to different positions, the kerf width can increase or decrease. This effect must be considered when cutting high-accuracy parts.

Surface finish is very dependent on the focal point. For the majority of metals, the focal point is set slightly below the work surface. For other materials, such as stainless steels, the focus is set well below the surface of the material to yield the best cut. However, the focal position itself is very dependent on the type of material and other process parameters and therefore must be manipulated to find the optimum setting.

Material Conditions. Several material conditions can affect the quality of the laser cut. First, surface cleanliness can have a detrimental effect on edge quality. All steel alloys should be either hot rolled, pickled, and oiled; or cold rolled. Mill scale, which can interfere with the beam, greatly reduces edge quality and dimensional accuracy. Rusted steel also decreases cut quality. No other special cleaning methods are required.

Second, flatness of the material to be cut affects the focal point of the beam. The focal point must be controlled to ±0.25 mm (0.010 in.) to achieve the best possible cut. Increasing surface roughness can deflect the assist gas, resulting in a nonlaminar assist gas flow, thereby decreasing edge quality. Most sheet steel is smooth enough to be laser cut.

Third, coatings on the material surface usually have no adverse effect on cutting. Thin layers of plastic on metal surfaces are cut without problem, although proper fume collection procedures must be used. Electrogalvanized steel can be laser cut provided that the galvanized layer is thin. Again, it is recommended that fume collection be used. Steels with paint on one surface should be cut without oxygen because a paint-oxygen reaction produces a very poor cut.

Finally, the ambient temperature of materials must be taken into consideration. Because carbon steels react exothermically with oxygen at low temperatures of approximately 40 °C (104 °F), high ambient temperatures result in a cut with wide, rough, low dimensional accuracy. This effect also must be taken into account when cutting very intricate geometries in carbon steels. However, pulse cutting at reduced feed rates reduces the heat input and allows satisfactory cutting of very small and intricate shapes.

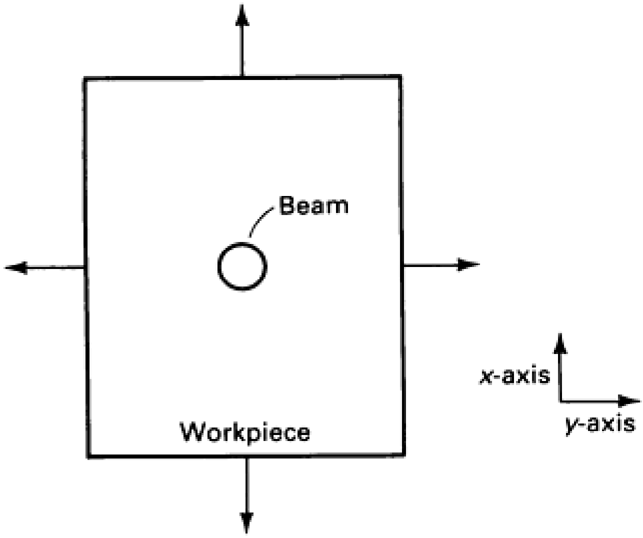
Laser Cutting

Gregg P. Simpson, Peerless Laser Processors Division, Peerless Saw Company; Thomas J. Culkin, Lumonics Materials Processing Corporation

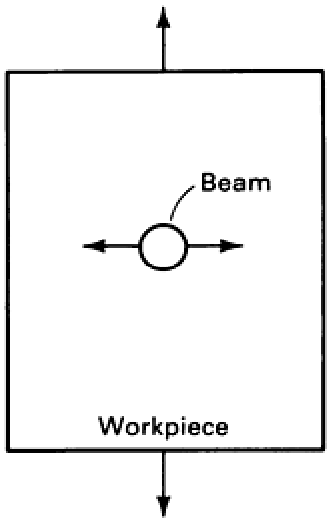
System Equipment

The basic laser-cutting system consists of a laser, a motion system, a controller that is computer numerically controlled (CNC), and a beam delivery system. Optional equipment includes water chillers, dust/fume collectors, compressed air equipment, transformers and related electrical equipment, and a computer-aided design/computer-aided manufacturing (CAD/CAM) system. Typical costs for an installed system can range from $100,000 for a small, two-axis cutting system to almost $1 million for a large, five-axis cutting system.

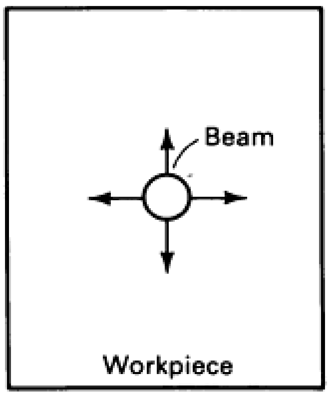
Many styles and sizes of motion systems are available. The most popular is the *x-y* axis table system. The *x-y* motion is coordinated by a CNC controller and is used to blank contours out of flat sheet stock. These systems range in size from 305 × 305 mm (12 × 12 in.) to 1.6 × 3.0 m (63 × 120 in.) for a large-bed sheet-cutting system. These two-axis motion systems are available in three styles, each of which manipulates the workpiece and/or beam differently in the course of contouring a part, as shown in Fig. 13.



(a)



(b)



(c)

Fig. 13 Three types of two-axis motion systems. (a) Moving *x-y* table, stationary beam. (b) Moving *x*-axis table, moving *y*-axis beam. (c) Moving *x-y* beam, stationary table.

The first system, shown in Fig. 13(a), has a moving workpiece and a stationary beam, which is the simplest and least costly system. Motion systems of this type usually provide the highest accuracies for laser cutting. For cutting areas larger than 1.2 × 1.2 m (48 × 48 in.), the mass of a 2-axis table system becomes large and therefore reduces travel speeds and accuracies. For large-sheet cutting requirements, it is advantageous to move the workpiece in one axis, while moving the beam and cutting head assembly in the other axis, as shown in Fig. 13(b). This allows for significantly less mass movement on the motion system, while incorporating some floor space savings. For systems that are 1.2 × 2.4 m (48 × 96 in.) or larger, it is more common to move the beam and optics on a gantry-style motion system, as shown in Fig. 13(c). These systems do, however, require more attention to beam alignment. A moving optics system can also be used on smaller systems in which the parts are too heavy to move accurately, or on assembly lines.

Most laser-cutting systems usually employ some type of floating third, or *z*, axis to allow the focused beam to be introduced to the workpiece, because a workpiece is not usually perfectly flat. These floating cutting heads sense height changes through contact and non-contact methods. Figure 14 shows a contact method using roller balls.

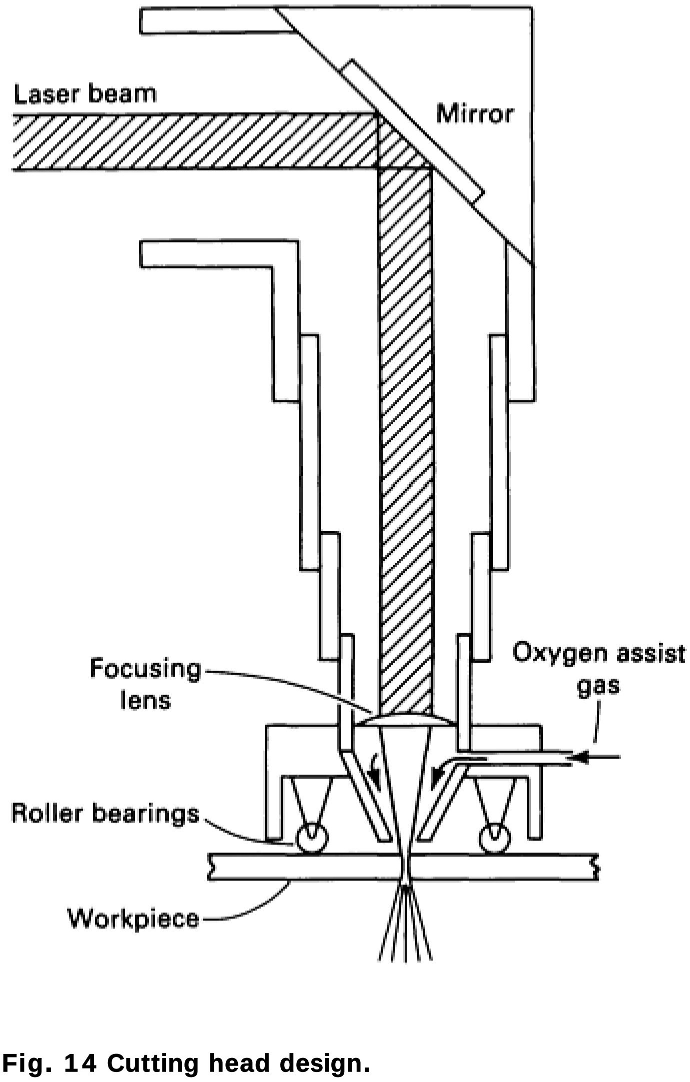


Fig. 14 Cutting head design.

Other types of motion systems have three, five, seven, and nine axes of programmable motion. The three-axis systems have either a programmable *z* or a rotary axis. The *z*-axis allows cutting on parts with different heights, whereas a rotary axis allows contour cutting of tubing. The five-axis gantry-style motion systems incorporate *x*, *y*, and *z* axes, with a wrist on the *z*-axis. A wrist is a set of orthogonal rotating mirrors providing increased beam manipulation. This system allows contour cutting on formed parts and is necessary because the beam must be normal to the surface being cut. Typical applications are the trimming of stamped parts such as automotive and motorcycle fenders. In specialized cases, a nine-axis robot can manipulate either the beam or the workpiece. Some applications include cutting holes for sunroofs in auto assembly lines or other types of ventilation.

A CNC controller is used to coordinate the motion and the laser operation. The controller reads standard NC programs that describe the contour to be cut. The NC programs are prepared with a CAD/CAM system. Then either the NC file is punched on paper tape and read into the controller by a tape reader, or a number of other methods including floppy disks, erasable programmable read-only memories, and a direct numerical control between the controller and the off-line computer.

A dust/fume collecting system should be installed: laser cutting of metallics produces dust, which should be removed, while non-metallics can produce smoke and fumes, which can be irritating and/or hazardous and likewise should be removed from the work area. Optional equipment includes a water chiller to cool the laser and external optics, transformers for proper electrical supply, and compressed dry air for the beam delivery and assist gas.

Laser Cutting

Laser-Cutting Applications

Virtually any metal can be laser cut. The conditions for cutting some metals, however, are difficult to obtain. Following is a general description of how well each metal group can be cut.

All carbon and alloy steels can be laser cut to over 13 mm (0.50 in.) thick with an oxygen assist gas. As Fig. 9 shows, the feed rates are dependent on available power at the workpiece. A general rule of thumb is that for a given thickness, the feed rate increases about 50% when power is doubled. The resulting kerfs can be as small as 0.1 mm (0.004 in.) thick with a 65 mm ($2\frac{1}{2}$ in.) focal length lens. The resulting HAZ is small (about 0.1 to 0.3 mm, or 0.004 to 0.012 in.), depending on thickness and speed. The edges are clean, smooth, and square.

Higher-carbon steel exhibits an improved edge quality, although the HAZ is slightly larger and harder. Impurities of phosphorus and sulfur can cause some edge burning: Lower-quality steels exhibit this edge burning, whereas alloy steels generally do not. In fact, the alloy steels, such as chrome-nickel-moly (for example, 4340), and chrome-moly (for example, 4130), are perfect candidates for extremely high quality edges that are very smooth and clean. These steels do, however, require about 50% more time to pulse a starting hole than is the case with a similar thickness of plain carbon steel. Another consideration is that the HAZ is slightly larger and harder (about 45 to 60 HRC) depending on the alloy and carbon content. This means that further processing can be difficult on the laser-cut edges unless they are annealed.

Laser-cut tool steels have almost the same results. The exceptions are the alloys that have very dense alloying elements, such as tungsten. These alloys retain a large amount of heat when molten, which helps to limit thickness and produce very rough cuts having heavy slag deposits. The air- and oil-hardened alloys exhibit very good edge quality and can be cut up to 10.2 mm (0.400 in.) thick at about 0.8 m/min (32 in./min) at 1300 W. Alloys such as D-2 and M-2 can only be cut up to about 4 mm (0.160 in.) thick with the same power.

Stainless steel alloys are also readily cut using a laser. The feed rates are reduced, however, because these alloys do not react as effectively with oxygen as carbon steel alloys do. An inert assist gas may be used to obtain a weld-ready edge, free of all oxides, at the expense of about one-half the oxygen-assisted speed. Stainless steels maintain their corrosion resistance because the HAZ is small.

In general, the ferritic (400 series) stainless steels produce smoother cuts with less slag than austenitic (300 series) stainless steels do. These stainless alloys do not contain nickel and can be cut to about 6.5 mm (0.260 in.) thick.

The added presence of nickel does affect the energy coupling and heat transfer in the alloy. This means that these alloys are not effectively laser cut above 5 mm (0.197 in.) thick. The viscosity of the molten nickel is very high and has a tendency to migrate and adhere to the bottom of the cut. This increases the heat in the metal and produces a large HAZ, as well as a rough cut starting approximately one-third to one-half the way through the material. This effect can be reduced by using high-pressure assist gas jets or rapid-cooling methods (such as water) in the cut.

Nonferrous Alloys. Aluminum alloys can readily be laser cut, but only to about 4 mm (0.160 in.) thick. The thickness is limited because aluminum has high reflectivity at infrared wavelengths and high thermal conductivity. To overcome these effects, the laser must have a TEM_{00} mode, which allows for tighter focusing and higher power outputs, that is, 500 W or more. To further improve the cutting, short focal length lenses and high assist gas pressures help reduce and/or eliminate slag that forms when molten material is blown to the back side of the cut and solidifies; the slag is very easily removed. Feed rates are generally 25% slower than when laser cutting stainless steels.

Copper, brass, and bronze are even more reflective and heat conductive than is aluminum. Because brass and bronze are alloys of copper, they can be laser cut, but with limited thickness and speed. The cuts can be rough, and a slag is present on the bottom of the cut. Copper has been cut under ideal conditions in thicknesses up to 6.35 mm (0.25 in.) with 1200 W. The speeds are extremely slow, so practical upper cutting is limited to about 2.6 mm (0.100 in.).

Other high-tech alloys can also be laser cut. Titanium cuts very well up to about 7 mm (0.275 in.) thick. An inert assist gas is usually employed to prevent an oxide layer from forming. Oxygen can be used, but because titanium reacts very strongly with it, high feed rates are needed to prevent burning the material.

Nonmetal Cutting. Most nonmetals rely on the same technique for laser cutting. The cutting action is dependent on the ability of the laser beam to be absorbed by and to vaporize the material being cut. Because the cut does not rely on an oxidation reaction, as in steel cutting, the laser vaporizes the material with the aid of an assist gas (either inert gas or compressed air) to help purge the cut of the vaporized material. The CO_2 laser is typically preferred for nonmetal cutting because of its good absorption by many materials and its high cutting speeds.

Acrylic is easily cut with the CO_2 laser. Thicknesses up to 50 mm (2 in.) have been cut for aircraft windshields, but most work is done at thicknesses of about 6.4 mm (0.25 in.), while a 150 W unit provides speeds of 1.25 m/min (50 in./min). The cut edge is usually frosted at these speeds. A fine polished edge is attainable in acrylic at about half speed with very low assist gas pressure.

Quartz and nontempered glass are commonly cut for a variety of applications. The edge quality of glass is rough compared to laser cuts in most other materials, at speeds up to 2.5 m/min (100 in./min) for a 3 mm (0.10 in.) thickness using a 600-W CO_2 laser, and about 5 m/min (200 in./min) for a 1200 W unit.

Quartz, on the other hand, cuts with a fine, clean edge with speeds of 5 m/min (200 in./min) for 1 mm (0.040 in.) thick material and 1 m/min (40 in./min) for 3 mm at the 600 W level.

Ceramic of 96% Al_2O_3 (alumina) is used for electronic substrates and is very brittle; the noncontact cutting characteristic of the laser therefore makes it the preferred method. The laser is used in the pulse mode to minimize heat input to the part. A high-quality edge is produced at 0.5 m/min (20 in./min) for alumina substrates up to 1 mm (0.04 in.) and 0.25 m/min (10 in./min) in the 1 to 2 mm (0.04 to 0.08 in.) range with a 500 W CO_2 laser in the pulsed mode.

Aramid fibers have tensile strengths that exceed those of steel. The fiber is woven into sheets for use as bullet-proof vests and is bonded in layers with epoxy for structural aircraft parts. Its high strength makes it very difficult to cut with conventional cutting methods. The CO_2 laser cuts with high travel speeds and can bond the cut edges of aramid and most other woven fabrics to prevent fraying. Aramid, bonded in layers with epoxy, can be cut in thicknesses up to 10 mm (0.40 in.). Because of the nature of the epoxy, the cut edge of the aramid-epoxy composite is darkened upon laser cutting. This is more pronounced in thicker samples with heavy epoxy layers. At the 600 W level, typical speeds are 12.75 m/min (500 in./min) for 1.25 mm (0.05 in.) thick material and about 7.75 m/min (300 in./min) for 3 mm (0.10 in.) aramid-epoxy composites.

Intricate shapes can be cut from wood with thicknesses well over 25 mm (1.0 in.). A solid wood product cuts very nicely and leaves a smooth but darkened edge. A popular application is cutting patterns in 15 to 19 mm (0.60 to 0.75 in.) beech plywood for steel rule die boards. Speed and focus changes create different width slots for different width blades (up to about 2 mm, or 0.08 in.). Therefore, speeds range from 0.5 to 1.8 m/min (20 to 70 in./min) for a 600 W CO_2 laser.

The laser is becoming an increasingly popular machine tool because of its flexibility in material processing. However, laser technology is still a relatively new manufacturing process and much education is still necessary in the industrial sector before its advantages can be fully realized.

Abrasive Waterjet Cutting

J. Gerin Sylvia, Department of Industrial and Manufacturing Engineering, University of Rhode Island

Introduction

ABRASIVE WATERJET CUTTING operates by the impingement of a high-velocity abrasive-laden fluid jet against the workpiece, yet it produces no heat (and therefore no heat-affected zone) to degrade metals or other materials. The finished edge obtained by the process often eliminates the need for postmachining to improve surface finish.

A coherent fluid jet is formed by forcing high-pressure abrasive-laden water through a tiny sapphire orifice. The accelerated jet exiting the nozzle travels at more than twice the speed of sound and cuts as it passes through the workpiece. Cuts can be initiated at any point on the workpiece and can be made in any direction of contour--linear or tangential. The narrow kerf produced by the stream results in neither delamination nor thermal or nonthermal stresses along the cutting path.

In addition to applications in the machining of superalloys; armor plate; titanium; and high-nickel, -chromium, and -molybdenum alloys, abrasive waterjet machining can also be used to cut concrete, rock, glass, ceramics, composites, and plastics. The ability of the abrasive waterjet to cut most metals without any thermal or mechanical distortion places this innovative process on the leading edge of material cutting technology.

Development of Abrasive Waterjet Technology. In 1968, Dr. Norman Franz filed his first patents on the use of high-pressure water streams to cut materials. The first commercial application of this process, in 1971, involved the cutting of 9.5 mm ($\frac{3}{8}$ in.) thick pressed board for manufacturing furniture forms. Since then, numerous waterjet units have been installed by various manufacturers worldwide. Waterjet cutting technology, which involves pumping a 0.08 to 0.46 mm (0.003 to 0.018 in.) diam water stream at 207 to 414 MPa (30 to 60 ksi), was initially developed to cut or slit nonwoven materials, fiberglass building products, corrugated box materials, and plastics.

It was later found that hard or extremely dense materials such as metals and aerospace composites could be cut when particles of dry abrasives such as garnet and silica were added to the waterjet. This modification produced the abrasive waterjet and is responsible for the ability to cut advanced materials much more efficiently than with standard mechanical or thermal cutting methods. With abrasives added to the waterjet, the liquid stream itself is merely the medium that propels the abrasive instead of being the primary cutting force.

Abrasive waterjet cutting is used to cut metals and composite materials, such as boron/aluminum honeycomb, aluminum/boron carbide, and graphite composites, into intricate shapes and curves with virtually no heat input into the workpiece. It has been in use in industrial applications since 1983.

Metals and advanced composites developed for use in the aerospace industry are among the most difficult-to-machine materials. Whether hard as steel or flexible as rubber, these materials must be able to withstand the stresses of supersonic flight. Ironically, the same properties that make space-age materials invaluable for aerospace applications also make them all but impossible to machine. Reciprocating or ultrasonic knives can be used to cut uncured epoxy-base composites, but not the finished components. The cutting rates provided by lasers and plasma arc systems are adequate, but their extreme heat changes the chemical composition of the composite materials and leaves a heat-affected zone in metal-matrix materials.

Abrasive waterjet technology eliminates the problems of delamination and frayed areas, which add to the cost of machining. This elimination of secondary machining has spurred interest in this technology and has accelerated its development.

Advantages. The advantages of abrasive waterjet machining are summarized as follows:

- Ability to cut through most sections of dense or hard materials, such as metals and glass, leaving a clean, finished edge--3.2 to 6.3 μm (125 to 250 μin.) roughness with 60, 80, or 100 grit abrasive at 0.22 to 1.1 kg/min (0.5 to 2.5 lb/min)--without the need for secondary machining
- Ability to produce contours, shape-cutting, bevels of any angle, and three-dimensional profiling, because the process is omnidirectional
- Easy integration into computer-controlled systems, optical tracers, and full-scale six-axis robots. The cutting head weighs as little as 4.5 kg (10 lb) for easy mounting on robotic arms; precision robotics can accommodate cutting heads weighing 23 to 32 kg (50 to 70 lb)
- Wide availability and low cost of garnet and silica, the most common abrasive materials used
- Low water consumption (0.473 L/min, or 0.125 gal./min), which translates to 28 L/h (7.5 gal./h) despite the high pressures used

Limitations. This device cannot replace tools that mill, turn, or drill blind holes or perform other operations that involve cutting or drilling to a partial depth. Glass and composite materials should be pierced at low pressures (70 to 83 MPa, or 10 to 12 ksi) to minimize chipping and delamination. Tempered glass is an example of one material that should not be machined with an abrasive waterjet.

Abrasive Waterjet Cutting

J. Gerin Sylvia, Department of Industrial and Manufacturing Engineering, University of Rhode Island

Operating Principles and Abrasive System Components

A hand-held abrasive waterjet unit can be used, but accuracy and quality are compromised because of human instability. The abrasive nozzle must be held firmly and accurately, and the standoff of the nozzle, as well as the rate of cut, must be closely controlled. Modern abrasive waterjet installations require a six-axis servo-type robot, such as the IRb-60 (Fig. 1), that is programmed for point-to-point linear movements in which arcs or circles are approximated by numerous short straight-line segments.

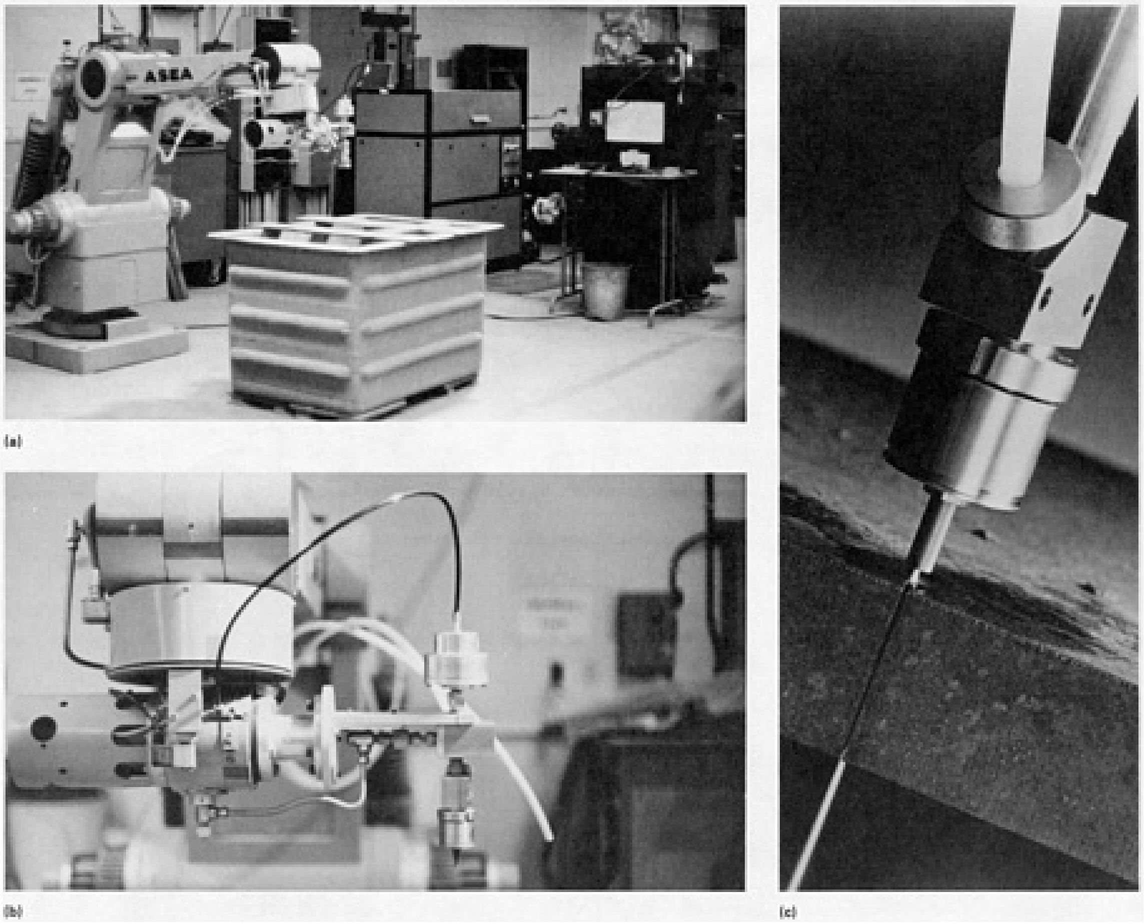

Fig. 1 State-of-the-art abrasive waterjet installation. (a) IRb-60 robot with containment tank. High-pressure pump is shown to the right of the robot. Robot controller is to right of tank. (b) Abrasive waterjet nozzle assembly mounted on IRb-60 robot arm to interface with robot. Black air line on top is connected to electric solenoid located on robot arm. High-pressure water line attaches at center-left of nozzle and flexes as robot arm moves and rotates. Cutting Principle

The abrasive waterjet cuts material by the action of abrasive solids (entrained by the waterjet) on the workpiece. Depending on the properties of the material, cutting occurs by erosion, shearing, failure under rapidly changing localized stress fields, or micromachining effects. A small abrasive jet nozzle is used (Fig. 2). Water is pressurized to 414 MPa (60 ksi) and expelled through a sapphire nozzle to form a coherent high-velocity (914 m/s, or 3000 ft/s) jet. A stream of abrasive particles is introduced into the nozzle to form a concentrated abrasive jet slurry (0.5 to 2.5 kg/L, or 4 to 20 lb/gal.). The momentum of the waterjet as it travels toward the nozzle is transferred to the solid particles, and thus their velocities are rapidly increased.

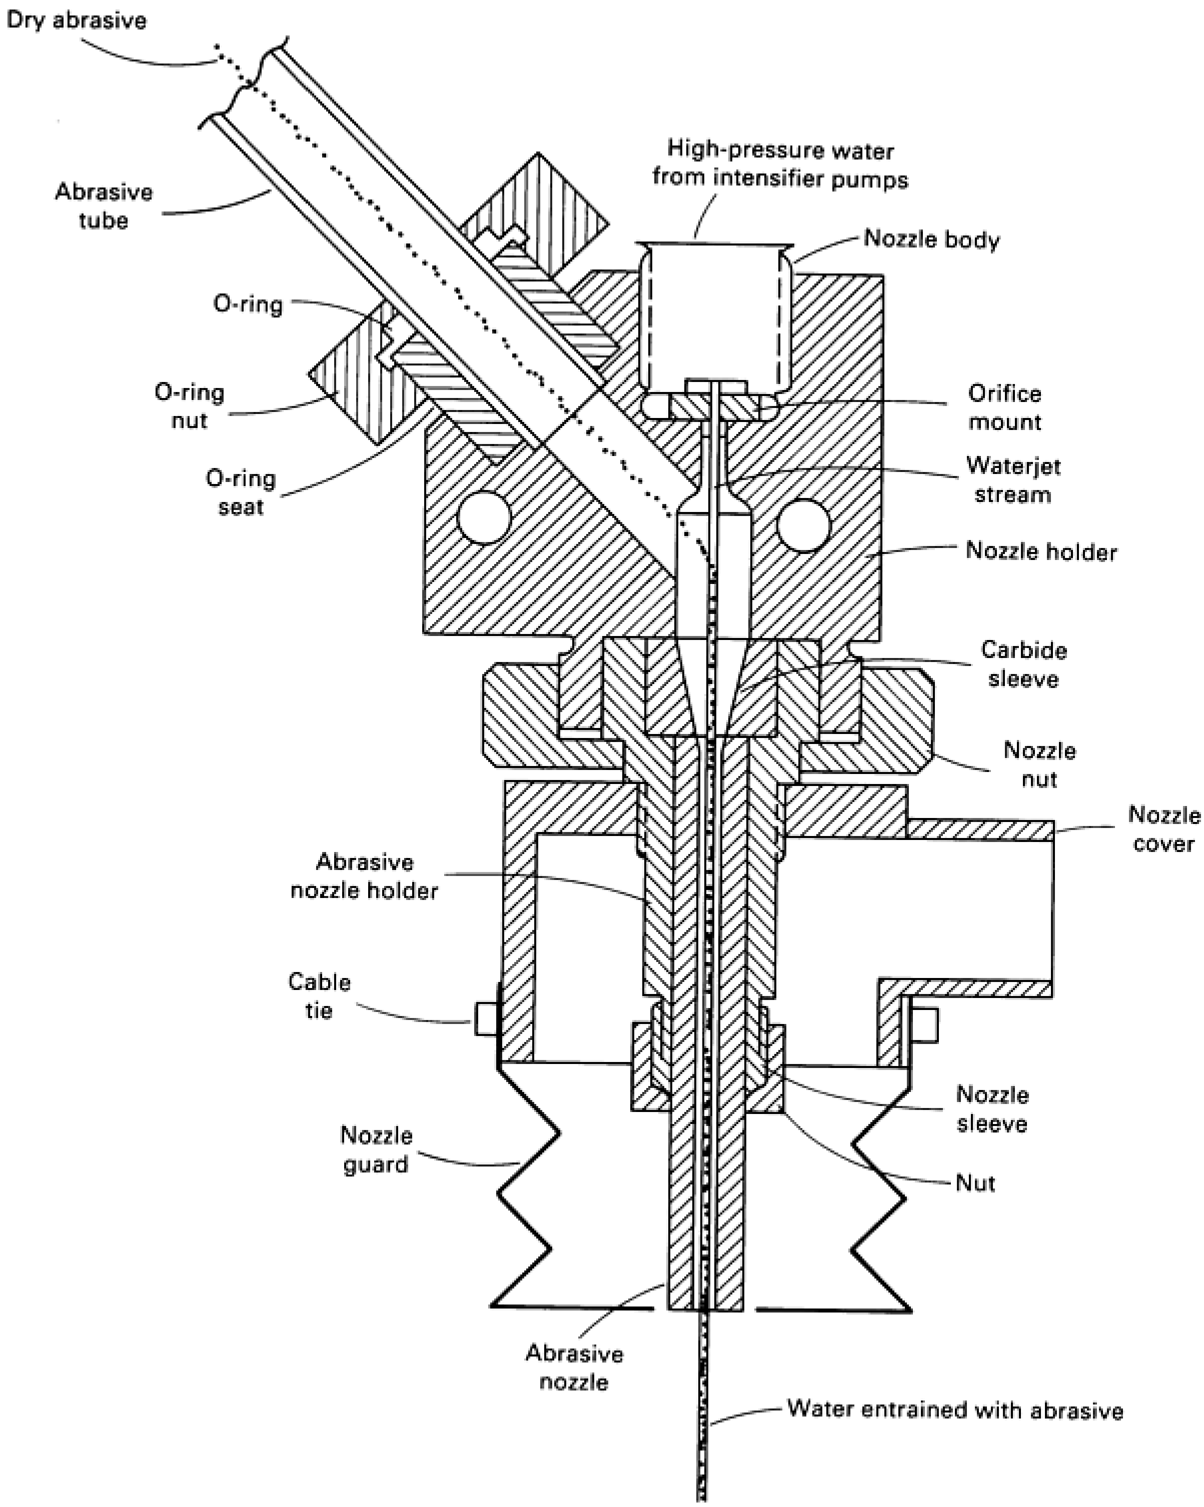

Fig. 2 Cross-sectional view of abrasive nozzle assembly showing path of water and abrasives.
